Abstract

Purpose Patients with Hirschsprung disease (HD) can have persistent obstructive symptoms after resection of the aganglionic segment. If obstructive symptoms are treated inadequately, this may lead to recurrent faecal stasis and impaction, and may result in severe distension of the bowel. A permanently distended bowel which not responds to conservative treatment may be an indication for redo surgery. The aim of this study is to describe our experiences and the short-term results of a novel technique: longitudinal antimesenteric resection with a longitudinal anastomosis.

Methods We reviewed the medical records of our three patients who underwent longitudinal resection of severe distended bowel. This technique aims to improve defecation by improving faecal passage and is characterized by resection of the antimesenteric side of the distended intestinal segment, followed by plication with a longitudinal anastomosis. In this paper, this novel technique is described in detail, as well as short-term outcomes.

Results All patients had an uneventful recovery after longitudinal antimesenteric resection. During follow-up, the functional outcomes were excellent, with a large improvement of bowel function. All patients were continent for faeces, and treated with low-dose laxatives or occasional preventive irrigation in one patient. There were no more complaints of persistent constipation or soiling.

Conclusion Longitudinal resection is a surgical redo-procedure offering large benefits for patients with Hirschsprung disease with distended bowel after primary surgery.

Keywords Hirschsprung disease · Re-operation · Obstructive symptoms · Case report

Introduction

Hirschsprung disease (HD) is a congenital motility disorder characterized by aganglionosis of the distal colon, for which surgery to resect aganglionic bowel is necessary. Thirty to 50% of patients experience defecation problems after primary surgical treatment [1, 2], of which persistent obstructive problems such as constipation are the most common. Possible causes for persistent obstructive complaints include

anastomotic stricture, residual aganglionosis, mechanical obstruction due to adhesions, sphincter problems and stool holding behaviour [3]. Persistent obstructive defecation problems are primarily treated with conservative measures, including laxatives, rectal irrigation, intrasphincteric botulinum toxin injections or anal dilatation [3]. If obstructive symptoms are treated inadequately, this may lead to recurrent faecal stasis and impaction resulting in progressing and permanent distension of the bowel. Severe bowel distension negatively affects bowel motility, thereby aggravating faecal stasis and increasing the risk of developing Hirschsprung-associated enterocolitis (HAEC), which can be life-threatening [4, 5]. In these patients with persistent obstructive symptoms and permanently dilated bowel, redo surgery may be indicated [6]. Most often a redo pull-through is performed in order to surgically remove the distended non-motile bowel and restore faecal passage. However, redo surgery is complex and associated with relatively high rates of soiling or faecal incontinence and enterocolitis [7–9].

Table 1 Clinical characteristics of patients who underwent longitudinal antimesenteric resection

	A	B	C
Sex	Male	Male	Male
Age at primary pull-through	15 days	4 months	14 days
Length initial affected and resected segment	Rectosigmoid	Descending colon	Rectosigmoid
Previous interventions	Botulinum toxin injections (age 4 years): no improvement of obstructive symptoms	None	Anal dilatations and redo pull-through (age 8.5 months) because of anastomotic stricture: initially good improvement of obstructive symptoms
Age at longitudinal resection	5 years	i. 8 years ii. 9 years	3 years
Bowel segment treated with longitudinal resection	50 cm descending colon	First longitudinal resection: (i) Proximal 10 cm of ascending colon and (ii) remaining descending colon until rectal fold Second longitudinal resection: 100 cm of ileum located 50 cm proximal to the ileocolic valve	27 cm of remaining colon after redo pull-through
Open vs laparoscopic	Laparoscopic	i. Open ii. Open	Open
Suturing	Stapler	i. Running handsewn suture ii. Stapler	Running handsewn suture
Protection with ostomy	Temporary transverse colostomy	i. No ostomy ii. Temporary ileostomy	Temporary ileostomy
Follow-up after longitudinal resection	4 years	4 years	1.5 years
Complications after longitudinal resection	No	No	No

In this paper, we present a case series of three patients successfully treated with an alternative technique for redo surgery in patients with extremely dilated non-motile bowel: resection of the antimesenteric side of the dilated non-motile bowel segment, followed by plication with a longitudinal anastomosis.

Methods

The medical records of three patients who underwent longitudinal resection and plication were retrospectively reviewed. Data on (1) demographic characteristics of patients (i.e. sex, age at primary pull-through, age at longitudinal resection), (2) disease characteristics and clinical course (i.e. length of the initial affected and resected segment, previous interventions), (3) the procedure of longitudinal resection (i.e. what bowel segment was treated with longitudinal resection, how long this segment was, whether an open or laparoscopic procedure was performed, what type of suturing was used, whether the operation was performed under the protection of an ostomy) and (4) clinical course after longitudinal resection (i.e. occurrence of complications, occurrence of obstructive symptoms, use of

laxatives or rectal irrigation, faecal continence and length of follow-up) was extracted from the medical records. Based on this data, a summary of our experiences with the clinical course of these patients before redo surgery, description of the operation technique and a summary of experiences with the clinical recovery of these patients were provided in this paper.

Results

Three patients with HD and persistent obstructive symptoms developed a severely dilated non-motile colon, after primary pull-through despite treatment with laxatives, enemas and rectal irrigation. In these three patients, there were no (more) signs of an anastomotic stricture, anal outlet obstruction or residual aganglionosis, which were excluded by contrast enema and biopsy (three patients) and botulinum toxin injections (in one patient). Characteristics of the clinical course before longitudinal resection, details about the procedure and occurrence of complications in each individual patient are provided in Table 1.

Fig. 1 Illustration of the technique of longitudinal antimesenteric resection

Description of the procedure

The patients in this series underwent longitudinal antimesenteric resection of the distended colon with a longitudinal anastomosis, instead of complete resection of the dilated segment followed by a redo pull-through, in order to preserve as much bowel (function) and vascularization as possible. Figure 1 illustrates the technique. The key is to resect the antimesenteric side of the circumference over the length of the distended segment. The amount of bowel to resect is dependent of the degree of distension, as the purpose is to recreate normal bowel diameter. A longitudinal anastomosis is created in order to reconnect both ends of the bowel wall, which can either be done by hand-suturing or by stapling. A protective temporary ostomy was created in all three patients.

Clinical outcomes in follow-up

Our three patients had uneventful recovery after longitudinal resection. There was no mortality and there were no post-operative complications within 30 days. In follow-up, contrast

enemas confirmed good peristalsis of the plicated segment without signs of anastomotic leakage or stricture in the three patients after 2–8 weeks after longitudinal resection and the bowel remained of a normal diameter (Fig. 2, Fig. 3 and Fig. 4). Subsequently, in the three patients, the temporary protective ostomy could be closed within 2 months after longitudinal resection. In follow-up after closing the ostomy, the bowel function of all patients had substantially improved compared with before the procedure. All three patients have retained regular bowel movements since longitudinal resection with either low-dose oral laxatives (Macrogolum) (patient A) or occasional preventive rectal irrigation (patient C). Only patient B, who initially also had satisfactory clinical outcome with spontaneous bowel movements without laxatives or irrigation, withdrew from follow-up because of psychosocial factors and presented again 1 year later with recurrence of a severely dilated small bowel and an inflamed ileum, for which he underwent resection of the inflamed ileal segment and a second longitudinal resection of the dilated ileum. Since this second longitudinal resection, the patient again has regular bowel movements and uses no laxatives or irrigation. None

Fig. 2 Patient A before (a) and after (b) longitudinal antimesenteric resection

Fig. 3 Patient B before (a) and after (b) longitudinal antimesenteric resection

of the patients showed clinical signs of obstruction in the follow-up period after the last longitudinal resection.

Discussion

Our study shows excellent short to medium term results after longitudinal resection in patients who developed distended bowel and obstructive symptoms after primary surgery because of Hirschsprung disease, with good clinical recovery. This indicates that longitudinal antimesenteric resection might be a safe and effective alternative treatment strategy for Hirschsprung patients with extremely dilated bowel because of persistent obstructive defecation problems after a pull through.

There is currently no consensus on the best surgical procedure for this group of patients [7, 10–13]. Frequently used techniques for secondary surgery include resection of the dilated segment with or without a redo pull-through, myotomy of the sphincter or a permanent colostomy. Disadvantages of re-resection of the dilated segment without a redo pull-through

are further omission of bowel length and vascular supply, as well as jeopardizing the distal segment if the original distal anastomosis remains in place. Simultaneous resection of the distal segment as well carries higher risk of future defecation disorders, especially faecal incontinence [14]. Disadvantage of a permanent colostomy is the time-consuming daily care, as well as the risk of stoma-related complications such as skin problems, prolapse and parastomal herniation [15]. A longitudinal resection leads to recovery of normal bowel diameter, thus decreasing bowel wall tension and increasing intraluminal pressure, thereby improving peristalsis and passage of faeces through the bowel. Moreover, this technique offers the benefit of preservation of larger sections of the colon and thus its resorbing function, as well as sustaining optimal vascularization of the gut. This is important as both damage of the vascular arcade and interruption of intramural blood supply may result in bowel necrosis or fibrosis with possible devastating consequences for continence later in life. In this small series, we had no complications of longitudinal antimesenteric resection.

Fig. 4 Patient C before (a) and after (b) longitudinal antimesenteric resection

Despite the good results in terms of bowel diameter and clinical improvement in our patients, we still have limited experience with longitudinal antimesenteric resection. This technique is suitable for patients with a permanent severely dilated colon, without any signs of residual aganglionosis or an anastomotic stricture as cause of obstruction. Therefore, this treatment option can only be applied for a small and specific subgroup of patients with HD and obstructive symptoms. We have described our experience with longitudinal resection in three patients, but in the future, more and longer experience with this technique is necessary, to assess if the good results can be confirmed and which patients would benefit most of this technique.

In conclusion, longitudinal antimesenteric resection is a surgical procedure offering multiple benefits for patients with HD with obstructive complaints and distended bowel for whom redo surgery is indicated: the preservation of bowel and vascularization. In this case series, clinical outcomes were good, but further research on outcomes in long-term follow-up and possible complications is necessary before clinical implications can be recommended.
