Abstract. We introduce a new non-linear registration model based on a curvature type regularizer. We show that affine linear transformations belong to the kernel of this regularizer. Consequently, an additional global registration is superfluous. Furthermore, we present an implementation of the new scheme based on the numerical solution of the underlying Euler-Lagrange equations. The real discrete cosine transform is the backbone of our implementation and leads to a stable and fast $\mathcal{O}(n \log n)$ algorithm, where n denotes the number of voxels. We demonstrate the advantages of the new technique for synthetic data sets. Moreover, first convincing results for the registration of MR-mammography images are presented.

1 Introduction

Registration of 2D or 3D medical images is necessary in order to study the evolution of a pathology of a patient, or to take full advantage of the complementary information coming from multimodal imagery. In our application, which is related to MR-mammography, the time evolution of an agent injection has to be studied subject to patient motion. Recent examples of the use of deformable models to perform a non-rigid, automatic registration include [5, 2, 1, 6, 3]. Most of these schemes may be viewed as a procedure which minimizes a suitable distance measure subject to a regularization term or some interpolation restrictions.

There are several problems with fully automatic registration approaches. One of which is the problem that the technique is sensitive to initial positioning of the images to be matched. If the initial rigid alignment is off by too much, the non-rigid matching procedure may perform poorly. Therefore it is desirable to incorporate the rigid alignment step, also known as global matching, into the non-rigid scheme.

In this note we propose a novel curvature based penalizing term which not only provides smooth solutions but also allows for automatic rigid alignment. Moreover, we devise a fast and stable implementation for a finite difference approximation of the underlying partial differential equation.

2 Approach

We refer to the template image as T and the reference as R . For a particular point $\mathbf{x} \in \Omega := [0, 1]^d$, the value $T(\mathbf{x})$ is the intensity at $\mathbf{x}$. The registration algorithm described in this paper is applicable to images with any number of dimensions d .

The purpose of the registration is to determine a transformation of T onto R . Ideally, one wants to determine a displacement field $\mathbf{u} : \Omega \rightarrow \Omega$ such that $T(\mathbf{x} - \mathbf{u}(\mathbf{x})) = R(\mathbf{x})$. The question is how to find such a mapping $\mathbf{u} = (u_1, \dots, u_d)$. A typical approach is the minimization of a measure $\mathcal{D}$, for example

$$\mathcal{D}[\mathbf{u}] = \frac{1}{2} \|R - T(\cdot - \mathbf{u})\|_{L_2}^2 = \frac{1}{2} \int_{\Omega} (T(\mathbf{x} - \mathbf{u}(\mathbf{x})) - R(\mathbf{x}))^2 d\mathbf{x}. \quad (1)$$

Of course other choices, like the mutual information based measure or the normalized cross correlation might be used as well, as long as a Gateaux derivative exists. A regularizing term $\mathcal{S}$ is introduced in order to rule out discontinuous and/or suboptimal solutions. The problem now reads, find a mapping $\mathbf{u}$ which minimizes the joint criterion $\mathcal{J}[\mathbf{u}] = \alpha \mathcal{S}[\mathbf{u}] + \mathcal{D}[\mathbf{u}]$. Since the choice of the regularization parameter α is not an issue here, we set $\alpha = 1$.

In this note, we investigate the novel smoothing term

$$\mathcal{S}^{\text{curv}}[\mathbf{u}] = \sum_{\ell=1}^d \int_{\Omega} (\Delta u_{\ell})^2 d\mathbf{x}. \quad (2)$$

The reason for this particular choice is twofold. The integral might be viewed as an approximation to the curvature of the ℓ th component of the displacement field and therefore does penalize oscillations. Most interestingly, $\mathcal{S}^{\text{curv}}$ has a non-trivial kernel containing affine linear transformations, i.e.,

$$\mathcal{S}^{\text{curv}}[C\mathbf{x} + \mathbf{b}] = 0, \quad C \in \mathbb{R}^{d \times d}, \mathbf{b} \in \mathbb{R}^d.$$

Thus, in contrast to many other non-linear registration techniques, the new scheme does not require an additional affine linear pre-registration step to be successful.

To illustrate the difference between our new curvature based registration and the elastic registration approach [5] we consider an academic example. As the reference image a gray square on a white background positioned in the top left corner is used. In contrast, the considered template has the very same square in the bottom right corner. In other words, an appropriate affine linear transformation would produce a perfect registration result. It turns out, that both the curvature based, and the elastic registration, lead to a perfect registration, in the sense that the difference between the reference and deformed template vanishes. However, a tracking of the individual pixel reveals that the path towards the optimal registration is completely different. In Fig. 1 the templates as well as the interpolation grid, i.e., the points $\mathbf{x} - \mathbf{u}(\mathbf{x})$, are shown. As it is apparent from this figure, the curvature based registration finds the optimal registration result by computing an almost affine linear transformation, i.e. $\mathbf{u}(\mathbf{x}) \approx \text{const}$. In

Fig. 1. Template image with interpolation grid; LEFT: after curvature based registration; RIGHT: after elastic registration.

contrast, the displacement computed by the elastic registration scheme is highly non-linear.

Also, this is a striking example for the fact that the similarity between the deformed template and the reference does not necessarily ensure a reliable registration.

We would like to point out, that there is a close relation between the new curvature based approach and the computation of thin-plate-splines, cf., e.g., [9]. These functions are defined as minimizer of the following smoothing term

$$\mathcal{S}^{\text{TPS}}[\mathbf{u}] = \sum_{\ell=1}^d \int_{\mathbb{R}^d} \sum_{|\kappa|=q} c_{\kappa} (D^{\kappa} u_{\ell})^2 d\mathbf{x},$$

subject to some interpolatory constraints. Here, the multi-index $|\kappa| = \kappa_1 + \dots + \kappa_d$, and the set of coefficients $\{c_{\kappa} : |\kappa| = q\}$ are chosen such that $\mathcal{S}^{\text{TPS}}$ is rotationally invariant. The smoothing terms $\mathcal{S}^{\text{curv}}$ and $\mathcal{S}^{\text{TPS}}$ are closely related. These similarities might be used to design a new algorithm which incorporates interpolation conditions (landmarks) into the registration scheme outlined in this note. This approach will be investigated in a forthcoming paper.

In accordance with the calculus of variations, a function $\mathbf{u}$ which minimizes the joint functional $\mathcal{J}$ for the particular choice $\mathcal{S} = \mathcal{S}^{\text{curv}}$ has to satisfy the Euler-Lagrange equation

$$\mathbf{f}(\mathbf{x}, \mathbf{u}(\mathbf{x})) + \alpha \Delta^2 \mathbf{u}(\mathbf{x}) = 0 \text{ for } x \in \Omega, \quad (3)$$

subject to appropriate boundary conditions. The so-called force field $\mathbf{f}$ is the Gateaux derivative of the distance measure $\mathcal{D}$, i.e.,

$$\mathbf{f}(\mathbf{x}, \mathbf{u}(\mathbf{x})) = (T(\mathbf{x} - \mathbf{u}(\mathbf{x})) - S(\mathbf{x})) \nabla(T(\mathbf{x} - \mathbf{u}(\mathbf{x}))). \quad (4)$$

A popular approach to solve this PDE is to introduce an artificial time t and to compute the steady state solution of the time dependent PDE. Here, we

employ the following semi-implicit iterative scheme,

$$\partial_t \mathbf{u}^{k+1}(\mathbf{x}, t) - \Delta^2 \mathbf{u}^{k+1}(\mathbf{x}, t) = \mathbf{f}(\mathbf{x}, \mathbf{u}^k), \quad k = 1, 2, \dots, \quad (5)$$

where $\mathbf{u}^0$ is some initial deformation, typically $\mathbf{u}^0 = 0$.

The above fourth-order non-linear PDE is known as the bipotential or biharmonic equation and is well studied, see, e.g., [8]. To solve (5) numerically, we apply a finite difference discretization adapted to the particular simple geometry of the domain Ω . This approach results in a system of linear equations $\mathcal{A}\mathbf{u}^{k+1} = \mathbf{f}^k$. Consequently, the main work in the overall scheme is the repeated solution of this linear system. It can be shown that $\mathcal{A}$ is diagonalizable by cosine-transform matrices. Thus, a proper, real discrete cosine transform type technique leads to a fast and stable $\mathcal{O}(n \log n)$ implementation, where n denotes the number of voxels.

3 Experiments

To illustrate the performance of the new approach we present the registration of two clinical 2D magnet-resonance (MR) images of a female breast. We are indebted to Bruce L. Daniel (Department of Radiology, Stanford University) for providing the medical data. The task is to register low resolution MR-scans (256×256) of the wash-in and wash-out phase to a high resolution MR-scan (512×512), which are viewed as a gold-standard by the radiologist, taken just between the wash-in and wash-out phase. The overall goal is to study the dynamic behavior of the contrast agent in detail. Fig. 2 displays the arbitrarily chosen section 24 of the high resolution MR-scan and the difference to section 24 of a wash-in phase MR-scan before and after registration. Note that the difference has been reduced by about 30%.
