Sarcoidosis is a chronic granulomatous disorder characterized by a multisystem evolution with an unknown etiology, even if it is believed to be due to an exaggerated cellular immune response by the helper/inducer T lymphocytes to exogenous or auto-antigens. This disorder can potentially affect any organ: the most common sites are lymph nodes (especially intra-thoracic), lungs, liver, spleen, skin, and eyes. Sarcoidosis occurs most commonly in Scandinavian areas and in young adults, whilst clinically the more severe forms are reported in the black population. In 25–30%, sarcoidosis may involve the myocardium and its elective localization is represented by the interventricular septum.¹ Usually, the clinical consequences of cardiac sarcoidosis (CS) are conduction/rhythm disturbances and, in case of massive myocardial involvement, heart failure and death.² Cardiac involvement of sarcoidosis has a pivotal role in the assessment of prognosis and contributes to a major part of the disease morbidity and mortality.³ The gold standard for the diagnosis of CS is considered the endomyocardial biopsy (EMB): however, this invasive technique is characterized by potential complications⁴ and low sensitivity (<60%, even if repeated) in determining the non-caseating sarcoid granuloma, due to possible sampling errors.⁵ Therefore, the diagnosis of CS can be made on the basis of imaging and clinical features in addition to extracardiac biopsy evidence of

sarcoidosis. Consequently, radiological evaluation in suspected CS is nowadays largely required.⁶ Different features can be evaluated, and among them, the most relevant are myocardial fibrosis and inflammation. Indeed, the myocardial late-gadolinium enhancement (LGE) due to scar or edema in cardiac magnetic resonance imaging (CMRI) is considered a diagnostic criterion for CS.^{6,7} Fluorine-18 labeled 2-deoxy-2-fluoro-D-glucose positron emission computer tomography (¹⁸F-FDG-PET/CT) shows high accuracy⁸ and is widely used in the evaluation of CS activity (especially for active inflammation assessment), even in the prediction of adverse events.⁹ Obtaining a complete FDG-uptake suppression in normal myocardium through dietary protocols permits a more confident diagnosis of cardiac involvement; so it is important to check the rate of cardiac suppression obtained in own Center and modify/lengthen the dietary protocol, accordingly. Indeed, although several patterns of normal left-ventricular (LV) FDG-uptake have been described,^{10,11} non-homogeneous cardiac distribution of radiotracer may rise interpretative doubts; thus, a complete and robust clinical assessment is mandatory to determine the most probable diagnosis. In the current issue of the Journal, Tuominen et al. performed a retrospective analysis of 137 patients who underwent ¹⁸F-FDG-PET/CT imaging for suspected CS evaluation. In this cohort, 35/137 patients were already known to be affected by sarcoidosis, whilst 18/137 (13%) have been diagnosed with CS (confirmed by EMB in 7). They focused the attention in the prediction of cardiovascular events (defined as a reduction in LV ejection fraction, hospitalization due to cardiac arrhythmia and death) of either quantitative FDG-PET parameters as of the cardiac pathological pattern of FDG-uptake. In this paper, a relevant prognostic value of abnormal right-ventricular (RV) FDG-uptake (focal or focal on diffuse pattern) has been demonstrated in patients showing atrio-ventricular block, ventricular or supraventricular arrhythmia,

unexplained dilated cardiomyopathy, unexplained low ejection fraction (EF) on echocardiography, echocardiographic signs of cardiac sarcoidosis, or syncope. In the small group of patients who underwent both PET and CMRI, the positive predictive value of abnormal RV FDG-uptake was higher than the evidence of LGE at CMRI, whereas negative predictive values were similar.¹¹ The presence of RV FDG-uptake may reflect the spread of CS activity, being a predictor of death¹² or ventricular tachycardia events.¹³ In the cohort of Tuominen, cardiac events were not significantly more common in patients with diagnosed CS than those without: unlike RV FDG-uptake, cardiac PET positivity by itself was not predictive of cardiac events, and cardiologists should be aware of this clinical implication. It should be remembered that heart failure can be due to an increase in pulmonary vascular resistance secondary to diffuse interstitial fibrosis: in these cases, the picture of the chronic pulmonary heart is realized. In this sense, cardiac involvement should be detected as soon as possible in order to establish an early treatment. However, the main findings reported by Tuominen and Colleagues was that, in survival analysis, a total cardiac metabolic activity (tCMA) value of more than 900 MBq significantly predicted cardiac events ($p=0.032$) and that pathological RV FDG-uptake was more common in patients with cardiovascular events at follow-up than those without ($p=0.001$). Indeed, the association between a high tCMA and RV pathological FDG-uptake should be considered as a significant risk marker in patients with suspected CS.¹¹ In accordance with these results, Ahmandian et al.¹⁴ showed that a high tCMA was an independent predictor of cardiovascular events in CS patients. Similarly, in a recent study by Omote et al., CS patients with RV FDG-uptake showed notably higher cardiac metabolic volume (CMV), total lesion glycolysis (TLG), LV standardized-uptake-value (SUV) max, LV involvement, and cardiac adverse events than those without. RV FDG-uptake would indicate the spread of disease activity into the whole heart, the advanced stages of sarcoidosis, possibly predicting positive findings of EMB.¹⁵ Blankstein et al.¹³ showed that RV FDG-uptake in suspected CS patients, was related to a five-time improved risk for cardiovascular events, whilst Flores et al.¹⁶ demonstrated a strong correlation between a high SUV at the time of diagnosis of CS (especially in basal segments) and future cardiac events. The quantitative variations of FDG-uptake have shown to be a valuable tool in the assessment of CS pathological evolution: in long-term follow-up CS patients, it has been demonstrated that reduction in FDG-uptake strongly correlated with reduction of major cardiac adverse events.¹⁷ Furthermore, in a study by Osborne et al.¹⁸ FDG-uptake variations in terms of

metabolic activity/volume showed an inverse correlation with changes in systolic function. The information obtained by FGD-PET/CT and CMRI are usually complementary. The introduction and the desirable widespread of hybrid systems combining PET and MRI (PET/MRI) may be a real opportunity for CS imaging thus improving the imaging performance in this topic.¹⁹ Further studies evaluating the capability of ¹⁸F-FDG-PET in diagnosis and prognosis of cardiac disease as well as evaluation of new imaging approach—using radiopharmaceuticals as ⁶⁸Gallium-DOTANOC, ¹⁸F-Flurpiridaz, and ¹³Nitrogen-Ammonia that are currently undergoing testing and have shown promising results in initial small studies²⁰—are warranted to establish a unified approach, thus improving the assessment of CS.
