ABSTRACT

Development of controllable hypermutable cells can greatly benefit understanding and harnessing microbial evolution. However, there have not been any similar systems developed for *Clostridium*, an important bacterial genus. Here we report a novel two-step strategy for developing controllable hypermutable cells of *Clostridium acetobutylicum*, an important and representative industrial strain. Firstly, the *mutS/L* operon essential for methyl-directed mismatch repair (MMR) activity was inactivated from the genome of *C. acetobutylicum* to generate hypermutable cells with over 250-fold increased mutation rates. Secondly, a proofreading control system carrying an inducibly expressed *mutS/L* operon was constructed. The hypermutable cells and the proofreading control system were integrated to form a controllable hypermutable system SMBMutC, of which the mutation rates can be regulated by the concentration of anhydrotetracycline (aTc). Duplication of the *miniPthl-tetR* module of the proofreading control system further significantly expanded the regulatory space of the mutation rates, demonstrating hypermutable *Clostridium* cells with controllable mutation rates are generated. The developed *C. acetobutylicum* strain SMBMutC2 showed higher survival capacities than the control strain facing butanol-stress, indicating greatly increased evolvability and adaptability of the controllable hypermutable cells under environmental challenges.

KEYWORDS *Clostridium acetobutylicum*, mutation rates, hypermutable cells, artificial control

INTRODUCTION

Microbial evolution is promoted by genetic modifications on genomic architectures and compositions (Hastings et al., 2000; Matic et al., 2004; Conrad et al., 2009). Spontaneous mutations during DNA replication provide an important evolutionary force for microbes encountering environmental fluctuations, and accelerated accumulation of adaptive mutations can be expected to confer survival and growth advantages on individual cell level as well as on population level (Taddei et al., 1997; Tenaillon et al., 1999). Thus, hypermutable cells with elevated mutation rates play an important role for microbial adaptation and evolution under environmental stresses, e.g. rapid emergence of bacterial resistance to multi antibiotics (Tanabe et al., 1999; Perron et al., 2010). Recently hypermutable cells have also shown great potential in biotechnological applications, based on the ability of increasing the genetic variability at the genome level (Greener et al., 1997; Selifonova et al., 2001). However, the percentage of the hypermutable cells in microbial populations is generally low, and microbial cells tend to keep the mutation rates of genome replication at a relatively low level to avoid accumulation of deleterious spontaneous mutations (Kimura, 1967; Ishii et al., 1989; Kondrashov, 1995). Usually, the accuracy of genome replication is guaranteed by multiple and hierarchal mechanisms. This mainly includes base selection, 3'->5' exonuclease, and MMR (Methyl-directed Mismatch Repair) (Echols and Goodman, 1991; Kunkel and Bebenek, 2000). For better understanding and harnessing microbial evolution and genome plasticity, the natural quality control system of genome replication should be disturbed and replaced with artificial control mechanism, by which mutation rates of genome replication can be controlled and regulated as

requirement.

Clostridium is the second largest bacteria genera in size, and classified as Gram-positive endospore-forming obligate anaerobes (Andreesen, 1989; Rehner and Samuels, 1994). A large portion of *Clostridium* species, e.g. *C. botulinum*, *C. tetani*, *C. septicum*, and *C. difficile* pose serious threats to human health (Sakaguchi, 1982; Kennedy et al., 2005; Bartlett, 2006). On the other hand, many other *Clostridium* species, e.g. *C. acetobutylicum*, *C. thermocellum*, and *C. bifermentans*, show great significance on biotechnological application for solvents production and pollutant biodegradation (Jones and Woods, 1986; Lewis et al., 1996). Understanding and manipulating physiological and behavioral mechanisms of such *Clostridium* species requires better controllability of the microbial evolution, which can be achieved by construction of a controllable hypermutable system in *Clostridium*.

Previously, artificial regulation of cellular mutation rates was achieved by introducing proofreading-deficient DNA polymerase mutants (Selifonova et al., 2001; Shimoda et al., 2006; Abe et al., 2009) or inactivation of the nonessential proofreading mechanism (Sasaki et al., 2000; Emlyn-Jones et al., 2003), through which the natural quality-control mechanism for DNA replication can be disturbed. To date, this strategy has been applied in several model microbes, including *Escherichia coli*, *Bacillus subtilis*, and *Saccharomyces cerevisiae* (Selifonova et al., 2001; Emlyn-Jones et al., 2003; Endo et al., 2006; Shimoda et al., 2006), and the alteration of mutation rates is usually determined by a specific mutator gene, resulting in a single-switch control pattern. We aimed to design a novel and universal method through which microbial mutation rates can be rapidly regulated to diverse levels. To this end, we proposed a two-step strategy for construction of an artificial control of microbial mutation rates. The first step is to disrupt the natural cellular mechanisms for controlling the mutation rates by inactivating the relevant genes, generating cells with significantly increased mutation rates (hypermutable cells). The second step is to construct a proofreading control system carrying the genes that have been inactivated in the hypermutable cells, under the control of an inducible promoter. Combination of the hypermutable cells with the controlled expression of relevant genes is expected to generate an artificial control of mutation rates.

Using this concept, we constructed a controllable hypermutable system in *Clostridium acetobutylicum*, which is a representative species of the genus *Clostridium* with industrial relevance. By identification and deactivation of the chromosomally encoded *mutS/L* operon, we obtained a hypermutable cell SMBMut5, with over 250-fold increased mutation rates achieved. Subsequently, a proofreading control system bearing an anhydrotetracycline (aTc)-inducible *mutS/L* expression system was then constructed and introduced into SMBMut5, generating controllable hypermutable systems SMBMutC and SMBMutC2, in which the mutation rates of genome replication can be well controlled and regulated by the concentrations of exogenous aTc molecules. Facing butanol-stress, cells of SMBMutC2 under the evolving state showed much higher sur-

vival rate than the wildtype control, indicating that evolvability and adaptability of the controllable hypermutable *Clostridium* cells developed in this work were greatly increased. The newly developed controllable hypermutable system enables better harnessing of genome replication mutation rates of *C. acetobutylicum*, and will encourage the development of similar systems in other *Clostridium* species.
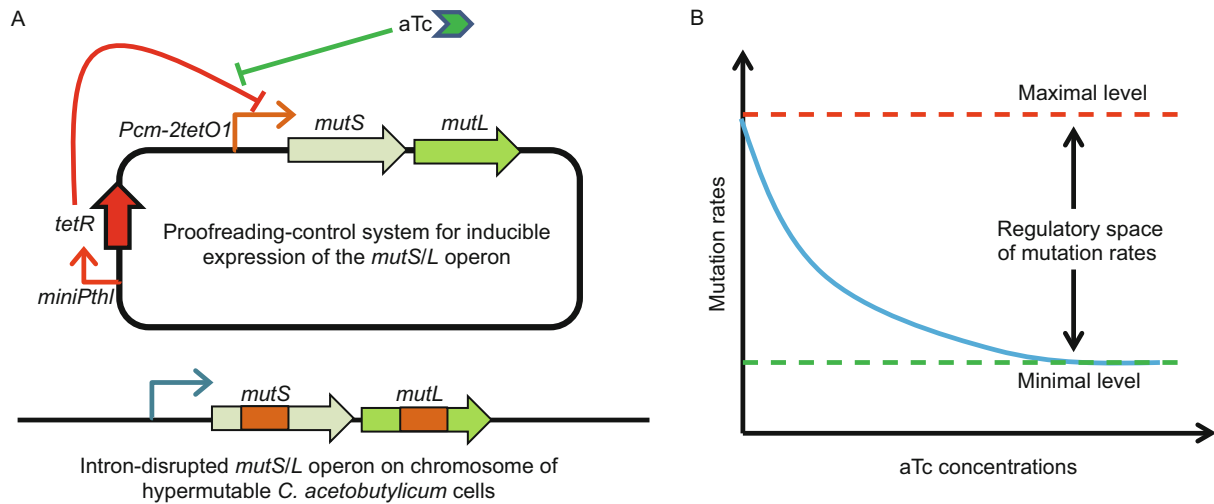

RESULTS

### Design of the controllable hypermutable system in *C. acetobutylicum*

To achieve artificial control of genome replication mutation rates in *C. acetobutylicum*, we designed a controllable hypermutable system consisted of a hypermutable cell and a proofreading control system, as shown in Fig. 1A. For construction of the hypermutable cell, the chromosomally located *mutS* and *mutL* on genome of *C. acetobutylicum* were knocked out. Since *mutS* and *mutL* are coding for activities of MMR, an important proofreading mechanism for DNA replication (Echols and Goodman, 1991; Kunkel and Bebenek, 2000; Kunkel, 2004), the resulted mutants are expected to exhibit significantly increased mutation rates due to decreased fidelity of genome replication. With regards to introduction of a proofreading control system, the *mutS/L* operon was placed under the control of an aTc inducible promoter that we developed previously for *Clostridium* (Dong et al., 2012). The hypermutable cell containing the proofreading control system thus forms a system that is capable of artificially controlling the mutation rate of genome replication. In the absence of aTc, the promoter is bound by TetR to block the expression of *mutS* and *mutL*, meaning the MMR function is deficient so as the mutation rate is elevated to a maximal level of the hypermutable state. In the presence of aTc, the TetR repressor is bound by aTc, thus the promoter will be induced to initiate the expression of *mutS* and *mutL*, ensuring a high fidelity of genome replication. As the expression strength is dependent on aTc concentration, the mutation rate can be gradually recovered to a regular level as aTc concentration increases (Fig. 1B). When aTc concentration achieved an optimal value for *mutS/L* expression, mutation rates will be regulated to the minimal level of the system. In summary, the switch ON/OFF and fine-tuning of the hypermutable state can be achieved in the absence or presence of an appropriate concentration of aTc.

Generation of hypermutable cells of *C. acetobutylicum* by inactivation of *mutS/L* operon

To create hypermutable cells of *C. acetobutylicum*, we aimed to inactivate the MMR-system-encoding genes. *C. acetobutylicum* SMB009 is a derivative of *C. acetobutylicum* DSM1731, of which the complete genome has been sequenced (Bao et al., 2011). Chromosomally located SMB_G1862 and SMB_G1861 genes were annotated as *mutS* and *mutL*, respectively. ClosTron method was then applied to inactivate these two

Figure 1. Design of the controllable hypermutable system in _C. acetobutylicum_. (A) Chromosome located _mutS_ and _mutL_ of _C. acetobutylicum_ were disrupted by intron. An exogenous vector carrying _mutS/L_ operon under control of an aTc inducible promoter _Pcm-2tetO1_ was introduced into the cell as a proofreading-control system. In the absence of aTc, the TetR molecules bound to the _Pcm-2tetO1_ promoter and inhibited expression of _mutS/L_, leading to an elevation of mutation rates. In the presence of aTc, the TetR molecules were bound by aTc, and the expression of _mutS/L_ was activated, leading to an increased fidelity of an increased fidelity of genome replication. (B) Mutation rates of the controllable hypermutable system in _C. acetobutylicum_ can be well controlled in a regulatory space by regulation of aTc concentrations. When aTc was completely absent, mutation rates achieved a maximal level due to the top level of TetR inhibition. When aTc concentration achieved an optimal value for _mutS/L_ expression, mutation rates were regulated to the minimal level for the system.
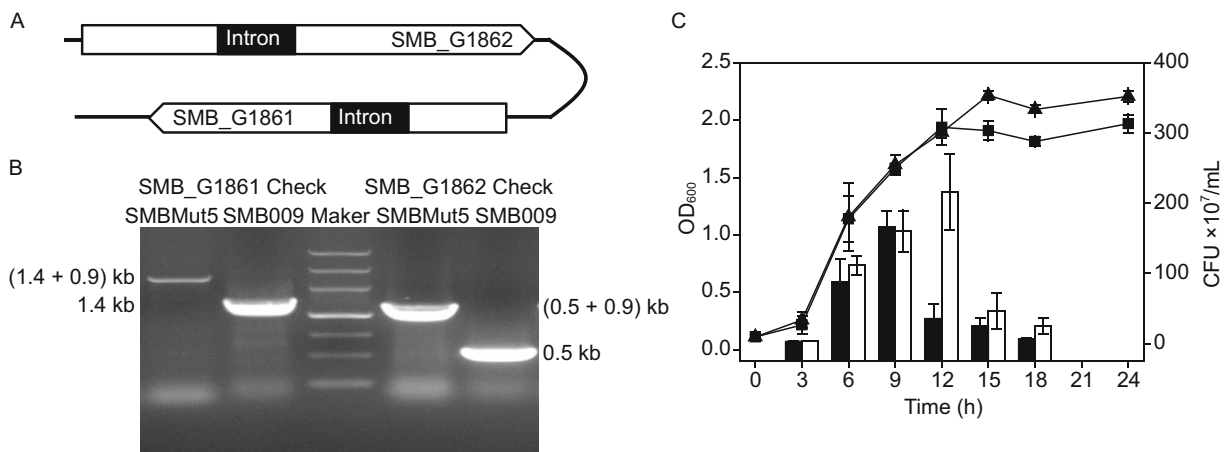

Figure 2. Construction and evaluation of _mutS/L_ disrupted strain SMBMut5. (A) Schematic show of the disruption pattern of _mutS/L_ operon on the genome. Two introns were separately inserted into the CDS of SMB_G1862 gene and SMB_G1861 gene for completely inactivation of _mutS/L_ operon. (B) Identification of the SMBMut5 and SMB009 strains by primers _mutS_-disruption-check-F/R (the right two lanes) and _mutL_-disruption-check-F/R (the left two lanes). (C) Growth assay of SMBMut5 and SMB009 strain. OD$_{600}$ value (points and lines) and CFU counts (bars) were measured during the growth of SMBMut5 (filed triangles and white bars) and SMB009 strains (filed squares and black bars) in 24 h.

genes (Fig. 2A), generating _mutS/mutL_ single mutant or _mutS-mutL_ double mutant (Table 1). Insertions of the ClosTron into the target gene sites were verified via PCR amplifications (Fig. 2B) and subsequent sequencing of PCR products.

To confirm whether the inactivation of _mutS/L_ operon led to

increase of mutation rates in _C. acetobutylicum_, we determined the frequencies of generating rifamycin-resistant (Rif25R) colonies, which were commonly used to reflect microbial mutation rates (Sasaki et al., 2000; Selifonova et al., 2001; Emlyn-Jones et al., 2003). As expected, inactivation of _mutS/L_ operon

Table 1. Genotypes and mutation rates evaluation of the series of *mutS/L* inactivated strains

Strain	Relative genotypes[a]	Mutation rates[b]	Relative mutation rates[c]
SMB009		$(0.0056 \pm 0.0003) \times 10^{-6}$	1
SMBMut2	*mutL*::intron	$(0.83 \pm 0.02) \times 10^{-6}$	148.8
SMBMut3	*mutS*::intron	$(0.87 \pm 0.17) \times 10^{-6}$	155.4
SMBMut5	*mutS*::intron, *mutL*::intron	$(1.44 \pm 0.16) \times 10^{-6}$	257.9

[a] All of the SMBMut2, SMBMut3, and SMBMut5 strains were obtained from SMB009 by genetic modification with ClosTron gene inactivation approach.

[b] Mutation rates data were calculated from both the total numbers of live cells and Rif25 resistant cells. To calculate the standard deviation, every experiment was repeated at least 3 times.

[c] Relative mutation rates were obtained by comparison with that of the SMB009 as 1.

significantly increased the mutation rates (Table 1). The *mutS-mutL* disrupted strain SMBMut5 showed an over 250-fold increased frequency for generating Rif25R colonies. In addition, the *mutL*-disrupted strain SMBMut2 and *mutS*-disrupted strain SMBMut3 also showed an approximately 150-fold increased mutation rate, respectively, comparing to that of the wildtype control *C. acetobutylicum* SMB009 (Table 1). Determination of the mutation rates indicated that inactivation of the *mutS/L* operon disturbed the quality control system for ensuring the high fidelity of genome replication in *C. acetobutylicum*, thus leading to accumulation of significantly increased spontaneous mutations.

Further analysis revealed that inactivation of the *mutS/L* operon did not inhibit the growth of *C. acetobutylicum*. The SMB-Mut5 strain showed a similar but prolonged growth curve with the control (Fig. 2C). Both the optical density and the live cells of strain SMBMut5 in culture broth kept increasing for a longer process than that of SMB009, possibly due to the enhanced adaptability caused by high mutation rates under complex and tough conditions when the culture entered stationary phase. Thus *C. acetobutylicum* SMBMut5 was selected as the hypermutable cell for further investigation.

Assembling and evaluation of the controllable hypermutable system in *C. acetobutylicum*

To artificially control the mutation rate of the hypermutable cells of *C. acetobutylicum*, we cloned the *mutS/L* operon from *C. acetobutylicum* DSM1731 and inserted it into a previously developed inducible-gene-expression system in *C. acetobutylicum*, pGusA2-2tetO1 (Dong et al., 2012). The new plasmid was termed as pMutS/L-2tetO1, in which the expression of *mutS/L* was controlled by an aTc inducible promoter. Plasmid pMutS/L-2tetO1 was transformed into strain SMBMut5, generating a new strain designed as SMBMutC (Fig. 3A). For evaluation and analysis, strain SMB009 carrying pMutS/L-2tetO1, designed as SMB9M, was used as a control.

The hypothesis is that strain SMBMutC generated by combination of the hypermutable cell with the proofreading control system should work as a controllable hypermutable system. To verify this, we determined the mutation rates of strains SMBMutC and SMB9M under serial concentrations of aTc. As shown in Fig. 3B, the mutation rate of SMBMutC is responsive

to the increased concentrations of aTc. In the absence of aTc, strain SMBMutC showed an elevated mutation rates (0.35×10^{-6}), 95-fold and 62-fold higher than that of strain SMB9M (0.0037×10^{-6}) and SMB009 (0.0056×10^{-6}), respectively. When an increased concentration aTc was added to the medium, the mutation rates of strain SMBMutC were gradually decreased. When the aTc concentrations reached 50 µg/mL, the mutation rates of SMBMutC reverted to a regular level (0.0063×10^{-6}) comparable to that of the controls.

Duplication of the *tetR* module optimized the controllability of the controllable hypermutable system

As shown in Table 1 and Fig. 3B, introduction of pMutS/L-2tetO1 into strain SMBMut5 led to a 4-fold decrease of background mutation rates in the absence of aTc (from 1.44×10^{-6} to 0.35×10^{-6}), indicating leaky expression of *mutS/L* occurs. To increase the capability of the controllable hypermutable system for regulating the mutation rate, we aimed to increase the stringency of the inducible *mutS/L* expression system. Since the *tetR* gene in pMutS/L-2tetO1 encodes a tetR protein, which recognizes and combines with the 2tetO1 region in the promoter, we hypothesized that increasing the gene dose of *tetR* might reduce leaky expression, thus improving the stringency of the system. We therefore duplicated the *miniPthl-tetR* module on pMutS/L-2tetO1 and obtained the new plasmid, which is designed as pMutS/L-2tetO1-2tetR.

We introduced the newly constructed pMutS/L-2tetO1-2tetR into strain SMBMut5 and obtained strain SMBMutc2 (Fig. 4A). Mutation rates determination (Fig. 4B) revealed that strain SMBMutC2 showed a better controllability than that of SMBMutC. In the absence of aTc, background mutation rates of SMBMutC2 (0.71×10^{-6}) is 2-fold higher than that of SMB-MutC (0.35×10^{-6}), suggesting the leaky expression of *mutS/L* was reduced in the new system. Further analysis revealed that the mutation rate of strain SMBMutC2 could also be well regulated by aTc concentrations. In the aTc concentration of 0, 50, 100, and 200 µg/mL, mutation rates of strain SMBMutC2 can be increased by 120-fold, 40-fold, 10-fold, and 3-fold respectively, comparing with that of the wildtype control SMB009, ranging over 3 orders of magnitudes.

Protein & Cell
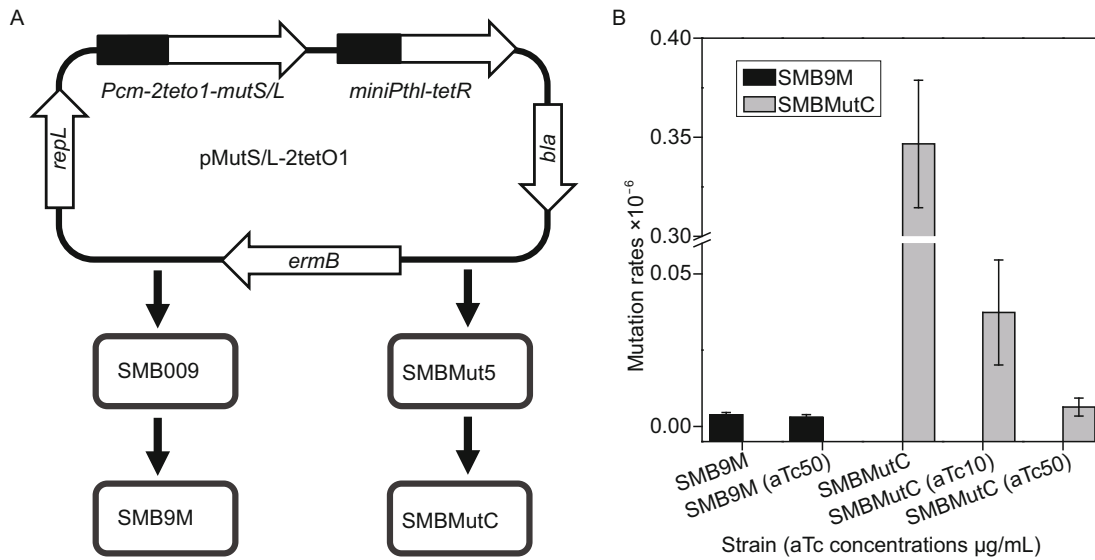

Figure 3. Construction and evaluation of SMBMutC strain. (A) A vector carrying the *mutS/L* operon under control of an aTc inducible promoter was constructed and termed as pMutS/L-2tetO1. The constructed plasmid was transformed into SMBMut5 and SMB009 to generate SMBMutC strain and SMB9M strain, respectively. (B) Mutation rates determination of SMBMutC strain (grey bars) and SMB9M strain (black bars) under serial concentrations of aTc molecule. Mutation rates were determined after cultivation of the strains for 6 h. Generation frequency of Rif25R colonies was calculated as mutation rates for genome replication. Error bars presented standard deviation among 3 independent determination experiments.

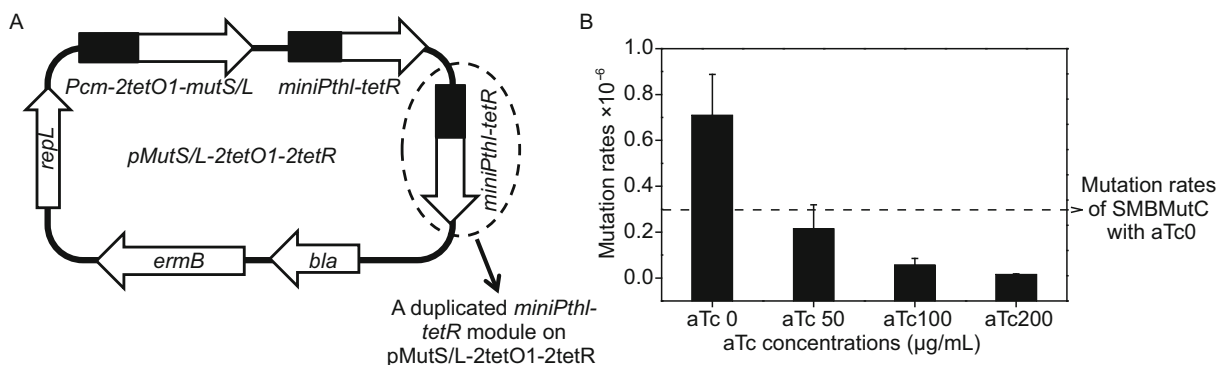

Figure 4. Construction and evaluation of SMBMutC2 strain. (A) *miniPthl-tetR* component of the pMutS/L-2tetO1 vector was duplicated to generate the pMutS/L-2tetO1-2tetR vector. The obtained vector was transformed into SMBMut5 to generate the SMBMutC2 strain. (B) Mutation rates were determined for SMBMutC2 strain under serial concentrations of aTc. Error bars presented standard deviation among 3 independent determination experiments. The dotted line represented for the mutation rates of SMBMutC with no aTc addition.

SMBMutC2 with elevated mutation rates showed increased survival and tolerance capacities than SMB9M facing butanol-stress

For further evaluating the evolvability and adaptability of the developed controllable hypermutable *Clostridium* cells, we analyzed and compared the survival and tolerance capacities of the SMBMutC2 and SMB9M under n-butanol challenging conditions. As the main fermentation products of *C. acetobutylicum*, high concentrations of n-butanol are greatly toxic and inhibitory for microbial growths. As designed, SMBMutC2 cells

with elevated mutation rates were expected to show enhanced survival and tolerance capacities facing butanol-stress.

After overnight cultivation under normal no-stress conditions, about 10^6 *Clostridium* cells were spread on RCM agar-plates containing series of concentrations of n-butanol and cultivated for 3 days before photographed. As shown in Fig. 5, on non-toxic n-butanol concentration of 10 g/L, growths of SMBMutC2 and SMB9M showed no difference, and both of them can generate high density lawn on the agar-plates, which were comparable with the growth on normal RCM plates. While on n-butanol concentrations of 12 g/L, which is toxic for

Figure 5. n-Butanol challenge of the SMBMutC2 and SMB9M strains. About 10^6 *Clostridium* cells of SMBMutC2 and SMB9M were spread on RCM agar-plates containing n-butanol concentrations from 10 g/L to 14 g/L, and cultivated for 3 days before photographed and counted. (A) Colonies of SMBMutC2 (left) and SMB9M (right) generated on RCM agar-plates containing 12 g/L n-butanol. (B) CFU counts of SMBMutC2 and SMB9M on serial concentrations of n-butanol from 10 g/L to 14 g/L. High density lawn means that the colonies densities were similar with that on n-butanol conditions.

cell growths, SMBMutC2 showed greatly increased survival rates than SMB9M (Fig. 5A). Similar phenomena were also observed on other butanol concentrations from 11 g/L to 14 g/L (Fig. 5B), meaning that the hypermutable *Clostridium* cells we developed showed increased evolvability and adaptability facing environmental challenges.

DISCUSSION

Artificial construction of hypermutable cells in which mutation rates were altered via genetic manipulation has been achieved in several microbes. Multiple mutator or anti-mutator genes related with fidelity of DNA replication have been identified in microbes (Horst et al., 1999; Sasaki et al., 2000; Yang et al., 2004), thus providing many targets for genetic manipulation. However, most existing systems for regulating mutation rates were developed by inactivation, over-expression, or modification of a specific mutator or anti-mutator gene, leading to a single-switch control pattern and a constant mutagenesis strength. For better understanding and harnessing microbial

evolution, an artificially controllable hypermutable system with fine-tuning capacity might be a better choice (Tenaillon et al., 1999; Loh et al., 2010; Gentile et al., 2011). In this work, we proposed a novel and universal strategy to replace natural cellular controlled expression of MMR system by artificially controlled expression, thus leading to well-controlled mutation rates of microbial genome replication. In *C. acetobutylicum*, an important and representative *Clostridium* species, we performed this strategy and constructed an artificially controllable hypermutable system, in which mutation rates of the cells can be well controlled by regulation of aTc concentrations.

Genome sequencing (Bao et al., 2011) and development of efficient genetic manipulation tools (Shao et al., 2007; Dong et al., 2010, 2012) in *C. acetobutylicum* enabled successful construction of the controllable hypermutable system. *mutS* and *mutL* involved in MMR system play an important role for quality control of DNA replication in microbes by recognizing and removing mismatches generated during DNA replication (Modrich and Lahue, 1996; Horst et al., 1999), and their defects have been proved responsible for generation of hypermutable cells in many microbes (LeClerc et al., 1996; Sniegowski et al., 1997; Shaver and Sniegowski, 2003). In this work, inactivation of the chromosome located *mutS/L* operon and introduction of an aTc-inducible *mutS/L* expression system successfully constructed an aTc-dose-responsive regulation on the mutation rates of *C. acetobutylicum*. In summary, with the controllable hypermutable strains SMBMutC and SMBMutC2, mutation rates of *C. acetobutylicum* cells can be regulated ranging over 3 orders of magnitudes, from normal level of the wildtype control to 120-fold increased level. Convenient switch between normal cells to hypermutable cells and fine-tuning of the strength of mutation rates indicated this system could act as a powerful tool for harnessing evolution of *C. acetobutylicum* (Hermann et al., 1985; Stephanopoulos, 2002; Liu et al., 2013).

Accuracy of genetic information transfer is guaranteed by multiple and hierarchical mechanisms in microbial cells (Kunkel, 2004), meaning many targets can be manipulated to trigger increased mutation rate for genome replication. Disturbing of different proofreading-related genes would bring influence of varying degrees to fidelity of DNA replication (Morrison et al., 1993; Sasaki et al., 2000). Knockout of the *mutS/L* operon led to a 250-fold increased mutation rate in *C. acetobutylicum*, and that is also the theoretically maximal mutagenesis strength that can be achieved in our system. For further expanding the regulatory space to generate higher mutagenesis strengths if needed, systematic modifying and engineering of other proofreading-related genes might be necessary.

The controllable hypermutable system of *C. acetobutylicum* showed improved controllability of genome replication mutation rates, and that confirmed the feasibility and effectiveness of our two-step strategy to replace natural cellular control of the replication-proofreading-mechanism by artificial control. In comparison with the previously developed hypermutable system in other microbes (Selifonova et al., 2001; Shimoda et al., 2006; Abe et al., 2009), the hypermutable cells developed with

our method enabled more convenient and regulatable control of cellular mutation rates. Fine-tuning of the mutation rates to diverse levels in our system can be achieved by addition or removal of exogenous signal aTc molecules, rather than complex genetic manipulations. In addition, when desired traits were obtained for the hypermutable cells, the convenient switch from mutational state to normal state will guarantee maintaining of the obtained phenotypes and genotypes by preventing possible back mutations or negative mutations. Based on development of efficient genetic manipulation approaches and genome sequencing technologies, our strategy will encourage and promote development of similar systems in other microbes.

MATERIALS AND METHODS

Bacterial strains, plasmids, and primers

Bacterial strains, plasmids, and primers used in this work are listed in Table 2. *E. coli* DH5α cells (TAKARA) were used for plasmid construction. All primers were synthesized by Invitrogen (Beijing, China) followed by polyacrylamide gel electrophoresis purification.

Cultivation and maintenance conditions

E. coli cells were aerobically cultivated in Luria-Bertani medium at 37°C with 200 rpm orbital shaking. All *C. acetobutylicum* strains were cultivated anaerobically at 37°C in RCM medium (Hirsch and Grinsted, 1954). Antibiotics were supplemented when necessary (ampicillin, 100 μg/mL, Amp100; chloramphenicol, 30 μg/mL, Cm30; erythromycin, 50 μg/mL, Em50). All *E. coli* and *C. acetobutylicum* strains were maintained in 15% glycerol at −80°C.

DNA isolation and manipulation

Total genomic DNA of *C. acetobutylicum* was extracted with TIANamp Bacterial DNA Kit (TIANGEN Biotech, Beijing, China). Plasmid extraction from *E. coli*, PCR products purification, and gel extraction were

performed with E.Z.N.A. Plasmid Extraction Kit, E.Z.N.A. Cycle Pure Kit, and E.Z.N.A. Gel Extraction Kit (Omega Biotek Inc., Guangzhou, China), respectively. DNA restriction and cloning were performed according to standard procedures (Sambrook and Russell, 2001). Enzymes used for DNA amplification and manipulation were from NEB (Beijing, China) and used according to the manufacturer's instructions. Electrotransformation of *C. acetobutylicum* was performed as previously described (Mermelstein et al., 1992).

Construction of *mutS/L* operon disrupted *C. acetobutylicum* strains

C. acetobutylicum strain SMB009 capable of accepting unmethylated DNA (Dong et al., 2010) was selected as parental strain for *mutS/L* operon disruption with ClosTron method previously developed (Shao et al., 2007). Three strains SMBMut2, SMBMut3, and SMBMut5 were constructed for further analysis and investigation, in which *mutS*, *mutL*, and both *mutS-mutL* were disrupted, respectively. Intron insertion sites on *mutS* and *mutL* were selected at the position of 570/571 (numbered from the initiator codon of the ORF) on the sense strand (for *mutS*) and the position of 210/211 on the sense strand (for *mutL*), and the intron retargeting PCR primers (i.e., *mutS*-570/571S-IBS, EBS-1d, EBS2) were designed according to a published computer algorithm (Perutka et al., 2004). Construction manipulation for the retargeting vectors and obtaining of the gene-knockout mutants were performed as previously introduced (Dong et al., 2010; Dong et al., 2012). SMBMut5 strain (*mutS*::intron, *mutL*::intron) was derived from SMBMut3 (*mutL*::intron).

Construction of *mutS/L* expression vector pMutS/L-2tetO1 and pMutS/L-2tetO1-2tetR

To construct a *mutS/L* operon expression vector based on the pGusA2-2tetO1 plasmid that we developed previously (Dong et al., 2012), *mutS/L* operon from the genome of *C. acetobutylicum* SMB009 was amplified with primer *mutS/L*-operon-F (*Nco*I) and *mutS/L*-operon-R (*Xho*I). The PCR products were used to replace the *gusA* gene on the pGusA2-2tetO1 plasmid, to which an *Nco*I site has been introduced in advance. The resulted plasmid was named as pMutS/L-2tetO1.

To improve the stringency of the aTc-inducible *mutS/L* expression system, the *miniPthl-tetR* component on the pMutS/L-2tetO1 vector was duplicated. To this end, the *miniPthl-tetR* component from the pMutS/L-2tetO1 was amplified with primer *miniPthl-tetR*-F (*Xho*I) and *miniPthl-tetR*-R (*Bam*HI), and the PCR products were inserted into the pMutS/L-2tetO1 between the *Xho*I and *Bam*HI sites to generate the pMutS/L-2tetO1-2tetR vector.

Mutation rates evaluation

Three single colonies of *C. acetobutylicum* strains were picked up and inoculated into RCM culture medium for overnight activation. The broth was transferred into fresh media with a ratio of 1:100 and cultivated for 6 h before spreading on RCM agar plates with or without 25 μg/mL of rifamycin. Mutation rates were calculated by dividing the number of rifamycin resistant (Rif25R) colonies by the number of total colonies. To calculate the total number of cells, series of dilutions were performed. Em50 was added to culture mediums when necessary.

n-Butanol challenge

Single colonies of SMBMutC2 and SMB9M were picked up and inocu-

lated into fresh RCM culture medium and cultivated overnight. Broths containing about 10^6 cells were spread on RCM agar-plates containing serial concentrations of n-butanol, from 10 g/L to 14 g/L. The plates were then cultivated anaerobically at 37°C for 3 days before photographed. Em50 was also added to the liquid medium and agar-plates.

COMPLIANCE WITH ETHICS GUIDELINES

Guodong Luan, Zhen Cai, Fuyu Gong, Hongjun Dong, Zhao Lin, Yanping Zhang, and Yin Li declare that they have no conflict of interest.

This article does not contain any studies with human or animal subjects performed by the any of the authors.
