**Abstract.** This paper contains several attacks on the hash function MD2 which has a hash code size of 128 bits. At Asiacrypt 2004 Muller presents the first known preimage attack on MD2. The time complexity of the attack is about  $2^{104}$  and the preimages consist always of 128 blocks. We present a preimage attack of complexity about  $2^{97}$  with the further advantage that the preimages are of variable lengths. Moreover we are always able to find many preimages for one given hash value. Also we introduce many new collisions for the MD2 compression function, which lead to the first known (pseudo) collisions for the full MD2 (including the checksum), but where the initial values differ. Finally we present a pseudo preimage attack of complexity  $2^{95}$  but where the preimages can have any desired lengths.

## 1 Introduction

A hash function is a function that takes an arbitrary long input, and produces a fixed length output. The output is often called a fingerprint of the input. A cryptographic hash function needs to satisfy certain security criteria in order to be called a secure hash function. Let

$$H : \{0, 1\}^* \rightarrow \{0, 1\}^n$$

denote a hash function, whose output is of length  $n$  bits. A cryptographic hash function should be resistant against the following attacks:

- **Collision:** Find  $x$  and  $x'$  such that  $x \neq x'$  and  $H(x) = H(x')$ .
- **2nd preimage:** Given  $x$  and  $y = H(x)$  find  $x' \neq x$  such that  $H(x') = y$ .
- **Preimage:** Given  $y = H(x)$ , find  $x'$  such that  $H(x') = y$ .

Typically one requires that there must not exist attacks of these three types which are better than brute-force methods. Thus, to find a collision should not have a lower complexity than about  $2^{n/2}$  and it should not be possible to find preimages in time less than  $2^n$ .

It is common to construct hash functions from iterating a so-called a compression function

$$h : \{0, 1\}^n \times \{0, 1\}^l \rightarrow \{0, 1\}^n,$$

which compresses a fixed number of bits. Here the output of one application of this function,  $h_i$ , of length  $n$  is called a chaining variable and is used as an input in the next iteration together with the next message block  $m_{i+1}$  of length  $l$ . If the design of a hash function follows the principles of Merkle and Damgård [4, 1], it can be shown that a collision for the hash function  $H$  implies a collision for the compression function  $h$ . Thus, if one can design a secure compression function, then one can also design a secure hash function. Still, the first step towards finding weaknesses in the hash function may be to find weaknesses in the compression function. The first chaining variable in an iterated hash function is often called the *IV* (initial value) and this is often fixed. Attacks on hash functions where the attacker is able to choose or change the *IV* are called pseudo attacks. Most popular hash functions are using an iterative compression function and a fixed *IV*. Examples are MD4, MD5, SHA-1, and RIPEMD-160.

The organisation of this paper is as follows. Section 2 presents the MD2 hash function. Section 3 presents some collision attacks on the compression function where many details are included in an appendix. Section 4 presents several attacks on MD2 (including the checksum). They are a pseudo collision attack, several preimage attacks, as well as a pseudo preimage attack. As far as we are informed the complexities of all these attacks are the lowest known today. Below is a summary of all known results on MD2, where an asterisk (\*) indicates that the attack is new.

	Collision	Preimage	Comments
Compression function	$2^8$ [6]	$2^{73}$ [5]	
Hash function (pseudo)	$2^{16}$ (*)	$2^{95}$ (*)	Arbitrary length messages
Hash function	-	$2^{104}$ [5]	Message length 128 blocks
Hash function	-	$2^{97.6} \cdot 2^{112}$ (*)	Message length 44-128 blocks

## 2 The MD2

The MD2 hash algorithm is designed by Ron Rivest and published in 1988[2, 3]. It is a function  $H : GF(256)^* \rightarrow GF(256)^{16}$ , which takes an arbitrary number of bytes  $GF(256)$  and outputs a string of 16 bytes  $GF(256)^{16}$ . The function consists of iterations of a compression function  $h : GF(256)^{16} \times GF(256)^{16} \rightarrow GF(256)^{16}$ ,  $h_i = h(h_{i-1}, m_i)$ , where the input  $h$  in the  $i$ th iteration is the  $i$ th message block  $m_i$  and the chaining variable  $h_{i-1}$ . The message  $m$  to be hashed is appended with some padding bytes and a checksum  $c$  before it is processed:  $m||p||c = m_1||m_2||\dots||m_{t+1}$ , where  $|m_i| = 128$  for  $i = 1, 2, \dots, t+1$ . At least one byte and at most 16 bytes of  $m_t$  are padded. Let  $b$  be the length of the message in bytes, and  $i \equiv b \pmod{16}$ ,  $i \in \{0, 1, \dots, 15\}$ , then  $d = 16 - i$  (represented in a byte) is added to the message  $d$  times. There is at least one byte padding, so if the length is  $b \equiv 15 \pmod{16}$ , then  $d = 1$  the byte  $p = 1$  is appended the message. If the message length in bytes is  $0 \pmod{16}$ , then  $d = 16$  and the byte sequence  $p = 16|\dots|16$  of length 16 bytes is added to the message, so that the length of the message still is  $0 \pmod{16}$ .

---

**Algorithm 1.** Algorithm to compute the checksum  $c = c_0 || c_1 || \dots || c_{15}$

---

```

for  $j = 0, 1, \dots, 15$ 
   $c_j = 0$ 
for  $i = 1$  to  $t$  do
  for  $j = 0$  to  $15$  do
     $c_j = s(c_{j-1} \bmod 16 \oplus m_{i,j}) \oplus c_j$ 
  end /*for  $i^*$ */
end /*for  $j^*$ */

```

---

**Algorithm 2.** The compression function in MD2, where the output is the 16 first bytes of  $h_{i,1} | h_{i,2} | \dots | h_{i,16} | \dots | h_{i,48}$

---

```

for  $j = 1$  to  $16$  do
   $h_{i,j} = h_{i-i,j}$ 
   $h_{i,16+j} = m_{i,j}$ 
   $h_{i,32+j} = h_{i-i,j} \oplus m_{i,j}$ 
t=0
for  $r = 1$  to  $18$  do
  for  $j = 1$  to  $48$  do
     $t = h_{i,j} = s(t) \oplus h_{i,j}$ 
  end /*for  $j^*$ */
   $t = r - 1 \bmod 256$ 
end /*for  $r^*$ */

```

---

Next a checksum block  $m_{t+1} = c = c_0 | c_1 | \dots | c_{15}$  is appended to the message. The checksum [Algorithm 1.] is generated processing every byte of the message one block at the time, starting at the first block. The checksum is initialized to 0,  $c_i = 0$  for  $i = 0, 1, \dots, 15$ . Then for all  $t$  message blocks,  $m_i$  for  $i = 1, 2, \dots, t$ , process all 16 bytes of that block and the checksum  $j = 0, 1, \dots, 15$  by the function  $c_j = s(c_{j-1} \oplus m_{i,j}) \oplus c_j$  where  $m_{i,j}$  is the  $j$ 'th byte of the  $i$ 'th block of the message and where  $s : \{0, 1\}^8 \rightarrow \{0, 1\}^8$  is a bijective mapping, which is also used in the compression function. The details of  $s$  are not important for the results in this paper. The hash function is iterated in the following way:

- $h_0 = iv = 0$
- $h_i = h(h_{i-1}, m_i)$  for  $i = 1, 2, \dots, t + 1$
- $H(m) = h_{t+1}$

The compression function [Algorithm 2.] of MD2 takes two inputs of each 128 bits, cf., earlier, and consists of an 18-round iterative process, where a vector of the 48 bytes constructed from  $h_{i-1} || m_i || h_{i-1} \oplus m_i$  and denoted

$$h_i = h_{i,1} || h_{i,2} || \dots || h_{i,48}$$

is repeatedly processed from left to right through the use of the same round function consisting of simple byte exclusive-ors and the eight-bit bijective mapping  $s()$ , also used in the checksum calculation.

### 3 Attacks on the Compression Function

In [6] a collision attack on the compression function of MD2 is given. Recall that this function computes  $h_i = h(h_{i-1}, m_i)$ . Rogier and Chavaud give 141 collisions for the compression function where for all collisions  $h_{i-1}$  is fixed to the value zero. Note that the *IV* of MD2 as stated in [2] is zero. We found some variations of this attack. First of all we found that the collision attack extends and it is possible to find many more collisions of this form. We implemented one improvement and found 32,784 collisions, all with  $h_{i-1} = 0$ . This attack takes very little time. Also we found that it is possible to find so-called multi-collisions for the compression function, that is, a set of different  $m_i$ s all with same output in the compression function and all with  $h_{i-1} = 0$ . With a complexity of about  $2^{72}$  one expects a multiple collision of eight messages.

Another variation of Rogier and Chavauds attack is to fix  $m_i$  to zero and find different values of  $h_{i-1}$  leading to identical outputs of the compression function and yet another variation is to fix  $m_i \oplus h_{i-1}$ . These variants are similar to the above original one, although the complexities are slightly higher. [6] also consider cases where only a subset of the bytes of  $h_{i-1}$  are zeros. We show similar results for the variations. The details of the variant where  $h_{i-1} = 0$  are described in Appendix B. The details of the other variants are described in an extended version of the paper available upon request.

In the next section we shall use some of the improvements and variations of the attacks on the compression function.

## 4 Attacks on the MD2 Hash Function

### 4.1 A Pseudo Collision Attack on MD2

In Section 3 we mention a collision attack on the compression function where  $m_i = m'_i = 0$  and  $h_{i-1} \neq h'_{i-1}$ , but where  $h_i = h'_i$ . Using this attack we are able to find collision for MD2 (including the checksum) but using different *IV*s. We have found 130 such collisions in 2 seconds on a single PC, and can find  $\approx 2^{15}$  such collisions in about 512 seconds (under 9 minutes) with that property. For any such collision  $h_{i-1} \neq h'_{i-1}$ , thus if two different *IV* values of MD2 are chosen to be  $IV = h_{i-1}$  and  $IV' = h'_{i-1}$  then one can find collisions for all of MD2 for a message using two different *IV*s.

- Find a pair  $(h_0, m_1) \neq (h'_0, m_1)$  where  $m_1 = 0$  such that  $h(h_0, m_1) = h(h'_0, m_1)$ .
- Set  $IV = h_0$  and  $IV' = h'_0$ .
- Choose message blocks  $m_2|m_3|, \dots, |m_t$ .
- Then clearly  $H(IV, m) = H(IV', m)$ , where  $m = m_1|m_2|m_3|, \dots, |m_t$ .

Notice that the checksums for both hashes are identical since the message blocks are identical, and therefore we have pseudo collision for MD2.

Let us now consider a situation where such collisions could become practical. Imagine a scenario where Alice and Bob use a digital signature system using a

hash function. Imagine that they are signing the same message  $m$  many times, e.g., “Alice owes Bob 100 US\$”. In order to avoid that the same message gives an identical signature, Alice suggests to use a time-stamp, but Bob convinces her that instead he shall send Alice a fresh random hash- $IV$  (e.g., a nonce) to be used in every new signature. Alice agrees to this, however demands that the  $IV$  Bob chooses should be run through the hash function first. And so, they agree on the following protocol.

- Bob chooses a random  $IV$
- Alice calculates  $r = h(IV, 0)$ , creates the hash as usual by  $h = H(r, m)$ , and signs the hash value,  $sign(h)$ .

Assuming that the digital signature scheme and the hash function are secure, it seems hard for Bob to cheat. In every new signature a different  $IV$  is used, so Bob cannot play the replay attack. However using MD2 in this protocol is a problem since Bob is able to find many collisions of the type  $h(IV, 0) = h(IV', 0)$ , and hence he is able to reuse the signature and message together with other  $IV$ s.

## 4.2 The Preimage Attack

In [5] F. Muller presents the first known preimage attack on MD2 faster than a brute-force attack. The attack is divided into two parts: in the first part one finds many preimages of the compression function and in the second part one finds those preimages which conform with the checksum function. Note that for most iterated hash functions a preimage attack of the compression function immediately gives at least a pseudo preimage on the hash function, but this is not true for MD2 because of the additional checksum block which is appended to the messages. [5] lists three different attacks on the compression function:

1. Given  $h_i$  and  $h_{i-1}$ , find a message  $m_i$  such that  $h_i = h(h_{i-1}, m_i)$ . The complexity is  $2^{95}$ .
2. Given  $h_i$  and  $m_i$ , find a value  $h_{i-i}$  such that  $h_i = h(h_{i-1}, m_i)$ . The complexity is  $2^{95}$ .
3. Given  $h_i$ , find a value  $h_{i-i}$  and a message  $m_i$  such that  $h_i = h(h_{i-1}, m_i)$ . The complexity is  $2^{73}$ .

Here one unit in the complexity measures is the time to run the compression function once. All these attacks are expected to give one solution, but there might also be zero or several solutions. Assuming that the compression function is a random function, the probability that there is no solution is  $(1 - 2^{-128})^{2^{128}}$ , and the probability that there are at least  $w$  solutions is:

$$p_w \approx 1 - \sum_{i=0}^{w-1} \left[ \binom{2^{128}}{i} 2^{-128i} \cdot (1 - 2^{-128})^{2^{128}-i} \right] \approx 1 - \left( \sum_{i=0}^{w-1} \frac{1}{i!} \right) e^{-1}.$$

The first attack above can be used to find also preimages for (all of) MD2[5]. With  $h_0 = 0$  and  $h = h_{128}$  the attack is as follows, where  $h_0$  is given and  $i$  is initialised to 1:

1. Choose a random value of  $h_i$ .
2. If more than 2 solutions of  $m_i$  satisfying  $h_i = h(h_{i-1}, m_i)$  is found: Increase  $i$  by 1. If  $i < 128$ : Goto step 1.
3. If no more than 2 solutions of  $m_{128}$  satisfying  $h_{128} = h(h_{127}, m_{128})$  is found: Set  $i$  to 127 and goto step 1.

This gives 128 consecutive pairs  $(h_{i-1}, h_i)$  for which there are at least 2 different values of  $m_i$  such that  $h_i = h(h_{i-1}, m_i)$ . Consequently there are at least  $2^{128}$  different messages  $m$  (of 128 blocks) such that  $h = H(m)$ , and therefore one of these messages is expected to conform with the checksum  $m_{128} = c$ . Let  $c[i]$  denote the checksum after  $i$  iterations ( $i$  message blocks). Using the birthday attack on the checksum function has a complexity of about  $2^{64}$ :

- Compute  $2^{64}$  values of  $c[64]$  by iterating the checksum function through  $2^{64}$  possible values of the blocks  $m_1, m_2, \dots, m_{64}$ .
- Compute  $2^{64}$  values of  $c[64]$  by calculating the checksum backwards through  $2^{64}$  possible values of the blocks  $m_{65}, m_{66}, \dots, m_{128} = c$ .
- Search for a collision between elements in the two lists.

The expected number of collisions in this last step is 1. The overall complexity of this attack is as follows. The probability of finding at least two solutions in the attack on the compression function is approximately  $p_2 = 1 - 2e^{-1}$ , and for each of the steps in the algorithm we expect  $p_2^{-1}$  repeats. So the total complexity is  $128 \cdot p_2^{-1} \cdot 2^{95} \approx 2^{104}$ . The padding bytes have not been considered in this attack, but it is straightforward to ensure that the preimages have correct padding without increasing the complexity of the attack[5]. One drawback of this preimage attack is that the messages always consist of 128 blocks. It is left as an open question in [5] to find preimages with fewer blocks. In the next section we give an improvement in complexity of the above attack as well as variants where the messages have fewer than 128 blocks.

### 4.3 Improvement of the Preimage Attack

First we give a preimage attack also with 128 blocks in the messages but with a lower complexity. We are given  $h_0 = 0$  and  $h = h_{128}$  and proceed as follows:

1. Given  $h_0 = 0$ ; use the collision attack from Section 3 (see also Appendix B) to find  $h_1$  and a collision for  $u \geq 4$  different values of  $m_1$  satisfying  $h_1 = h(h_0, m_1)$ .
2. Let  $h_{127} = h_1$ , and use the preimage attack to try to find  $v \geq 1$  values of  $m_{128}$  such that  $h_{128} = h(h_{127}, m_{128})$ . If there are no solutions, use another collision from step 1.
3. Let  $h_2 = h_1$  and find  $w \geq 2$  values of  $m_2$  such that  $h_2 = h(h_1, m_2)$ . If there are no solutions, repeat step 2 using another collision from step 1.
4. Set  $h_i = h_1$  for  $i = 3, \dots, 126$ .

This is a situation where  $h_0 = 0, h_1 = h_2 = \dots = h_{127}, h_{128} = h$ , and the use of the birthday attack on the checksum is expected to give 1 solution. The first

**Table 1.** Complexities of the preimage attack for different message lengths, where in each case one solution is expected

$w \geq$	message length	complexity
2	128	$2^{97.6}$
3	80	$2^{99.3}$
4	64	$2^{101.4}$
5	55	$2^{103.8}$
6	50	$2^{106.4}$
7	46	$2^{109.2}$
8	43	$2^{112.2}$

step has a relative small complexity as discussed before, but we might be forced to repeat steps 2 and 3. The probability of a solution in step 2 is approximately  $p_1 = 0.63$ , and the probability in the third step is approximately  $p_2 = 0.26$ . Total complexity of the attack is then

$$p_1^{-1} \cdot p_2^{-1} \cdot 2^{95} \leq 2^{97.6}.$$

There are possible ways to shorten the number of blocks in the preimages, but at the expense of higher complexity. If we require that  $w \geq 3$  in step 3, we expect a slightly higher complexity, but the number of blocks in the preimages would drop to approximately  $\log_3 2^{128}$ . Table 1 shows the complexities and lengths of the preimages for different lower bounds of  $w$ . As an example, it is possible to lower the number of blocks in the preimages to 55 instead of 128, by requiring  $w \geq 5$  in which case the complexity is  $\leq 2^{104}$ .

It is also possible to get more preimages without increasing the total (time) complexity. Since we use a preimage where  $h_{i-1} = h_i$ , the possible length of the chain in the middle can be arbitrarily long, however the length is limited by the complexity of the collision attack of the checksum. One example is an attack where the messages are of length 191 and where  $w \geq 2$ . This gives a memory and computational complexity of  $2^{95}$  in the birthday attack on the checksum, and it is expected to give  $2^{62}$  collisions and thereby  $2^{62}$  possible preimages, but total running time of the attack is unchanged.

#### 4.4 A Pseudo Preimage Attack on MD2

In this section we present a pseudo preimage attack on MD2 which has better complexity than the preimage attack, and where the messages can be (almost) as short or as long as we desire. This attack uses two attacks from [5] on the compression function having complexities  $2^{73}$  and  $2^{95}$  respectively.

Initially a hash value  $h$  is given, and we are able to find a message  $m$  and an  $IV$  which give us the desired hash value  $h = H(IV, m)$ . First use the method of finding pseudo preimages  $h_t$  and  $m_{t+1}$  of  $h_{t+1} = h$  in the compression function. Remember that the last message block  $m_{t+1}$  is the checksum block, and we might repeat this preimage attack to find the second last message block,

which also contains the padding bytes. Due to the high degree of freedom in the attack on the compression function, it is possible to choose between 1 and 16 suitable padding bytes in this message block  $m_t$ , but it is sufficient to choose the last byte of  $m_t$  equal to 1, and the attack still gives us  $m_t$  and  $h_{t-1}$  with complexity  $2^{73}$ .

Next we need to have at least one more message block in our preimage to make the checksum consistent with the (given) initial value  $c[0] = 0$ , (recall that  $c[i]$  denotes the checksum after  $i$  iterations ( $i$  message blocks)). A potential problem with the checksum could be to fit the two fixed ends  $c[0] = 0$  and  $c[t] = m_{t+1}$ . However it turns out to be easy to “glue” two consecutive checksum values  $c[i-1]$  and  $c[i]$  together by choosing an appropriate value  $m_i$ . Notice that it is also possible to calculate the checksum  $c[i] = c(c[i-1], m_i)$  backwards by inverting the function,  $c[i-1] = c^{-1}(c[i], m_i)$ . Now suppose we have found the message values  $m_2$  and the checksum, we compute  $c[2]$  and then  $c[1]$  by going backwards. We now “glue”  $c[0]$  and  $c[1]$  together by finding the appropriate  $m_1$ . To get a preimage of two blocks we set  $h_1 = h_{t-1}$  and  $m_1 = m_{t-1}$ , and use another pseudo preimage attack from [5], having complexity  $2^{95}$ , to find  $IV = h_0$ . Using the MD2 hash function on the  $IV$  and a message  $m$  will now give the required hash  $h = H(IV, m)$ . The total complexity in this situation where the message length is two, is  $2^{95}$ .

For a required message length  $t$ , and given  $h_{t+1} = h$  the algorithm is as follows:

- Find  $h_t$  and  $m_{t+1}(= c)$  such that  $h_{t+1} = h(h_t, m_{t+1})$ .
- Find  $h_{t-1}$  and  $m_t$  (included valid padding byte), such that  $h_t = h(h_{t-1}, m_t)$ .
- Repeat the preimage attack  $t - 2$  times to find  $h_1$  and  $m_2$ .
- Find  $c[1]$  by calculating the checksum backwards by using  $m_i$  for  $i = 2, 3, \dots, t + 1$
- Use special property in the checksum algorithm to find  $m_1$  such that  $c[1] = c(0, m_1)$ .
- Use the other pseudo preimage attack[5] to find  $IV = h_0$  given  $h_1$  and  $m_1$ .

The complexity of three first steps of the attack is  $t \cdot 2^{73}$  and the last step has complexity  $2^{95}$ . The other parts of the algorithm have relatively small complexity and the total complexity of the attack is  $2^{95}$  as long as  $t \leq 2^{21}$ . The message length could be as small as  $t = 2$ .

## 5 Conclusion

In this paper some new attacks on the hash function MD2 were presented. First some extended collision attacks on the compression function were given. Using one of these attacks it was shown to be possible to mount a pseudo collision on the MD2, which is the first known attack of its kind faster than the trivial attacks. The paper also presented the best known preimage attack on MD2 which is an improvement of a factor of 80 compared to existing attacks. Also, it was

shown that the lengths of the preimages can be made smaller than in previous attacks, where the lengths were fixed and relatively high. Moreover it was shown that it is possible to extend the attack such that many preimages are found.

## A Properties of the MD2 Compression Function

In order to be able to describe the attacks it is convenient to describe the compression function and its intermediate states in a  $19 \times 49$ -matrix

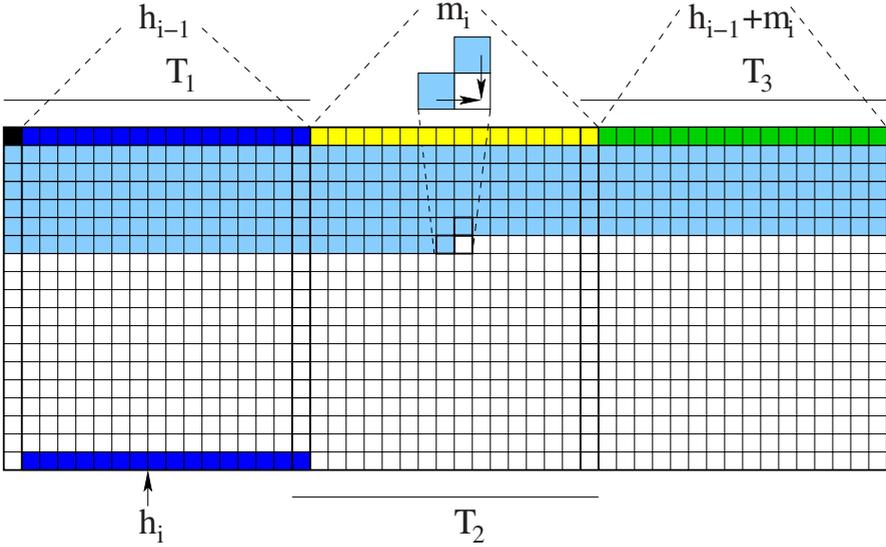

$$T = (T_{i,j})_{\substack{i=0,1,\dots,18 \\ j=0,1,\dots,48}},$$

which is also shown in Figure 1, where the first row is made from  $h_{i-1}$ ,  $m_i$  and  $h_{i-1} \oplus m_i$ . The first element  $T_{0,0}$  is never used, but  $(T_{0,j})_{j=1,2,\dots,48} = h_{i-1} \mid m_i \mid h_{i-1} \oplus m_{i-1}$ .

Next the rows of the matrix is processed in an iterative manner:

- $T_{1,0} = 0$
- $T_{i,0} = T_{i-1,48} + i - 2 \bmod 256$  for  $i = 2, 3, \dots, 18$  (but not for  $i = 1$ )
- $T_{i,j} = T_{i-1,j} \oplus s(T_{i,j-1})$  for  $i = 1, 2, \dots, 18$  and  $j = 1, 2, \dots, 48$
- $h_i = (T_{18,j})_{j=1,2,\dots,16}$

After this procedure the matrix contains all the states of the compression matrix. As we shall see, it is sometimes advantageous in a cryptanalytic approach to try and compute the values in the matrix in a different order than the above line by line approach. To help us do this, we have derived five computing rules directly from the algorithm. The three first rules are shown in Figure 2. The two remaining are just the dependencies between the first and last columns of  $T$ . The rules are:

**Fig. 1.** The MD2 compression function calculation shown as a matrix  $T$ . It also shows how the submatrices  $T_1$ ,  $T_2$  and  $T_3$  are defined, and one line at the time is computed from left to right. The 16 rightmost bytes of the last line of  $T_1$  (the dark area in the last line) contains  $h_i = h(h_{i-1}, m_i)$  when the matrix is completed

1.  $T_{i,j} = T_{i-1,j} \oplus s(T_{i,j-1})$ , where  $i = 1, 2, \dots, 18$  and  $j = 1, 2, \dots, 48$ .
2.  $T_{i-1,j} = T_{i,j} \oplus s(T_{i,j-1})$ , where  $i = 1, 2, \dots, 18$  and  $j = 1, 2, \dots, 48$ .
3.  $T_{i,j-1} = s^{-1}(T_{i,j} \oplus T_{i-1,j})$ , where  $i = 1, 2, \dots, 18$  and  $j = 1, 2, \dots, 48$ .
4.  $T_{i,0} = T_{i-1,48} + (i - 2) \bmod 256$ , where  $i = 2, 3, \dots, 18$ .
5.  $T_{i-1,48} = T_{i,0} - (i - 2) \bmod 256$ , where  $i = 2, 3, \dots, 18$ .

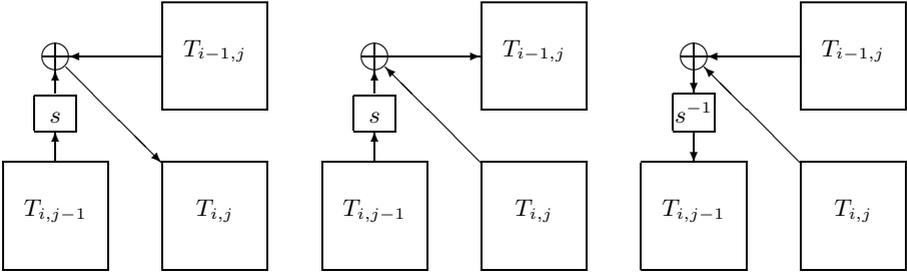

The three first rules give us five properties from [6] also shown in Figure 3 and Figure 4.

**Property 1:** Let  $k < m$  and  $l < n$ . If the elements  $(T_{k,j})_{j=l,l+1,\dots,n}$  from row  $k$  and  $(T_{i,l})_{i=k,k+1,\dots,m}$  from column  $l$  are known the submatrix  $(T_{i,j})_{j=l,l+1,\dots,n}^{i=k,k+1,\dots,m}$  is uniquely determined using rule 1 (Figure 3).

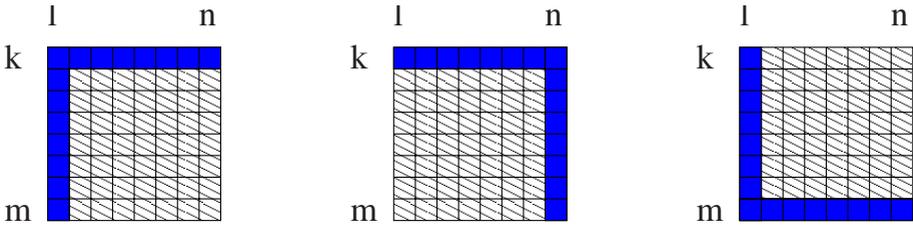

**Property 2:** Let  $k < m$  and  $l < n$ . If the elements  $(T_{k,j})_{j=l,l+1,\dots,n}$  from row  $k$  and  $(T_{i,n})_{i=k,k+1,\dots,m}$  from column  $n$  are known the matrix  $(T_{i,j})_{j=l,l+1,\dots,n}^{i=k,k+1,\dots,m}$  is uniquely determined using rule 3 (Figure 3).

**Property 3:** Let  $k < m$  and  $l < n$ . If the elements  $(T_{m,j})_{j=l,l+1,\dots,n}$  from row  $m$  and  $(T_{i,l})_{i=k,k+1,\dots,m}$  from column  $l$  are known the matrix  $(T_{i,j})_{j=l,l+1,\dots,n}^{i=k,k+1,\dots,m}$  is uniquely determined using rule 2 (Figure 3).

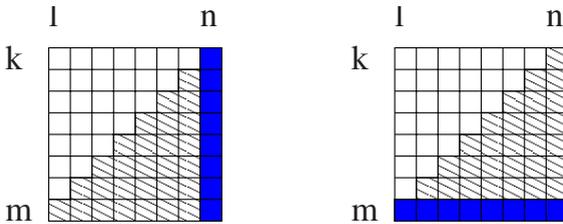

**Property 4:** Let  $l < n$  and  $k < m$ , such that  $m - k = n - l$ . If the elements  $(T_{i,n})_{i=k,k+1,\dots,m}$  from column  $n$  are known then half the square matrix  $(T_{i,j})_{j=l,l+1,\dots,n}^{i=k,k+1,\dots,m}$  is uniquely determined under the diagonal  $(T_{i,j})_{j=n+k-i,(n+k-i)+1,\dots,n}^{i=k,k+1,\dots,m}$  using rule 3 (Figure 4).

**Fig. 2.** The dependency of an element  $T_{i,j}$  in the matrix  $T$ . These three figures show these three dependencies  $T_{i,j} = T_{i-1,j} \oplus s(T_{i,j-1})$ ,  $T_{i-1,j} = T_{i,j} \oplus s(T_{i,j-1})$  and  $T_{i,j-1} = s^{-1}(T_{i,j} \oplus T_{i-1,j})$  respectively

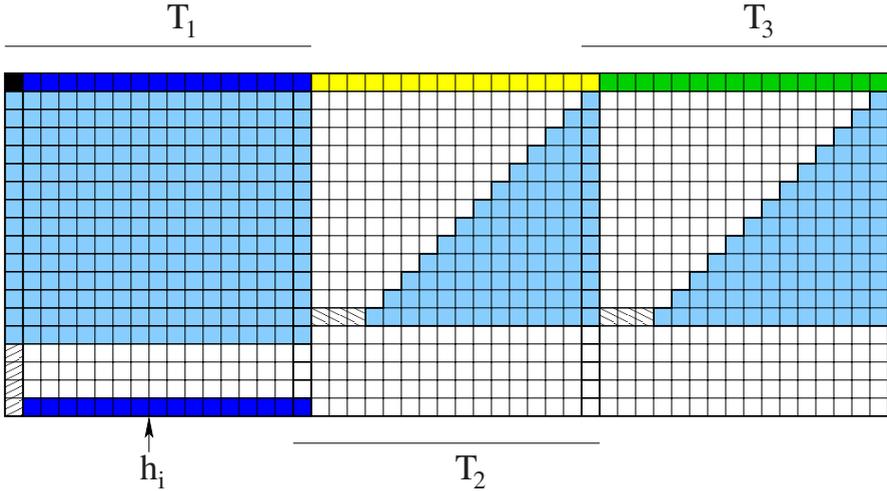

**Fig. 3.** The figure from left to right shows the Properties 1, 2 and 3 respectively. If the dark areas are known the rest of the matrix is uniquely defined

**Fig. 4.** Illustration of the Properties 4 and 5. If the bottom row or the rightmost column is known, the shaded triangle is uniquely defined

**Property 5:** Let  $k < m$  and  $l < n$ , such that  $n - l = m - k$ . If the elements  $(T_{m,j})_{j=l,l+1,\dots,n}$  from row  $m$  is known then half the square matrix  $(T_{i,j})_{j=l,l+1,\dots,n}^{i=k,k+1,\dots,m}$  is uniquely determined under the diagonal  $(T_{i,j})_{j=n+k-i,(n+k-i)+1,\dots,n}^{i=k,k+1,\dots,m}$  using rule 2 (Figure 4).

Observe that the Properties 4 and 5 are similar and define exactly the same triangle, and that the Properties 1, 2 and 3 define the same rectangle. In the attacks of the compression function it is useful to denote the leftmost 17, the middle 17 and the rightmost 17 columns of the matrix  $T$  by (the matrices)  $T_1$ ,

**Fig. 5.** The figure shows the collision attack on the compression function where  $h_{i-1} = 0$ . The dark areas are processed line by line

$T_2$ , respectively  $T_3$  as shown in Figure 1. Notice that the first and last column of  $T_2$  overlap with the last column of  $T_1$  and the first column of  $T_3$ .

## B Collision Attacks on the Compression Function of MD2

### B.1 Collision Attack Where $h_{i-1} = 0$

The first part of this section is from [6] with our extensions at the end. We shall consider a special case where  $h_{i-1} = 0$  and as a consequence  $m_i = h_{i-1} \oplus m_i$  and the first rows of  $T_2$  and  $T_3$  are equal. Since the first row of  $T_1$  and the first element in row 1 are known (defined to be 0), we are able to calculate row 1 of  $T_1$ . Now we try to find values of  $m_i$  such that the 13 first rows of  $T_2$  and  $T_3$  are equal, and in order to be equal the leftmost columns of  $T_2$  and  $T_3$  must be equal and the rightmost columns of  $T_2$  and  $T_3$  must be equal. Since the rightmost column of  $T_2$  coincide with the leftmost column of  $T_3$ , the four of them must be equal in order for the matrices to be equal. Having the rightmost element  $(T_1)_{1,16}$  in the first row of  $T_1$ , we know that we must have:

$$(T_1)_{1,16} = (T_2)_{1,0} = (T_3)_{1,0} = (T_2)_{1,16} = (T_3)_{1,16} = T_{1,48}$$

and if we know  $T_{1,48}$  we know that  $T_{2,0} = T_{1,48} + 0 \pmod{256}$ , so it is simple to complete row 2 of  $T_1$ . We continue until row  $k$ :

$$(T_1)_{i,16} = (T_2)_{i,16} = (T_3)_{i,16} \text{ for } i = 1, 2, \dots, k$$

and calculate row  $k + 1$  of  $T_1$ .

The  $k$  values in the right column of  $T_2$  and  $T_3$  are now known and we might complete a triangle in the rows  $1, 2, \dots, k$  of these two matrices according to property 2, shown in Figure 5. The figure shows the situation where 13 rows ( $k = 13$ ) are preprocessed and the triangles are completed, and there are 3 remaining bytes to be chosen to complete row 13 of  $T_2$  and  $T_3$ . The  $2^{24}$  possible choices of these bytes will determine  $2^{24}$  different first rows  $m_i = h_{i-1} \oplus m_i$  (property 3) and will complete row 13 in both of these matrices, and since the first 14 rows of  $T_1$  is already fixed we have a multi collision in:

$$((T_1)_{i,0})_{i=1,2,\dots,14}$$

containing  $(2^8)^3$  different messages  $m_i$ . It remains to find collisions among these in the last 4 rows of column 0:

$$((T_1)_{i,0})_{i=15,16,17,18}$$

and equal values in row 0 and column 0 of  $T_1$  give an equal matrix by property 1, and we also have collisions in 16 bytes of the last row of  $T_1$ , which is the chaining variable  $h_i$ . The expected number of collisions in this case is approximately

$$(((2^8)^3)^2/2)/((2^8)^4) = 2^{15} = 32768$$

in theory, and we found 32784 collisions in practice. In [6]  $k = 14$  and 2 bytes are varied, and the expected number of collisions were 128 and in practice there were 141 collisions, but to decrease  $k$  to get more collisions is not mentioned explicitly in the paper.

In general we would expect

$$(((2^8)^{16-k})^2/2)/((2^8)^{18-(k+1)}) = 2^{8(15-k)-1}$$

collisions, only depending on the choice of  $k$ . The memory and computational complexity is proportional to the number of bytes varied:  $2^{8(16-k)}$ .

In the preimage attack described earlier in this paper it is advantageous to use this attack when  $h_0 = 0$  and to get collisions in  $m_1$ . It is possible to get more than 2 different  $m_1$  such that all of them give the same output  $h_1$ , and if so we have a multiple collision. If we look for a  $d$ -tuple collision and we are able to vary  $b = 16 - k$  bytes in the first phase of the attack, we expect

$$\binom{2^{8b}}{d} / 2^{8(b+1)(d-1)} \approx 2^{8(b+1-d)} / d!$$

$d$ -tuple collisions. If  $b = 9$  and  $d = 8$  we expect  $\approx 2^{0.7} \geq 1$  multiple collisions of size 8, and the complexity is approximately  $2^{72}$ .

There are similar attacks on the compression function where  $m_i = 0$  or where  $h_{i-1} \oplus m_i = 0$ . For these two attacks and the one where  $h_{i-1} = 0$  there are generalizations which are described in detail in an extended version of the paper available at <http://www.iu.uib.no/~johnm/publications/md2-procExtended.pdf>
