Abstract

This study explores the capacity of synthesized Fe₂O₃ nanoparticles (NPs) under sunlight for the degradation of dissolved organic matter (DOM) from synthetic (Procion blue dye) solution as well as from textile wastewater (TWW). Fe₂O₃ NPs were properly synthesized and confirmed by UV absorbance, FTIR spectra and SEM image analysis. Photocatalytic degradation of DOM from TWW and synthetic solution was performed by catalyst Fe₂O₃ NPs (5 mg/L) in the presence of solar irradiation (up to 40 h). The DOM degradation of the TWW and synthetic solution has been analyzed by fluorescence 3D excitation emission matrix (3D EEM). Synergistic effect was expected and it was found that the rate of decrease of fluorescence intensity increased with time. Within 20 h, for the synthetic solution, reduction of fluorescence intensity (80%) reaches an equilibrium. In contrast, the rate of decrease in the fluorescence intensity is highest (91%) in 40 h of irradiation for TWW. This reduction of fluorescence intensity indicates the degradation of DOM and can be expressed well by second-order model kinetics. Reduction of TOC, BOD₅ and COD load again validated the degradation of DOM from TWW by catalyst Fe₂O₃ NPs-induced solar irradiation. We applied the treated wastewater on the plant to observe the reusability of the treated TWW, and the morphological data analysis of the plant demonstrates that the catalyst Fe₂O₃ NPs-induced solar-irradiated wastewater exhibits less adverse impact on plant morphology.

Introduction

The textile industry is the main creator of effluent wastewater in Bangladesh, due to a greater consumption of water for its different wet and dye processing operations. This effluent wastewater has been recognized to have high color, high BOD and COD load, as well as high dissolved organic

matter (DOM) concentration (Paul et al. 2012). According to the World Bank estimation, textile dyeing and finishing treatment given to a fabric generates around 17–20% of industrial wastewater (Kant 2012). Selection of the suitable method and material for the sustainable textile wastewater (TWW) treatment is a highly complex task, where we have to consider four factors, quality standard to be met, the treatment efficiency, the cost of treatment and also the reusability of the treated water (Huang et al. 2008; Zhang and Fang 2010; Oller et al. 2011). In an effort to combat the problem of water pollution, rapid and significant progresses in wastewater treatment have been made, including photocatalytic oxidation, adsorption/separation processing and bioremediation (Long et al. 2011; Pang et al. 2011; Parvin et al. 2015, 2017). However, their applications have been restricted by many factors, such as processing efficiency, operational method, energy requirements and economic benefit. Recently, nanomaterials (NMs) have been suggested to be efficient, cost-effective and environmental friendly alternative to existing treatment materials, from the standpoints

of both resource conservation and environmental remediation (Dimitrov 2006; Dastjerdi and Montazer 2010).

Degradation of DOM and azo dye of water using semiconductor oxide nanomaterials-based photocatalysts is a useful process, where pollutants are mineralized by the photocatalytic mechanism (Akhavan and Azimirad 2009). Photocatalysis refers to the rate of photoreactions (oxidation/reduction) brought on by the activation of a catalyst, usually a semiconductor oxide, through illumination under ultraviolet (UV) or visible light. The direct band-gap excitation of semiconductors generates electron–hole pairs, which participate in reduction and oxidation processes. Among numerous oxide semiconductor photocatalysts (e.g., TiO_2 , ZrO_2 , ZnO , MoO_3 , SnO_2 , $\alpha\text{-Fe}_2\text{O}_3$), anatase crystalline forms of Fe_2O_3 and TiO_2 nanomaterial are suitable photocatalysts, as those are nontoxic and have vigorous oxidizing capacity (Park and Choi 2004; Nagaveni et al. 2004; Zou et al. 2001). However, one limitation of TiO_2 is that it mainly absorbs UV light, which covers only 4–6% of the solar spectrum. In this regard, iron oxide nanoparticle (Fe_2O_3 NP) with band gap around 2.3 eV is a suitable candidate to absorb solar light, greater surface area and be used as a photocatalyst.

Akhavan and Azimirad (2009) use mercury lamp as a source of visible light prior to investigating the effect of semiconductor nanocatalyst in dye removal and wastewater treatment. However, using this kind of source is not viable in pilot-scale work or in practical application. Hence, use of direct sunlight is more practicable (Bishnoi et al. 2018) because of its availability. In addition, because of the geographical position of Bangladesh, total solar insolation that reaches different locations of Bangladesh vary from 4 to 5 $\text{kWh/m}^2/\text{day}$, whereas the global solar insolation varies from 3.8 to 6.4 $\text{kWh/m}^2/\text{day}$ (Nandi et al. 2012). Thus considering the fact, it is wise to use direct sunlight to elucidate the effect of nano-photocatalyst.

Recently, Fe-doped TiO_2 photocatalysts and $\text{Fe}_2\text{O}_3\text{-TiO}_2$ coupled semiconductor photocatalysts have been designed for photodegradation of toxic and organic pollutant substances in visible light (Akhavan and Azimirad 2009). However, we always look for those techniques which are inexpensive and easy to prepare. Hence, several laboratories have examined the efficiency of Fe_2O_3 NPs (without doping) during the photocatalytic purification of dye mixed water (Bandra et al. 2001; Cunningham et al. 1988; Fernandez et al. 1998). However, another big problem in wastewater is DOM. The presence of DOM not only affects the current discharge standards, but also presents significant challenges in wastewater reclamation (Gou et al. 2011). DOM contains large amounts of unsaturated and aromatic structures with different functional groups that have fluorescence characteristics, which allows for the utilization of fluorescence spectroscopy to extract information on the degradation of DOM at the time of TWW treatment. In particular, DOM includes

organic molecules with chromophoric (light absorbing) and fluorophoric (light emitting) moieties (Wang et al. 2009). Therefore, three-dimensional excitation emission matrix (3DEEM) fluorescence spectroscopy has been widely used to detect detailed changes and transformations of organic matter in wastewater (Wang et al. 2009).

In this study, Fe_2O_3 NPs have been synthesized and, for the first time, the efficacy of Fe_2O_3 NPs as a photocatalyst under solar irradiation in degrading DOM from synthetic dye (Procion blue) solution and TWW has been observed using fluorescence spectroscopy and characterized by 3DEEM. Additionally, the effect of the degraded wastewater on plant growth has also been studied to check the reusability of TWW.

Experimental

Synthesis of Fe_2O_3 NPs

We synthesized the Fe_2O_3 NPs according to the method described in Rahman et al. (2011). In brief, both FeCl_3 and urea were slowly dissolved in de-ionized water separately at room temperature to make 0.5 M concentration of FeCl_3 and urea solution. Then the solutions were mixed gently and stirred until the two solutions mixed properly. The pH of the solution was adjusted using ammonia solution dropwise to approximately 9.66. Then the mixture was put into a hydrothermal cell (Teflon line autoclave) to be placed in an oven for 6 h at 150 °C. Then the solution was washed with acetone and kept for drying at room temperature (Rahman et al. 2011).

Characterization of Fe_2O_3 NPs

The structural and optical properties of the synthesized Fe_2O_3 NPs were tested. The $\lambda\text{-max}$ of the synthesized iron particles was measured using UV/visible spectrophotometer (Shimadzu, Model no: mini-1240). The IR spectra were measured by FTIR spectrophotometer (Shimadzu, Model no-IR Prestige 21) to study the structural properties of the NPs. The FTIR spectrum was taken in a transmittance mode. The spectra were obtained at a resolution of 4 cm^{-1} in the range of 400–4000 cm^{-1} in KBr media. The surface morphology of the synthesized Fe_2O_3 NPs was assessed by a scanning electron microscope (SEM) (JSM-630 JEOL, Japan).

Wastewater sampling and photocatalytic irradiation

TWW used in this work was sampled from a textile industry named Pakiza Group Ltd., which is situated at Savar, Bangladesh. The sample was a mixture of wastewater, discharged

Fig. 1 Solar irradiation of water samples in the presence of Fe_2O_3 NPs

from several sections such as washing, dyeing, waxing and rinsing. The samples (40 ml) were then exposed to solar radiation for up to 40 h (10 days: every day 4 h, from 10 AM to 2 PM) (both in the presence and absence of catalyst Fe_2O_3 NPs) as explained in Bishnoi et al. (2018). Here, a constant catalyst (Fe_2O_3 NPs) concentration (5 mg/L) was used. The water samples were kept in vials by adding Fe_2O_3 NPs and sealed with cap to avoid evaporation of water (Fig. 1). We conducted this study in February at the rooftop of our laboratory, when the solar insolation for Dhaka was reported to be 4.79 kWh/m^2 (Nandi et al. 2012). Similar procedures were also applied for the synthetic dye (Procion blue) solution. We used 40 mL of synthetic solutions (50 mg/L of dye) and added 5 mg/L Fe_2O_3 NPs. This dye was purchased from Sigma-Aldrich. The properties of the Procion blue (PB) dye are as follows:

- Linear formula: $\text{C}_{23}\text{H}_{14}\text{Cl}_2\text{N}_6\text{O}_8\text{S}_2$.
- Molecular weight: 637.437.
- Lambda max: 607 nm.
- MDL number: MFCD00001218.

Characterization of the degraded wastewater

Fluorescent dissolved organic matter degradation study

The rate of degradation of DOM in dye solution and TWW after photocatalytic solar irradiation was studied by a fluorescence spectrophotometer (F-4600, HITACHI, Tokyo, Japan) by a method described in Tareq et al. 2013 and Yamashita and Tanoue 2003. Briefly, all the samples were filtered through a glass-fiber membrane ($0.45 \mu\text{m}$) to remove suspended materials that may react with DOM. Excitation emission matrices (EEMs) were created using FL Solutions software. Before analysis, water samples were diluted 1000 times to keep the spectra within the upper limit of analysis. To generate an EEM, excitation wavelengths were scanned

from 225 to 500 nm in 5 nm steps, and the emitted fluorescence detected between 240 and 600 nm in 2 nm steps. Excitation and emission slit widths were 5 nm. Scan speed was 1200 nm/min, permitting collection of a complete EEM in 18 min. Excitation emission matrix (EEM) data were calibrated by normalization to water Raman scattering.

Physicochemical parameter of TWW

Changes in the environmentally important parameters (BOD, COD, TOC) of the TWW after solar irradiation (both in the presence and absence of catalyst Fe_2O_3 NPs) were analyzed. The 5-day BOD test of the samples was conducted according to the standard method (ASTM-5210 B). The COD of the samples was determined by the closed reflux colorimetric method (ASTM-5220 D). Total organic carbon (TOC) was measured by the high temperature catalytic oxidation method with a TOC 5000A (Shimadzu, Japan) using potassium hydrogen phthalate (KHP) as a standard (Tareq et al. 2013).

Analysis of the effect of treated wastewater in plant growth

The treated and raw textile wastewaters were irrigated into Malabar spinach to observe the effect of solar-irradiated textile wastewaters on plant growth using pot experiments. For this purpose, the real TWW was solar irradiated without any dilution both in presence of catalyst iron oxide nanoparticles in a glass reactor which containing at least 7 l of wastewater at a time and catalyst (Fig. 2). Every day, 1 l of water samples (treated and untreated) was poured on the soil of each pot, where the plant was sown, as described in Parvin et al. (2015). Four pots of Malabar spinach (3 replications) were prepared by adding garden soil with the appropriate moisture content and successively nourished with water, raw and treated textile wastewater. Every week, the plants were monitored prior to measuring the plant morphology to

Fig. 2 Solar irradiation of textile wastewater samples in the presence of Fe_2O_3 NPs for irrigating on plants

compare the effect of treated textile effluent with the raw and control one. At 45 DAS (days after sowing) the plants were harvested and the lengths of roots and dry mass were measured. The morphology of the plants was measured according to the method described in Parvin et al. (2013, 2015).

Results and discussion

Characterizations of Fe₂O₃ NPs

The optical property of the Fe₂O₃ NPs is one of the significant properties for determining its optical and photocatalytic activity. The absorption spectrum of as-grown Fe₂O₃ NPs solution was measured by UV–visible spectrophotometer and an onset of absorption maxima was found at 444.0 nm in the visible range (200–800) nm wavelength. The lambda maxima of the synthesized NPs are quite similar to those reported by Cornell and Schwertmann (2003) and Rahman et al. (2011) and this wavelength indicates the formation of Fe₂O₃ NPs. Band-gap energy is calculated on the basis of the maximum absorption band (444 nm) of Fe₂O₃ NPs. The band-gap energy of NPs was 2.792 eV, according to the following equation:

$$E_{bg} = \frac{1240}{\lambda} (\text{eV}),$$

where E_{bg} is the band-gap energy and λ_{max} is the wavelength (444.0 nm) of the NPs.

FTIR, an excellent tool for recognizing the types of chemical bonds in a molecule, was recorded for Fe₂O₃ NPs (Fig. 3). It displays several bands at 447, 561, 935, 1400, 1630, 1751 and 3134 cm⁻¹ and it is known from the literature that Fe₂O₃ NPs give absorption bands at those wavelengths (Rahman et al. 2011; Ma and Qi 2007). The band observed at 447.49 and 561.29 represents Fe–O–Fe stretching vibration, and these vibration bands at low frequency regions indicate the formation of Fe₂O₃ NPs. The vibration bands observed at 1400 and 1630 cm⁻¹ are assigned to O=C=O stretching and OH bending vibration. The band observed at 1751.36 cm⁻¹ represents the C=O stretching of carbonyl. The strong absorption band at 3032 and 3134.33 cm⁻¹ represents the C–H stretching vibration of alkanes and alkenes. Rahman et al. (2011) reported that, the absorption bands at these wavelengths normally arise from the carbon dioxide and water which usually nanomaterials absorbed from the environment due to their mesoporous structure.

The SEM image has been used here to verify the particle size and morphology of Fe₂O₃ NPs. Figure 4 shows that the different diameters of NPs grown by the hydrothermal process possessed almost uniform spherical shape. The particles are aggregated with small crystals with a broad size distribution up to 500 nm (Fig. 4a) and grown at a very high density.

Fig. 3 FTIR spectra of Fe₂O₃ NPs

Fig. 4 High- to low-resolution SEM image of Fe_2O_3 NPs

From this figure, it is clear that the synthesized material is an NP and the morphology of the synthesized iron dioxide NPs is identical. The diameter of the synthesized iron NPs is found in the range of 56–83 nm (Fig. 4b), whereas the average diameter of Fe_2O_3 NPs is close to 71 nm (Rahman et al. 2011). From those analyses, it is clear that Fe_2O_3 NPs has been properly synthesized.

Synergistic effect of Fe_2O_3 NPs in the presence of solar radiation for the degradation of DOM from textile wastewater

Study of fluorescence intensity

The occurrence of dissolved organic matter is rather common in dye-containing industrial wastewater. Given that Fe_2O_3 with a band gap of 2.3–2.7 eV (Akhavan and Azimirad 2009) is an n-type semiconducting material and a suitable candidate for photodegradation of dye compounds under visible light condition and consequently degradation of DOM, we examined the synergistic effect of Fe_2O_3 NPs under solar radiation for the degradation of DOM of dye (PB) solution and TWW (Fig. 5a, b) by means of fluorescence intensity. In the case of synthetic dye (PB) solution (Fig. 5a), the reduction in fluorescence intensity reaches in equilibrium (80%) within 20 h of solar irradiation. When Fe_2O_3 NPs are illuminated under visible light, electrons from the valence band jump into the conduction band, causing generation of electrons and positively charged holes and leading to the formation of active oxidation species, which are responsible for enhanced DOM degradation. Generally, the sites near the chromophore (for instance, C–N=N– bond) is the attacked area in the photocatalytic degradation process, and photocatalytic destruction of the C–N=N– and –N=N– bonds leads to fading of the dyes (Khataee and

Fig. 5 Time-dependent changes in fluorescence intensity at 350 nm/450 nm of the PB dye and TWW

Kasiri 2010) and in a consequent degradation of DOM. For TWW, the reduction in fluorescence intensity increases with increase in time (Fig. 5b). Maximum reduction (91%) was achieved on 40 h of irradiation.

To investigate the kinetic mechanism of DOM degradation, we looked for the reaction kinetics. We elucidated the reaction kinetics using the fluorescence intensity (a.u.) from 3D EEMs against time, as the fluorescence intensity is

thought to be proportional to the concentration of the analyte (Wang et al. 2009). The first-order reaction rate constant for the reaction was determined by fitting the fluorescence intensities of the samples to the first-order equation:

$$\ln(I_t) = -k_1 t + \ln(I_0),$$

where I_t and I_0 are the fluorescence intensities at time t and at the initial time. k_1 is the first-order rate constant. k_1 and $I_{0,\text{cal}}$ were calculated from the slope and intercept of the plots of $\ln(I_t)$ vs. t . As for the second-order kinetics, the model can be expressed by the following equation:

$$\frac{1}{I_t} = k_2 t + \frac{1}{I_0},$$

where k_2 is the second-order rate constant and k_2 and $I_{0,\text{cal}}$ were calculated from the slope and intercept of the plots of $1/I_t$ vs. t . The first- and second-order model kinetics of DOM degradation of PB dye and TWW are given in Fig. 6. For both the dye solutions and TWW, the experimental data show relatively lower correlation ($R^2 = 0.89\text{--}0.96$) in the first-order rate expressions (Fig. 6a, c). In contrast, a high degree of linearity and high correlation ($R^2 = 0.99$) with the experimental data were found for second-order rate expression (Fig. 6b, d). These results suggest that the second-order kinetic model is best fitted for describing the DOM degradation from the dye solution, as well as from TWW and the DOM degraded by bimolecular reaction. Here, in Fig. 6a, b, the kinetics for synthetic dye (PB) solution was shown for up to 20 h. As this is a pure dye solution, within 20 h

the rate of degradation reaches an equilibrium stage. We calculate the half-life ($t_{1/2}$) of second-order reactions using the following equation:

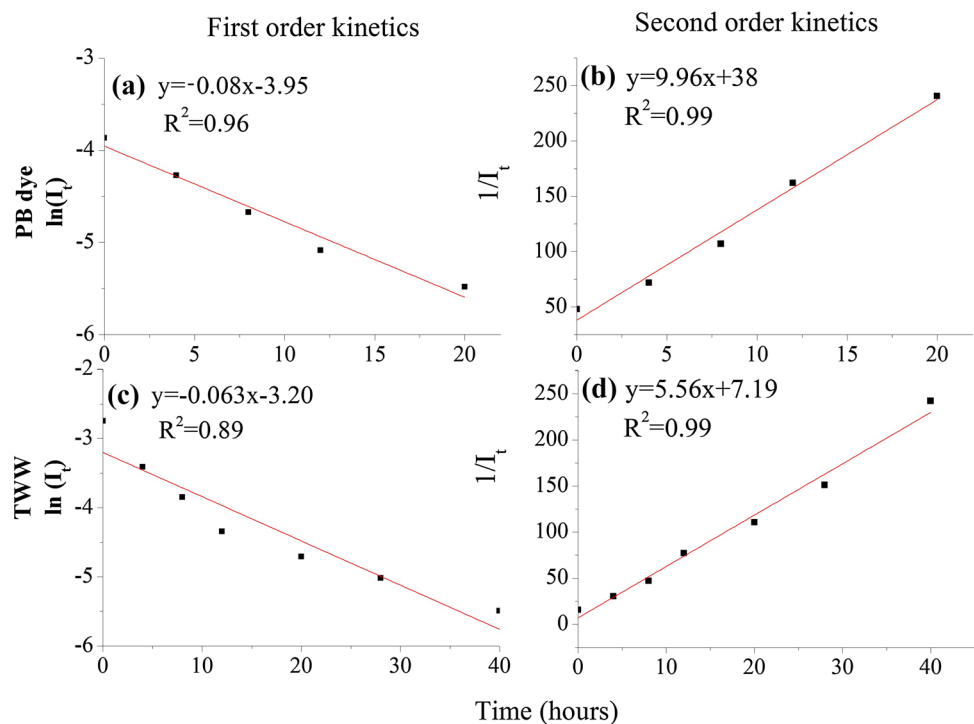

$$t_{1/2} = \frac{1}{(k_2 \times I_0)},$$

and the $t_{1/2}$ of Pb dye is 5.02 h. As for TWW, the $t_{1/2}$ is 2.99 h.

3D EEM analysis

To examine the extent of DOM degradation in synthetic dye solutions and TWW by Fe_2O_3 NPs-induced solar irradiation, 3D excitation emission matrices (EEMs) were created by determining three fluorescent parameters (excitation wavelength, emission wavelength, and the intensity of fluorescence) (Yamashita and Tanoue 2003). The results are arranged in a grid (excitation \times emission \times intensity). The specific excitation and emission wavelengths are characteristics of a particular molecular conformation (i.e., fluorophore) that can indicate the composition of organic compounds. Thus, the measured fluorescent peak intensity (Raman unit, nm^{-1}) of DOM is directly related to the concentration of the responsible fluorophore in the sample (Henderson et al. 2009). Here, the rate of DOM degradation increases with increase in irradiation time and we get the best result for 40 h of irradiation for TWW. However, in the

Fig. 6 First-order (a, c) and second-order (b, d) kinetics of the degradation DOM of PB dye and TWW with Fe_2O_3 NPs under visible light irradiation

dye solution the rate of degradation reaches in equilibrium within 20 h. Hence, we show the degradation of fluorescent DOM using 3DEEM of synthetic dye solution and TWW only at 20 and 40 h of irradiation, respectively (Figs. 7, 8).

The fluorescence intensity of the synthetic dye (PB) solution was close to 0.17RU, which decreased to 0.04RU after 20 h of photodegradation (Fig. 7a, b). As for TWW, after solar irradiation the relative fluorescence intensity has also decreased (from RU 0.17 to RU 0.10) (Fig. 8). In wastewater samples, the fluorescence peak at around $Ex/Em = 390\text{--}440\text{ nm}/442\text{--}508\text{ nm}$ indicates the humic substances (Table 1), which is the specific fluorescence indicator of azo dye in TWW (Li et al. 2015). Additionally, two other peaks at around $Ex/Em = 300\text{--}315\text{ nm}/380\text{--}382\text{ nm}$ indicate the protein-like materials and the peak at around $Ex/Em = 270\text{--}295\text{ nm}/350\text{--}362\text{ nm}$ indicates fulvic acid. The synergistic effect of Fe_2O_3 NPs-induced solar irradiation caused a redshift in excitation emission wavelength of all organic matters and the fluorescence intensity also decreased (Table 1). The resulting redshift could be due to the destruction of various fluorophores (all absorbing at long wavelength) via indirect photochemistry excited at long wavelength. In addition, destruction of fluorophores by direct photochemistry excited at both wavelength or by

some means coupled with fluorophores excited at shorter wavelength can also cause redshift in the excitation emission spectra (Coble et al. 2014). If two double bonds are separated by a single bond, the double bonds are termed conjugated. Conjugation of double bonds further induces a redshift in the absorption (a so-called bathochromic shift). From fluorescence spectra analysis, it is clear that irradiation for 40 h gives best results for TWW. Hence, irradiation for 40 h was chosen for further analysis with TWW.

Reduction in TOC, COD and BOD of TWW after catalyst-induced solar irradiation

Fluorescence data of wastewater as well as treated wastewater are thought to well correlate with other parameters including biochemical oxygen demand (BOD), chemical oxygen demand (COD) and total organic carbon (TOC) (Reynolds 2002). In addition, removal of dyes also reduces BOD, COD and TOC of wastewater. Hence, to validate the degradation of DOM of TWW under solar irradiation in the presence of Fe_2O_3 NPs, we also measure the environmentally important parameters (BOD_5 , COD and TOC) of TWW. Table 2 represents the percent removal of TOC, COD and BOD of TWW after catalyst-induced solar irradiation (40 h). The BOD, COD and TOC of

Fe_2O_3 induced solar irradiated for 40 h	0.008 (440 nm/508 nm)	0.009 (315 nm/382 nm)	0.01 (295 nm/362 nm)

Table 2 Reduction in TOC, COD and BOD of real textile wastewater after the treatment process (40 h)

	BOD (%)	COD (%)	TOC (%)
After catalyst-induced solar irradiation days	37.89	44.68	42.2

TWW are 208, 409 and 89 mg/L, respectively. Data in Table 2 indicates that all those properties were improved after 40 h of solar irradiation with catalyst Fe_2O_3 NPs. After 40 h of photocatalytic irradiation, TOC, COD and BOD were reduced by 42.2, 44.68 and 37.89%, respectively. By the influence of solar irradiation in the presence of Fe_2O_3 NPs, complex organic compounds are converted to simple compounds such as carbon dioxide, water, nitrate, amide and carboxylic acids (Hussein and Abbas 2010; Xu et al. 2012) and consequently the BOD, COD load and TOC of TWW are decreased. This result again

proves the degradation of DOM from TWW using Fe_2O_3 NPs under solar irradiation. However, the improvement rate is less in comparison to some other treatment, i.e., at 10 kGy direct gamma irradiation, the BOD and COD of TWW reduced by 59 and 61%, respectively (Parvin et al. 2015). These rates of reduction (Table 2) suggest that degradation compounds, especially low molecular weight aldehydes and organic acids, still remain in solution. So, it is recommended that, to achieve complete mineralization, a little higher concentration of Fe_2O_3 NPs in wastewater is necessary.

Effect of degraded wastewater on plant growth

Textile wastewaters are thought to hinder plant growth (Parvin et al. 2015), as the water quality is worse compared to the standard for use for irrigation purpose. Hence, the treated wastewater was irrigated to plants to compare the effect of treated wastewater on plant growth with raw wastewater. Figure 9 represents the morphological parameter of Malabar spinach nourished by water (control), TWW and catalyst-induced solar-irradiated TWW (TWW1), respectively. The morphological data (e.g., plant height, number of leaves, root length and dry mass) given in Fig. 9 were measured after 45 days as shown. As expected, plants irrigated by TWW showed very low morphological properties in comparison with plants treated with normal water, because wastewaters having low DO, higher concentration of DOM and BOD load hinder plant growth. However, when we nourish the plants with catalyst-induced solar-irradiated wastewater, the value of plant growth becomes higher, though these values of plant morphology are still less in comparison to the values of the control. However, in our previous work (Parvin et al. 2015), we decolorized TWW, using ionizing gamma irradiation, which showed a fertilizing effect on plant growth. The possible explanation is solar radiation is not so intense like the most penetrating ionizing gamma irradiation to break the azo dye completely into nitrogen and ammonia, which is the reason for suppressing the plant growth (though little), instead of acting as a fertilizer. However, using solar radiation is cost-effective and renewable compared to gamma radiation, as gamma radiation plants require high maintenance cost and the source Co^{60} is not renewable. Hence, the use of a relatively high concentration of Fe_2O_3 NPs (more than 5 mg/l) to accelerate the degradation ability of solar radiation is recommended in degrading the dye and DOM completely.

Conclusions

We synthesized properly Fe_2O_3 NPs and it has also been proved by UV–Vis, FTIR spectra and SEM images analysis. Degradation of DOM of the dye solution and TWW

Fig. 9 Morphological properties of Malabar spinach after irrigation with water (control), wastewater (TWW) and catalyst-induced irradiated wastewater (TWW1)

linearly increased with time and the best results were found at 40 h of solar irradiation for TWW. As for Pb dye solution of 50 mg/L concentration, the rate of degradation (80%) reached in equilibrium within 20 h using 5 mg/l Fe_2O_3 NPs. The degradation of fluorescent DOM of textile wastewater and dye solution by means of fluorescence intensity can be described well by the second-order kinetic model. Analysis of 3DEEM revealed that, after photocatalytic irradiation, the intensity of humic acid is reduced, which is the main fluorescence indicator of azo dye in TWW. The degradation of DOM is again supported by the reduction of BOD, COD and TOC of TWW, indicating the applicability of this method (use of nanocatalyst under sunlight) in open lagoon/pond of the textile wastewater treatment plant. The catalyst-induced solar-irradiated wastewater is found to have less effect on plant growth compared to raw wastewater. However, a little higher concentration of Fe_2O_3 NPs is recommended for the complete degradation of DOM. Hence, in our next work, we will focus on catalyst Fe_2O_3 NPs concentration-dependent dye

and the DOM degradation of synthetic dye solution and TWW.
