Abstract Prompt diagnosis and rapid initiation of medical treatment are critical for the best outcomes in infants with congenital toxoplasmosis. This is important for pregnant women, fetuses, and infants, including those with active retinitis and choroidal neovascular membranes. For hydrocephalus, prompt placement of a ventriculoperitoneal shunt is key for improved outcomes. Pyrimethamine and Sulfadiazine with Leucovorin are first-line medicines. For later recurrences of active retinitis, Azithromycin or Clindamycin are sometimes substituted for Sulfadiazine as second-line treatments, given with Pyramethamine. Following resolution of active retinitis, these medicines may be useful without Pyrimethamine for suppression and avoid the risk of hypersensitivity from Trimethoprim/Sulfamethoxazole. Antibody to VEGF, in conjunction with antimicrobial therapy, results in resolution of choroidal neovascular membranes. Serologic screening of seronegative pregnant women to detect primary infection during gestation, and facilitating medicine administration and thereby preventing or treating fetal infection, is an optimal,

Introduction

In 1939, Wolf and Cowen reported the first case of congenital toxoplasmosis attributed to *Toxoplasma gondii* [1]. This infected infant presented with ultimately fatal encephalitis [1] and was diagnosed with *T. gondii* infection by Sabin [2]. Other cases were described in the following years. Understanding of clinical manifestations, pathogenesis, pathology, and development of current approaches to optimal management evolved over the next decades [3, 4, 5•, 6–16, 17••, 18–21, 22••, 23–34, 35••, 36, 37•, 38–41, 42••, 43–47, 48•, 49–62, 63•, 64–67, 68•, 69. 70•, 71–78, 79••, 80••, 81••, 82•, 83, 84•, 85•, 86, 87•, 88–90, 91•, 92, 93, 94••, 95, 96, 97•, 98••, 99–111, 112•, 113•114–118, 119•, 207]. In the 1950s and 1960s, the severity of infection was recognized to be inversely correlated with gestational age at the time of infection. Transmission rates were low early in gestation but were associated with more severe clinical disease, while transmission occurred more frequently later in gestation but was frequently subclinical [23–30, 36–40, 43, 44, 63•, 64]. Prognosis was guarded for those infants with substantial manifestations of active disease at birth in the absence of subsequent treatment [43, 44]. Untreated subclinical infections were noted to harm children later in life, particularly causing cognitive decline and recurrent retinal disease [63•, 64]. The presence of meningitis or retinal disease was noted in up to 50 % of infants whose infection went unnoticed with standard newborn examinations. In France, Austria, and Germany, gestational serologic screening programs were developed to detect acquisition of infection during fetal life [21, 28, 31, 49, 61, 62, 115, 117, 118]. Treatment to prevent infection and disease in the fetus and infant was optimized (Fig. 1; [21, 28, 31, 49, 61, 62, 69, 70•, 71–78, 79••, 80••, 81••, 107, 115–118], 119•, 120••, 121••, 207). In a phase 1 study and in a phase 2 randomized trial of a higher and lower dosage of Pyrimethamine treatment of infants compared with untreated historical controls (Fig. 2), and treated children with recurrent eye disease had improved outcomes [35, 69, 70•, 71–78, 79••, 80••, 81••, 92, 93, 114, 121••, 207]. Effective treatments in infancy and through the first year of life were defined in the USA, and this work changed the approach to management of the disease in the next decades in the USA [69, 70•, 71–78, 79••, 80••, 81••, 121••, 207], as well as in France, Austria, Germany, and other countries [3, 69, 70•, 71–78, 79••, 80••, 81••, 90, 207]. Mathematical analyses suggest that such serologic screening will be cost-effective in the USA, and these methods of analysis are also being applied in other countries such as

Fig. 1 Gestational screening and treatment to improve outcomes. ▶ **a** Serologic screening for *T. gondii* infection during pregnancy an algorithm for early diagnosis of acquisition of *T. gondii* infection. For boxes shaded with blue, consult with high-risk maternal-fetal medicine. Adapted with permission from McLeod et al. [206, 207]. **b** Screening for toxoplasmosis throughout pregnancy. Diagram indicating when and how screening for *T. gondii* infection should occur, prenatally and 1 month after birth. Adapted with permission from McLeod et al. [206, 207]. **c** Amniocentesis to Detect Congenital *T. gondii* Infection. Relationship between percentage of pregnant women undergoing amniocentesis (*open bars*) and those with fetuses with congenital toxoplasmosis (*filled bars*) as a function of the gestational age at seroconversion. The *inserted table* indicates the sensitivity, specificity, and positive and negative predictive values of PCR analysis of samples obtained via amniocentesis as a function of trimester. Adapted with permission from Wallon et al. [119]. **d** Gestational age and its relationship to parasitemia. Relationship between the gestational age at the time of maternal infection with *T. gondii* and the magnitude of parasitemia (parasites/mL). Note early infection is correlated with more severe disease. Empty bars are indicative of subclinical infection, while filled bars represent symptomatic infection. Adapted with permission from Romand et al. [103]. **e** French algorithm and its impact on outcomes in congenital toxoplasmosis. Summary of outcomes for congenitally infected individuals. Adapted with permission from Mehta et al. [208]. **f** Impact of the french approach on likelihood of congenital infection with *T. gondii*. Impact of utilization of French algorithm on probability of fetal infection following gestational infection as a function of gestational age. In the Lyon Cohort, this approach to early screening/treatment was implemented in 1992, and, at that time, probability of fetal infection decreased. Accompanying table indicates both reduction in the risk of infection and of clinical signs of congenital *Toxoplasma* infection following changes in screening policy in 1992 and prenatal diagnosis and treatment in 1995. Adapted with permission from Wallon et al. [120]. **g** Impact of early detection/treatment on frequency of eye disease at 3 years of age. Kaplan–Meier plot depicting the impact of early diagnosis and treatment on the fraction of patients without eye disease. In patients with less than 4 weeks of delay between gestational infection and initiation of treatment (*solid line*) and with between four and 8 weeks of delay (*dashed line*), eye disease is much less common than for those patients with an interval of greater than eight weeks between infection and treatment (*dotted line*). Adapted with permission from Kieffer et al. [62]. **h** Conclusions regarding the outcomes of *T. gondii* infection in those infants with prenatal screening, diagnosis, and treatment. Adapted with permission from and McLeod et al. [207]. (I)—A Time and Treatment of *T. gondii* Infection Adapted with permission from McLeod et al. [206, 207]. Outcomes Using the French Algorithm
• **Diagnose Mother:** Systematic serologic screening before conception, intrapartum, and postpartum.
• **Treat Mother:** If acute serology, spiramycin reduces transmission of *T. gondii* across placenta to fetus, but does not treat the fetus. • Untreated 94 (60%) of 154 vs. treated 91 (23%) of 388[a].
• **Diagnose Fetus**: Ultrasounds, amniocentesis, PCR at ≥ 18 wk gestation[b]. • Sensitivity 37 (97%) of 38; specificity 301 of 301[c]. For mid-gestation infections, please see Figure 2.
• **Treat Fetus:** Treat mother with pyrimethamine and sulfadiazine, which cross the placenta to treat the fetus.
• **Hohlfeld[c, d]:** N=54 live births; 34 terminations; All 54 normal development. 19% subtle findings: 7 (13%) intracranial calcifications, 3 (6%) chorioretinal scars. Follow-up of 18 children (median age 4.5 yr; range 1-11 yr): 39% retinal scars, most scars were peripheral.
• **Couvreur[e]:** Compared to a spiramycin regimen, adding pyrimethamine and sulfadiazine to a spiramycin regimen reduce the number of isolates from placenta from 77% to 42%, reduced *T. gondii*-specific immunoglobulin load at birth from 139 IU/g IgG to 86 IU/g IgG and at 6 mo. from 137 IU/g IgG to 70 IU/g IgG, reduced *T. gondii*-specific IgM prevalence in the neonate from 69% to 17%, and increased subclinical infections, presumably by delaying transmission, from 17% to 30%.
• **Kieffer[f]:** Shorter interval between diagnosis and treatment reduces subsequent retinal disease.
• **Syrocot[g]:** Shorter interval between diagnosis and treatment reduces subsequent neurologic disease.
• **Conclusion:** Favorable outcomes with treatment *in utero* in France and as French Algorithm applied in U.S.[h, i].

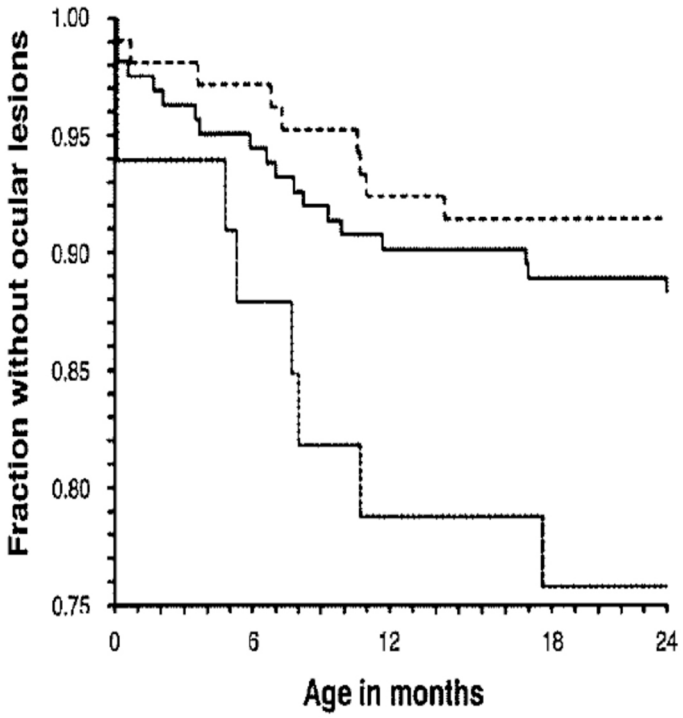
manage this infection to optimize the quality of life for infected individuals and their families [78, 79••]. The more rapidly the diagnosis is made, with prompt initiation of treatment, the better the observed outcome.

Prevention, Diagnosis, and Treatment of Congenital Toxoplasmosis During Gestation

Optimal management of congenital *T. gondii* infection begins with prenatal diagnosis, prevention of transmission to

G



H

Conclusions:

- Gestational age of *T. gondii* infection acquisition predicts maternal-fetal transmission
- Delay in prenatal treatment increases the risk of clinical signs in infected children
- Prenatal treatment results in:
  - Decreased number of cases with severe infection
  - Decreased number of cases with mild infection
  - Decreased incidence of sequelae at birth
  - Decreased number of late sequelae
  - Decreased incidence of vertical transmission

the fetus, and treatment of the fetus as soon after acquisition as possible [3, 4, 5•, 6–16, 17••, 18–21, 22••, 23–34, 35••, 36, 37•, 38–41, 42••, 43–47, 48•, 49–62, 63•, 64–67, 68•, 69. 70•, 71–78, 79••, 80••, 81••, 82•, 83, 84•, 85•, 86, 87•, 88–90, 91•, 92, 93, 94••, 95, 96, 97•, 98••, 99–111, 112•, 113•114–118, 119•, 120••, 207]. This approach was developed in France (Fig. 1) and is currently the gold standard of care for all pregnant women in that country. Preconception or serologic screening by 11 weeks identifies seronegative women who undergo monthly serologic screening for *T. gondii* IgG and IgM beginning at 11 weeks' gestation and continuing through the first postpartum month. This approach identifies gestational infection in the previously seronegative pregnant woman by detecting the presence of new *T. gondii*-specific serum antibody. When a pregnant woman seroconverts, treatment with Spiramycin, which is concentrated in the placenta, can block transmission to the fetus up to 50 % of the time [95]. This approach is used for maternal infection prior to the 17th week of gestation without known transmission to the fetus. Further therapy is stratified based on the presence or absence of fetal infection; amniocentesis with PCR for *T. gondii* DNA is utilized to diagnose fetal infection

A

NARRATIVE FOR DIAGNOSIS OF CONGENITAL TOXOPLAMOSIS IN NEWBORN INFANT

I) SAMPLES OBTAINED IN DELIVERY ROOM

This includes: Placenta to go to reference laboratory for A-subinoculation into mice and B-PCR. Amniotic fluid, if available

A. 200 gram sample of placenta from the cord insertion area on the fetal side (100 gram is approximately 14cm x 3cm x 3cm) for subinoculation into mice and PCR.

1. **Storage**
   Store sterilely in sterile saline (NO FORMALIN OR OTHER PRESERVATIVE, DO NOT FREEZE). Penicillin (100 units per mL) and Streptomycin (100 µgm/mL) or gentamicin to laboratory capable of subinoculation should be added. Keep placenta cool (NOT FROZEN) with ice bag or preferably frozen cold packs.
2. **Shipping**
   Ship immediately (ASAP) by Federal Express.
   The US Reference Laboratory Address:
   Research Institute
   Palo Alto Medical Foundation
   Attn: Serology
   Ames Building
   795 El Camino Real Palo Alto, CA 94301
   (650) 853-4828

   Call receiving laboratory when the placenta is obtained so proper handling upon receipt is assured. Note that samples for subinoculation must be received within 72 hours of collection.

   European Laboratory, where available:
   Contact Herve Pelloux
   HPelloux@chu-grenoble.fr

B. 10-20 mL (or more) amniotic fluid, if available (for PCR of pellet and subinoculation). Not essential if obtained early.

1. **Storage and shipping**
   Keep cold (NOT FROZEN) and ship with sample I(A) as described above.
   Each sample for PCR should be placed in a separate sealed bag to prevent cross-contamination.
   To be centrifuged by Reference Laboratory.

II) CLINICAL EXAMINATIONS AND EVALUATIONS OF BABY FOLLOWING BIRTH

A. General Examination

B. Pediatric Ophthalmologist

C. Pediatric Neurologist

D. CT scan of the brain. Baby should not be sedated and may be gently swaddled. This examination is done without contrast. Examine for ventricular size and brain calcifications.

E. Auditory Acoustic Emissions or BAER (hearing test) Currently Available Test in French and American Reference Laboratories.

III) SAMPLES OBTAINED FROM INFANT SUBSEQUENT TO DELIVERY AT DELIVERING HOSPITAL

The following samples and tests are obtained for the newborn infant and processed and analyzed at the delivering hospital.

1. **CBC with differential and platelet count**
2. **Serum: total IgM, IgG, IgA, albumin**
3. **Serum: SGPT, SGOT, total and direct bilirubin, creatinine**
4. **Urinalysis**
5. **Lumbar puncture**
   a) Cerebrospinal fluid: cell count, glucose protein and total IgG.
   b) Please note that an additional 0.5 mL is to be collected for IgG and IgM specific for *T. gondii* to be sent to a reference lab such as Palo Alto Medical Foundation as described below in **"IV) 3."**
   c) If available, hold 1.5 mL frozen cerebrospinal fluid for quantitative IgG if needed later to calculate antibody load (0.5 mL) and pcr (1.0 mL). Place 0.5 mL and 1.0 mL in separate tubes.

IV) The following samples are to be sent to a reference lab such as Palo Alto Medical Foundation (address above). They should be kept cold (NOT FROZEN). Remember to include the permission form for the PAMF to release serologic and isolation results to the Toxoplasmosis Research Institute and Center / Dr.McLeod. Note that these may be stored and shipped with sample I(A) described above.

1. **2 mL sterile infant peripheral blood**
   This is peripheral blood (i.e. not umbilical cord blood).
   Place in two purple top tubes of 1 mL each.
   This is for PCR and subinoculation of buffy coat.
   Also send sterile clot from **"2"** below.
2. **1mL serum**
   This is for the Toxoplasma Baby Panel: Sabin Feldman Dye test, IgM ISAGA, IgA ELISA. **Clot below this sample.** See **"IV) 1."**
3. **0.5 mL cerebrospinal fluid**
   This is for T.gondii specific IgG (dye test) and IgM ELISA. (See **"III) 5"** above.)
4. **5 cc urine - Investigational. Not proven sensitivity.**
   For PCR.

V) SAMPLES OBTAINED FROM MOTHER SUBSEQUENT TO DELIVERY

2 mL Maternal Serum

Adult panel to go to a reference laboratory such as Palo Alto Medical Foundation (address above) with **I) A** and **IV)**.
To be used for IgG in parallel with infant IgG test and cab ne used for IgM and IgA if clinically indicated.

VI) Amounts, Handling, and Shipping of *T. gondii*-specific Tests and Samples Table. Currently available tests in US or France Reference Laboratories.

Test	Sample	Preferred (Min. Amount)	Store/Ship	Additional Comments
Dye Test IgG	Serum[a]	0.25 mL (0.050 mL)	Cool[b]	
Direct Agglutination IgG	Serum	0.25 mL	Cool	
IgM ELISA	Serum	0.25 mL	Cool	
IgM ISAGA	Serum	0.25 mL	Cool	Only for babies<6 months
IgA ELISA	Serum	0.25 mL	Cool	
IgE ELISA	Serum	0.25 mL	Cool	Limited clinical use
AC/HS	Serum	0.25 mL	Cool	For pregnant woman
Avidity	Serum	0.25 mL	Cool	For pregnant woman
Subinoculation[c]	Buffy coat	1 mL purple top (EDTA) tube	Cool	Do NOT freeze
	Clot	1 mL (from same red top tube as whole blood)	Cool	Do NOT freeze
	Placenta	200 g[c]	Cool	Do NOT freeze
	Other tissue	1 g (minimum)	Cool	Do NOT freeze
PCR	Buffy coat	1 mL purple top (EDTA) tube	Cool	Do NOT freeze
	Amniotic fluid	Unspun 10-20 cc	Cool	Do NOT freeze
	Placenta	Same 200 g as above	Cool	Do NOT freeze
	CSF	0.5-1 mL	Cool or frozen[e]	
	Other tissue	25-50 mg	Cool or frozen	
	Urine	Sediment from 5 cc	Cool or frozen	

[a] From peripheral blood. Do NOT use umbilical cord blood.
[b] Cool = Use ice packs. Do NOT freeze subinoculation samples or EDTA tubes.
[c] Subinoculation = Samples for subinoculation must be shipped promptly by overnight courier and received in laboratory within 72 hours of collection.
[d] Amounts differ depending on reference laboratory performing this procedure.
[e] Frozen = ≤ -20° C. Note: only for PCR; NOT placenta, clot, or buffy coat. Placenta must NOT be frozen.
Commercially available tests that are reliable when performed in accredited hospital laboratories: Tg IgG; Avidity.

Fig. 2 continued

and prompt fetal treatment via Pyrimethamine, Sulfadiazine, and Leucovorin (PSL) administered to the pregnant woman. Infection may be detected by amniotic fluid PCR of the 20 copy *T. gondii* B1 gene or the more sensitive 300 copy repeat gene of unknown function [115] at 17 weeks or later in gestation. PSL maternal therapy is administered to the

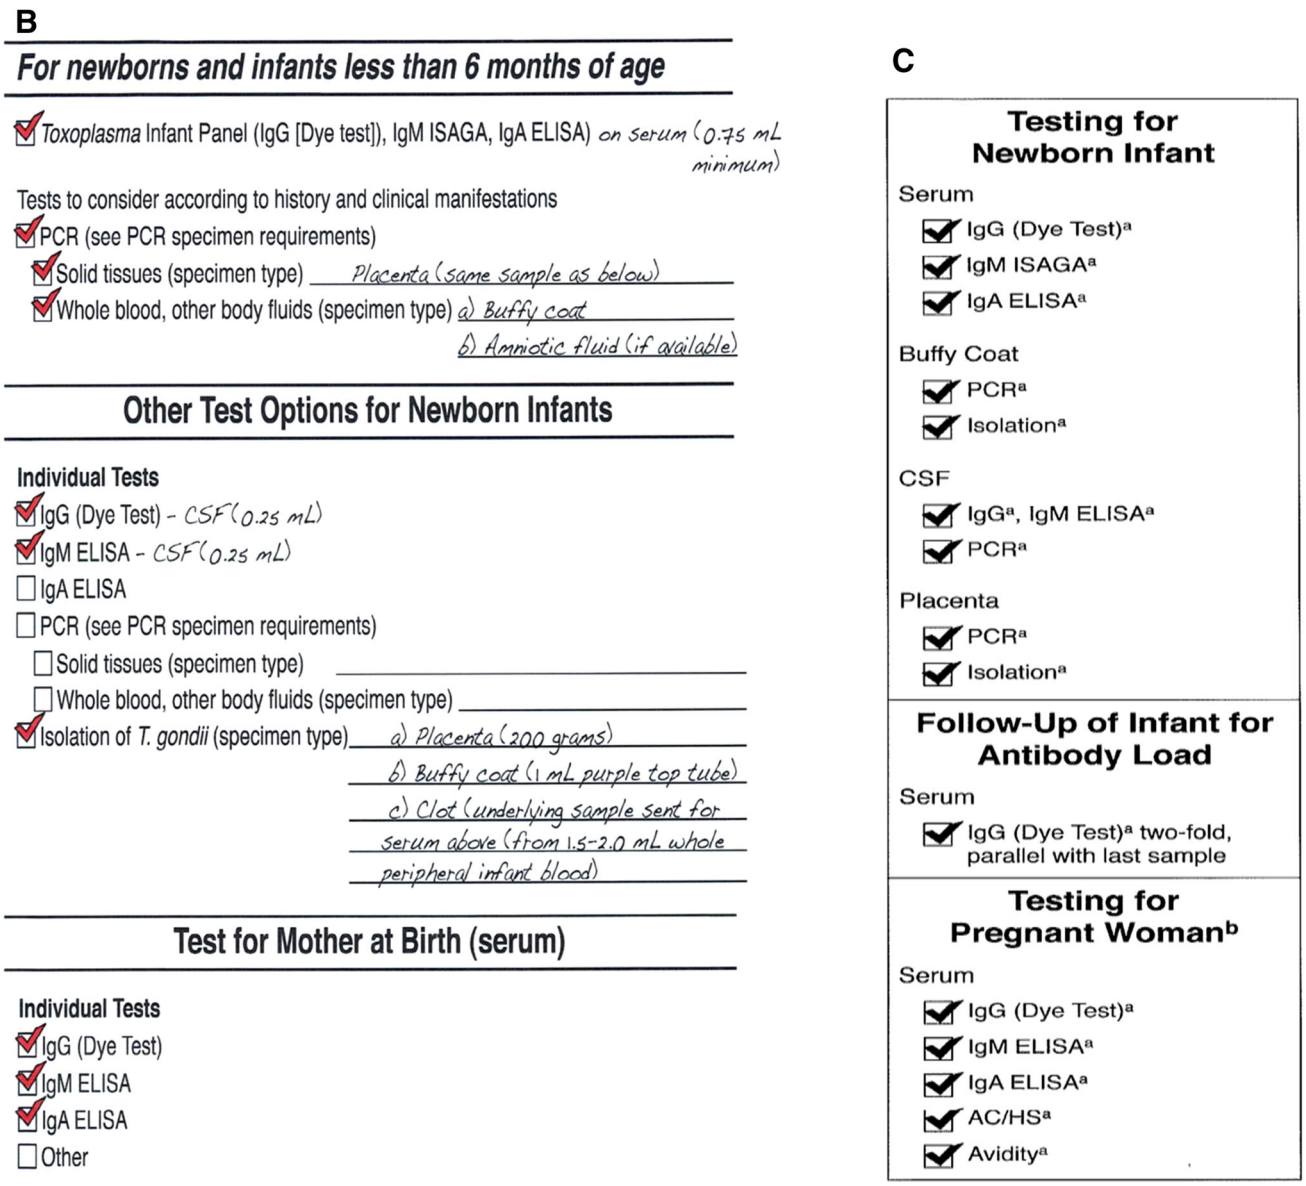

Fig. 2 continued

pregnant women after the 11th week in T. gondii PCR-positive pregnancies; Sulfadiazine is used alone before that time. Findings compatible with toxoplasmosis in the fetus of an acutely infected pregnant woman should also prompt treatment. Pyrimethamine is not used in the first trimester due to possible teratogenic effects. An alternate approach of treating all acutely infected pregnant women with Pyrimethamine, Sulfadiazine, and Leucovorin, again withholding Pyrimethamine in the first trimester, was developed in Austria [118]. This appears to be equally effective in promoting favorable outcomes in the newborn infant and subsequently, later in life, for the congenitally infected person [81••, 118]. Treatment of the fetus is followed by treatment of the infant throughout the first year of life for congenital toxoplasmosis with Pyrimethamine, Sulfadiazine, and Leucovorin [69, 70•, 71–78, 79••, 80••, 81••] (see below). Most patients whose infection is detected and treated during fetal life are doing well as young adults as demonstrated in longitudinal studies in Lyon, France (Fig. 1). The more rapid the diagnosis (Table 1; Fig. 2) and consequent rapid initiation of treatment (Table 2; Fig. 3), the better the outcomes (69, 70•, 71–78, 79••, 80••, 81••, 207; Figs. 1, 4).

Diagnosis of the Newborn Infant

This can be accomplished by recognition of clinical findings compatible with the congenital infection in the infant

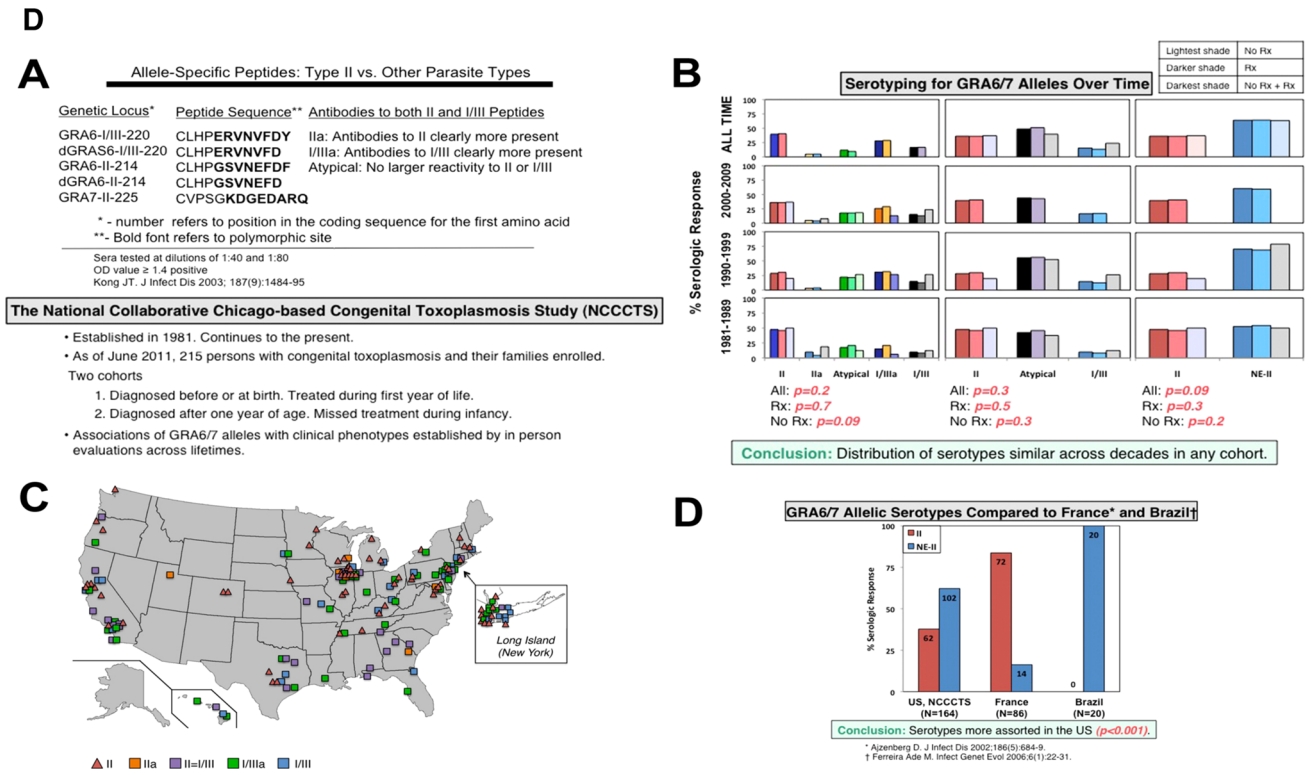

Fig. 2 continued

of an acutely infected mother (Table 1, Fig. 2). Typical clinical findings include prematurity, intrauterine growth retardation, being small for gestational age, "rule out sepsis," blueberry muffin rash, petechiae, hepatitis, splenomegaly, hepatomegaly, anemia, leukopenia, thrombocytopenia, abnormal cerebrospinal fluid cells, protein, or glucose, IgM specific for *T. gondii* or cerebrospinal fluid with *T. gondii*-specific DNA present demonstrated by PCR, intracerebral calcifications, microcephalus, hydrocephalus, chorioretinal scars or choroiditis and vitritis, vitreal veils, uveitis, and cataracts. Diagnosis may be confirmed by isolation of *T. gondii* from placenta or peripheral blood buffy coat [95], demonstration of *T. gondii* by PCR of placenta, or serologic testing with the demonstration of *T. gondii*-specific IgM or IgA. These antibodies are present in only approximately 70 % of infected babies. Images depicting some of these findings, and their improvement with treatment, are shown in Figs. 2, 3, 4. In general, disease manifestations among untreated infants are more severe when infection is acquired earlier in pregnancy and less severe when acquired later in gestation, although parasite and host genetics play a major role in outcomes as well [77, 121••,122, 123••, 124–128, 129•, 130•, 131, 132, 133••, 134••, 135•, 136•, 137–140, 141•, 142–147]. There appear to be four primary genetic parasite types in the USA. Type 2 parasites, similar to those in Europe, also are present in the USA. There is less severe disease and risk of prematurity in those with Type 2 infection, although there is not a complete correlation between parasite type and severity of congenital infection. The inoculum size of ingested parasites, including acquisition of oocysts and contaminated meat in epidemic settings, likely also play a role in outcomes [148] Obstructive hydrocephalus due to obstruction of the Aqueduct of Sylvius results in third ventricular dilatation. This pattern of hydrocephalus may be associated with cerebrospinal fluid protein levels of >1 g/dL. Obstruction of the Foramen of Monroe can lead to unilateral or bilateral ventricular dilatation. Hydrocephalus can also occur without anatomic obstruction of CSF circulation. For example, communicating hydrocephalus, which may be due to loss of brain parenchyma, or hydrocephalus associated with poor reabsorption of cerebrospinal fluid, presumably due to a fibrotic process, can occur. This latter pathogenesis is apparently similar to that seen in normal pressure hydrocephalus in adults. All patterns of hydrocephalus can benefit from shunt placement (Hutson, McLeod, McLone, Frim, et al., in preparation 2014);the prognosis is guarded if a shunt is not placed or placement is delayed when necessary.

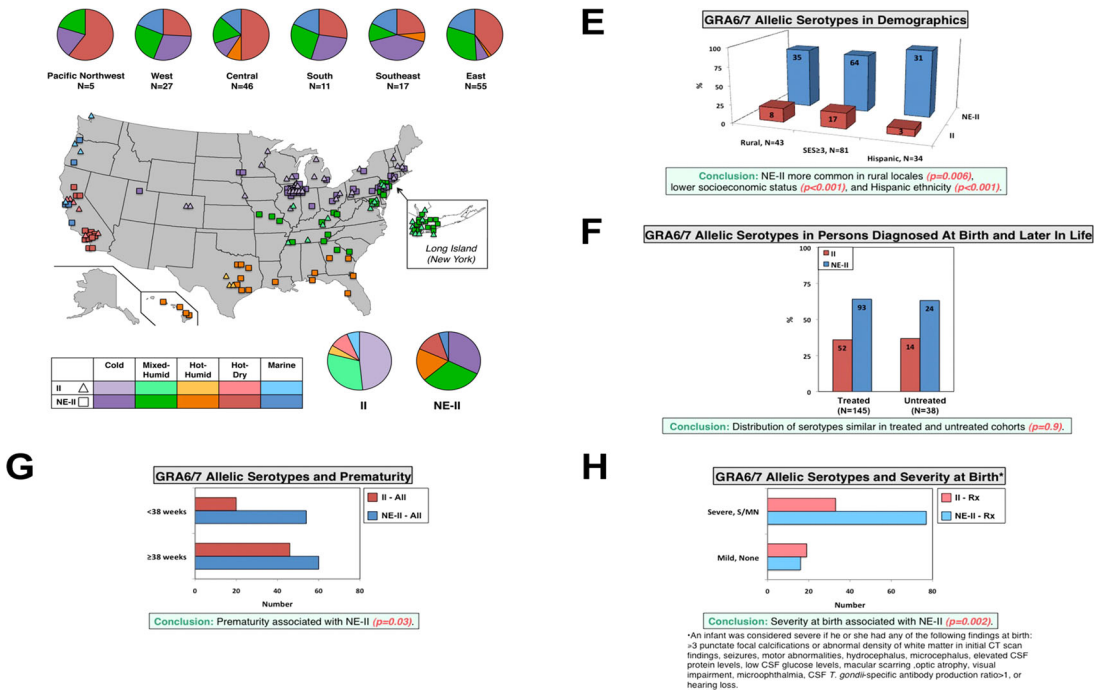

Fig. 2 continued

Treatment of the Infant from Birth to 1 year of Age with Pyrimethamine, Sulfadiazine, and Leucovorin

Treatment with Pyrimethamine (1 mg/kg/day, beginning on the third day following a loading dose of 1 mg/kg b.i.d. for 2 days), Sulfadiazine (50 mg/kg b.i.d.), and Leucovorin (5–10 mg per dose daily or Monday, Wednesday, Friday depending on weight and neutrophil count) from birth to 1 year of age appears to result in much more favorable outcomes than reported for untreated infants earlier [52, 69, 70•, 71–78, 79••, 80••, 81••, 121••, 207]. Typical presenting signs and symptoms, preparation, administration, and monitoring of this treatment and outcomes are summarized in Figs. 2 and 3. Infants are weighed weekly and medications, made fresh each week, are dosed based on increasing weight each week. Signs of active infection and neurologic outcomes appear to be improved relative to those reported in earlier decades without treatment. Signs of active infection appear to resolve early (in weeks) during treatment. Neutrophil counts should be measured via heel prick with only 0.3 mL of blood collected in a tube for a pediatric complete blood count each Monday and Thursday while taking Pyrimethamine and in the week after this regimen is discontinued. See Table 1 and Fig. 3. Most children have an absolute neutrophil count ~900–1,200 neutrophils/mm^3 during this year of treatment. Leucovorin can be increased to 10–20 mg daily if needed. Pyrimethamine is changed from daily administration to Monday, Wednesday, and Friday dosing after 2 or 6 months. A randomized study did not demonstrate different outcomes with these two dosing schedules for children followed to 15 years of age [74]. Thus, with milder infections, 2 months of daily treatment is often utilized. In cases with more severe initial disease, 6 months of daily treatment is utilized. Leucovorin is continued for a week after Pyrimethamine is discontinued due to the long half-life of Pyrimethamine with its attendant myelosuppressive effects. Care is taken to make certain that the baby's teeth are cleaned after medicine administration because of the sugar-suspending agents leading to the development of dental carries. When neutrophil count is less than 1000 neutrophils/mm^3, a manual differential counting 500 white blood cells is performed to improve accuracy. With neutrophil counts less than 700-1000 neutrophils/mm^3, Leucovorin dosage may be increased to a maximum of 20 mg per day. With less than or equal to 600 neutrophils/mm^3, Pyramethamine and Sulfadiazine are withheld, and Leucovorin continued. These medicines are held until neutrophil count is greater than 1000 neutrophils/mm^3.

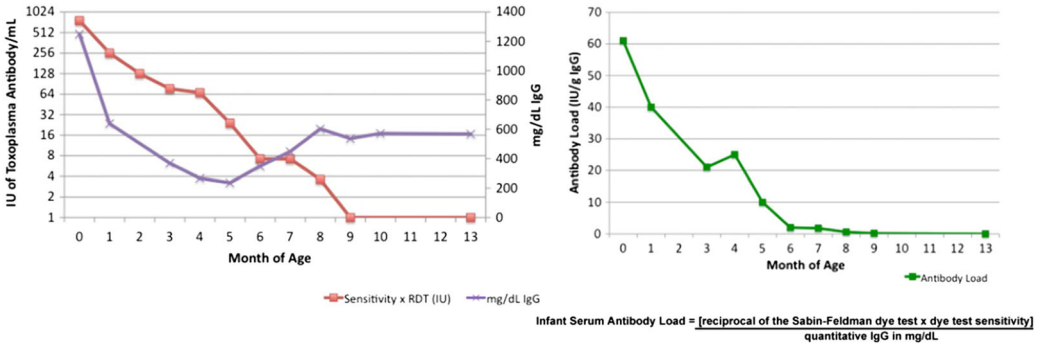
Steroid Treatment

Based on early data from France, Prednisone (1 mg/kg/day) is given for a short time with end points being until active vitritis threatening the posterior pole (fovea and optic nerve) of the eye resolves, or when CSF protein declines below 1 g/dL if it is initially >1 g/dL. Steroids are begun after loading doses of Pyrimethamine with

Table 1 Adapted from McLeod et al. [207] , with permission

Summary of laboratory findings in the diagnosis of toxoplasmosis

- *Acute infection (e.g., Lymphadenitis)* IgM and IgA serology are positive. Avidity is usually low. If avidity is high, this indicates an infection occurred >12–16 week earlier. A high avidity can be useful to date onset of the infection to longer than 12–16 week. Serial serum specimens at a 3-week interval can demonstrate seroconversion or a rising titer.
- *Acute toxoplasmosis in pregnancy* The serologic response is similar to that seen for other persons with acute *T. gondii* infection above; however, the issue for assessing the risk of disease transmission is determining if the infection occurred during or before pregnancy, as *T. gondii*-specific IgM can persist for months or years after the acute infection. Risk for transmission is considered to be present if the infection occurred during pregnancy. The use of IgG avidity (high in most chronic infections, see above), differential agglutination (AC/HS), and the presence of IgA and/or IgE antibodies (which disappear more quickly than IgM) can help determine the timing of the infection, whether an amniocentesis is indicated to identify congenital toxoplasmosis, or if use of medicines would be helpful
- *Chronic infection* IgM is negative and IgG is present. Antibody levels do not change with serial specimens. Avidity is high and AC/HS has a chronic pattern
- *Reactivation of disease during immune-suppression (e.g., Toxoplasma encephalitis in HIV/AIDS)* IgM is negative and IgG may be present. In some cases, there is no detectable serologic response to *T. gondii*. However, if clinical presentation is highly suspicious of infection in the absence of positive serologic results, CSF, blood, and possibly tissue samples should be obtained for diagnosis as indicated. While the sensitivity of PCR has been variable in this setting, if positive, PCR can be useful for diagnosis. In some clinical circumstances, presumptive treatment may be warranted
- *Congenital toxoplasmosis* For diagnosis in utero for a fetus of an acutely infected pregnant woman who appears to have acquired the infection during gestation, PCR of amniotic fluid and ultrasound imaging of the fetus are used to establish fetal infection. Newborns will be IgG positive, due to passage of maternal antibody across the placenta. Compatible clinical findings in an infant of an acutely infected mother or the presence of *T. gondii*-specific IgM or IgA in a newborn confirms the diagnosis of congenital infection. Serial serology with a stable or rising IgG titer can also confirm the diagnosis of congenital infection. An example of fall in *T. gondii*-specific antibody load is as follows:



Sulfadiazine have been administered. There have been no randomized controlled studies to demonstrate whether such treatment with Prednisone improves outcomes.

Approach to Cerebral Ventricular Enlargement

Hydrocephalus due to congenital toxoplasmosis is treated with ventriculoperitoneal shunting. It is not clear from initial neuroimaging studies which children will benefit most from aggressive CSF drainage. This question is further confounded by the observation that despite progressive ventricular dilatation and cortical compression, measured CSF pressures may remain low (Hutson, McLeod, McLone, Frim, et al. in preparation, 96). Thus, it is imperative to proceed as though all children with hydrocephalus would benefit from CSF shunting as early drainage can promote cortical reconstitution and remarkably good functional outcomes. One recent advance in neuroimaging for following hydrocephalus and/or shunt function is a two sequence, 45-s magnetic resonance imaging (MRI) study of the brain, which does not require sedation or contrast administration. This can be used to follow the progress of ventricular dilatation or the correction of hydrocephalus in a manner that is easy and comfortable for both parent and child. There are two sequences, collectively referred to as "brain shunt hydrocephalus screen" in some US hospitals. These two sequences are T2 axial and coronal single shots with images at 3-mm intervals.

Delays in shunt placement have been associated with less favorable outcomes [96]. Endoscopic third ventriculocisternostomy (ETV) frequently fails as a treatment for aqueductal obstruction causing hydrocephalus in this

Table 2 Guidelines for treatment of toxoplasmosis

Clinical setting and manifestation	Treatment
• Acute, asymptomatic infection	The current standard of care is no treatment
• Acute infection with self-limited adenopathy, fever, or malaise in immune-competent persons	
• Latent, asymptomatic infection detected by positive serologic test	
• Severely symptomatic disease in immune-competent adults	• Pyrimethamine[b], Sulfadiazine[d], and Leucovorin (folinic acid)[b]
• Laboratory infection with *T. gondii* tachyzoites	
•Active disease in immune-compromised persons	
• In pregnant women infected during gestation:	
• First 18 weeks' gestation, or until term, if fetus found not to be infected by amniocentesis at 18 weeks' gestation and to have no clinical findings	• Spiramycin[a]
• If fetal infection confirmed or if infection acquired after 24 weeks' gestation	• Pyrimethamine[b] *, Sulfadiazine[d], and Leucovorin (folinic acid}[b] * Do NOT use Pyrimethamine in the first 14 week of gestation
• Congenital *T. gondii* infection in infant	• Pyrimethamine[b, c], Sulfadiazine[d], and Leucovorin (folinic acid)[b] • Occasionally corticosteroids (prednisone)[e] have been used when CSF protein is ≥1 g/dL or when active chorioretinitis threatens vision
• Active chorioretinitis in older children and adults	• Pyrimethamine[b], Sulfadiazine[d], and Leucovorin (folinic acid)[b] • Corticosteriods (prednisone)[e] if macula or posterior pole is involved or vitritis threatens vision
• Active choroidal neovascular membrane due to T. gondii infection[f]	• Pyrimethamine[b], Sulfadiazine[d], and Leucovorin (folinic acid)[b] • Lucentis (antibody to VEGF) used as in algorithm' below

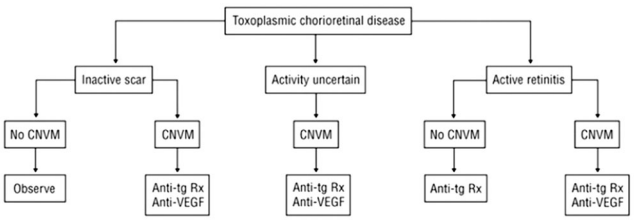


Table and caption adapted from Remington et al. [98••] with permission

[a] In the USA, available only on request from the U.S. Food and Drug Administration (telephone number 301-443-5680), and then with this approval by the physician's request to Aventis (908-231-3365)

[b] Adjusted for granulocytopenia; complete blood counts, including platelets, should be monitored each Monday and Thursday. A standard adult dose for a 50-kg person is 50 mg bid for the first 2 days then 50 mg per day Pyrimethamine beginning on the third day. A standard dose of Leucovorin for a 50-kg person is 10 mg daily

[c] Both regimens, a higher and a lower dose, appear to be feasible and relatively safe. The duration of therapy is unknown for infants and children, especially those with AIDS

[d] A standard dose of Sulfadiazine for a 50- to 75-kg person is 1.5–2 g per day bid with 8 glasses of water or non-acidic beverages each day to limit development of nephrolithiasis. Alternative medicines for patients with atopy or severe intolerance of sulfonamides have included Pyrimethamine and Leucovorin with clindamycin or azithromycin or atovaquone, with standard dosages as recommended according to weight. In the unusual circumstance that medicines cannot be administered orally or by intraintestinal tube feeding, trimethoprim, sulfamethoxazole, and clindamycin have been administered intravenously

[e] Corticosteroids should be used only in conjunction with Pyrimethamine, Sulfadiazine, and Leucovorin treatment and should be continued until signs of inflammation (high CSF protein, ≥1 g/dL) or active chorioretinitis that threatens vision have subsided, ususally ~10–14 days; dosage can then be tapered and the steroids discontinued

[f] Image figure from: Benevento et al. [173], with permission

disease [96] and should not be used [96]. A possible cause of this failure of ETV is entry of inflammatory CSF into the subarachnoid space, resulting in adhesions and inadequate CSF absorption. It is not uncommon for children to have cortical expansion and restoration of normal ventricular volume and neurologic function (Fig. 4). High CSF protein and diabetes insipidus have been linked to less favorable outcomes, but this is not absolute.

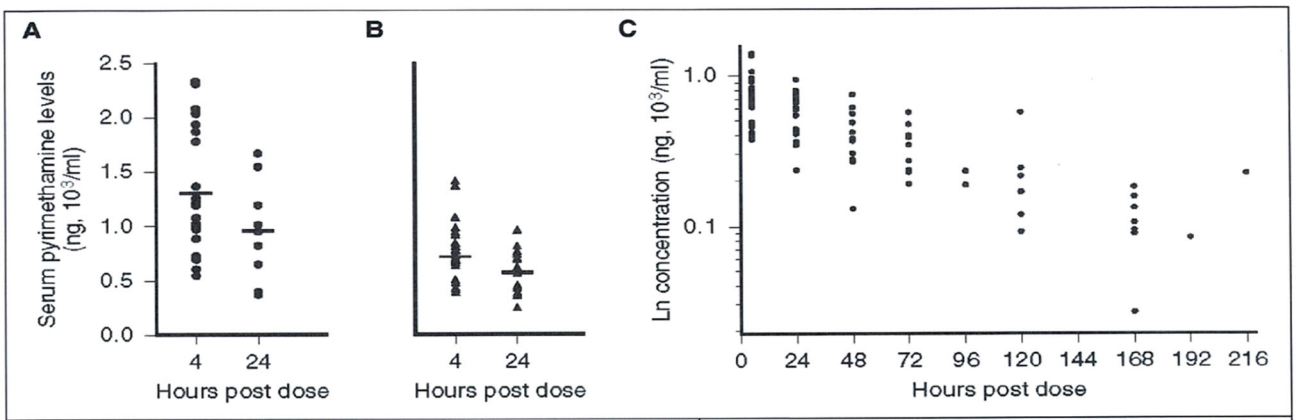
Seizures and other Neurologic Findings Early in Infancy and Later

Seizures due to *T. gondii* have been treated effectively with Levetiracetam (Keppra®). In contrast to Phenobarbital, this anti-epileptic does not induce hepatic enzymes that degrade Pyrimethamine. It does not displace Sulfadiazine binding from albumin, as Phenytoin (Dilantin®) does, nor does it trigger the bone marrow toxicity associated with Carbamazepine (Tegretol®). It has less sedative hypnotic type effects than certain other anti-epileptic medicines. In some cases, intractable myoclonic seizures associated with recurrent central nervous system disease responded to ketogenic diet therapy (McLeod, Swisher, Hood, Heydemann, et al. in preparation). In some cases, treatment of the acute encephalitic findings caused by active *T. gondii* in the perinatal period, with Pyrimethamine and Sulfadiazine, has made it possible to discontinue anti-epileptic medicine without recurrence of seizures upon their discontinuation. It is not common to develop progressive and/or recrudescent central nervous system disease in treated children, but it can occur and may present as new seizures (McLeod et al., in preparation, 2014). Serum, CSF, neuroimaging, and biomarkers indicate that this is secondary to active central nervous system disease and parasite proliferation (McLeod et al. in preparation 2014).

C



D **Pyrimethamine Pharmacokinetics and Toxicity**

- Pyrimethamine half life = 64±12 hours
- Serum levels with 1 mg/kg/d dose = 1.3±0.5/ugm/ml 4 hrs after dose
- CSF levels are approximately 10% - 25% concomitant serum levels
- Phenobarbital shortens pyrimethamine 1/2 life (33±12 hrs) lowering levels
- Serum and CSF levels in potentially therapeutic range (in vitro studies)
- Toxicity: reversible neutropenia, discoloration teeth (sugar suspensions)
- Similar incidence of reversible neutropenia for high and low dose

Toxicity and Complications

- Reversible neutropenia requiring temporary withholding of medications did not differ for treatment groups
- Eleven deaths, not related to treatment

E **Episodes of Reversible Neutropenia Requiring Temporary Withholding of Medications for the US National Collaborative Study**

	No. Episodes Medication Withheld (Mean ± S.D. [RANGE])	No. of Patients Who Stopped Medication/ No. in Cohort Who Have Completed 1 Year of Therapy (%)			No. Who Discontinued Medications Due To Neutropenia ≥ 4 Times
		Feasibility	Randomized	All	
Treatment A	2 ± 1 [1-4]	6/14 (43)	13/36 (36)	21/57 (37)	2
Treatment C	3 ± 3 [1-11]	6/11 (55)	10/28 (36)	20/59 ()	7

F

Fig. 3 continued

Earlier studies [4, 64, 65] suggested recurrent and/or progressive disease occurred in untreated children. To date, relapsing central nervous system infection is uncommon in treated children in the National Collaborative Chicago-Based Congenital Toxoplasmosis Study (NCCCTS), which encompassed most of the clinical experience based on direct observation in a single center longitudinal study in North America from 1981 to the present. The incidence and extent of unrecognized CNS sequelae [148, 149••, 150••, 151, 152••, 153–157, 158•, 159–161] in postnatally or congenitally infected children remain to be determined.

Recrudescent Eye Disease and Management of Active Retinitis After the First Year of Life

Retinal disease due to *T. gondii* becomes quiescent with treatment in the first year of life [162–164, 165••, 166••, 167, 168], with fewer recurrences in promptly treated children than for those referred after the first year of life (Fig. 4). Recurrence occurs most frequently at the age of school entry, in puberty and adolescence (Fig. 4), and in the presence of substantial stress (e.g., bereavement, surgery, or trauma). Pyrimethamine, Sulfadiazine, and Leucovorin are used in retreatment

(Table 2). Active infection in all parts of the retina require therapy; prompt therapy is associated with more rapid lesion resolution. Treatment is continued for several weeks after the borders of the lesions become sharply demarcated and the edges pigmented (Fig. 4). This often occurs within a few weeks after initiating treatment. If there is hypersensitivity to sulfonamides, Azithromycin is offered instead of Sulfadiazine. Azithromycin suppressive therapy has been utilized successfully in patients with recurrent chorioretinitis following resolution of active disease, particularly when recurrence of lesions is vision threatening. Although TMP–SMX successfully suppressed recurrences in a series in Sao Paulo, Brazil [168], it had an unacceptably high incidence of hypersensitivity. TMP/SMX suppression may lead to sulfonamide hypersensitivity and appears to be less efficacious than Pyrimethamine plus Sulfadiazine treatment, likely due to suboptimal TMP/SMX dose ratios and lesser efficacy of TMP than Pyrimethamine and SMX than Sulfadiazine. The optimal duration of prophylaxis to prevent the loss of vision or frequently recurring retinal disease has not been determined.

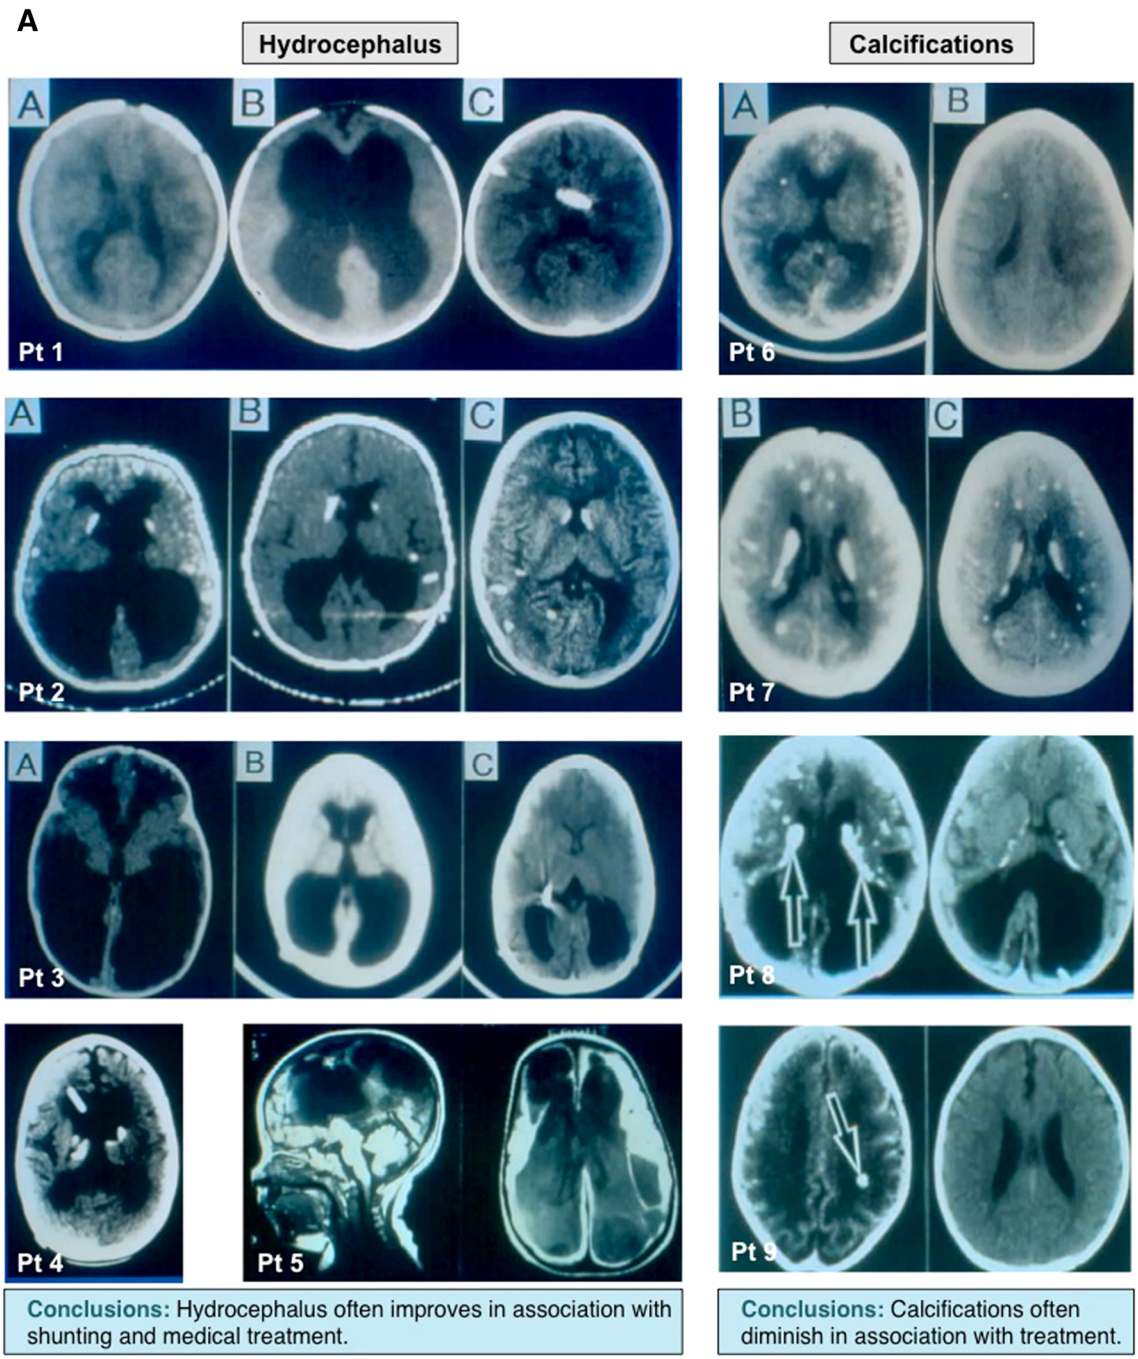
Choroidal Neovascular Membranes

Choroidal neovascular membranes (CNVM) [169, 170, 171•] occur rarely as a complication of chorioretinal disease due to *T. gondii* infection. Diagnosis is determined by clinical examination with the findings of subretinal blood or fluid, leaky vasculature visualized by fluorescein angiography and ocular coherence tomography (OCT). Infection with *T. gondii* drives increased expression of hypoxia-inducible factor 1-α (HIF1-α), which leads to increased levels of vascular endothelial growth factor (VEGF) transcription. VEGF promotes the growth of new blood vessels. Infiltration of vasculature arising from the choroid disrupts Bruch's membrane, causing retinal scars. Fluid accumulates in the subretinal space. Hemorrhage can result from new, leaky blood vessels with resultant sudden loss of vision. This pathologic process can be abrogated by antibodies against VEGF. Ranibizumab (Lucentis®), in conjunction with standard anti-parasitic therapies, has been used. Bevacizumab (Avastin®) treated persons also had improved outcomes with CNVM due to toxoplasmosis. These α-VEGF medicines are injected intravitreally. Dosages can be found in Table 2. Infants have received α-VEGF safely for retinopathy of prematurity, but we are unaware of their use for CNVM due to *T. gondii* [170]. The recommended form of management for this complication is α-VEGF, in combination with anti-parasitic medications. This regimen has been effective in persons with CNVM due to *T. gondii*. Photodynamic therapy has also been reported to have efficacy [169, 170, 171•].

Fig. 4 Manifestations of congenital toxoplasmosis and outcomes of treatment. **a** Neurologic manifestations of congenital toxoplasmosis and response to treatment. Effect of treatment on the recurrence of eye lesions secondary to *T. gondii* infection, with increased frequency of occurrence at entrance into school and at adolescence. **c** Response of active eye lesions to treatment. Treatment of eye lesions leads to resolution of overlying vitritis, hazy margins and sharp demarcation and hyperpigmented lesions. **d** Choroidal neovascular lesions and their response to anti-T.gondii treatment and antibody to VEGF. The first image is a patient with choroidal neovascular membrane and the resultant resolution with treatment. Note the presence of blood and subretinal fluid, which decreases following treatment with appropriate therapy. Adapted with permission from Benevento, McLeod et al. [206, 207]. Additional choroidal neovascular membranes and their response to treatment in additional patients. The impact of prompt, appropriate treatment of choroidal neovascular membranes in a series of patients. Evidence of bleeding decreases, as does the presence of subretinal fluid in these patients. Adapted with permission from Benevento, McLeod et al. [206]. **e** Literature outcomes in congenital toxoplasmosis and outcomes in the NCCCTS cohort. A comparison of frequency of outcomes as reported by literature and within the National Collaborative Chicago-based Congenital Toxoplasmosis Study cohort. Note the dramatic decreases in the frequency of outcomes in this particular cohort relative to literature sources. This is true for many outcomes, including IQ, motor function, retinal lesions, and central nervous system manifestations. Adapted with permission from McLeod et al. [206, 207]. **f** The treatment of congenital toxoplasmosis, in utero, and outcomes due to this early treatment. The impact of treatment, in utero, on the frequency of disease manifestation in congenital *T. gondii* infection. Note the increased frequency of most disease manifestations without the initiation of treatment, in utero. Adapted with permission from and McLeod et al. [207]. **g** Parasite serotype and its relationship to treatment efficacy. Tabular representation of the impact of parasite type on outcomes in treated patients. Postnatal treatment was effective (i.e., improved outcomes) in both type II and type NE-II parasites, indicating that both respond to treatment. Adapted with permission from and McLeod et al. [207]. **h** Outcomes in NCCCTS cohort compared to the literature. Data indicating improved outcomes in treated patients over preexisting literature data on pre-established endpoints, including neurologic outcomes, reductions in IQ, worsened vision, new retinal lesions, and hearing loss. Adapted with permission from McLeod et al. [206, 207]. (I) Dosage of Pyrimethamine and its Impact on Treatment Outcomes. Kaplan–Meier plots indicating no significant differences in outcomes between two treatment arms receiving higher doses of Pyrimethamine versus lower doses. In practice, infants with less severe manifestations often receive the lower dose of Pyrimethamine, though with severe disease often are still treated with higher doses. Adapted with permission from McLeod et al. [206, 207]

Implications of Congenital Infection for Family Members and Those who Share Risk Factors for Acquisition of Infection

Acquisition of *T. gondii* infection by multiple family members due to common exposures is not infrequent. Thus,



it is reasonable to determine whether other family members were also acutely infected at the time a pregnant woman has acquired infection or a congenitally infected baby is born. Because retinal disease may occur in up to 10 % of mothers of infected babies and may occur in family members who could benefit from treatment, it may be prudent to also test other family members of infected babies [172, 173].

Prognosis

Many children born with congenital toxoplasmosis who are treated in utero and throughout the first year of life have normal cognitive development and function well, being able to continue on to university and having families of their own. There is more retinal disease among children born in the USA who missed being treated in utero and

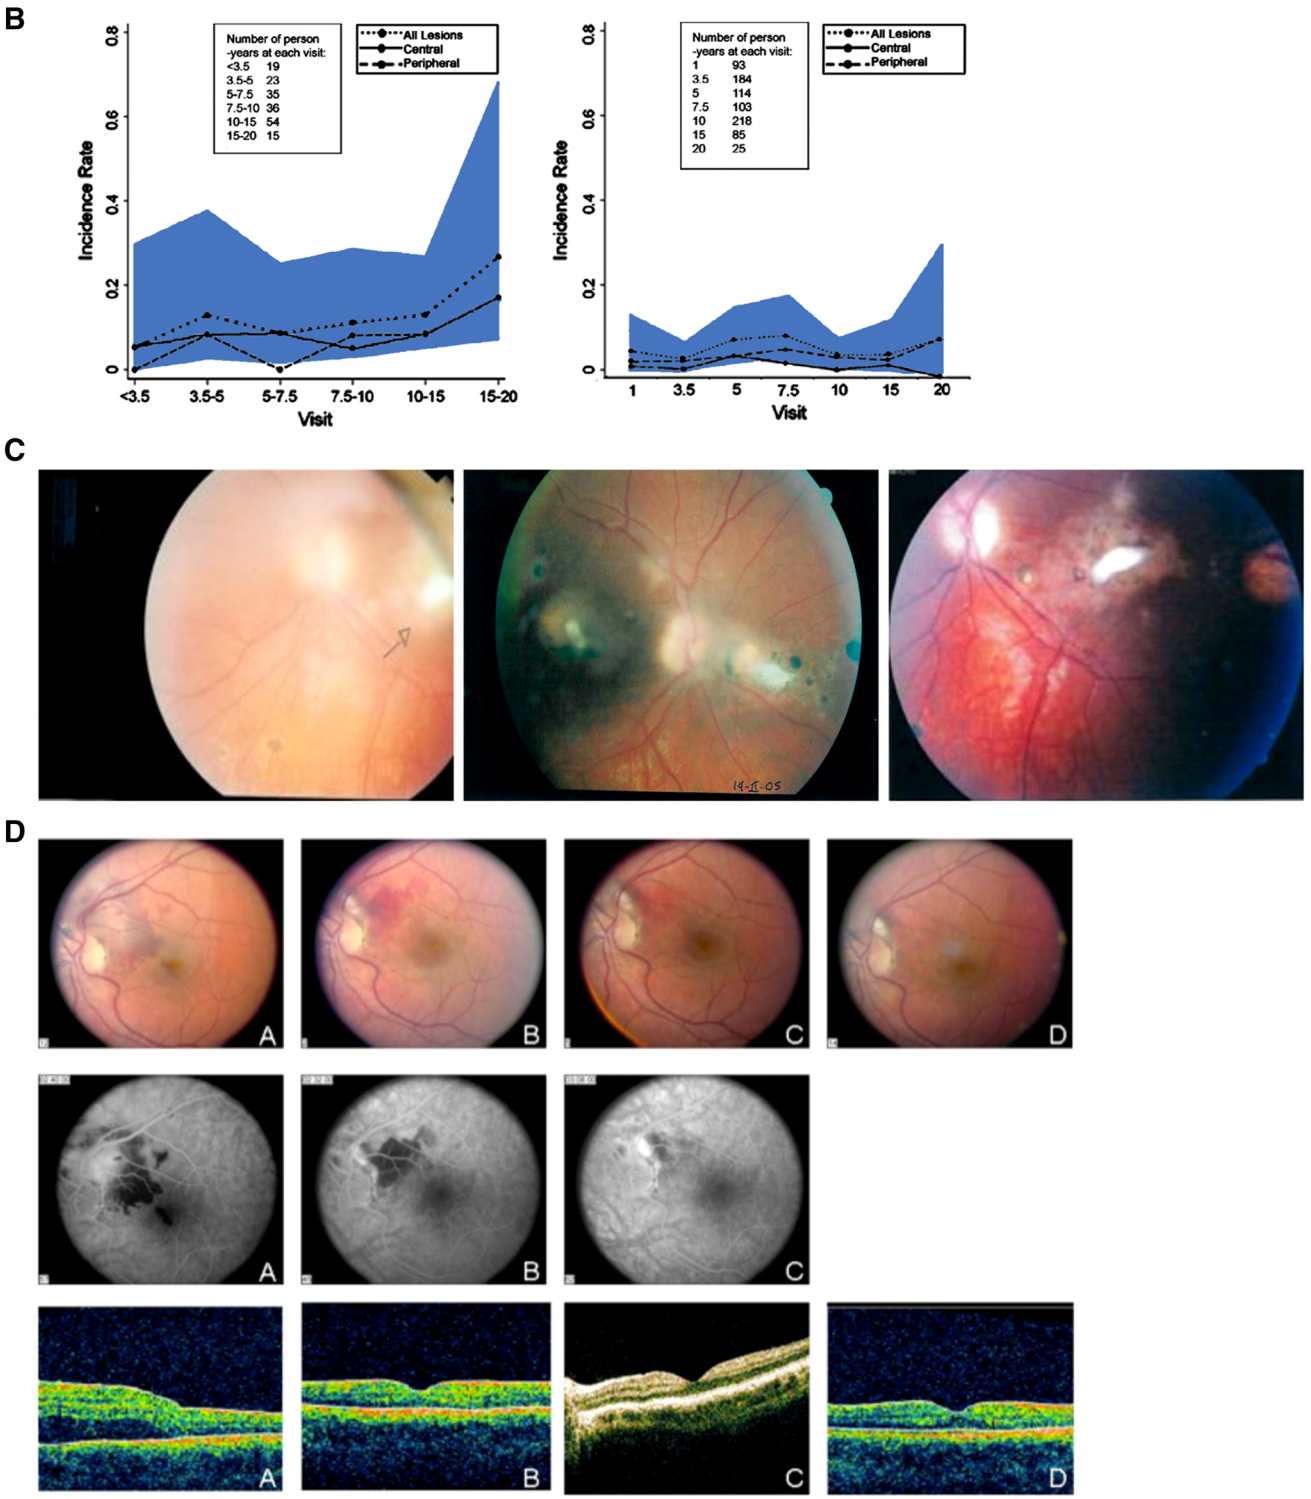


Fig. 4 continued

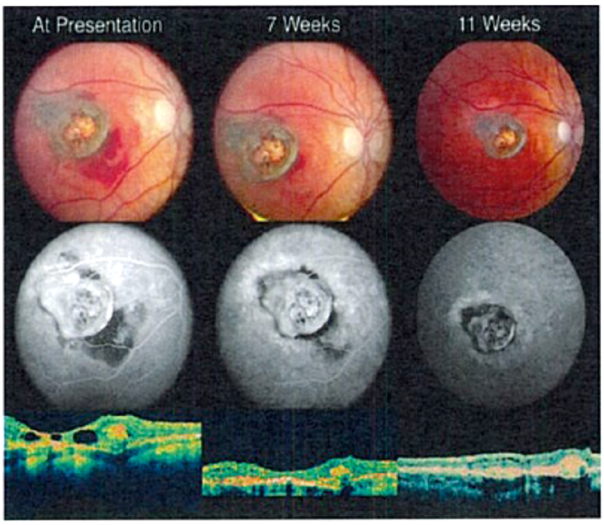
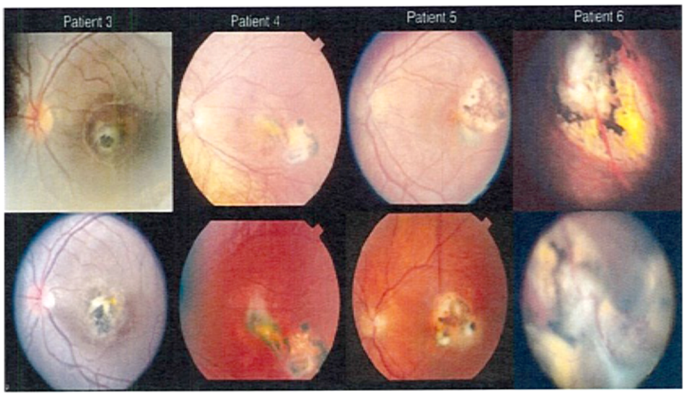
appears to occur more often in those who were not diagnosed and treated in the first year of life. There is a gradation in outcomes from severe impairment to completely functional children and young adults, both with and without treatment in the first year of life. It appears that outcomes with treatment for those who are born with moderate





Patient	Age at time of Neovascular Lesion Noted	Lesion Type	Probable Duration of Lesion	Anti-parasitic Treatment[a]	Treatment of Neovascular Lesion (# of Injections)	Pre-lesion Visual Acuity	Visual Acuity at Time of Treatment	Post-Treatment Visual Acuity[c]	Time to Resolution/ Duration of Follow Up

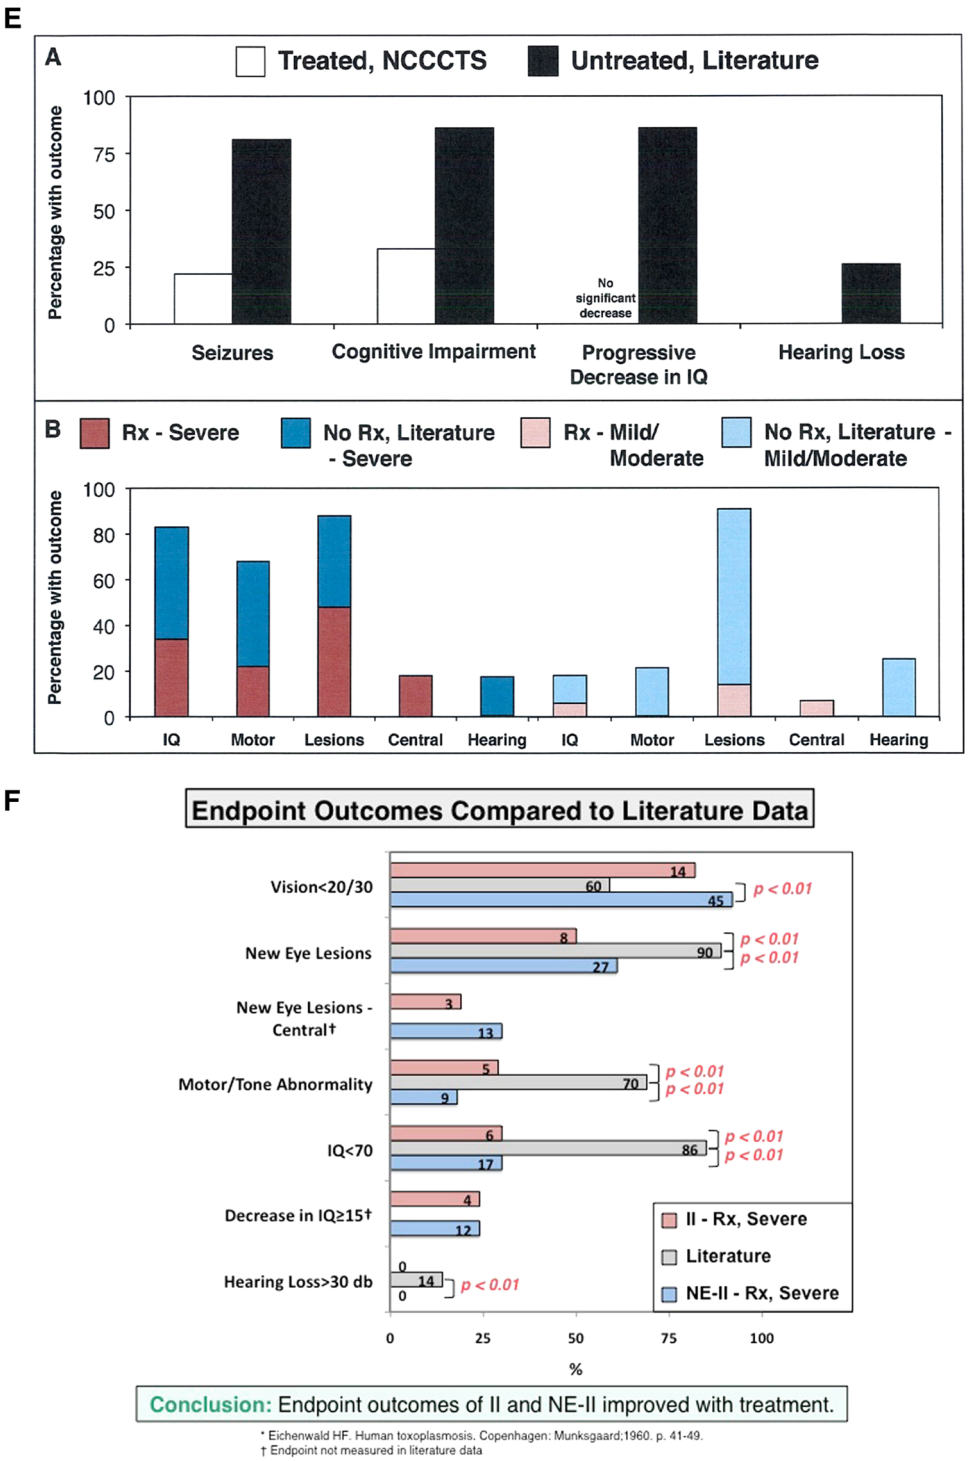
Fig. 4 continued

or severe involvement at birth are markedly better than that reported in the older literature for those who were not treated or treated for only 1 month [43, 44, 62, 64, 65, 69, 81••]. Approximately 70 % of children who had generalized systemic or neurologic manifestations and thus would have been expected to have severe disability have done well. Interestingly, for treated children, intracerebral calcifications may resolve partially or completely during the first year of life [90]. However, there may also be significant impairment. Severe involvement may impact quality of life when treatment is started too late to effect a markedly improved outcome [174].

The Future

At the present time, there is a substantial need for less toxic, improved medicines for tachyzoites and medicines effective against encysted bradyzoites [175–180, 181••, 182–184, 185••, 186•, 187–189], as well as an effective vaccine [190•, 191•, 192•, 193•, 194, 195, 205]. There are robust efforts to develop such agents, with recent successes in developing compounds that eliminate bradyzoites and reduce toxicity of treatment of the active infection. These advances are likely to lead to improved approaches to treatments and outcomes for this infection in the near future. Prenatal screening [61, 62, 95, 107] is another significant advance that likely will occur in the USA during the next decade and result in decreased congenital toxoplasmosis and reduce costs for care [120••, 202•]. Additional insights into pathogenesis are also arising from new genetic studies and associations of ocular disease with unusual parasite types [200•, 201•, 202•, 203•]. Live vaccines can now prevent infections in animal models [203•] and translation of the protective mechanisms to non-live reagents and to clinical use through immuno-sense [194], approaches may offer substantial advances. Whether there is clear cause and effect for congenital toxoplasmosis leading to other neurobehavioral diseases remains to be determined [196, 197, 198•, 199•, 201•]; although it is not evident in the US cohort of families followed from 1981 to the present.

Fig. 4 continued



Conclusions

Effective management requires recognition of infection early during its pathogenesis to lessen the significant impact of congenital toxoplasmosis on long-term health. Prevention through detection of *T. gondii* infection in the pregnant woman facilitates treatment and is critical for optimal management. Treatment is initiated following detection of acute *T. gondii* infection in the pregnant woman through serologic testing or in the fetus due to clinical findings and confirmed by amniocentesis. Spiramycin is used to prevent infection early in fetal development. Later in development,

G **Manifestations at Birth for Groups with Gestational Treatment**

	In Utero Rx		No *In Utero* Rx		p value‡
	Type II	Type NE-II	Type II	Type NE-II	
Gestational Age <38 weeks	3*/15† (20%)	3/13 (23%)	15/37 (41%)	40/79 (51%)	0.82
Severe, S/MN	8/15 (53%)	6/13 (46%)	25/37 (68%)	71/80 (89%)	0.08
Splenomegaly	1/15 (7%)	1/13 (8%)	8/36 (22%)	36/78 (46%)	0.54
Hepatomegaly	4/15 (27%)	2/13 (15%)	10/36 (28%)	40/78 (51%)	0.11
Skin Rash	1/15 (7%)	0/13 (0%)	7/36 (19%)	29/78 (37%)	Not Estimable
Chorioretinal Scars	8/15 (53%)	5/13 (38%)	24/37 (65%)	67/80 (84%)	0.07

Conclusion: Without gestational Rx, prematurity, severity, hepatomegaly, splenomegaly, skin rash, chorioretinal scars more prevalent with NE-II.
With gestational Rx, associations of NE-II with manifestations at birth no longer significant, less prevalent with NE-II.

Not Estimable = due to 0 cell.
* Number of patients with manifestation at birth in each *in utero* treatment and parasite serotype cohort.
† Total number of patients in each *in utero* treatment and parasite serotype cohort; table only includes those diagnosed at birth and treated during the first year of life.
‡ Based on a test of the *in utero* treatment group by parasite serotype interaction from a logistic regression model. A statistically significant interaction would indicate that the effect of parasite serotype on disease manifestations depends on whether *in utero* treatment was received.

Hearing loss >30 db	There was no hearing loss in any group.				-	-	-	-

Conclusion: Treatment dosage and endpoint outcomes not associated.
Serotype and endpoint outcomes not associated.

* Number of persons with endpoint in each parasite serotype and treatment group cohort.
† Total number of persons in each parasite serotype and treatment group cohort.
‡ Based on a test of the treatment group by parasite serotype interaction from a logistic regression model. A statistically significant interaction would indicate that the effect of treatment on outcome depends on parasite serotype.
§ P values are from two-sided Fisher's exact tests.
A = treatment of daily pyrimethamine and sulfadiazine for two months, followed by pyrimethamine on Monday, Wednesday, and Friday, and continued daily sulfadiazine for the remainder of the year of therapy. Both randomized and feasibility cohorts included.
C = treatment of daily pyrimethamine and sulfadiazine for six months, followed by pyrimethamine on Monday, Wednesday, and Friday, and continued daily sulfadiazine for the remainder of the year. Both randomized and feasibility cohorts included.

Conclusions:
- Endpoint outcomes for II and NE-II serotypes improve with treatment.
- Associations of NE-II manifestations at birth are not significant with gestational treatment.
- Associations are not absolute.
- **Prompt prenatal diagnosis and treatment is likely to be especially important for those with NE-II serotype, but critical for all infected persons.**

Fig. 4 continued

in infancy, or in patients with recurrent eye disease, treatment is with Pyrimethamine with Leucovorin and Sulfadiazine. The earlier the treatment is offered in each clinical setting, the more likely disease will be arrested and outcomes improved. This approach to early treatment also applies to ventricular shunting for hydrocephalus. Seizures respond to anti-parasitic and anti-epileptic medications. Choroidal neovascular membranes secondary to *T. gondii* infection

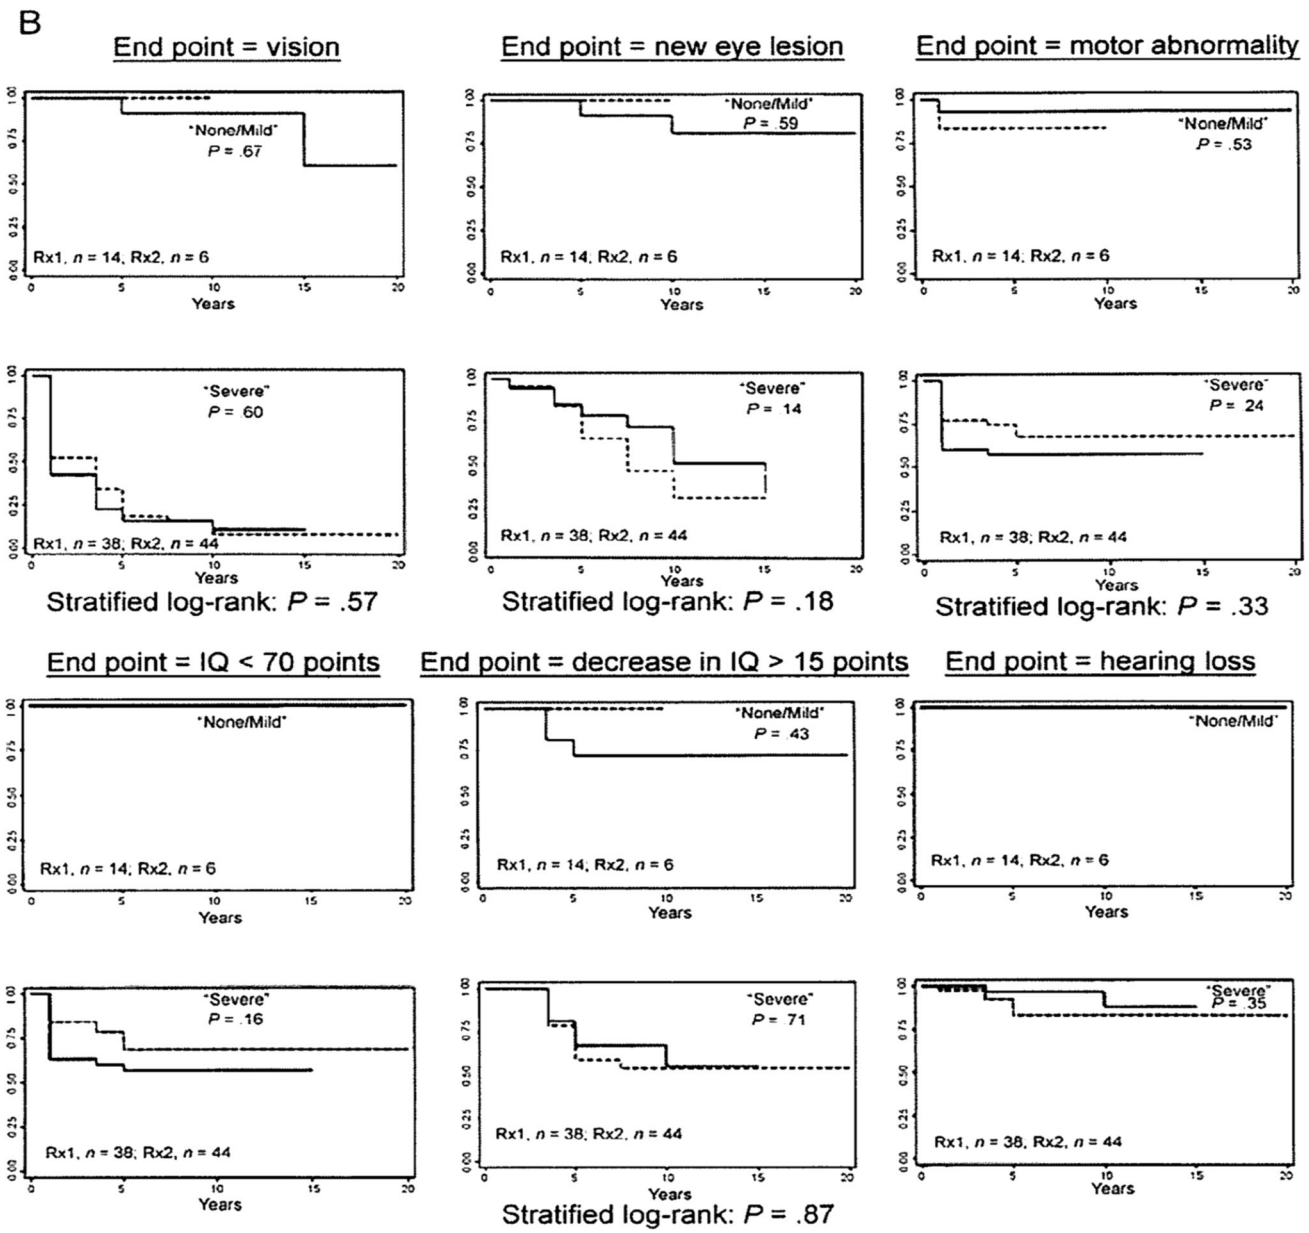

Fig. 4 continued

respond to treatment with α-VEGF and anti-parasitic medicines. New medicines with less toxicity and hypersensitivity, and improved efficacy by targeting the latent stage of the parasite, will change the management of this disease markedly in the future. For the first time, there appear to be promising candidate compounds in development with these properties. Similarly, there is promise in recent work for vaccine development. Neither new medicines nor vaccines are in clinical trials at this time.

Acknowledgments We gratefully acknowledge the support of NIH R01 DMID AI 27530, the Mann and Cornwell Family, the Morel Family, the Rooney Alden Family, The Engel family, The Samuel family and friends, The Pritzker family, The Harris family, The Mussilami Family, and the Hyatt Hotels Foundation. We are grateful for the many patients and physicians who have worked with us in the NCCCTS and have helped us to learn how to manage this infection.

Disclosure Rima McLeod, Joseph Lykins, A. Gwendolyn Noble, Peter Rabiah,, Charles N. Swisher, MD, Peter T. Heydemann, David McLone, David Frim, Shawn Withers, Fatima Clouser, and Kenneth Boyer declare that they have no conflict of interest.
