Part III
Clinical Topics

Approach to the Patient with Sleep Complaints

26

Sudhansu Chokroverty

Introduction

Several epidemiologic studies have clearly shown that sleep complaints are very common in the general population [1–26]. Two important multiple-center studies were conducted by Coleman and his colleagues [7, 8]. The first study [8], conducted over a 2-year period (1978–1980), included 4698 patients, each of whom underwent a polysomnographic (PSG) study. The proportions of diagnostic categories in those patients with sleep complaints, after excluding those evaluated for impotency, are 51 % with hypersomnia, 31 % with insomnia, 15 % with parasomnia, and 3 % with sleep–wake schedule disorders. A subsequent report by Coleman [8] on 3085 patients over a one-year period (1981–1982) showed remarkable consistency with the results of the first study. The most frequent disease categories included in these surveys were sleep apnea, narcolepsy, and insomnia related to psychiatric or psychophysiologic disorders.

The 1979 Institute of Medicine [6] study concluded that about one-third of all adults in the United States experienced some sleep disturbances. Surveys conducted more recently [11–14] confirmed these findings. Approximately 35 % of adults aged 18–79 years reported difficulty in the preceding year falling asleep, staying asleep, or both [11]. In the survey conducted between 1981 and 1985 by the U.S. National Institute of Mental Health Epidemiologic Catchment Area Study [10], 10 % reported difficulty in sleeping for 2 weeks or longer in the preceding 6 months, for which no medical or psychiatric cause could be found. In a 2005 telephone interview survey [1] of 25,500 individuals (aged 15–100 years) using the sleep-EVAL system covering 7 European countries (France, United Kingdom, Germany, Italy, Portugal, Spain, and Finland), nonrestorative sleep was prevalent in 10.8 % of this sample. The prevalence was higher in women than in men and was the highest in the United Kingdom and Germany, and lowest in Spain. The author concluded that nonrestorative sleep was associated with daytime impairment of function and the author identified several factors, such as young age, stress, anxiety, depression, or a physical disease as well as dissatisfaction with sleep. A high prevalence of insomnia was also noted by Morin et al. [2, 3].

Ohayon and Paiva [14] directed our attention to assessment of global sleep dissatisfaction as an indicator of insomnia severity in a general population survey in Portugal. Using the sleep-EVAL system, the authors interviewed by telephone 1858 participants aged 18 years or older who were representative of the general population of Portugal. The authors gave a figure of 28.1 % of the sample having insomnia symptoms for at least 3 nights a week, and global sleep dissatisfaction was noted in 10.1 % of the sample. The most frequent symptom was difficulty in maintaining sleep (21 %). Global sleep dissatisfaction was noted in 29.4 % of the subjects with insomnia symptoms. They noted daytime consequences more frequently among subjects with insomnia symptoms and global sleep dissatisfaction.

Some recent important international surveys were conducted by Soldatos et al. [4] and Leger et al. [15–17]. Leger et al. [15] reported the results of an international survey of sleep problems in the general population of the United States, France, Germany, Italy, Spain, and the United Kingdom. The sleeping problems imposed considerable burden, but were underreported and undertreated. In subsequent international questionnaire-based survey of sleep problems in primary care setting in 10 countries (5293 subjects), Ledger et al. [16] reported that a combination of all types of insomnia symptoms was the most frequent (38.6 %) complaint, and 20–33 % of those having combination of all types of symptoms had sever daytime impairment [17].

The survey by Soldatos et al. [4] on International Sleep Well Day (March 21) in 2002 showed that 24 % of subjects did not sleep well and 31.6 % had insomnia. In a study of 10-year trend in insomnia problem among adult Norwegian population, sleep-onset insomnia was seen in 13.1–15.8 % and daytime impairment in 14.8–18.8 % [22]. The authors concluded that insomnia is on the rise in the general adult population in Norway. Results from two population-based prospective studies from Norway [23] (HUNT 2 in 1995–97 and HUNT 3 in 2006–08) comprising 24,715 people showed that chronic insomnia predicts cumulative incidence of several physical and mental conditions. In the Sao Paulo, Brazil epidemiologic sleep study [24], the prevalence of objective insomnia (using polysomnography in 1042 adults between 20 and 80 years) was 32 %. In a prospective cohort study of 23,447 US men, insomnia symptoms, particularly difficulty in initiating sleep and nonrestorative sleep, are associated with increased risk of mortality. A population-based longitudinal study from the Korean Genome and Epidemiology Study [26] (KoGES) covering 1247 individuals (40.1 % men; mean age = 54.3 years) over a four-year period reported highly prevalent and persistent insomnia symptoms in one-third of individuals and that sleep-interfering behaviors and poor sleep quality were the strongest risk factors for persistence of symptoms. In an earlier population-based longitudinal study (1395 adults followed up after 7.5 years), Vgontzas et al. [21] performed one-night polysomnographic study and observed that objective short sleep duration and mental health problems are the strongest predictors of persistent insomnia.

Self-reported sleep problems could be underestimated in the general population. In all of these studies, there is a prevalence of sleep complaints in about one-third of the adult population, and in about 10 % insomnia is a persistent complaint associated with impairment of daytime function. In a report by Ancoli-Israel and Roth [27], the percentage of individuals with insomnia symptoms is as follows: waking up feeling drowsy or tired, 72 %; waking up in the middle of the night, 67 %; difficulty going back to sleep after waking up, 57 %; difficulty falling asleep, 56 %; and waking up too early, 44 %. Martikainen et al. [28]. described the adverse impact of insomnia on somatic health problems in middle-aged individuals. In a population-based study, Young [29] reported excessive daytime sleepiness in one in five adults. Some important epidemiologic factors identified in various studies include old age, female gender, poor education and lower socioeconomic status, recent stress, depression, anxiety, alcohol, drug abuse, and a physical disease. It is important for physicians to be aware of this high prevalence of sleep disturbances, which cause considerable physical and psychological stress.

Categories of Sleep Disorders

An approach to a patient with sleep complaints must begin with a comprehensive knowledge of the disorders listed in the third edition of the International Classification of Sleep Disorders (ICSD-3) [30], so that the patient can be evaluated in a proper manner, paying particular attention to the history and physical findings before ordering laboratory tests. The ICSD-3 lists seven broad categories of disorders of sleep along with several subcategories under each category, as well as additional sleep-related disorders in Appendices A and B (see Chap. 27). The seven broad categories consist of (1) insomnia, (2) sleep-related breathing disorders, (3) central disorders of hypersomnolence, (4) circadian rhythm sleep disorders, (5) parasomnias, (6) sleep-related movement disorders, and (7) other sleep disorder.

The category of *insomnia* in ICSD-3 includes three types: chronic insomnia disorder, acute insomnia (short term), and other insomnia disorders (do not meet the criteria of other two types). In this edition, all the other pathophysiological subtypes listed in the ICSD-2 have been merged into a single category of chronic insomnia disorder. ICSD-2 subtypes considered the following: psychophysiologic insomnia; paradoxical insomnia (sleep state misperception); idiopathic insomnia; insomnia due to a mental disorder; inadequate sleep hygiene; behavioral insomnia of childhood; insomnia due to a drug or substance; insomnia due to a medical condition; insomnia not due to a substance, sleep-related breathing disorder, or other nonphysiologic condition, unspecified (nonorganic); and physiologic insomnia, unspecified (organic).

The category of *sleep-related breathing disorders* includes central sleep apnea syndromes, including primary central sleep apnea, central sleep apnea with Cheyne–Stokes breathing, central sleep apnea due to high-altitude periodic breathing, central sleep apnea due to a medical condition without Cheyne–Stokes breathing, central sleep apnea due to a drug or substance, primary central sleep apnea of infancy (formerly primary sleep apnea of newborns), primary central apnea of prematurity, and treatment-emergent central sleep apnea. Also included in this category are obstructive sleep apnea syndromes (OSASs), including adult obstructive and pediatric obstructive sleep apnea, sleep-related hypoventilation disorders, and sleep-related hypoxemia disorder.

Central disorders of hypersomnolence which include narcolepsy type 1, narcolepsy type 2, idiopathic hypersomnia, Kleine–Levin syndrome, insufficient sleep syndrome, hypersomnia due to a medical condition, hypersomnia due to a drug or substance, and hypersomnia associated with a psychiatric disorder.

Circadian rhythm sleep disorders include delayed sleep-phase type, advanced sleep-phase disorder, irregular

sleep–wake rhythm disorder, non-24-h sleep–wake rhythm disorder, jet lag disorder, shift work disorder, circadian sleep–wake disorder not otherwise, specified (NOS).

Parasomnias are characterized by abnormal movements and behavior during sleep, but do not necessarily disrupt sleep architecture. Parasomnias include disorders of arousal (from nonrapid eye movement [NREM] sleep) (confusional arousals, sleepwalking, and sleep terrors, sleep-related eating disorders); rapid eye movement (REM)-related parasomnias (REM sleep behavior disorder; recurrent isolated sleep paralysis; and nightmare disorder); and other parasomnias (sleep enuresis, exploding head syndrome, sleep-related hallucinations, parasomnia unspecified, parasomnia due to a drug or substance, and parasomnia due to a medical condition).

Sleep-related movement disorders include restless legs syndrome (RLS), periodic limb movement disorder, sleep-related leg cramps, sleep-related bruxism, sleep-related rhythmic movement disorder, sleep-related movement disorder unspecified, sleep-related movement disorder due to a drug or substance, sleep-related movement disorder due to a medical condition, benign sleep myoclonus of infancy, and propriospinal myoclonus at sleep onset.

Isolated symptoms, apparently normal variants, and unresolved issues including long sleeper, short sleeper, snoring, sleep talking, sleep starts (hypnic jerks), hypnagogic foot tremor and alternating leg muscle activation during sleep, and excessive fragmentary myoclonus, which were listed in a separate category in ICSD-2, have been moved to relevant and most applicable sections in ICSD-3.

The *other sleep disorder* category containing sleep disorders that cannot be classified elsewhere in the ICSD-3 are listed here including environmental sleep disorder.

Appendix A includes sleep-related medical and neurologic disorders: fatal familial insomnia, sleep-related epilepsy, sleep-related headaches, sleep-related gastroesophageal reflux disease, sleep-related myocardial ischemia, and sleep-related laryngospasm.

Appendix B includes substance-induced sleep disorders (e.g., those induced by alcohol, opioid, cocaine, cannabis, sedative-hypnotic, anxiolytic, other stimulants, nicotine, hallucinogens, inhalants, and other psychoactive substances). Thus the ICSD-3 indicates major changes from the ICSD-2 in several areas. For example, the ICSD-3 has simplified classification of insomnias, expanded sleep-related breathing disorders, classified narcolepsy into type 1 and type 2 with slight changes in interpretations of sleep-onset REMs (SOREMs) in multiple sleep latency test (MSLT) and consolidated idiopathic hypersomnias and recurrent hypersomnias into single entities.

Clinical Characteristics of Common Sleep Complaints

More detailed discussion of common sleep complaints is provided in several chapters (Chaps. 27, 32, 33, 37–41, and 46–53) of this volume. The following sections summarize these complaints.

Some common sleep complaints are trouble falling asleep and staying asleep (insomnia); falling asleep during the day (daytime hypersomnolence); inability to sleep at the right time (circadian rhythm sleep disorders); and complaints of thrashing or moving about in bed with repeated leg jerking (parasomnias and other abnormal movements, including nocturnal seizures and RLS). Box 26.1 lists the common sleep complaints.

Box 26.1 Common Sleep Complaints

- Cannot sleep (trouble falling asleep and staying asleep, with nonrestorative sleep)
- Cannot stay awake (falling asleep during the day)
- Cannot sleep at the right time
- Thrashing and moving about in bed and experiencing repeated leg jerking.

Cardinal manifestations in a patient complaining of insomnia include all or some of the following:

- Difficulty falling sleep
- Frequent awakenings, including early morning awakening
- Insufficient or total lack of sleep
- Nonrestorative or unrefreshing sleep
- Daytime fatigue, tiredness, or sleepiness
- Lack of concentration or irritability
- Anxiety and sometimes depression
- Forgetfulness
- Preoccupation with psychosomatic symptoms such as aches and pains

Cardinal manifestations of hypersomnia include the following:

- Excessive daytime somnolence (EDS)
- Falling asleep in inappropriate places and other inappropriate circumstances
- Lack of relief of symptoms after additional sleep at night
- Daytime fatigue and inability to concentrate
- Impairment of motor skills and cognition.

Additional symptoms of hypersomnia depend on the nature of the underlying sleep disorder (e.g., snoring and apneas during sleep witnessed by a bed partner in patients

with OSAS; attacks of cataplexy, hypnagogic hallucinations, sleep paralysis, automatic behavior, and disturbed night sleep in patients with narcolepsy).

Etiologic Diagnosis

Insomnia and hypersomnia are symptoms and do not constitute a specific diagnosis. Every attempt should be made to find a cause for these complaints. The causes are described in several chapters in this book (Chaps. 32, 33, 37–41, 46–53) and are briefly enumerated here.

Insomnia is defined as an inability to obtain an adequate amount of sleep to feel restored and refreshed in the morning, and to function adequately in the daytime [30]. The insomnia complaint does not necessarily depend on the total hours of sleep. There is considerable individual variation in sleep requirement. The category of short-term insomnia (acute or adjustment insomnia) often results from an identifiable stressful situation. This lasts from a few days to a few weeks, 3 months at most. Once the stressful event is removed and the patient adjusts to the event, the sleep disturbance resolves. Causes of acute insomnia include a change of sleeping environment (the most common cause of transient insomnia, the so-called first-night effect; jet lag; unpleasant room temperature); stressful life events (e.g., loss of a loved one, divorce, loss of employment, preparing to take an examination); acute medical or surgical illnesses (including intensive care unit stays); and use of stimulant medications (e.g., theophylline, β-blockers, corticosteroids, digoxin, bronchodilators) or withdrawal of central nervous system (CNS) depressant medications. Causes of chronic insomnia are listed earlier in the section listing pathophysiologic subtypes of the ICSD-2 [31].

Etiologic differential diagnosis of EDS includes both physiologic and pathologic causes (see Chap. 3). Briefly, physiologic causes include sleep deprivation and sleepiness related to lifestyle and irregular sleep–wake causes. Pathologic causes of EDS include primary sleep disorders (obstructive sleep apnea and central sleep apnea syndromes, narcolepsy or idiopathic hypersomnia, circadian rhythm sleep disorders, periodic hypersomnia, occasional complaints in patients with RLS or periodic limb movements in sleep [PLMS], insufficient sleep syndrome, and inadequate sleep hygiene); general medical, psychiatric, and neurologic causes; and medication- and toxin/alcohol-related hypersomnia.

For patients complaining of abnormal movements and behavior during sleep, the differential diagnosis should include disorders of arousal from NREM sleep (confusional arousals, sleepwalking, and sleep terror); REM sleep parasomnias (REM sleep behavior disorder [RBD], recurrent isolated sleep paralysis, and nightmare disorder); and other parasomnias that were listed earlier. The differential diagnosis for patients complaining about abnormal movements and behaviors should also include the sleep-related movement disorders listed previously. In addition, sleep-related epilepsy, including nocturnal frontal lobe epilepsy, must be considered in the differential diagnosis of abnormal movements and behaviors during sleep.

Method of Clinical Evaluation

A physician equipped with this background knowledge should attempt to make a clinical diagnosis based on the history and physical examination of a patient who complains of sleep disturbance. Polysomnographic (PSG) study, the MSLT, and other laboratory tests must be confirmatory and secondary to the clinical diagnosis, which depends on a multifactorial analysis of many facets of a sleep complaint.

History

The first step in the diagnosis and assessment of a sleep/wakefulness disturbance is a careful evaluation of the sleep complaints. The history should seek information on sleep habits; drug and alcohol consumption; psychiatric, medical, and neurologic illnesses; history of previous illness; and family history [32–35] (Box 26.2).

Box 26.2 Clinical Evaluation by History of a Patient with Sleep Complaints

- Sleep history
- Sleep questionnaire
- Sleep log or diary
- Drug and alcohol history
- Psychiatric history
- General medical history
- Neurologic history
- History of previous illnesses
- Family history.

Sleep History

The sleep history [32–35] is fundamentally important and is the first step in identifying the nature of the sleep disorder. Symptoms during the entire 24 h should be evaluated, not just those that occur at sleep onset or during sleep at night. In addition to intrinsic and extrinsic dyssomnias, 24-h symptomatic evaluation helps diagnose and manage circadian rhythm sleep disorders. The clinician should pay attention to symptoms that occur in the early evening or at sleep onset (e.g., paresthesias and uncontrollable limb movements of RLS), during sleep at night (e.g., repeated awakenings,

snoring, and cessation of breathing in OSAS), on awakening in the morning (e.g., feeling exhausted and sleepy in OSAS), or in the late morning and afternoon (e.g., daytime fatigue and excessive somnolence in OSAS and irresistible desire to have brief sleep in narcolepsy). Early morning awakening may be noted in insomnia due to depression. Abnormal motor activities may be associated with RBD and other parasomnias and found in patients with seizures.

In evaluating sleep history, Kales and coworkers [32–34] enumerated six important principles: (1) define the specific sleep problem, (2) assess the clinical course, (3) differentiate between various sleep disorders, (4) evaluate sleep/wakefulness patterns, (5) question the bed partner, and (6) evaluate the impact of the disorder on the patient.

One should analyze the onset, frequency, duration, and severity of the sleep complaint; its progression, evolution, and fluctuation over time; and any events that could have initiated it [30]. An analysis of these factors may differentiate transient disorders from persistent ones. The physician should inquire about the patient's functional status and mood during the day, any medicines and their effects on the sleep complaint, and sleep hygiene [35].

Finally, psychological, social, medical, and biological factors and their interactions should be considered to understand the patient's problem [36]. An interview with the bed partner, caregiver, and, in the case of a child, a parent, is important for diagnosis of abnormal movements (PLMS or other body movements), abnormal behavior (parasomnias, nocturnal seizures), and breathing disorders during sleep. The bed partner may also be able to answer questions about the patient's sleeping habits, history of drug use, psychosocial problems (e.g., stress at home, work, or school), and changes in sleep habits.

Sleep Questionnaire

A sleep questionnaire containing a list of pertinent questions relating to sleep complaints; sleep hygiene; sleep patterns; medical, psychiatric, and neurologic disorders; and drug or alcohol use may be filled out by the patient to save time in obtaining the history.

Sleep Log or Sleep Diary

A sleep log kept over a 2-week period is a valuable indicator of sleep hygiene and can also be used to monitor progression following therapeutic intervention. Such a log should include notations of bedtime, arising time, daytime naps, amount of time needed to go to sleep, number of nighttime awakenings, total sleep time, and feelings on arousal (e.g., refreshed or drowsy).

Drug and Alcohol History

The physician should inquire about drugs that could cause insomnia (e.g., CNS stimulants, bronchodilators, β-blockers, corticosteroids, sedative-hypnotics) or hypersomnolence. In addition, the physician should have information about alcohol consumption and dependence as well as about insomnia related to drug withdrawal (e.g., intermediate- or short-acting benzodiazepines, nonbenzodiazepine hypnotics) [32–34]. Caffeine consumption and smoking should also be considered as contributing factors to insomnia.

Psychiatric History

Attention should be paid to signs of possible psychiatric or psychophysiologic disorders (e.g., depression, anxiety, psychosis, obsession, life stress, personality traits) [32–35]. If sleep disorders are secondary to a psychiatric illness, treating it alleviates the sleep disturbance in most cases. If the sleep complaint persists after such treatment, an additional cause or a primary sleep disorder should be suspected.

Medical and Neurologic History

The physician should question the patient about any reported symptom that has been associated with a variety of medical and neurologic illnesses (see Chaps. 41 and 47). These symptoms direct attention to secondary sleep disorders.

History of Past Illnesses

The patient history might contain information about past medical, psychiatric, or neurologic disorders that could be responsible for the present sleep disturbance. It is also important to learn about and evaluate the premorbid personality of the patient. Finally, a history of a drug or alcohol habit or use of street drugs may reveal the role of these agents in the sleep complaint.

Family History

In certain sleep disorders, family history is very important [32]. A family history is found in about one-third of patients with narcolepsy and RLS. OSAS, with or without obesity, has also been described in family members. There is a high prevalence of sleepwalking, sleep terrors, and primary enuresis in family members. Many neurologic disorders, including fatal familial insomnia, have a family history. Currently, an intensive search is ongoing for a gene specific for narcolepsy and RLS.

Physical Examination

It is essential to conduct a thorough physical examination of every patient with a sleep complaint. It may uncover clues to important medical disorders, such as those involving respiratory, cardiovascular, gastrointestinal, or endocrine systems, or to a neurologic disease, especially one affecting the neuromuscular system, cervical spinal cord, or brain stem region, which may cause sleep-related breathing disorders as well as insomnias. In OSAS, physical examination may

uncover upper airway anatomic abnormalities, which may need surgical correction if medical and continuous positive airway pressure (CPAP) treatments fail to relieve the symptoms. Examination may reveal systemic hypertension, which is a risk factor for sleep apnea. Box 26.3 lists physical findings which may be noted in patients with OSAS.

Box 26.3 Physical Findings in Patients with Obstructive Sleep Apnea Syndrome

- Obesity in the majority of patients (70 %)
- Increased body mass index (BMI) [body weight in kg/height in m^2]; overweight: 25 to 29 BMI;
- Obese: 30 or over BMI
- Increased neck circumference (>17 in. in men and >16 in. in women)
- In some patients, the following may be observed:
  - Large edematous uvula
  - Low-hanging soft palate
  - Large tonsils and adenoids (especially in children)
  - Retrognathia
  - Micrognathia
  - Polycythemia
  - Hypertension
  - Cardiac arrhythmias
  - Evidence of congestive heart failure.

Subjective Measures of Sleepiness

A variety of scales have been developed to assist the subjective degree of sleepiness. The Stanford Sleepiness Scale (Box 26.4) is a 7-point scale that measures subjective sleepiness but may not be reliable with persistent sleepiness. The Karolinska Sleepiness Scale [37] which is somewhat similar to the Stanford Sleepiness Scale is another subjective measure on a 9-point scare (1 = very alert; 9 = very sleepy).

Box 26.4 Stanford Sleepiness Scale
Modified from Hoddes et al. [38].

Score State Before Testing

1. Wide awake, active, and alert
2. Awake and able to concentrate but not functioning at peak
3. Relaxed, awake, and responsive but not fully alert
4. Feeling a little foggy
5. Difficulty staying awake
6. Sleepy, prefer to lie down
7. Cannot stay awake; sleep onset is imminent.

Another scale is the visual analog scale of alertness and well-being. In this scale, subjects are asked to indicate their feelings on an arbitrary line measuring from 0 mm on the left side to 100 mm on the right side. This scale has been used successfully in circadian rhythm disorders. The Epworth Sleepiness Scale evaluates general level of sleepiness [39, 40]. The patient is rated on eight situations each of which is scored as 0–3 (with 3 being the highest chance of dozing off). The maximum score is 24, and a score greater than 10 suggests the presence of excessive sleepiness (Box 26.5). This scale has been weakly correlated with MSLT scores.

Box 26.5 Epworth Sleepiness Scale*
Modified from Johns [39].

Eight Situations

1. Sitting and reading
2. Watching television
3. Sitting in a public place (e.g., a theater or a meeting)
4. Sitting in car as a passenger for an hour without a break
5. Lying down to rest in the afternoon
6. Sitting and talking to someone
7. Sitting quietly after a lunch without alcohol
8. In a car, while stopped for a few minutes in traffic.

*Scale to determine the individual scores: 0 = would never doze; 1 = slight chance of dozing; 2 = moderate chance of dozing; 3 = high chance of dozing. Total score is the sum of the individual scores.

Clinical Phenomenology

Clinical characteristics of some common sleep disorders are briefly described in the following sections. More detailed discussion can be found in several chapters of this volume (Chaps. 32, 33, 37–41, 44, 46–52).

Obstructive Sleep Apnea Syndrome

Based on the definition of 15 or more apneas or hypopneas per hour of sleep accompanied by EDS, the prevalence of moderate-to-severe OSAS in the latest Wisconsin sleep cohort study data [41] is 10 % in men and 3 % in women between 30 and 49 years, but 17 % in men and 9 % in women between 50 and 70 years. There is a strong association between OSAS and male gender, increasing age, and obesity. The condition is common in men older than age 40, and among women the incidence of OSAS is greater after menopause. Approximately 85 % of patients with OSAS are men, and obesity is present in about 70 % of OSAS patients. Several risk factors are associated with OSAS (Box 26.6).

Box 26.6 Risk Factors for Sleep Apnea

- Male sex
- Menopause
- Increasing age
- Obesity
- Increasing neck size (>17 in. in men and >16 in. in women)
- Alcohol consumption
- Smoking
- Racial factors (e.g., increasing prevalence in United States among African Americans, Mexican Americans, and Pacific Islanders)
- Familial aggregates
- Endocrine diseases (e.g., hypothyroidism, acromegaly)
- Craniofacial abnormalities (e.g., Marfan's, Pierre-Robin or Down syndrome)
- Increasing drug use
- Nasal allergies or congestion
- Autonomic failure
- Polycystic ovary syndrome.

The symptoms of OSAS can be divided into two groups (see Chap. 32): those occurring during sleep and those occurring during waking hours (Box 26.7). Nocturnal symptoms include habitual loud snoring, choking during sleep, and cessation of breathing and abnormal motor activities during sleep (e.g., shaking and jerking movements, confusional arousals, or sleepwalking), severe sleep disruption, heartburn as a result of gastroesophageal reflux, nocturnal enuresis (noted mostly in children), and profuse sweating at night. The daytime symptoms include EDS, which is characterized by sleep attacks lasting 0.5–2 h and occurring mostly when the patient is relaxing (e.g., sitting down or watching television). The prolonged duration and the nonrefreshing nature of the sleep attacks differentiate them from narcoleptic sleep attacks. Other diurnal events include personality changes such as impairment of memory, irritability, impairment of motor skills, morning headache, sometimes hypnagogic hallucinations, automatic behavior with retrograde amnesia, and hyperactivity (in children). In men, erectile dysfunction is often associated with severe and long-standing cases of OSAS [42]. Physical examination may reveal obesity in approximately 70 % of cases, in addition to anatomic abnormalities in the upper airway. In severe cases, polycythemia and evidence of cardiac failure, pulmonary hypertension, and cardiac arrhythmias may be noted (see Box 26.3).

Box 26.7 Signs and Symptoms in Obstructive Sleep Apnea Syndrome

Nocturnal Symptoms During Sleep

- Loud snoring (often with a long history)
- Choking during sleep
- Cessation of breathing (apneas witnessed by bed partner)
- Sitting up or fighting for breath
- Abnormal motor activities (e.g., thrashing about in bed)
- Severe sleep disruption
- Gastroesophageal reflux causing heartburn
- Nocturia and nocturnal enuresis (mostly in children)
- Insomnia (in some patients)
- Excessive nocturnal sweating (in some patients).

Daytime Symptoms

- Excessive daytime somnolence
- Forgetfulness
- Personality changes
- Decreased libido and erectile dysfunction in men
- Dryness of mouth on awakening
- Morning headache (in some patients)
- Automatic behavior with retrograde amnesia
- Hyperactivity in children
- Hearing impairment (in some patients).

OSAS is associated with increased morbidity and mortality as a result of both short-term consequences (impairment of quality of life and increasing traffic- and work-related accidents), and long-term consequences resulting from comorbid conditions such as hypertension, heart failure, myocardial infarction, cardiac arrhythmia, and stroke due to both supratentorial and infratentorial infarctions and transient ischemic attacks, as well as cognitive dysfunction, depression, and insomnia [43–46]. Several prospective longitudinal studies have shown a clear association between OSAS and systemic hypertension, which may be noted in approximately 50 % of patients with OSAS. In contrast, in about 30 % of cases of essential hypertension, OSAS is noted. Several studies have shown improvement of hypertension or reduction of need for antihypertensive medications after effective treatment of OSAS with CPAP titration (see Chap. 34). Pulmonary hypertension is noted in approximately 15–20 % of cases. Cardiac arrhythmias in the form of premature ventricular contractions, ventricular tachycardia, sinus pauses, and third-degree heart block as well as sudden cardiac death

have been attributed to OSAS. Heart failure, mostly systolic but also diastolic (in which the studies are limited), is associated with both obstructive and central sleep apneas but mostly central sleep apneas (including Cheyne–Stokes breathing) [44, 47, 48, 49, 50]. The presence of central apnea including Cheyne–Stokes breathing increases the mortality of patients with heart failure. Cognitive dysfunction is noted in moderately severe to severe OSAS patients, but this shows improvement after satisfactory treatment with CPAP titration (see Chap. 34). There is an increasing awareness about the presence of depression and insomnia in patients with OSAS but, in the absence of adequate studies, the exact prevalence and impact of these conditions on OSAS cannot be determined. There is also an increased association between OSAS and metabolic syndrome (a combination of hypertension, increased insulin resistance with type 2 diabetes mellitus, hypertriglyceridemia, and obesity) [45, 51, 52]. Recent studies have also shown an association between OSAS and an increased risk of cancer [53].

Narcolepsy-Cataplexy Syndrome

The onset of narcolepsy-cataplexy in most cases is in adolescents and young adults, with a peak incidence between the ages of 15 and 30. The ICSD-3 [30] divides narcolepsy into two types: narcolepsy type 1 and narcolepsy type 2. The ICSD-3 also lists a subtype as narcolepsy type 1 due to a medical condition, mostly CNS disorder (when CSF hypocretin levels are undetectable or very low) or narcolepsy type 2 (when CSF hypocretin level is similar to that noted in type 2). The major clinical manifestations of narcolepsy include narcoleptic sleep attacks (100 %), cataplexy (70 %), sleep paralysis (25–50 %), hypnagogic hallucinations (20–40 %), disturbed night sleep (70–80 %), and automatic behavior (20–40 %) (Box 26.8). In addition to the major manifestations, patients with narcolepsy may have several important comorbid conditions (Box 26.8): sleep apnea, PLMS, RBD, nocturnal eating disorder, anxiety and depression, obesity, and several fatigue unrelated to sleepiness. The classic sleep attack is an irresistible desire to fall asleep in inappropriate circumstances and at inappropriate places (e.g., while talking, driving, eating, playing, walking, running, working, sitting, listening to lectures, or watching television or movies; during sexual intercourse; or when involved in boring or monotonous circumstances). These spells last from a few minutes to as long as 20–30 min, and the patient generally feels refreshed upon waking. There are wide variations in frequency of attacks, anywhere from daily, weekly, or monthly to every few weeks to months. Attacks generally persist throughout the patient's lifetime, although fluctuations and rare temporary remissions may occur. Patients often show a decline in performance at school and work and encounter psychosocial and socioeconomic difficulties as a result of sleep attacks and EDS.

Box 26.8 Major Manifestations and Comorbid Conditions (Percentage Occurrence)

Major Manifestations

Narcoleptic sleep attacks (100 %)
Cataplexy (70 %)
Sleep paralysis (25–50 %)
Hypnagogic hallucinations (20–40 %)
Disturbed night sleep (70–80 %)
Automatic behavior (20–40 %).

Comorbid Conditions

Sleep apnea (Up to 30 %)
Periodic limb movements in sleep (10–60 %)
REM sleep behavior disorder (Up to 36 %)
Sleep-related eating disorder (prevalence not known)
Anxiety and depression (prevalence not known but may be up to 30 %)
Obesity (prevalence not known)
Severe fatigue unrelated to sleepiness (prevalence not known).

These sleep attacks are often accompanied by cataplexy, characterized by sudden loss of tone in all voluntary muscles except respiratory and ocular muscles. The attacks are triggered by emotional factors such as laughter, rage, or anger more than 95 % of the time. The attacks may become partial and are rarely unilateral. Most commonly, patients may momentarily have head nodding, sagging of the jaw, buckling of the knees, dropping of objects from hands, or dysarthria or loss of voice, but sometimes they may slump or fall forward to the ground for a few seconds. The duration is usually a few seconds to minutes, and consciousness is retained completely during the attack. Generally, cataplectic spells begin to occur months to years after the onset of sleep attacks, but occasionally cataplexy is the initial manifestation. Cataplexy is a lifelong condition, but it generally is less severe and may even disappear in old age. Rarely, status cataplecticus occurs particularly after withdrawal of anticataplectic medications. Sleep paralysis, hypnagogic hallucinations, disturbed night sleep, and automatic behavior are the other manifestations of narcolepsy-cataplexy syndrome. The clinical presentation of childhood narcolepsy-cataplexy may differ from adult presentation in having prolonged nocturnal sleep, daytime hyperactive behavior, and characteristic cataplectic facies (droopy facial appearance, tongue

protrusions, or perioral dystonic movements) not triggered by emotional excitement.

Symptomatic or secondary narcolepsy-cataplexy may result from diencephalic and midbrain tumors, multiple sclerosis, strokes, vascular malformations, encephalitis, cerebral trauma, and paraneoplastic syndrome, in which anti-Ma2 antibodies may present with narcoleptic-like sleep attacks and other manifestations. Symptomatic narcolepsy is associated with cataplexy and develops in children affected with type C Niemann–Pick disease.

Idiopathic Hypersomnia

Idiopathic hypersomnia closely resembles narcolepsy syndrome. This disorder is characterized by EDS that has a presumed but not proven CNS cause and is associated with a total 24-h sleep time of 660 min or longer documented by history, actigraphy, sleep logs, or PSG [30]. The onset of the disease is generally around the same age as narcolepsy (15–30 years). The sleep pattern, however, is different from that of narcolepsy. The patient generally sleeps for hours, but the sleep is not refreshing. Because of EDS, the condition may be mistaken for sleep apnea. However, the patient does not give a history of cataplexy, snoring, or repeated awakenings throughout the night. Some patients may have automatic behavior with amnesia for the events. Physical examination uncovers no abnormal neurologic findings. This disabling and lifelong condition should be differentiated from other causes of EDS (see Chap. 3). There is no clear association between idiopathic hypersomnia and human leukocyte antigens (HLAs). The MSLT shows evidence of pathologic sleepiness without sleep-onset REMs.

Insomnia

Insomnia is the most common sleep disorder affecting the population and is the most common disease encountered in the practice of sleep medicine. Insomniacs complain of difficulty in initiating and maintaining sleep, including early morning awakening and unrefreshing sleep occurring three times per week persisting for at least three months and associated with an impairment of daytime function. Short-term insomnia disorder (acute insomnia) may be associated with an identifiable stressful situation. Most cases of insomnia are chronic (chronic insomnia disorder) and comorbid with other conditions, which include psychiatric, medical, and neurologic disorders or drug and alcohol abuse. The ICSD-3 [30] lists a third category (other insomnia disorder) which does not meet the full criteria for the short-term or chronic insomnia disorder.

Restless Legs Syndrome

RLS (Willis–Ekbom Disease or WED) is the most common movement disorder but is uncommonly recognized and treated despite a lucid description of the entity in the middle of the last century. There is not a single diagnostic test for RLS/WED; hence, the diagnosis rests entirely on clinical features and is based on the International Restless Legs Syndrome Study Group (IRLSSG) criteria first established in 1995 [54], modified slightly in 2003 [55], and modified again in 2012 [56]. These criteria include essential criteria and supportive features as well as specifiers for clinical significance and course for RLS as listed in Box 26.9. These IRLSSG diagnostic criteria differ from the AASM (ICSD-3) [30] and the Diagnostic and Statistical Manual (DSM-5) diagnostic criteria. The ICSD-3 must include the specifiers for clinical significance in the diagnostic criteria whereas DSM-5 [57] diagnostic criteria require a frequency of at least three times a week and a duration of at least three months for RLS/WED symptoms. RLS/WED is a lifelong sensorimotor neurologic disorder that often begins at a very young age but is mostly diagnosed in the middle or later years. Prevalence increases with age and plateaus for some unknown reason around age 85–90. All five essential diagnostic criteria (see Box 26.9) are needed to establish the diagnosis of RLS. The overall prevalence has been estimated at about 7.2 % for adult populations, but the prevalence of most severe cases is approximately 2.7 %. In most surveys, the prevalence is greater in women than in men and the disease is chronic and progressive. Family studies of RLS suggest an increased incidence (around 40–50 %) in first-degree relatives of idiopathic cases. A high concordance (83 %) in monozygotic twins and complex segregation analysis suggests an autosomal dominant mode of inheritance. Linkage analysis documented significant linkage to at least five different chromosomes (12Q, 14Q, 9P, 2Q, and 22P). A recent genome-wide association study of RLS has identified common variants in certain genomic regions conferring more than 50 % increase in risks to RLS. These recent results linking certain genes to RLS suggest a biological basis for the condition.

Box 26.9 Five Essential Diagnostic Criteria For RLS/WED

Criterion 1. An urge to move the legs, usually but not always accompanied by uncomfortable sensations in the legs.

Criterion 2. The urge to move the legs with any accompanying unpleasant sensations begins or worsens during periods of inactivity or quiescence such as lying down or sitting.

Criterion 3. The urge to move the legs with any accompanying unpleasant sensations is partially or totally relieved by movement, such as walking or stretching, as long as the activity continues.
Criterion 4. The urge to move the legs with any accompanying unpleasant sensations during rest or inactivity only occurs or is worse in the evening or night than during the day.
Criterion 5. The above features are not accounted by another medical or behavioral condition (e.g., myalgia, arthritis, venous stasis, leg cramps, positional discomfort, or habitual foot tapping).

The sensory manifestations of RLS include intense disagreeable feelings that are described as creeping, crawling, tingling, burning, aching, cramping, knife-like, or itching sensations. These sensations occur mostly between the knees and ankles, causing an intense urge to move the limbs to relieve the feelings. Sometimes, similar symptoms occur in the arms or other parts of the body, particularly in advanced stages of the disease or when the patient develops augmentation (a hypermotor syndrome with symptoms occurring at least 2 h earlier than the initial period with intensification and spreading to other body parts) resulting from long-standing use of dopaminergic medications. Up to 30–50 % of RLS/WED patients complain of aching pain and not just uncomfortable sensation. Most of the movements, especially in the early stages, are noted in the evening when the patient is resting in bed. In severe cases, movements may be noted in the daytime when the patient is sitting or lying down. At least 80 % of RLS patients have PLMS and may also have periodic limb movement in wakefulness. The condition generally has a profound impact on sleep; often the patient seeks medical attention because of sleep disturbance, which is a problem of initiation, although difficulty in maintaining sleep also occurs because of associated PLMS. Neurologic examination is generally normal in the idiopathic form.

Parasomnias

Parasomnias can be defined as abnormal movements or behaviors, including those that occur into sleep or during arousals from sleep, intermittent or episodic, or without disturbing the sleep architecture [30]. The ICSD-3 lists 10 core categories of parasomnias. Several parasomnias may be mistaken for seizures, especially complex partial seizures and nocturnal frontal lobe epilepsy. Somnambulism, night terror, confusional arousals, sleep enuresis, RBD, and nightmares are some of the parasomnias that can be mistaken for seizures. Characteristic clinical features combined with electroencephalographic (EEG) and PSG recordings are essential to differentiate these conditions.

Sleepwalking (Somnambulism)

Sleepwalking is common in children between the ages of 5 and 12 (Box 26.10). Sometimes, it persists into adulthood or, rarely, begins in adults. Sleepwalking begins with an abrupt onset of motor activity arising out of slow-wave sleep during the first third of sleep. Episodes generally last less than 10 min. There is a high incidence of positive family history. Injuries and violent activities have been reported during sleepwalking episodes, but generally individuals can negotiate their way around the room. Rarely, the occurrence of homicide has been reported and sometimes abnormal sexual behavior occurs; sleep deprivation, fatigue, concurrent illness, and sedative-hypnotics are precipitating factors.

Box 26.10 Features of Sleepwalking (Somnambulism)

- Onset: common between ages 5 and 12 year
- High incidence of positive family history
- Abrupt onset of motor activity arising out of slow-wave sleep during the first third of the night
- Duration: <10 min
- Injuries and violent activity reported occasionally
- Precipitating factors: sleep deprivation, fatigue, concurrent illness, sedatives
- Treatment: precaution, benzodiazepines, imipramine.

Sleep Terror (Pavor Nocturnus)

Sleep terror also occurs during slow-wave sleep (Box 26.11). Peak onset is between the ages of 5 and 7 years. As with sleepwalking, there is a high incidence of family history of sleep terror. Episodes of sleep terror are characterized by intense autonomic and motor symptoms, including a loud, piercing scream. Patients appear highly confused and fearful. Many patients also have a history of sleepwalking episodes. Precipitating factors are similar to those described in sleepwalking.

Box 26.11 Features of Sleep Terrors

- Onset: peak is between ages 5 and 7 year
- High incidence of familial occurrences
- Abrupt arousal from slow-wave sleep during the first third of the night with a loud, piercing scream
- Intense autonomic and motor components
- Sleepwalking also seen in many patients
- Precipitating factors: stress, sleep deprivation, fever

- Treatment: psychotherapy, benzodiazepines, tricyclic antidepressants.

Confusional Arousals

These occur mostly before age of five years. As in sleepwalking and sleep terror, there is a high incidence of familial cases and the episodes arise out of slow-wave sleep but occasionally may occur out of stage N2 sleep. The patient may have some automatic and inappropriate behavior, including abnormal sexual behavior (sex-somnia or sleep sex) when the episodes occur in adults. The majority of spells are benign, but sometimes violent and homicidal episodes in adults have been described. Precipitating factors are the same as in sleepwalking or sleep terror.

REM Sleep Behavior Disorder

RBD is an important REM sleep parasomnia commonly seen in elderly individuals (Box 26.12). A characteristic feature of RBD is intermittent loss of REM sleep-related muscle hypotonia or atonia and the appearance of various abnormal motor activities during sleep. The patient experiences violent and dream-enacting behavior during REM sleep, often causing self-injury or injury to the bed partner. RBD may be idiopathic or secondary; most cases are now thought to be prodromal stage of neurodegenerative diseases. It is seen with increasing prevalence in patients with Parkinson's disease (PD), multiple system atrophy (MSA), and diffuse Lewy body disease with dementia (DLBD), and sometime seen in corticobasal degeneration, olivopontocerebellar atrophy, and progressive supranuclear palsy. Many patients with narcolepsy, a probable autoimmune disease causing depletion of hypocretin-containing neurons in the lateral hypothalamus, may also present with RBD. Some authors have proposed that RBD may be an α-synucleinopathy disorder because α-synuclein inclusions have been observed in many of the associated neurodegenerative diseases (e.g., PD, MSA, DLBD). RBD may precede many of these degenerative diseases by more than 10 years and up to 81 % of what was thought to be idiopathic RBD cases eventually develop neurodegenerative diseases. RBD may sometimes be drug induced (e.g., sedative-hypnotics, tricyclic antidepressants, anticholinergics, selective serotonin reuptake inhibitors) or associated with alcoholism and structural brain stem lesions. RBD has been linked to dopamine dysfunction based on positron emission tomography scan findings of reduced striatal presynaptic dopamine transporter and single-photon emission computed tomography scan findings of reduced postsynaptic dopamine D_2 receptors. A number of studies have demonstrated diverse potential markers of neurodegeneration in idiopathic RBD which include subtle cognitive dysfunction, awake EEG slowing, visuospatial impairment, impairment of olfaction and color vision, autonomic dysfunction (orthostatic hypotension in particular), midbrain hyperechogenicity, and subtle dopaminergic denervation (as noted in dopaminergic PET and SPECT imaging). REM sleep without muscle atonia is the most important PSG finding. Experimentally, similar behavior has been noted after bilateral peri-locus coeruleus lesions in cats.

Box 26.12 Features of REM Sleep Behavior Disorder

- Onset: middle-aged or elderly men
- Presents with violent dream-enacting behavior during sleep, causing injury to self or bed partner
- Often misdiagnosed as a psychiatric disorder or nocturnal seizure (partial complex seizure)
- Etiology:
  - Around 20% idiopathic
  - >80% causal association with neurodegenerative disorders, structural central nervous system lesion, or use of alcohol or drugs (sedative-hypnotics, tricyclic antidepressants, anticholinergics, selective serotonin reuptake inhibitors)
- Polysomnography: REM sleep without muscle atonia and excessive phasic muscle bursts
- Experimental model: Bilateral peri-locus coeruleus lesions
- Treatment: clonazepam or melatonin is beneficial in most of the cases.

Nightmares

Nightmares—intense, frightening dreams followed by awakening and vivid recall—occur during REM sleep. The most common time of occurrence, therefore, is from the middle to the late part of the night. Nightmares are typically normal phenomena. Approximately 50 % of children have nightmares beginning at 3–5 years of age. The incidence of nightmares continues to decrease as one grows older, and the elderly have very few or no nightmares. Nightmares are common after sudden withdrawal of REM-suppressant drugs and can also occur as side effects of certain medications, such as antiparkinsonian drugs, anticholinergics, and β-blockers.

Sleep-Related Eating Disorders

Sleep-related eating disorders are common in women between the ages of 20 and 30 and consist of recurrent episodes of involuntary eating and drinking during partial arousals from sleep. Sometimes, the patient displays strange eating behavior (e.g., consumption of inedible or toxic substances such as frozen pizza, raw bacon, and cat food). The episodes cause sleep disruption with weight gain; occasionally, injury has been reported. The condition can be either idiopathic or comorbid

with other sleep disorders (e.g., sleepwalking, RLS-PLMS, OSAS, narcolepsy, irregular sleep–wake circadian rhythm disorder) and with use of medications such as triazolam, zolpidem, quetiapine, and other psychotropic agents. The most common PSG findings are multiple confusional arousals with or without eating, arising predominantly from slow-wave sleep but also from other stages of NREM sleep and occasionally from REM sleep.

Catathrenia (Expiratory Groaning)

This entity, included in the sleep-related breathing disorder section as isolated symptom, is characterized by recurrent episodes of expiratory groaning (high-pitched, loud humming, or roaring sounds) that occur in clusters predominantly during REM sleep but may also occur during NREM sleep [58–60]. Polysomnographic findings resemble central apnea with protracted expiratory bradypnea without oxygen desaturation. Simultaneous audio recordings will bring out the characteristic groaning. The clinical relevance and pathophysiology of this condition remain unknown.

Sleep-Related Movement Disorders

The category of sleep-related movement disorders in the ICSD-3 [30] consists of relatively simple stereotyped movements disturbing sleep. RLS, PLMS, rhythmic movement disorder, bruxism, leg cramps, benign sleep myoclonus of infancy, and propriospinal myoclonus at sleep onset are included in this category.

Rhythmic Movement Disorder

Rhythmic movement disorder is noted mostly in those younger than age 18 months and is occasionally associated with mental retardation. It is a sleep–wake transition disorder with three characteristic movements: head banging, head rolling, and body rocking. Rhythmic movement disorder is a benign condition, and the patient outgrows the episodes.

Sleep-Related Leg Cramps

These are intensely painful conditions accompanied by muscle tightness that occurs during sleep. The spasms usually last for a few seconds but sometimes persist for several minutes. Cramps during sleep are generally associated with awakening. Many normal individuals have nocturnal leg cramps; the cause remains unknown. Local massage or movement of the limbs usually relieves the cramps.

Bruxism (Tooth Grinding)

Bruxism often presents between ages 10 and 20, but it may persist throughout life, often leading to secondary problems such as temporomandibular joint dysfunction. Both diurnal and nocturnal bruxism may be also associated with various movement and degenerative disorders such as oromandibular dystonia and Huntington's disease. It is also commonly noted in children with mental retardation or cerebral palsy. Nocturnal bruxism is noted most prominently during stages 1 and 2 NREM sleep and REM sleep. The episode is characterized by stereotypical tooth grinding and is precipitated by anxiety, stress, and dental disease. Occasionally, familial cases have been described. Local injections of botulinum toxin into the masseter muscle may be used to prevent dental and temporomandibular joint complications.

Laboratory Investigations

Laboratory investigations for sleep disorders should be considered an extension of the history and physical examination. First and foremost in the diagnosis of sleep disorders is a detailed history including sleep and other conditions as outlined earlier. This should be followed by careful physical examination to uncover any underlying medical, neurologic, or other causes of sleep dysfunction. Laboratory tests should include a diagnostic workup for the primary condition causing secondary or comorbid sleep disturbance and a workup for the sleep disturbance itself. The two most important laboratory tests for diagnosing sleep disturbance are PSG and the MSLT. Various other tests are also important for assessment of a patient with sleep dysfunction (Box 26.13).

Box 26.13 Laboratory Tests to Assess Sleep Disorder

- Diagnostic workup for the primary or comorbid condition causing sleep disturbance
- Laboratory tests for the diagnosis and monitoring of sleep disorders
  - Overnight polysomnography (PSG)
  - Multiple Sleep Latency Test (MSLT)
  - Maintenance of Wakefulness Test
  - Actigraphy
  - Video-PSG
  - Standard electroencephalography (EEG) and video-EEG monitoring for suspected seizure disorders
- Imaging studies
  - Upper airway imaging for obstructive sleep apnea syndrome
  - Neuroimaging studies (e.g., computed tomography, magnetic resonance imaging and cerebral angiography in cases of suspected neurologic illness causing sleep disorder);
  - Positron emission tomography and single-photon emission computed tomography in special situations

- Pulmonary function tests in cases of suspected bronchopulmonary and neuromuscular disorders causing sleep-disordered breathing
- Miscellaneous tests
  - Human leukocyte antigen for suspected narcolepsy
  - Cerebrospinal fluid hypocretin 1 level in suspected narcolepsy
  - Serum iron and ferritin levels for patients with restless legs syndrome
  - Electromyography and nerve conduction studies to exclude comorbid or secondary restless legs syndrome.

Polysomnographic Study

An overnight PSG study is the single most important laboratory test for the diagnosis and treatment of patients with sleep disorders, particularly those associated with EDS. An all-night PSG study is required rather than a single-day nap study. The single-day nap study generally misses REM sleep, and the most severe apneic episodes are noted during REM sleep. Maximum oxygen desaturation also occurs at this stage; therefore, a daytime study cannot assess severity of symptoms. For CPAP titration, an all-night sleep study is essential. To determine the optimum level of pressure during CPAP titration, both REM and NREM sleeps are required, including titration in supine position.

Indications for Polysomnography

Box 26.14 lists indications for overnight PSG in a sleep laboratory as proposed by the American Academy of Sleep Medicine (AASM). These include diagnosis of sleep-related breathing disorders, CPAP titration in patients with sleep-related breathing disorders, follow-up to assess effectiveness of treatment in OSAS patients, preoperative procedure in patients undergoing upper airway surgery for OSAS, evaluation of suspected narcolepsy, evaluation of atypical or violent parasomnias including RBD, and diagnosis of periodic limb movement disorder (PLMD) and nocturnal seizures [61, 62].

Box 26.14 Indications for Overnight Polysomnography

- A PSG study is routinely indicated:
  - For the diagnosis of sleep-related breathing disorders
  - For CPAP titration in patients with sleep-related breathing disorders
  - Before undergoing uvulopalatopharyngoplasty
  - For assessment of results after an oral appliance treatment for obstructive sleep apnea syndrome
  - For parasomnias if these are unusual or atypical or if the behaviors are violent or otherwise potentially injurious to the patient or others
  - For diagnosis of REM sleep behavior disorder
  - In patients suspected of having nocturnal seizures
  - A PSG study may be indicated for patients whose insomnia has not responded satisfactorily to a comprehensive behavioral or pharmacologic treatment program for the management of insomnia. If a sleep-related breathing disorder or associated periodic limb movements in sleep (PLMS) are strongly suspected in a patient with insomnia, a PSG study is indicated.
- A follow-up PSG is indicated:
  - When the clinical response is inadequate or when symptoms reappear despite a good initial treatment with CPAP.
  - After substantial weight loss or weight gain, which may have occurred in patients previously treated successfully with CPAP.
- An overnight PSG followed by a MSLT the next day is routinely indicated in patients with suspected narcolepsy.
- An overnight PSG is required in persons with suspected PLMS but is not routinely performed to diagnose restless legs syndrome.
- An overnight PSG, preferably video-PSG with multiple channels of EEG, is indicated in patients suspected of having nocturnal seizures.
- For parasomnias, the AASM [61] made the following recommendations: PSG is indicated for evaluating sleep-related behaviors that are violent or otherwise potentially injurious to the patient or others, as well as for patients who have unusual or atypical behaviors during sleep. PSG may also be indicated in situations with forensic considerations. However, PSG is not routinely indicated for typical and uncomplicated parasomnias.

PSG is not routinely indicated to diagnose or treat RLS/WED. PSG is indicated when a diagnosis of PLMD is considered as a result of a complaint by the patient or bed partner of repetitive limb movements during sleep, frequent awakenings, difficulty maintaining sleep, or EDS.

PSG is not routinely indicated for diagnosis of circadian rhythm sleep disorders or depression. Indications for PSG in patients with insomnia are somewhat controversial. The diagnosis of insomnia is basically clinical. The AASM guidelines [60] do not list PSG for routine evaluation of short-term or chronic insomnia disorder. PSG may be useful, however, when the cause of insomnia is uncertain or when behavioral or pharmacologic treatment is unsuccessful. If a patient with insomnia is suspected of having a sleep-related breathing disorder or PLMS, PSG is indicated as outlined earlier.

Indications for Ambulatory PSG

Box 26.15 lists indications and guidelines for unattended portable (ambulatory) PSG monitoring as proposed by the Task Force of the AASM [63].

Box 26.15 Guidelines for Unattended Portable (Ambulatory) PSG Monitoring (Home Sleep Apnea Testing [HSAT])

- Unattended portable PSG monitoring is indicated:
  - As an alternative to in-laboratory PSG in patients with a high pretest probability of moderate-to-severe obstructive sleep apnea (OSA)
  - For the diagnosis of OSA in patients for whom in-laboratory PSG is not possible because of immobility, safety concerns, or critical illness
  - To monitor the therapeutic response to treatment other than CPAP for sleep apnea
- Unattended portable PSG monitoring is not indicated for:
  - The diagnosis of OSA in those with significant comorbid medical disorders
  - The diagnostic evaluation of patients with suspected comorbid sleep disorders
  - General screening of asymptomatic individuals
- The recording must be supervised by a physician who is either board-certified in sleep medicine or eligible for such certification, who must review the raw data and edit if needed.
- An experienced technologist must apply the sensors.
- At a minimum, the recording must include airflow, respiratory effort, and blood oxygen saturation.
- A follow-up visit to review the results should be performed.
- A negative or technically inadequate recording in a patient with a high degree of clinical suspicion for OSA should require an in-laboratory PSG.

Polysomnographic Findings in Sleep Disorders [62]

Characteristic PSG findings in OSAS include recurrent episodes of apneas and hypopneas (Fig. 26.1) that are mostly obstructive or mixed and a few episodes of central apnea accompanied by oxygen desaturation and followed by arousals with resumption of breathing. An apnea–hypopnea index (AHI, the number of apneas/hypopneas per hour of sleep) of 5 or below is considered normal, and an AHI index of 5–15 may be considered evidence of mild OSA, 16–29 as evidence of moderate OSA, and 30 or more as evidence of severe OSA. Similarly, oxygen saturation of 85–89 % may be found in mild OSAS, whereas in moderate OSAS 80–84 % is typical and in severe OSA 79 % and below is the usual finding. An arousal index of up to 10 is considered normal, and 10–15 can be considered borderline; an arousal index above 15 is definitely abnormal. There are some sleep architectural changes in OSA (reduction of slow-wave and REM sleep); most of the sleep is spent in stage N2 sleep. Other findings include short latency, increased time spent awake after sleep onset, and excessive snoring. In patients with central sleep apnea syndrome, the apneas are all central for at least 50 % of apneas. PSG findings in patients with Cheyne–Stokes breathing consist of a characteristic crescendo–decrescendo pattern of breathing followed by apneas or hypopneas (Fig. 26.2) for at least 3 consecutive cycles and five or more central apneas or hypopneas per hour of sleep or at least 10 consecutive minutes of cycle duration.

Overnight PSG findings in patients with narcolepsy include short sleep latency, excessive disruption of sleep with frequent arousal, reduced total sleep time, excessive body movements, reduced slow-wave sleep, and sleep-onset REM (seen in 40–50 % of patients). Some narcoleptic patients may have associated sleep apnea, particularly central apnea. In approximately 9–59 % of patients, PLMS has been noted, and in up to 36 % of narcoleptic patients RBD has been described.

The characteristic PSG findings in RBD consist of absence of muscle atonia and presence of increased phasic electromyographic (EMG) activities in the upper and lower limbs during REM sleep. It is important to record EMGs from both upper and lower limbs because, in some patients with RBD, excessive EMG activities are present in the upper limbs but not in the lower limbs.

In RLS, PSG findings document sleep disturbance and PLMS (see Fig. 26.3), which is found in at least 80 % of patients. Diagnosis of periodic limb movement disorder is based on the PLMS index (number of periodic limb movements per hour of sleep) of 15 and over plus symptoms of sleep disturbance. A high PLMS index with arousal is more significant than an index without arousal.

Pitfalls of PSG

PSG is the single most important laboratory test for assessment of sleep disorders, particularly in patients presenting with EDS and those suspected of nocturnal seizures, parasomnias, or other abnormal motor activities. However, PSG has considerable limitations. There is no standardized uniform protocol used consistently in all sleep laboratories, making the comparison of the data from one laboratory to another somewhat misleading. The most severe limitations are that an overnight in-laboratory PSG is labor-intensive, time-consuming, and expensive. A single-night PSG may miss the diagnosis of mild OSAS, PLMS, parasomnias, and nocturnal seizures. PSG data and the patient's clinical

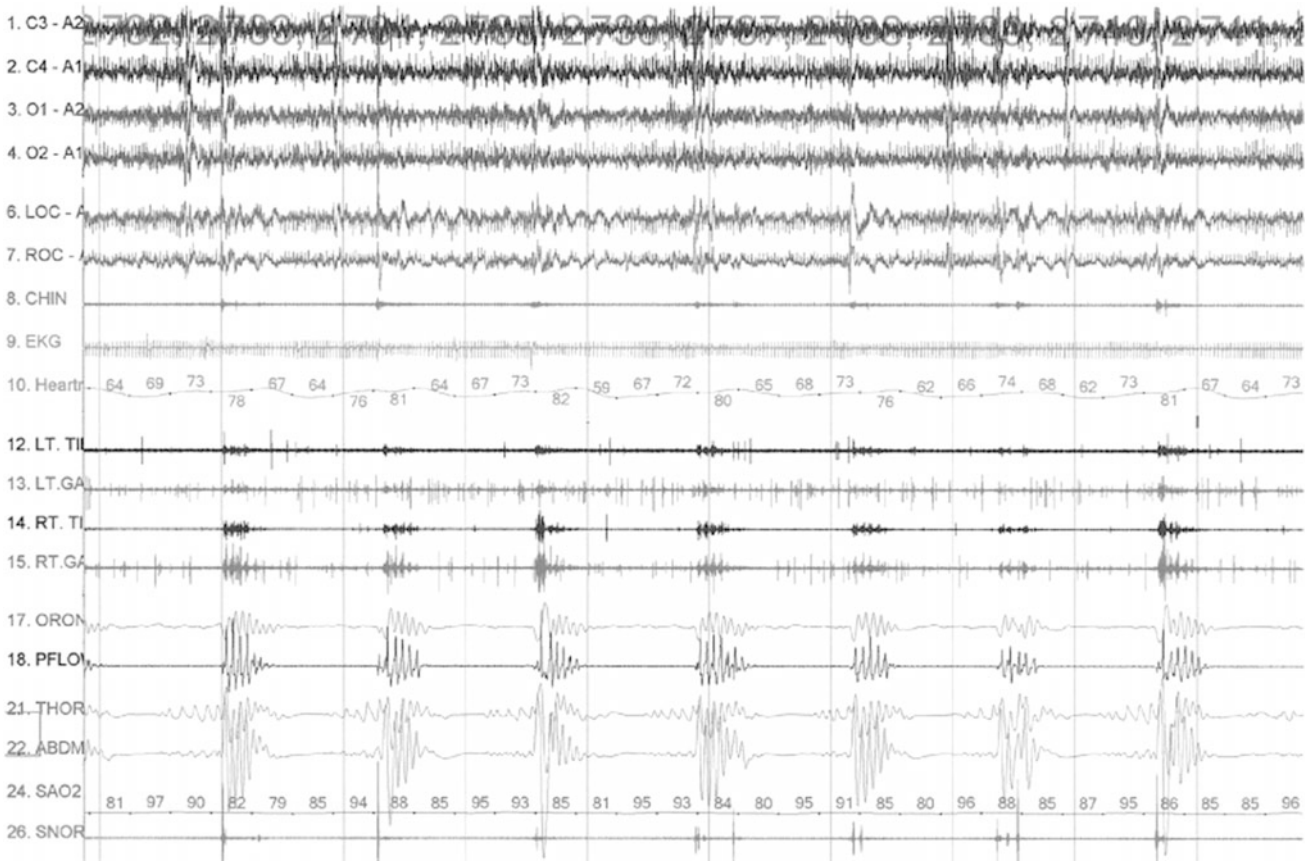

Fig. 26.1 Overnight polysomnographic (PSG) recording in a patient with upper airway obstructive sleep apnea syndrome (OSAS) showing recurrent episodes of mixed apneas (initial control followed by obstructive events) during stage 2 NREM (N2) sleep. Top 4 channels show electroencephalograms (international nomenclature). (A1, left ear; A2, right ear; Loc, left electro-oculogram; ROC, right electro-oculogram; CHIN, submental electromyogram (EMG); EKG, electrocardiogram; LT TA, left tibialis anterior EMG; LT GA left gastrocnemius EMG; RT TA, right tibialus anterior EMG; RT GA, right gastrocnemius EMG; ORON, oronasal airflow; PFLO, nasal pressure transducer recording airflow; THOR, chest respiratory effort; ABDM abdominal respiratory effort; SaO_2, Oxygen saturation (%) by finger oximetry; SNOR, snoring sound recording. l

findings may not be concordant. Standard PSG study cannot diagnose upper airway resistance syndrome definitively. PSG cannot determine the etiology of apnea–hypopnea syndrome. PSG is not helpful in the diagnosis of insomnia, the most common sleep disorder in the general population. PSG is not helpful in the diagnosis or treatment of circadian rhythm sleep disorders. PSG data may be confounded by first-night effects (e.g., increased wakefulness and stage 1 NREM sleep, and decreased slow-wave and REM sleep). Standard PSG does not measure arterial partial pressure of CO_2 and thus may miss hypoventilation, which is an early abnormality (particularly REM hypoventilation) in neuromuscular disorders. Standard PSG does not adequately measure cardiac function (one channel of electrocardiography [ECG] is inadequate), which may affect the prognosis of OSAS. Furthermore, cardiorespiratory sleep studies, which do not include EEG, may produce false-negative findings in mild-to-moderate OSAS patients. Standard PSG does not include autonomic monitoring, which may be important for assessment of autonomic activation as well as for assessing autonomic changes that are intense during sleep.

Video-Polysomnographic Study

A video-PSG study is important for documenting abnormal movements and behavior during sleep at night in patients with parasomnias, including RBD, nocturnal seizures, and other unusual movements occurring during sleep [62]. Parasomnias are generally diagnosed on the basis of a clinical history, but sometimes a video-PSG study is required to document the condition. For suspected nocturnal epilepsy, a video-PSG study using additional electrodes to include multiple-channel EEG and multiple montages covering both parasagittal and temporal regions bilaterally is required for optimal detection of epileptiform activities.

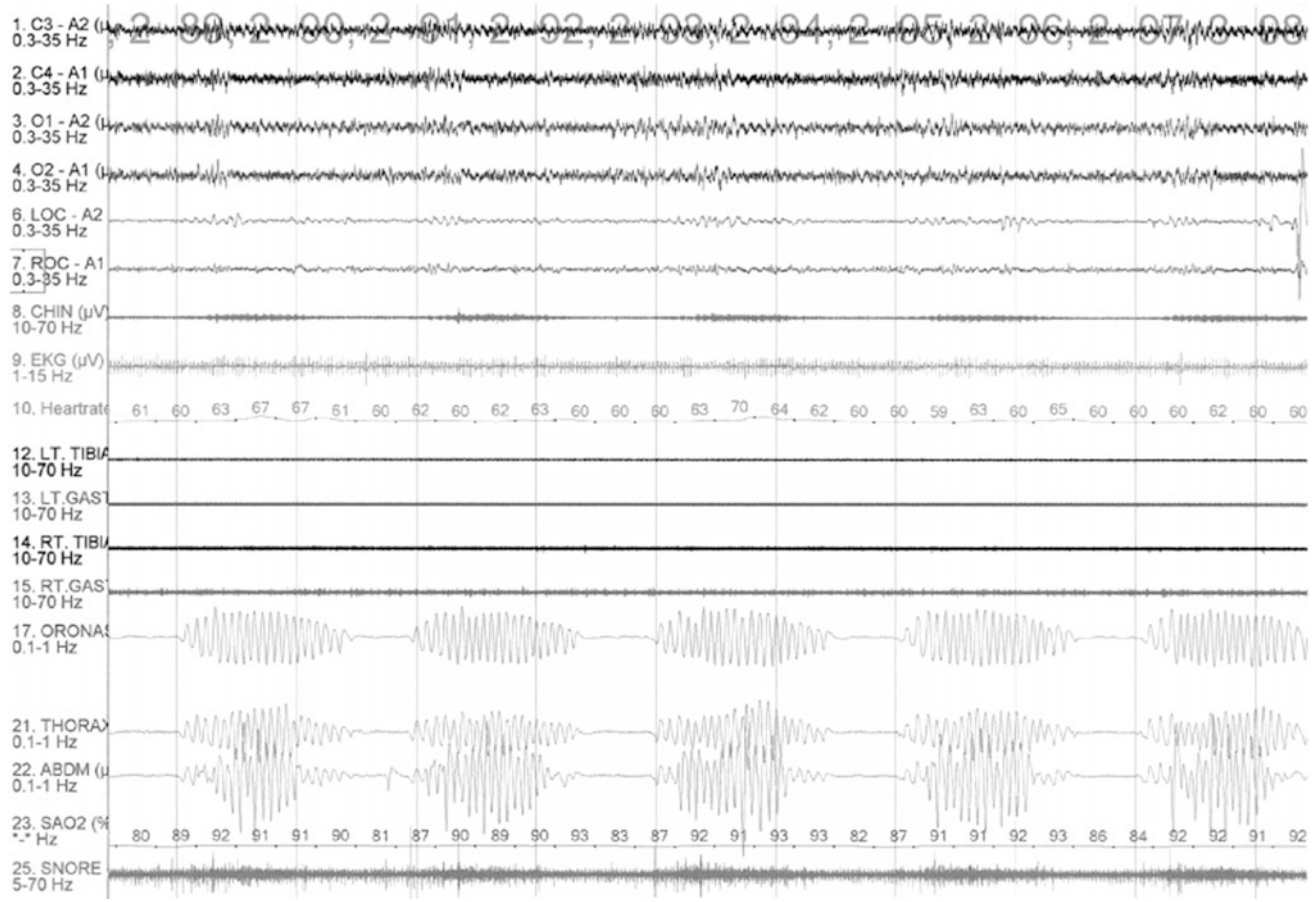

Fig. 26.2 PSG recording from a 70-year-old woman showing the classic crescendo–decrescendo pattern of Cheyne–Stokes breathing (CSB) during stage 2 NREM sleep. The presence of CSB throughout most of the NREM sleep (with marked decrement or absence during REM sleep) in this patient with a history of hypertension and excessive daytime sleepiness suggests occult left ventricular failure. The PSG montage is similar to that in Fig. 26.1

Ideally, if sleep epilepsy is suspected, video-PSG recordings should be interpreted using EEG analysis at the standard EEG speed of 30 mm/sec to identify epileptiform discharges. Multiple EMG channels to record from additional muscles (e.g., forearm flexor and extensor muscles, masseter and other muscles) for patients with suspected RBD and bruxism are recommended.

Video-PSG may help characterize the movements, differentiate one jerk from another, identify a specific entity, and most important, differentiate abnormal motor activities from nocturnal seizures. Video-PSG may aid in the diagnosis of other coexisting sleep disorders (e.g., OSAS, RBD, narcolepsy). Video-PSG does help us classify abnormal motor activities during sleep into several identifiable entities (e.g., motor parasomnias, nocturnal seizures, involuntary diurnal movements persisting during sleep, PLMS, excessive fragmentary myoclonus seen in a variety of sleep disorders, dissociative disorders, nocturnal jerks, and body movements seen in patients with OSAS). Many parasomnias may be mistaken for nocturnal seizures (e.g., confusional arousals, sleepwalking, sleep terror, sleep talking, bruxism, rhythmic movement disorder, RBD, nightmares, and dissociative disorders). RBD and nightmares occur during REM sleep. These conditions can be diagnosed and differentiated from one another based on characteristic clinical features combined with EEG and video-PSG findings. Box 26.16 lists indications for video-PSG.

Box 26.16 Indications for Video-PSG

- Unusual and complex arousal disorders
- Complex behaviors suspicious of RBD but not absolutely certain based on the history
- Behavior and motor events at night suggesting possible nocturnal seizure disorder
- EDS in patients with epilepsy, to determine whether excessive sleepiness is due to repeated nocturnal seizures, an undesirable side effect of antiepileptic medications, or an associative sleep disorder (e.g., sleep apnea)
- Suspected psychogenic dissociative disorder

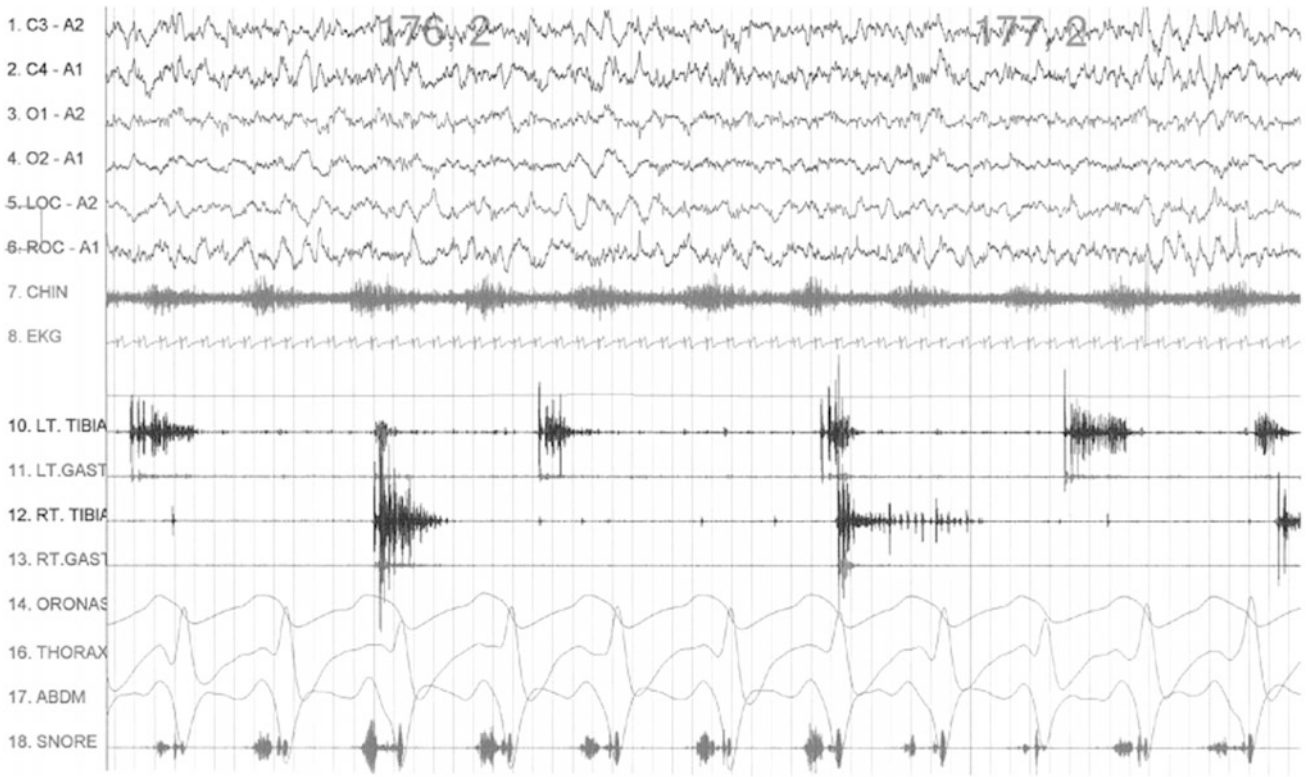

Fig. 26.3 Polysomnographic (*PSG*) recording showing periodic limb movements in sleep (*PLMS*) characterized by dystonic and dystonicmyoclonic electromyographic (*EMG*) bursts in left (*LT*) and right (*RT*) tibialis (*TIBIA*) and gastrocnemius (*GAST*) muscles during stage 2 (N2) non-rapid eye movement (*NREM*) sleep in an adult patient with restless legs syndrome (*RLS*). Top 4 channels show electroencephalograms (*EEG*) using international nomenclature. (A1, left ear; A2, right ear; LOC, left electroculogram; ROC right electro-oculogram; CHIN, submental EMG; EKG electrocardiogram; ORONAS, oronasal airflow; THORAX, chest respiratory effort; ABDM, abdominal respiratory effort (Reproduced with permission from Chokroverty [64])

- Sleep-related movement disorders (e.g., rhythmic movement disorders, bruxism), which may be mistaken for nocturnal seizures
- Involuntary diurnal movement disorder persisting during sleep
- Coexisting secondary sleep disorder (e.g., narcolepsy and RBD; OSAS and sleepwalking; narcolepsy and sleep apnea)
- For medicolegal purpose when the patient presents with violent behavior during sleep; video-PSG studies are mandatory to evaluate suspicions for correct diagnosis of parasomnias or seizure disorders.

Multiple Sleep Latency Test

The MSLT is an important test to effectively document EDS (see Chap. 22). Narcolepsy is the single most important indication for performing MSLT. The presence of two or more sleep-onset REM periods (SOREMP) from four or five nap studies (a SOREMP in the preceding overnight PSG study may substitute for one MSLT SOREMP) and sleep-onset latency of less than 8 min strongly suggest a diagnosis of narcolepsy [30] (Fig. 26.4). Abnormalities of REM sleep regulatory mechanisms (e.g., OSAS, insufficient sleep syndrome, use of REM-suppressant medications) or circadian rhythm sleep disturbance may also lead to REM sleep abnormalities during an MSLT.

Maintenance of Wakefulness Test

The maintenance of wakefulness test (MWT) is a variant of the MSLT (see Chap. 23), measuring a subject's ability to stay awake. It also consists of four to five trials of remaining awake occurring every 2 h. Each trial is terminated if no sleep occurs after 40 min or immediately after the first 3 consecutive epochs of stage 1 NREM sleep or the first epoch of any other stage of sleep [61, 62]. If the mean sleep latency is less than 8 min, it is then considered an abnormal test. The MWT is less sensitive than the MSLT as a diagnostic test for narcolepsy but is more sensitive in assessing the effect of treatment (e.g., CPAP titration in OSAS and stimulant therapy in narcolepsy).

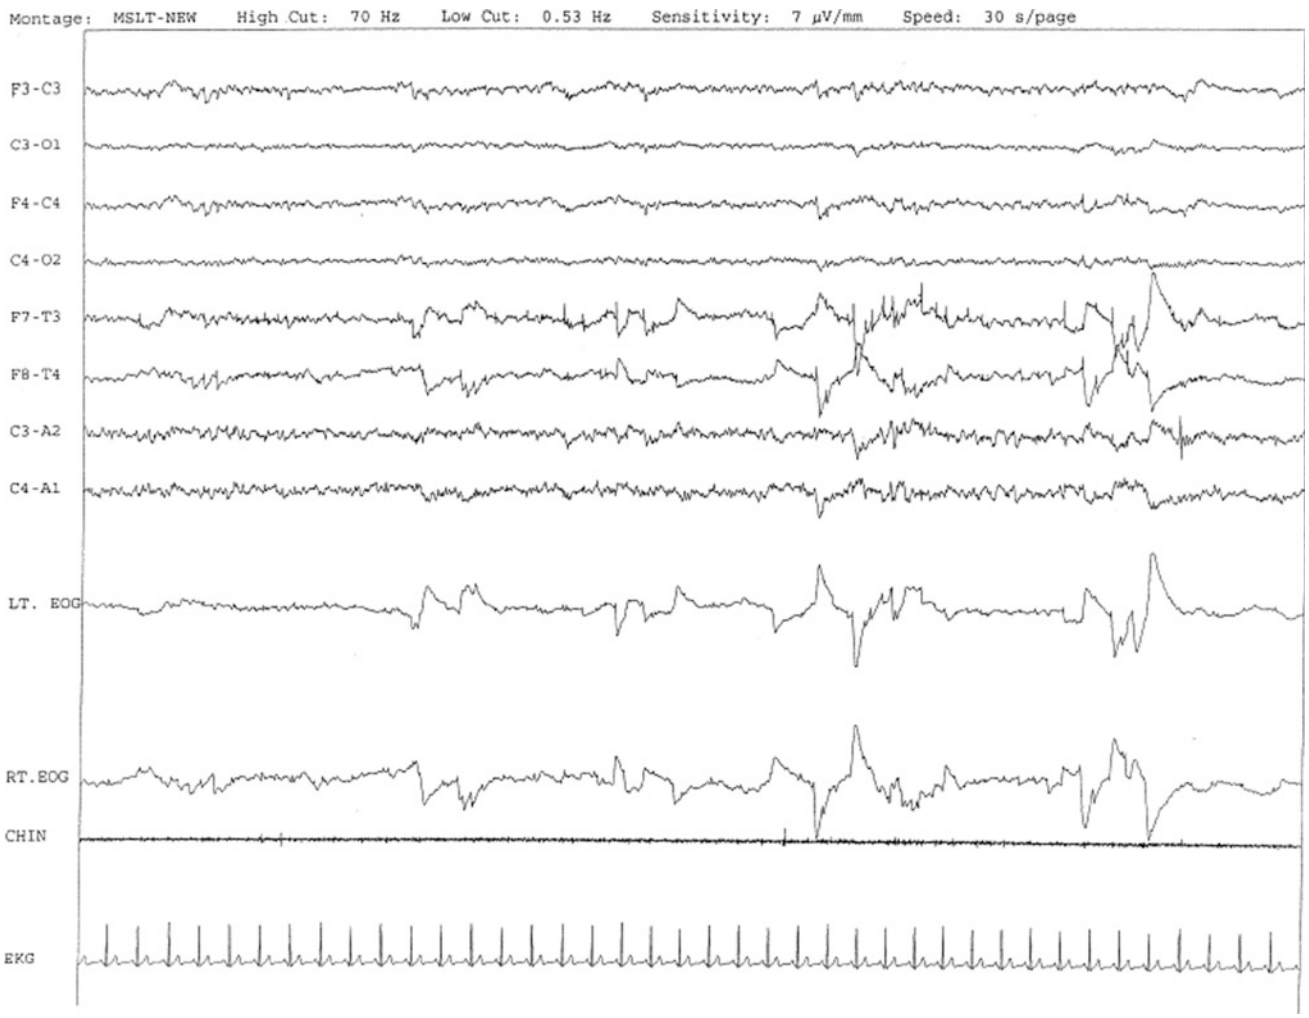

Fig. 26.4 A case of narcolepsy in a 60-year-old woman with new onset of intermittent episodes of sudden transient bilateral leg weakness, excessive daytime sleepiness, and intermittent periods of transient confusion. A daytime EEG was normal. Overnight PSG was significant for sleep architecture changes with an immediate sleep-onset latency, presence of only 1 REM cycle, with a decreased REM sleep percentage (7 %), an increased arousal index of 23 without associated apnea or periodic limb movements, and excessive fragmentary myoclonus in NREM and REM sleep. The MSLT showed a mean sleep latency of 1.6 min, consistent with pathologic sleepiness, and the presence of 2 (of 4) sleep-onset REM naps suggestive of REM sleep dysregulation as seen in narcolepsy. A 30-sec epoch from the MSLT showing the presence of sleep-onset REM occurring 7 min after sleep onset. Prominent REMs are seen in the EOG channels and anterior temporal EEG electrodes. Eye movements, characteristic of REM sleep, are noted as described. CHIN, electromyography of chin; EEG, top eight channels; EKG, electrocardiography; Lt. and Rt. EOG, left and right electro-oculograms. (Reproduced with permission from Chokroverty [64])

Standard Electroencephalographic Study

An EEG is necessary to investigate suspected epilepsy (see Chap. 44).

Ambulatory Electroencephalography or Polysomnography

Ambulatory EEG or PSG is sometimes useful for patients with suspected sleep epilepsy, for understanding circadian variation and for studying circadian rhythm sleep disorders. However, technical problems associated with unattended recording are serious limitations.

Actigraphy

This is another laboratory test for assessing sleep disorders that use an actigraph (also known as an actometer) worn on the wrist or ankle to record acceleration or deceleration of body movements (Fig. 26.5), which indirectly indicates the

state of sleep or wakefulness. The actigraph can be worn for days or weeks, and this test complements a sleep log or diary in diagnosing circadian rhythm sleep disorders (Fig. 26.6) and in assessing patients with insomnia (Fig. 26.7), including paradoxical insomnia or sleep state misperception; inadequate sleep hygiene; and prolonged daytime sleepiness. Actigraphy is useful to document rest–activity patterns over days and weeks when a sleep log is not able to provide such data. Advantages of actigraphy over PSG include the following: easy accessibility; inexpensive recording over extended periods of days, weeks, or months; recording of 24-h activities at all sites (home, work, laboratory); usefulness in uncooperative and demented patients when laboratory PSG study is not possible; ability to conduct longitudinal studies during therapeutic intervention (e.g., cognitive behavioral therapy or pharmacologic treatment) in patients with insomnia; usefulness in paradoxical insomnia; and ability to document delayed or advanced sleep-phase state or circadian rhythm sleep disorder, free-running type. Although not adequately standardized, actigraphy may have a role in patients with RLS and PLMS.

Neuroimaging Studies

Neuroimaging studies include anatomic and functional (physiologic) studies. These studies are essential when a neurologic illness is suspected of causing a sleep disturbance (see Chap. 41)

Pulmonary Function Tests

Pulmonary function tests are important for excluding intrinsic bronchopulmonary disease, which may affect sleep-related breathing disorders (see Chaps. 20 and 47).

Electrodiagnosis of the Respiratory Muscles

Electromyographic recordings of the upper airway and diaphragmatic and intercostal muscles may detect changes in these muscles in various neurologic diseases (see Chap. 41).

Other Laboratory Tests

Appropriate laboratory tests should always be performed to exclude any suspected medical disorder that may be the cause of a patient's insomnia or hypersomnia. These tests may include blood and urinalysis, ECG, Holter monitor ECG, echocardiogram chest radiography, and other investigations to rule out gastrointestinal, pulmonary, cardiovascular, endocrine, and renal disorders. In rare patients, when

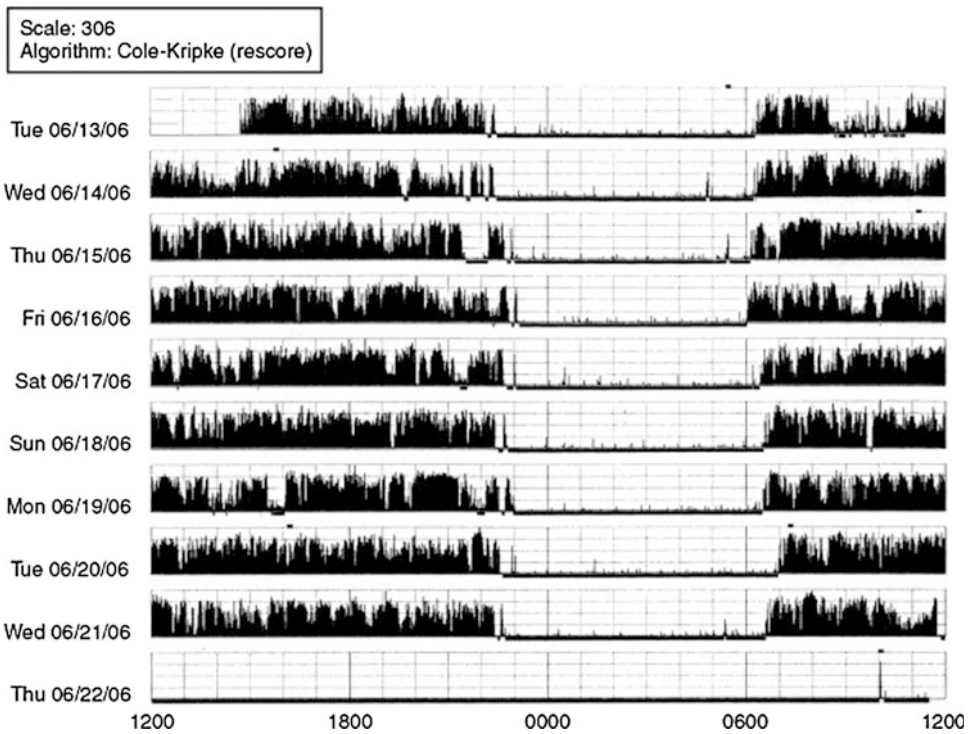

Fig. 26.5 Normal sleep–wake schedule. This wrist actigraphic recording from a 50-year-old healthy woman without sleep complaints shows a fairly regular sleep–wake schedule. She goes to bed between 10:30 and 11:00 P.M. and wakes up around 6:30 A.M. except on the fourth and eighth day. Physiologic body shifts and movements during sleep are indicated by a few *black bars* in the *white areas*. The waking period is indicated by *black bars*

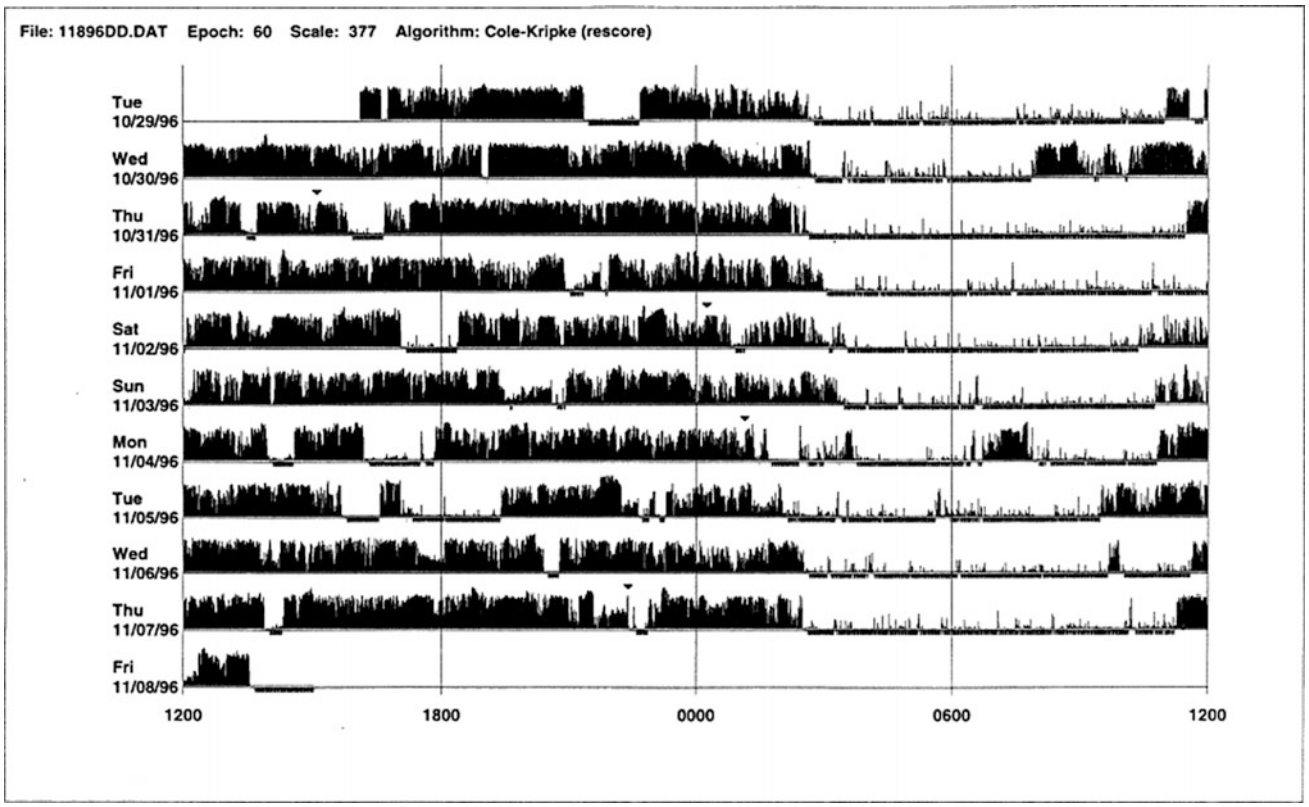

Fig. 26.6 Primary delayed sleep-phase syndrome. This wrist actigraphic recording is taken from a 29-year-old man with a lifelong history of delayed sleep onset and delayed wake-up time. The actigram shows his typical sleep period from 3:00 A.M. to 4:00 A.M. to 9:00 A.M. to noon (*white areas*). If he has to wake up early in the morning, he feels exhausted and sleepy all day. He feels fine if he is allowed to follow his own schedule. Melatonin at night did not help him. Morning bright light therapy was suggested but the patient declined. (Reproduced with permission from Chokroverty [64])

autonomic failure causes a sleep disturbance or sleep-related breathing disorder, autonomic function tests may be required for the diagnosis of the primary condition. In patients with narcolepsy, HLA typing may be performed because most patients with narcolepsy show positivity for HLA DR2 DQ1 and DQB1*0602 antigens. Another important test is measurement of cerebrospinal fluid hypocretin 1 levels, which are found to be low (<110 pg/ml) in patients with narcolepsy type 1 who are HLA DQB1*0602 positive. In patients with narcolepsy type 2 and in some other neurologic conditions, cerebrospinal fluid hypocretin may be low normal. In selected patients suspected of having a psychiatric cause of EDS, neuropsychiatric testing (e.g., the Minnesota Multiphasic Personality Inventory) may be helpful.

In patients with RLS, EMG and nerve conduction studies are important to exclude polyneuropathies or lumbosacral radiculopathies and other lower motor neuron disorders that may be associated with RLS or cause symptoms resembling idiopathic RLS. Other important laboratory tests in patients with RLS include those necessary to exclude diabetes mellitus, uremia, anemia, and other associated conditions. It is particularly important to obtain levels of serum iron (including serum ferritin and transferrin), serum folate, fasting blood glucose, blood urea nitrogen, and creatinine. In a subgroup of patients with RLS, serum iron and ferritin levels are found to be low; it is important to measure these because correction of these abnormalities may improve the condition. The role of nerve biopsy remains controversial. In the vast majority of patients, a nerve biopsy is not necessary, but it may be obtained for research purposes and when there is strong suspicion of polyneuropathy.

Principles of Management of Sleep Disorders

The first principle of treatment of sleep disorders is to find the cause of the sleep disturbance and vigorously treat the primary or comorbid condition causing the sleep

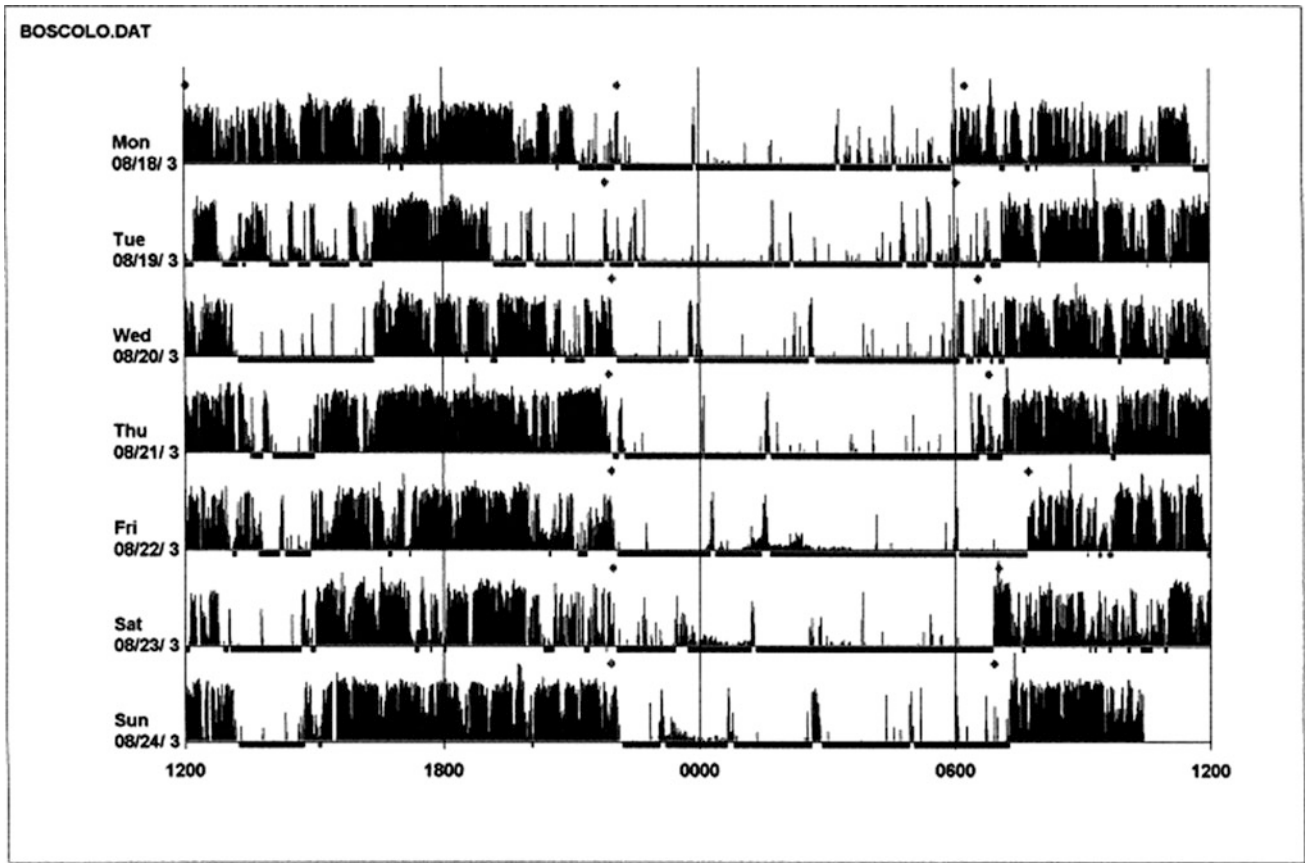

Fig. 26.7 Actigraphy in insomnia (sleep state misperception). A 59-year-old man complaining of insomnia since the age of 12 years was diagnosed to have an Axis 2 personality disorder (dependent personality) according to the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition,* as well as panic attacks, and is being treated with benzodiazepines (diazepam 3 mg, flurazepam 30 mg) and zolpidem 10 mg. He denies any symptoms of restless legs syndrome (RLS), excessive daytime sleepiness, or daytime sleep attacks. Subjective sleep duration is 3–4 h per night. In the past, he had used numerous drugs for sleep amelioration, but no clear and stable subjective improvement was noted. Actigraphic monitoring (during drug dosage reduction: diazepam 2 mg, flurazepam 15 mg, and no zolpidem) shows a clear misperception of sleep duration and quality. The recording shows normal nocturnal motor activity and sleep efficiency and duration; note sleep period during the afternoon. He complained of sleeping not more than 3 h each night. PSG on the third night revealed the following: TST, 387 min; SE, 73.5; WASO, 122 min; number of awakenings, 17; SWS %, 1.3; PLMS index, 1.9. (PLMS, periodic limb movements in sleep; PSG, polysomnography; SE, sleep efficiency; SWS, slow-wave sleep; TST, total sleep time; WASO, wake after sleep onset.) (Reproduced with permission from Chokroverty [64])

disturbance. If a satisfactory treatment is not available for the primary condition or does not resolve the problem, then treatment should be directed at a specific sleep disturbance. It is beyond the scope of this chapter to discuss the management of various neurologic and medical disorders causing sleep disturbances, and the reader is referred to several chapters (Chaps. 32–34, 36–38, 40, 41, 44, 46, 47, 48–51, 55) in this volume. Some general sleep hygiene measures (Box 26.17) should apply to all sleep disorder patients.

Box 26.17 Sleep Hygiene Measures

- Keep a regular sleep–wake schedule, including weekends.
- Avoid caffeinated beverages after lunch.
- Avoid smoking, especially in the evening.
- Avoid alcohol near bedtime.
- Restrict sleep to amount needed to feel rested.
- Do not go to bed hungry.
- Adjust bedroom environment.

- Do not engage in planning the next day's activities at bedtime.
- Exercise regularly for about 20–30 min, preferably 4–5 h before bedtime and not immediately before bedtime.

International Classification of Sleep Disorders 27

Michael Thorpy

The *International Classification of Sleep Disorders* (ICSD-3) produced by the American Academy of Sleep Medicine was updated in 2014 [1] (Table 27.1). In 2013, the American Psychiatric Association (APA) published the revised version of the *Diagnostic and Statistical Manual of Mental Disorders, fifth edition* (*DSM-V*) which includes a section entitled 'Sleep Wake Disorders,' an update of the DSM-IV section [2] (Table 27.2). The intention of the APA classification system was to produce a classification for mental health and general medical clinicians who are not experts in sleep medicine. However, the presence of two competing classifications produces some confusion, especially for health insurance companies and for epidemiological research. *The International Classification of Diseases* modified version, the ICD-10-CM [3], that will be adopted in the USA in 2015 contains a classification that more closely conforms to the ICSD-3 (Table 27.3).

DSM-V

The DSM-V contains 10 disorders or disorder groups: insomnia disorders, hypersomnolence disorder, narcolepsy, breathing-related sleep disorders, circadian rhythm sleep–wake disorders, non-rapid eye movement (NREM) sleep arousal disorders, nightmare disorder, rapid eye movement (REM) sleep behavior disorder, restless legs syndrome, and substance/medication-induced sleep disorder. These disorders have disrupted nocturnal sleep or daytime sleepiness as primary sleep complaints and are all associated with impaired daytime functioning.

The first entry in the DSM-V is insomnia disorder, and this diagnostic entry requires dissatisfaction with sleep quantity or quality and a complaint of difficulty initiating or maintaining sleep. There must be the presence of at least one sleep complaint, such as difficulty initiating sleep, which must be present at least 3 nights per week for at least 3 months. Non-restorative sleep is not a specific complaint in insomnia disorder but if present in isolation can be diagnosed as specified or unspecified insomnia disorder. The diagnosis of insomnia disorder can be coded along with other mental, medical, and sleep disorders. A little confusing is that the diagnosis can be specified as being episodic if it occurs for at least one month; however, acute and short-term insomnia which has symptoms of less than 3 months should be diagnosed as 'other specified insomnia disorder.'

Hypersomnolence disorder includes symptoms of excessive quantity of sleep, deteriorated quality of wakefulness, and sleep inertia. A diagnosis is made if there is a 3-month history of excessive sleepiness, despite a main sleep period of at least 7 h, in the presence of significant distress or other impairment and it is not due to another sleep disorder. Objective documentation is not required. This diagnosis can be coded along with other mental, medical, and sleep disorders. Narcolepsy is defined as recurrent episodes of sleep that occur for at least 3 months along with one of three additional features, such as cataplexy, hypocretin deficiency, or polysomnographic features, either a sleep-onset REM period (SOREMP) on a nighttime polysomnogram (PSG) or a multiple sleep latency test (MSLT) showing a mean sleep latency less than 8 min and 2 or more SOREMPs. So narcolepsy can be diagnosed in DSM-V if just sleepiness occurs for 3 months and there is a SOREMP on the nocturnal PSG. This has the potential of leading to errors in diagnosis as other disorders including obstructive sleep apnea syndrome (OSA) can produce similar features. Five subtypes are specified according to the presence or absence of hypocretin deficiency, autosomal dominant cerebellar ataxia, deafness and narcolepsy (ADCADN), autosomal dominant narcolepsy, obesity and type 2 diabetes (ADNOD), or secondary to another medical condition.

- Other specified hypersomnolence disorder
- Unspecified sleep–wake disorder
- Unspecified insomnia disorder
- Unspecified hypersomnolence disorder
- Unspecified sleep–wake disorder

Adapted from [2]

Obstructive sleep apnea syndrome (OSA) is defined as an apnea hypopnea index (AHI) of at least 5 per hour along with typical nocturnal respiratory symptoms, or daytime excessive sleepiness or fatigue. Alternatively the diagnosis requires an AHI of at least 15 regardless of accompanying symptoms. Mild is regarded as an AHI of 5 to less than 15, moderate 15–30, and severe greater than 30. Central sleep apnea requires the presence of 5 or more central apneas per hour of sleep. Subtypes include idiopathic central apnea, Cheyne–Stokes breathing, and central apnea comorbid with opioid use. Sleep-related hypoventilation has PSG evidence of decreased ventilation with either elevated CO_2 levels or persistent oxygen desaturation unassociated with apneic/hypopneic events. Idiopathic hypoventilation, congenital central alveolar hypoventilation, and comorbid sleep-related hypoventilation can be specified as subtypes.

Circadian rhythm sleep–wake disorders with five subtypes are defined as a persistent of recurrent pattern of sleep disruption due to an alteration or misalignment of the endogenous circadian rhythm and the individuals required sleep–wake schedule, along with symptoms of either insomnia or excessive sleepiness or both. The subtypes are the following: delayed sleep phase (DSP) type, advanced sleep phase (ASP) type, irregular sleep–wake (ISW) type, non-24-h (non-24) sleep–wake type, and shift work (SW) type none of which have specific diagnostic criteria. DSP and ASP can have familial subtypes. DSP can be subtyped as overlapping with non-24.

The parasomnias are subdivided into five disorders: non-rapid eye movement (NREM) sleep arousal disorder, nightmare disorder, rapid eye movement sleep behavior disorder, restless legs syndrome, and substance/medication-induced sleep disorder. Non-rapid eye movement sleep arousal disorder is divided into two types by the typical features of either sleepwalking or sleep terrors. The sleepwalking type is further subtyped if associated with sleep-related eating or sleep-related sexual behavior (sexsomnia). Confusional arousals as defined

in ICSD-3 are not included as a specific DSM-V disorder. Nightmare disorder is defined as repeated occurrences of extended, dysphoric, and well-remembered dreams that threaten the individual. Rapid orientation and alertness follow the episode and cause significant distress. It can be subtyped as that occurring during sleep onset, or associated with non-sleep disorder, other medical condition, or another sleep disorder. Rapid eye movement sleep behavior disorder (RBD) is characterized by repeated episodes of arousal with vocalization and/or complex movements from REM sleep documented by either PSG or a history suggesting a synucleinopathy. Sleep studies are not required as they are in the ICSD-3 diagnostic criteria for RBD. Restless legs syndrome (RLS) is an urge to move the legs accompanied by uncomfortable sensations in the legs with the typical features that occur at least 3 times per week for at least 3 months. It is unclear from where the definition of 3 times a week was derived. Sleep medication or substance-induced sleep disorder is a sleep disturbance either during or soon after substance intoxication or after withdrawal, or the substance is known to cause sleep disturbance. The substance should be specified.

Other specified insomnia disorder is specified when the insomnia does not meet the criteria for insomnia disorder, and other hypersomnolence disorder is diagnosed when the excessive sleepiness does not meet the criteria for hypersomnolence disorder. Similarly, unspecified sleep–wake disorder is diagnosed when the sleep–wake disorder does not meet the full criteria for the specified sleep–wake disorders. Unspecified forms of insomnia disorder, hypersomnolence disorder, and sleep–wake disorder exist.

International Classification of Sleep Disorders 3rd Revision

The *International Classification of Sleep Disorders* (ICSD-3) is a major revision of the ICSD-2 and was published in March of 2014. The main change was the simplification of the insomnia disorders and an expansion of the sleep-related breathing disorders.

The organization of the ICSD-3 produced a greater degree of standardization between disorder texts. It includes information in all the following categories where available: Alternate Names, Diagnostic Criteria, Essential Features, Associated Features, Clinical and Pathophysiological Subtypes; Demographics: Prevalence, Gender bias, Racial/ethnic bias, Cultural issues: Predisposing and Precipitating Factors: Risk factors, Familial Pattern (Genetics, Familial clusters); Onset, Course and Complications: Medical, Neurological, Psychiatric/social; Developmental Issues(Pediatric, Geriatric), Pathology and Pathophysiology, Objective Findings; Sleep logs, Actigraphy, Questionnaires, Polysomnography, Multiple sleep latency test, Neurological (Electroencephalogram, Cerebrospinal fluid, Neuroimaging, Electromyogram, Autonomic), Endocrine, Genetic testing; Respiratory (Arterial blood gas, Pulmonary function, Ventilatory response), Cardiac, (Electrocardiogram, Echocardiogram, Cardiac catheterization), and Serum chemistry. Several disorders are now classified as isolated symptoms and normal variants, which include excessive time in bed, short sleeper, snoring, catathrenia, long sleeper, sleep talking, excessive fragmentary myoclonus, hypnagogic foot tremor and alternating leg muscle activation, and sleep starts (hypnic jerks).

Insomnia Disorders

The insomnia disorders are characterized by one major disorder termed chronic insomnia disorder. This recognizes the fact that the clinical features of insomnia can be the result of a primary or secondary process but the consequences are similar no matter what is the etiology [4]. The previous terminology of primary insomnia is no longer used as the disorder is now recognized that whether it is comorbid with other medical or psychiatric disorders or exists in isolation is immaterial to the underlying insomnia process. The disorder still needs to be treated, and the treatment of the insomnia should occur irrespective of the treatment of any associated disorder. The diagnosis of chronic insomnia disorder rests upon a sleep symptom such as difficulty initiating sleep that occurs three times per week for at least 3 months and has daytime

consequences. The previous diagnostic types of insomnia in ICSD-2 such as psychophysiological insomnia and paradoxical insomnia are now no longer used although the initiating mechanisms and characteristics may still be important in understanding the insomnia and are therefore discussed in the text. The inclusion of short-term insomnia disorder with similar diagnostic criteria to chronic insomnia disorder applies to insomnia that is less than 3 months in duration. Excessive time in bed and short sleeper are included as isolated symptoms and normal variants, not as specific disorders.

Sleep-related Breathing Disorders

The sleep-related breathing disorders are organized into four main categories: obstructive sleep apnea (OSA) disorders, central sleep apnea (CSA) syndromes, sleep-related hypoventilation disorders, and sleep-related hypoxemia disorder. The central sleep apnea syndromes are divided into eight types: two related to Cheyne–Stokes breathing (CSB), high altitude, substance, three primary CSA disorders of which one is infancy and the other prematurity, and a new entity entitled treatment-emergent central sleep apnea. The latter category applies to central apnea that follows CPAP administration.

Obstructive sleep apnea syndrome (OSA) is divided into adult and pediatric types. OSA adult maintains the criterion of 5 or more respiratory events per hour of sleep when studied in a sleep center or by out of center sleep studies (OCST), so long as typical symptoms are present, otherwise 15 or more predominantly obstructive respiratory events are sufficient to make the diagnosis. In the pediatric criteria, for those less than 18 years of age, only one obstructive event is required per hour of sleep so long as respiratory symptoms or sleepiness are present; alternatively, obstructive hypoventilation along with symptoms is required.

Central sleep apnea with Cheyne–Stokes breathing (CSA-CSB) is 5 or more central apnea or hypopneas per hour of sleep with a pattern that meets criteria for CSB. Central sleep apnea without CSB is diagnosed as central sleep apnea due to a medical disorder without Cheyne–Stokes breathing that occurs as a consequence of a medical or neurological disorder. Central sleep apnea due to high-altitude periodic breathing is central apnea attributable to high altitude of at least 1500 m but usually above 2500 m. Central sleep apnea due to a medicine or substance is most typically due to an opioid or respiratory depressant not associated with CSB. Primary central sleep apnea (CSA) is 5 or more central apneas or central hypopneas per hour of sleep in the absence of CSB and of unknown etiology. Primary central sleep apnea of infancy occurs in an infant with greater than 37 weeks conceptional age with recurrent, prolonged (>20 s duration) central apneas and periodic breathing for more than 5 % of total sleep time during sleep. Primary central sleep apnea of prematurity occurs in an infant of less than 37 weeks conceptional age with similar respiratory events.

Treatment-emergent central sleep apnea is diagnosed when five or more obstructive events during a PSG with CPAP showing resolution of obstructive events and presence of central apneas or hypopneas [5], without evidence of heart failure.

Central Disorders of Hypersomnolence

The central disorders of hypersomnolence comprise eight disorders. Narcolepsy has undergone a major revision with elimination of the terms, with or without cataplexy. Type 1 narcolepsy is that presumed to be due to hypocretin loss with either measured reduction in cerebrospinal fluid (csf) hypocretin or cataplexy with associated electrophysiological findings. Narcolepsy type 2 is that which is confirmed by electrophysiological studies in the absence of cataplexy or with a normal csf hypocretin level. A major change in the narcolepsy criteria is the addition of including a sleep-onset rapid eye movement period (SOREMP) on the nocturnal PSG as one of the two required to meet the MSLT criteria of two SOREMPs for diagnosis. This is based upon a study that indicates that the positive predictive value of a SOREMP on the nocturnal PSG for narcolepsy is 92 % [6]. Approximately 50 % of patients with narcolepsy will have a SOREMP less than 15 min on the nocturnal PSG. If the MSLT criteria are not met but narcolepsy type 1 is clinically suspected, then a possible strategy is to repeat the MSLT. The ICSD-3 also recognizes that narcolepsy can present differently in children and that the excessive sleepiness in children may manifest as a long nighttime sleep period or as resumption of discontinued napping. Cataplexy in children may include mouth opening with tongue protrusion, dystonic and dyskinetic facies, and unsteady gait which are not necessarily related to emotion.

Idiopathic hypersomnia is a single entity with elimination of the two ICSD-2 hypersomnia disorders that had specific sleep duration criteria. The new idiopathic hypersomnia disorder requires either an MSLT mean sleep latency of 8 min or less, showing fewer than two SOREMP, or a 24-h sleep duration of at least 660 min. The ICSD-2 category of recurrent hypersomnia has been reduced to a single entry, Kleine–Levin syndrome with a subtype of menstrual related Kleine–Levin syndrome [7]. The sleepiness must persist for 2 days to 5 weeks and at least once every 18 months. There must be at least one of the following symptoms during the episodes: cognitive dysfunction, altered perception, eating disorder, or disinhibited behavior.

Insufficient sleep syndrome is the new term for the previous more cumbersome term of behaviorally induced insufficient sleep syndrome. The reduced sleep must be present most days for at least 3 months. Extension of sleep time must result in resolution of symptoms. The other three items in the hypersomnia disorders section are hypersomnia related to a medical disorder, medication or substances, or psychiatric disorder.

Long sleeper is no longer regarded as a disorder but as a normal variant. There are no diagnostic criteria but a total sleep time of 10 or more hours is suggested as being usually accepted.

Circadian Rhythm Sleep–Wake Disorders

The circadian rhythm sleep–wake disorders comprise six specific disorders including delayed sleep–wake phase disorder (DSWPD), advanced sleep–wake phase disorder (ASWPD), irregular sleep–wake rhythm disorder (ISWRD), non-24 h sleep–wake rhythm disorder (N24SWD), shift work disorder (SWD), and jet lag disorder (JLD). These disorders arise when there is a substantial misalignment between the internal circadian rhythm and the desired sleep–wake schedule. Symptoms of insomnia and/or excessive sleepiness are the resulting symptoms. Specific general diagnostic criteria are given for circadian rhythm sleep–wake disorder (CRSWD). A three-month duration of symptoms is a requirement for diagnosing all these disorders except for jet lag disorder which has a requirement of jet travel across at least two time zones. DSWPD and ASWPD require that a sleep log, and if possible actigraphy, must demonstrate either a delay in the time of the habitual sleep period in the case of DSWPD, or an advance of the sleep period in the case of ASWPD, for at least seven days. IRSWRD requires documentation of the habitual sleep pattern that demonstrates no major sleep period and multiple irregular sleep bouts (at least three) during a 24-h period. N24SWD requires two weeks of documentation of a sleep–wake pattern that typically shows a delay each day with a circadian period longer than 24 h. This disorder is most typically seen in totally blind individuals. SWD requires a two documentation of the sleep–wake pattern by sleep log or actigraphy, preferably with light exposure measurement. JLD requires a complaint of insomnia or excessive sleepiness within one to two days of travel across at least two time zones. A circadian rhythm disorder not otherwise specified (NOS) is listed for patients who have a circadian rhythm sleep–wake disorder who meet all the criteria for CRSWD but not the specific types.

Parasomnias

The parasomnias are divided into three groups: the NREM-related parasomnias, REM-related parasomnias, and other parasomnias category. They are defined as undesirable physical events or experiences that occur during entry into sleep, within sleep, during arousal from sleep.

The NREM-related parasomnias comprise general diagnostic criteria for the group heading of disorders of arousal (from NREM sleep). Specific general diagnostic criteria are given for disorders of arousal (DA) and the detailed text applies to all of the DA's as no text is presented for each of the specific DA's except for diagnostic criteria. The main criterion is recurrent episodes of incomplete awakening from sleep that usually occurs in the first-third of the major sleep episode. Partial or complete amnesia for the episode is typical. Diagnostic criteria are given for three disorders: confusional arousals, sleepwalking, and sleep terrors. Confusional arousals are episodes of confusion or confused behavior that occurs while in bed. Sleepwalking is arousal associated with ambulation or other complex behaviors out of bed. Sleep terrors are episodes of abrupt terror, typically beginning with alarming vocalization such as a frightening scream. Sleep-related abnormal sexual behaviors are listed as a subtype to be classified under confusional arousals. Terminology for these behaviors includes atypical sexual behavior during sleep, sexsomnia, and sleep sex. The presence of an overlap disorder, in which RBD and partial arousal disorder (sleepwalking or sleep terrors) are comorbid in a person, may complicate the diagnosis of each disorder. The final NREM-related parasomnia is sleep-related eating disorder (SRED) that requires an arousal from the main sleep period to distinguish it from night eating syndrome (NES) which is excessive eating between dinner and bedtime, and SRED requires an adverse health consequence from the disorder [8]. SRED is one or more of the consumption of food or toxic substances, injurious behaviors in the pursuit of food, or adverse health consequences from recurrent nocturnal eating.

The REM-related parasomnias include REM sleep behavior disorder (RBD), recurrent isolated sleep paralysis (RISP), and nightmare disorder. RBD is repeated episodes of vocalizations and/or complex motor behaviors requiring the polysomnographic evidence of REM sleep without atonia (RWA) [9]. The episodes are usually correlated with simultaneously occurring dream mentation, leading to the frequent report of 'acting out one's dreams.' RISP is the recurrent inability to move the trunk and all of the limbs at sleep onset or upon awakening from sleep that lasts seconds

to a few minutes that causes distress or fear of sleep. Nightmare disorder is repeated occurrences of extended, extremely dysphoric, and well-remembered dreams that usually involve threats to survival, security, or physical integrity. The episodes are followed by rapid orientation to the environment and alertness. Significant distress and impairment in social, occupational, or other areas of functioning are reported. Up to 80 % of patients with posttraumatic stress disorder (PTSD) have nightmares although 50 % have resolution of the episodes within three months. Nightmares are common in acute stress disorder (ASD).

The other parasomnia section includes three specific disorders: exploding head syndrome (EHS), sleep-related hallucinations, and sleep enuresis. EHS is a complaint of a sudden noise or sense of explosion in the head either at the wake–sleep transition or upon awakening during the night associated with abrupt arousal. Idiopathic stabbing headache (ice-pick headache) and thunderclap headache usually do not occur at sleep onset or during sleep. Sleep-related hallucinations are predominantly visual hallucinations that are experienced just prior to sleep onset or upon awakening during the night or in the morning. Those occurring at sleep onset may be difficult to differentiate from sleep-onset dreaming. The form is usually of complex, vivid, relatively immobile images of people or animals sometimes distorted in shape or size. Sleep enuresis is involuntary voiding during sleep at least twice a week in people older than 5 years of age. Two forms are recognized, primary sleep enuresis in which the individual has never been consistently dry during sleep, and secondary sleep enuresis that occurs in a person who has been consistently dry during sleep for at least six months. Parasomnias associated with medical disorders, and medication or substance and unspecific parasomnia, comprise the other entries in this category. Sleep talking is a normal variant that can occur in both NREM or REM sleep and can be associated with parasomnias such as RBD or DAs.

The sleep-related movement disorders (SRMD) category comprises seven specific disorders: restless legs syndrome, periodic limb movement disorder (PLMD), sleep-related leg cramps, sleep bruxism, sleep-related rhythmic movement disorder (RMD), benign sleep myoclonus of infancy (BSMI), and propriospinal myoclonus at sleep onset (PSM). SRMDs are relatively simple, usually stereotyped movements that disturb sleep or its onset.

Restless legs syndrome (also known as Willis–Ekbom disease) is an urge to move the legs, usually accompanied by or thought to be caused by uncomfortable and unpleasant sensations in the legs. The symptoms consist of episodes beginning or worsening during periods of rest or immobility exclusively or that are partially or totally relieved by movement and that occur predominantly in the evening or night, and these features are not solely accounted for by another condition (RLS mimics). The ICSD-3 criteria also require the patients to have distress and impairment of functioning in several important areas (not part of the essential diagnostic criteria established by the International Restless Legs Syndrome Study Group or IRLSSG but widely accepted) but do not include any frequency or duration criteria as is contained in the DSM-V criteria.

PLMD is defined by the polysomnographic demonstration of periodic limb movements (PLMS) of >5/h in children and >15/h in adults that cause significant sleep disturbance or impairment of functioning. It is essential to establish a reasonable cause-and-effect relationship between the insomnia or hypersomnia and the PLMS. PLMD cannot be diagnosed in the presence of RLS, narcolepsy, OSA, or RBD, although PLMS commonly occur in these disorders. Sleep-related leg cramps are painful sensations that occur in the leg or foot with sudden, involuntary muscle hardness or tightness. They usually occur in the calf or small muscles of the foot and can be relieved by stretching the affected muscle. Sleep-related bruxism is tooth grinding during sleep that is associated with tooth wear or morning jaw muscle pain or fatigue. Ideally, polysomnographic monitoring with masseter muscle activity monitoring is helpful. RMD is repetitive, stereotyped, and rhythmic motor behaviors involving large muscle groups that are sleep related. The behaviors interfere with sleep or daytime functioning and can cause body injury. BSMI is repetitive myoclonic jerks that involve the limbs, trunk, or whole body that occurs from birth to 6 months of age during sleep. They occur exclusively during sleep which helps differentiate them from epileptic activity. As PSM mainly occurs during relaxed wakefulness and drowsiness as the patient attempts to sleep, the term ‘at sleep onset’ has been added to the propriospinal myoclonus name. The episodes are sudden jerks of the abdomen, trunk, or neck that disappear upon mental activation and with stable sleep. PSM can cause a complaint of insomnia. The three final categories are related to a medical disorder, medication or substance, and an unspecified parasomnia.

Isolated symptoms and normal variants include excessive fragmentary myoclonus (EFM), hypnagogic foot tremor and alternating muscle activation, and sleep starts (hypnic jerks). EFM is now regarded as a normal variant found on polysomnographic EMG recordings that are characterized by small movements of the corners of the mouth, fingers, or toes or without visible movement. Hypnagogic foot tremor (HFT) is rhythmic movement of the feet or toes that occurs in the transition between wake and sleep or in light NREM sleep, and alternating muscle activation (ALMA) is brief activation of the anterior tibialis in one leg with alternation in the other leg. Sleep starts (hypnic jerks) are brief,

simultaneous contractions of the body or one or more body segments occurring at sleep onset.

The final category in the ICSD-3 is a general other sleep disorder category for disorders that cannot be classified elsewhere.

Conclusion

The new ICSD-3 is a major advance over previous versions but it is unfortunate that some of the diagnostic criteria differ from that of DSM-V, for example, the criteria for narcolepsy. However, the DSM-V serves as an entry-level classification, mainly for psychiatrists, and it is to be hoped that in the future the two classifications will be merged into one that will cause less confusion not only for clinicians but also for agencies that reimburse for healthcare and provide for treatment options.

Appendix A lists several disorders that are coded in other sections of ICD 10 other than the sleep sections and include fatal familial insomnia, sleep-related epilepsy, sleep-related headaches, sleep-related laryngospasm, sleep-related gastroesophageal reflux, sleep-related myocardial ischemia. Appendix B lists the ICD sleep-related substance-induced sleep disorders.

Epidemiology: Principles and Application in Sleep Medicine

28

Markku Partinen and Erkki Kronholm

In sleep medicine, sleep has been traditionally conceptualized as a biomedical phenomenon with connections to social lifestyle factors. Epidemiologically, sleep may be reconceptualized also as a social behavior which is closely bound up with its social environment [1]. Epidemiology of sleep and its disorders is currently facing a challenge of possible consequences of rapidly changing societies on population's sleep, health, and functional well-being. An enormous variety of adverse health risks associated with sleep duration and quality as well as timing of sleep and wakefulness has been published. It is indeed amazing to ponder why seemingly so different health outcomes such as all-cause mortality, cardiovascular mortality and morbidity, metabolic diseases such as diabetes, metabolic syndrome, obesity, changes in immune function, changes in brain functions such as memory, learning, and affect as well as impairment in mental health, like depression, are all associated with self-reported sleep duration and/or insomnia. The evidence is strong and there is also biological plausibility behind these associations [2]. On the other hand, there is also evidence that, at least in some cases, there might be causal associations. What might then be the underlying function of sleep, impairment of which would be reflected in such a variety of detrimental health outcomes? And importantly, do these associations between sleep and health consequences have anything to do with changes in our societies and our lifestyle? In this chapter, some epidemiological principles are discussed in order to guide the reader into the epidemiological methods of sleep science followed by epidemiological figures of some common sleep disorders. Also, the current discussion in scientific community about sleep and society is partly reflected.

Epidemiological Methods in Sleep Medicine

Epidemiological sleep medicine may be divided into clinical epidemiology and population-based epidemiological studies. Modern epidemiology includes study of chronic, evaluation of health status, and genetic and environmental factors associated with diseases or symptoms in defined populations [3–5]. A common misunderstanding is that epidemiological studies are limited to large population studies. Miettinen defines epidemiology as the discipline of how to study the occurrence of phenomena of interest in the health field [4]. Thus, it delineates major principles of study design and data analysis in research into frequency of occurrence of illness and related phenomena in human populations, whether in the community or in different clinical settings.

Analytical Studies

Research questions like whether an association exists between an exposure (e.g., short sleep duration) and a disease (e.g., cardiovascular disease) are examined in so-called analytical studies. There are two main types of analytical studies: experimental (also called interventional) studies and observational (also called descriptive) studies. For obvious reasons, observational studies in which observations are made without any intervention are usually applied into a large-scale epidemiological context. Observational epidemiological studies can be further divided into cross-sectional, cohort, and case–control studies [3–5].

Descriptive (observational) studies have many limitations. Classic examples are **cross-sectional studies** with data collected on a defined moment and **retrospective studies** that are based on existing medical histories or other previously collected data. In observational studies, distributions are given with, perhaps, some computations of statistical significance between different groups of subjects. Retrospective studies are highly dependent on the quality of collected data. Ideally, the data have been collected

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_28

systematically by qualified researchers/clinicians/assistants and always in the same format on a database. Data should be collected using validated instruments. If the study population, or the sample, is representative of a target population (general population, hospital population), generalizations can be made to that base population, but not necessarily to other populations. In the latter case, the external validity of the study may be poor. In cross-sectional observational studies, the temporal relationship between outcome (disease) and exposure cannot be determined; therefore, they do not allow any causal or etiological inferences. Such inferences are more or less speculative. However, well-conducted cross-sectional observational studies can provide an accurate estimate of the prevalence of a given phenomenon/symptom/disease at one particular time point among the study population. Therefore, they are also called as **prevalence studies**.

Are retrospective studies useless? No, they may be very useful, for example, in explaining occurrence of different new findings/symptoms in well-defined setting, which allows generalizations to other populations. Hundreds of descriptive epidemiological studies on various sleep disorders have been published about sleeping habits and different sleep disorders from different countries.

Interventions (experimental studies) are commonly used in clinical epidemiological research, for example, to study the effect of a new hypnotic in insomnia, or to study the effect of weight loss in treatment of sleep apnea. Ideally, a **randomized controlled trial (RCT)** is designed.

Observational Population Surveys

Cohort and case–control studies are valuable in providing the time dimension in relationships between the exposure and outcome. In other words, they have prospective or retrospective study design. Therefore, they allow more inferences to be done when compared to cross-sectional studies. However, all observational studies are always vulnerable to influences by unpredictable confounding factors, which the researchers may be unaware or unable to control for.

Cohort studies. In epidemiology, the word "cohort" denotes to a population of subjects with defined characteristics in a defined setting and a defined time. Once a cohort has been defined, it exists forever. The established cohort remains even if all the persons in the initial cohort have died. A cohort may be static or dynamic. New persons, fulfilling the entry criteria, may enter a dynamic cohort after the initial cohort has been established. People in the cohort are followed up to determine incidence of defined outcomes such as occurrence of a disease, death, or some other outcomes. Longitudinal studies may be retrospective or prospective in time. Prospective **cohort studies** are also called follow-up studies or prolective cohort studies. Retrospective follow-up studies are also called "trohoc" studies, retrolective cohort studies, or retrospective cohort studies [3, 6]. A prospective **cohort** study may give huge amounts of valuable information. Examples of well-defined cohorts are the Framingham Cohort, Wisconsin Sleep Cohort, Sleep Heart Cohort, and the Finnish Twin Cohort.

The quality of a retrospective study depends on the quality of collected information in past time. We have only the information that has been saved. Missing data are a problem. If the subjects have always been examined and treated by the same personnel with use of the same standardized methods, we can usually trust the information.

Case–control studies. A well-designed and properly analyzed case–control study is an efficient way of answering many questions. Practical reasons of economy and feasibility often tell whether a case–control study is more appropriate than a cohort study. Usually, a case–control study is both faster and cheaper than a cohort study. The use and understanding of case–control studies is the development of modern epidemiology [4, 7]. The modern case–control study methodology was described in full for the first time in a classic study suggesting an association between smoking and lung cancer in the 1950s [8]. In a case–control study, cases and control subjects are collected and occurrence of defined risk factors preceding the onset of disease will then be analyzed. In this way, case–control studies are retrospective in nature. In a **nested case-control study,** the cases and their controls are selected from an existing cohort. To prove the results, a case–control study should usually be followed by a prospective study or by a RCT.

Data Collection

Most often questionnaires are used. Other possibilities include personal interviews, telephone surveys, and tabulation of information, e.g., from medical records.

Structured questionnaire is often a practical method. If possible, validated tools should be used. To allow comparability, the wording should mean same thing in different languages. In translating a questionnaire from one language to another, cross-translation, or back translation, should be used. Questionnaire studies are usually relatively cheap. If mailed, one needs funding for printing of the forms, envelopes (to send and prepaid return envelope), and mailing costs. In addition, one needs funding to enter data into a database.

Telephone surveys may be almost as good as personal interviews and considerably easier to do. Computer-assisted telephone interview (**CATI**) software can control the interview process and record the responses as the interview proceeds. It can be combined with random digit dialing [9] to identify subjects and to enhance the efficiency of telephone methods for

the data collection. In sleep research, they have been used quite often in Europe since the beginning of 1980s. Telephone surveys are often faster to do than mailed questionnaire studies. On the other hand, they are more expensive and they may exaggerate some figures. The National Institute of Mental Health Epidemiologic Catchment Area (ECA) study about psychiatric disorders including sleep disturbances was done in the early 80s [10]. The Diagnostic Interview Schedule (DIS) is a structured interview, administered by lay interviewers, that assigns a number of DSM-III using a computer algorithm. More recently, a similar method, called Sleep-EVAL, has been used mainly by one group of researchers [11, 12]. There are problems with such closed methods because the studies cannot be replicated by others. This means that it is difficult to judge the correctness of the results. In a properly conducted study, the wording of each question is given, or alternatively the wordings of all questions are given as an attachment, or in Internet.

We already know quite a lot about prevalence of different sleep disorders, but many more prospective longitudinal studies and genetic epidemiological studies are needed. Such studies are out of the scope of a cross-sectional telephone survey. Names, social security information, addresses, and other strictly personal information cannot be collected without written informed consent.

Personal face-to-face interviews using a structured questionnaire are a very good method supposing that the interviewers are properly trained and unbiased. Personal interviews are more expensive to carry out than mailed questionnaires or telephone surveys, but the response rate is, on the other hand, much better than in the other methods, especially if the interviewers travel to meet the persons.

In conclusion, at least in very large-scale studies, one should usually start with a well-designed questionnaire study. Telephone survey methods do not differ from other epidemiological survey methods. They can be used to estimate prevalence but they cannot be used to make final diagnoses. If needed, one can complete the questionnaire data by telephoning to those that did not answer to the questionnaire and ask them to send the questionnaire. In some cases, one can ask the questions by phone but caution is then needed before combining the data with the mail questionnaire data. Sometimes one can even visit persons who have not answered. Another approach is to pull a representative sample from the population to participate in thorough medical and laboratory examinations. This approach has been used, e.g., in the well-known Wisconsin Sleep Cohort study [13, 14], and the Finnish Health 2000 and 2011 cohort study [15].

Register-based studies. National registers may be used in epidemiological studies. In some countries (especially in the Nordic countries: Denmark, Finland, and Sweden), hospitalizations and other health-related data have been entered into National register for decades. With proper ethical permissions linking clinical and questionnaire data with register-based data allows researchers to gather information about medications, morbidity, occurrence of cancer, accidents, and other events on a longitudinal basis.

Size of population. Statistical estimation (calculating the values of parameters based on observed data) is more accurate in large samples than in small ones. This is caused by the decrease of random measurement error by increasing sample size. Consequently, the most efficient, but also expensive, method to reduce random measurement error is to increase the size of the study. Note, however, that a possible systematic measurement error does not depend on sample size. Sample size estimation and power calculations (statistical power analysis) may be used to estimate beforehand how large a sample is needed for sound statistical inferences in the study at hand (see below). The size of the population in an epidemiological study could easily be less than 30 (e.g., rare diseases) or more than 100,000. Large populations may give smaller confidence intervals meaning that even very small differences between compared groups will be statistically significant. But this does not necessarily mean that these differences are clinically (or even in any other way) meaningful. The researcher must make the final inferences, and they should not be based only on a ritualized null hypothesis significance testing as noted well by Cohen [16] several years ago. When interpreting the results, a useful way is to use the so-called effect size indices which are not statistical tests (and thus do not have any absolute cutoff points). They can be used in order to compare the size of the difference between groups or the size of the effect of the exposure with a known meaningful reference.

Power calculations. Power calculations should be done before a study is started [17, 18]. Before doing computations, one should determine the level of clinical meaningfulness of expected (hypothesized) results. This is done in order to determine what is the probability that the statistical test used in the study will be able to detect the effects of that expected size in the given study sample. From prior studies, we can estimate the expected standard deviation. Using statistical computer programs, it is easy to compute how many subjects are needed to find significant statistical differences, say, with a power of 80 or 90 %. Before starting a study, one should also compute costs of the study. For example, it would be illogical to spend excessive amounts of money to find a 5 min difference in total sleeping time, which is certainly not clinically significant.

In the case of small sample sizes, sufficient raw data should be reported so that readers can make their own inferences. Such studies may contain a lot of useful information. Researchers and editors seem to prefer "positive"

results leading to so-called publication bias. To avoid publication bias, also important negative results should be published if the hypothesis has been relevant, studies have been well conducted, and proper methods have been used. When raw data are given, meta-analytic methods can be used to combine results of several studies on the same topic in order to increase strength of the inferences.

The P Value

Among researchers, there is an increasing awareness about the dangers of the misuse of *P* values for null hypothesis significance testing (NHST). ***P value*** (N.B. that the *P* is originally a large "*P*") [3, 18], a pure statistical significance alone, that is, small *P* value, does **not** prove that the null hypothesis is not true given the observed data. The *P* value gives the probability of the observed data given that the null hypothesis is true [16]. It is notable that whether the null hypothesis is true or not is something we simply do not know. NHST is not designed to prove anything instead it is designed to reject the null hypothesis when it is not correct. NHST can do this only with more or less probability. This probability is called the statistical power or sensitivity of the study. If the information is too sparse (study sample includes too small number of subjects), the statistical power (sensitivity) of the study decreases, and the *P* value does not reject false null hypothesis. This is called Type II error or false negative statistical inference. In other words, one makes a false conclusion accepting the null hypothesis that there is no difference between, for example, two group means tested. If, on the contrary, very large populations are used and statistical power of the study increases so much that even very small differences will provide a very small P value. That is called Type I error or false positive statistical inference. In this case, one makes a false conclusion of rejecting a true null hypothesis and concluding that there is a "real" difference between, for example, two group means tested. Another problem in NHST is so-called alpha inflation meaning that *P* value becomes inaccurate when multiple NHSTs are conducted simultaneously [19]. Conducting multiple comparisons simultaneously increases the probability of Type I error. The problem is often counteracted by using corrections like Bonferroni correction. The take home message from the problems in NHST is that one should not make a research conclusion based merely on *P* value. What one should do is to analyze such data quantitatively. Cohen [16] recommends to report effect sizes in the form of confidence interval which instead of a single value is an interval estimate of a population parameter and contains all the information to be found in NHSTs. In addition, speaking about "significant" *P* values, one should always make clear that they are "statistically significant" and their significance or meaningfulness in other sense is a different issue.

Suppose that we are studying two different treatments Th1 and Th2. The mean total sleeping time (TST) during Th1 is 480 min, and the standard deviation is 20 min. Using Th2, the respective figures are 475 and 20 min. If we studied 15 subjects in both groups, the *P* value is 0.499 (statistically not significant), and the 95 % CI for the difference between means is −10 to 20 min. If we studied 125 subjects per group, the *P* value would have been less than 0.05 (probability that the difference is caused by chance is less than 5 %), and the CI would have been 0–10 min. In both groups, 1000 subjects would have given *P* value less than 0.0001 (statistically highly significant difference in total sleep time), and the CI would have been 3–7 min. The truth is of course that there was only a 5 min difference between the two treatments which is not clinically significant. In this example, the most useful information for a clinician is given by the smallest study, not by the largest study It should also be remembered that because NHST does not prove anything we must always rely, in the end, on replication. This is especially true as regards isolated findings.

Validity

The validity of a study may be divided into internal validity and external validity. ***Internal validity*** derives from the inferences that can be made based on the actual data. It is a measure of quality and of the study methods. Selection bias and information bias should be avoided and confounding factors should be identified and controlled. ***External validity*** is a measure of representativeness of the study population compared to a more general population. Good internal validity is needed to have good and adequate external validity. As Rothman writes: "The separation of relevant from irrelevant factors is the beginning of knowledge" [6].

For example, a study of a new drug among 18–70-year-old people with many exclusion criteria cannot be generalized to normal clinical patients of a treating physician, because many patients have some of the diseases that have been listed among the exclusions. The results can be generalized only to such patients that fulfill the same inclusion and exclusion criteria. This is often not taken into consideration when new treatments are entering the markets. For example, for most hypnotics, most studies are done with patients having chronic insomnia, lasting for more than one month. In spite of this, in many countries, the official label writes that this same hypnotic is indicated to treat insomnia on a short-term basis. We know that ideally hypnotics might be useful in initial short-term treatment of transient insomnia. We also know that there is no long term, say 3 years

clinical follow-up studies, of hypnotics treatment that have shown good efficacy without development of tolerance or adverse effects. Similar examples exist from almost all other types of drugs, not only hypnotics. A clinician must use her/his own clinical knowledge when making final inferences. In this respect, it is also interesting to note that pharmacologists, other theoreticians, and also investigators of RCTs may give instructions about how to treat a specified disease even if they have rarely or never taken the responsibility of treating such patients in real world.

Selection bias. An essential element of a study is a comparison of two or more groups for occurrence of a disease or exposure. One form of bias is a ***self-selection bias***. Another type of bias is ***diagnostic bias***. Many other types of selection bias exist. Some epidemiologic studies, e.g., on narcolepsy, are based on newspaper advertisements. People with given symptoms are asked to contact the researchers. Such studies may be used to have a rough estimate of prevalence of a very rare and serious disease such as central alveolar hypoventilation, but they cannot be used for insomnia, restless legs syndrome, or sleep apnea. Of course, one might use such selection methods when recruiting subjects into drug trials. One should keep in mind, however, that the subjects contacting a center do not necessarily represent a typical patient with the disease concerned. If study subjects are receiving honorary fees for participation, the bias may be even larger because the motivation to participate may be to earn money, and the subjects may report relief from the symptoms more easily. Same may be true when, e.g., opiates are studied. For this reason, drug screens should be used always when one is studying drugs with CNS effects.

Information bias. The information obtained and entered into a database should be based on comparable methods. To improve comparability, quantitative or semiquantitative scales should be used always when possible. Wordings such as "always," "often," "sometimes," and "rarely" may be interpreted differently by different persons. For one patient having a migraine attack once per month might mean "often." For another person it might mean "rarely." Having trouble sleeping "often" may mean "on 3–4 nights per month" or "on 3–4 nights per week." It is obvious that quantitative scales allow better comparisons between individuals. The basic Nordic sleep questionnaire (BNSQ) is an example of a questionnaire with quantitative wordings [20]. Similar wordings are used also in the Wisconsin Sleep Cohort studies and in many other studies. Qualitative research has its own benefits and usages that are not handled here.

Recall bias is an example of information bias. Diseased people often remember better some things that have occurred in the past. On the other hand, they may also misremember some things, for example, after reading about some possible adverse effects from an article. If one wants to have information about effects of an intervention/treatment, same measure should be used at baseline and later during time. Sometimes patients have been asked, e.g., "how do you find this treatment compared to another or compared to no treatment." If the treating physician is valued and respected by the patient, the placebo effect is great and the patient may evaluate the treatment effect as very good. The time lapsed between the exposure and the recall is an important indicator of the accuracy of recall. We have recently faced the problem of a potential recall bias, e.g., in studying the association between an adjuvanted pH1N1 vaccine (Pandemrix®) and narcolepsy. Having more information from prior medical reports and from other sources may help. The first contact with a health personnel (e.g., school nurse) may give a more reliable date of onset than trying to figure the date of onset if it occurred several years before.

Cultural changes in social psychology of the society may also lead to a specific information bias. People may change their answering behavior depending on how "important" or "acceptable" it is to speak about some issues in their cultural environment. Therefore, for example, today the current increasing public awareness of the importance of sleep and its disorders may modify people's answering behavior in a different way when compared to studies some decades ago.

Different types of risk factors. All causal factors are risk factors but many risk factors are not causal. As an example, eating ice cream is a "***statistical risk factor***" of drowning deaths, but of course eating ice cream is not "**a causal risk factor**" of deaths. There is only a temporal relationship. Most deaths by drowning occur at summer time when people eat more ice cream than during winter.

Five different types of risk factors may be defined as follows: proxy, overlapping, independent, mediating, and moderating risk factors [21]. *B* is a "***proxy risk factor***" for *A* for the outcome *O* if *A* and *B* are correlated, if there is no temporal precedence of either *A* or *B* or if *A* precedes *B*, and if, in either case, *A* dominates [21]. Let us take an example. Obesity (*A*) is one of the strongest risk factors of arterial hypertension (*O*). There is also evidence that obstructive sleep apnea (*B*) is a risk factor of *O*. In this case, obstructive sleep apnea may be considered as a proxy risk factor of obesity. Other proxy risk factors of obesity are excessive use of alcohol, chronic sleep deprivation, use of antipsychotics, lower socioeconomic status, etc. As an "***overlapping risk factor,***" neither *A* nor *B* has temporal precedence, *A* and *B* are correlated, and *A* and *B* are codominant. Smoking and use of alcohol are overlapping risk factors of many disorders. Kraemer et al. propose to call *A* and *B* "***independent risk factors***" if there is no temporal precedence of *A* or *B*, *A* and *B* are uncorrelated, and *A* and *B* are codominant. "**Mediating risk factors**": A mediator variable (*B*) explains how or why another variable (*A*) affects an outcome (*O*) [6, 21, 22]. This kind of relationship is common in medicine.

For example, in presence of genetic susceptibility for narcolepsy (e.g., HLA DQB1*0602), T-cell receptors may be mediated by different environmental factors causing loss of hypocretin neurons and narcolepsy type 1. According to Baron and Kenny [22], a "***moderator***" (*A*) specifies on whom or under what conditions another variable (*B*) will operate to produce the outcome (*O*). A moderator (*A*) is supposed to affect the relationship between the other variable (*B*) and the outcome (*O*), whereas a mediator (*B*) is supposed to be influenced by the other variable (*A*) directly. For example, certain CYP genotypes (*A*) moderate effects of, e.g., hypnotics (*B*) in treatment of insomnia to have longer total sleeping time (*O*).

Confounders. Understanding and controlling ***confounding*** has a central role in modern epidemiology. It must be separated from a risk factor. For example, age is not a causal risk factor but it is a potential confounding factor in many situations. For an extraneous factor to be a confounder, it must have an effect on the occurrence of disease, but it does not have to be a causal factor. In general terms, a confounding factor must be associated with both the exposure and the disease. One can consider the following flow/connections of development of a disease equation: exposure → altered physiology (altered body/mental functions) → disease. A variable measuring altered function is a risk factor for disease, and it is correlated with exposure, because it results from exposure. However, it is not a confounding factor because the effect of exposure is mediated through effect of altered physiology [4, 6].

Precision and Comparability of Information; Randomized Controlled Trials

Precision refers to reduction of random measurement error. Precision can be improved by increasing number of subjects or by increasing accuracy of obtained information by improving used measures. A statistical effort to correct for measurement error is to model it in the so-called measurement model. This approach is applied in modern statistical models belonging to the model family called structural equation models. However, most commonly errors occur during the process of selecting study subjects. The attendant random error is called **sampling error**.

The best method to gather new valid information about, e.g., a new treatment is a randomized controlled trial (**RCT**). In an experimental study, a population is selected for a planned treatment or intervention whose effects are measured by comparing the outcome in the experimental group with the outcome in a control group. For avoidance of bias, members of the intervention (treatment) group and the control group should be comparable except in the regimen that is offered them [23]. Allocation of individuals is ideally by randomization. Stratified sampling may be used.

In a valid experimental RCT study:

1. Populations are comparable (randomization in randomized controlled trials)
2. Information is comparable (use of blinding), and
3. Effects are comparable (use of placebo and/or active comparator treatment).

Standardization, Matching

After the data are collected, the effect of covariates may be controlled by use of various standardizations. Stratification and different standardization methods (direct or indirect standardization) are well described in most books of epidemiology. During the collection of the data, *matching* can be used. One must, however, avoid ***overmatching***. For example, if we want to study effects of obstructive sleep apnea syndrome on cerebral circulation, we could compare patients with OSAS to patients without OSAS. We select one control subject without OSAS for each patient with OSAS. If we match the subjects (matching of each pair) too strictly, say, for age, gender, body mass index, waist circumference, and blood pressure, we risk losing most differences. Instead of matching for all these variables, it is often better to analyze the results using potential modifiers and other common risk factors as covariates. One commonly used method is to apply logistic regression analysis. In all cases, it is important to work with an experienced epidemiologist/statistician already when designing a study.

Population-Based Rates

Prevalence. Prevalence is defined as the number of instances of a given disease or other condition in a given population at a designated time [23]. Most commonly, prevalence rates represent cross-sectional events, noted at a single point in time for the state of the group under study [3, 24]. This is called point prevalence. A period prevalence refers to the number of cases that occur during a specified period of time, e.g., one year. This is now rarely used. It usually takes some time to conduct a study and find all cases; and in such case, it is generally possible to estimate point prevalence (that can be called just "prevalence"). The prevalence rate is given as the number of cases for a specified number of persons in the population (number of cases at a specified time/number of persons in the population at that time). Prevalence focuses

on disease status, and it should not be confused with incidence.

Incidence. Incidence (I) has a focus on new events while prevalence focuses on disease status. Incidence rates represent longitudinal events, noted in the follow-up of a cohort. It is defined as the number of instances of illness commencing, or persons falling ill, during a given period of time in a specified (cohort) population (incidence = number of new cases during a specified period of time/number of persons exposed to risk of developing the disease during that period of time). Incidence thus refers to the number of new events or new cases in a defined period of time, whereas prevalence refers to the number of existing cases. It is essential to give the time unit that has been used when counting incidence rate. If one knows the incidence rate and the average duration of the disease concerned, one can assume that prevalence = incidence × duration (D) of the disease (using same unit of time, e.g., years). More generally [25], one can give that prevalence = $(I \times D)/(1 + (I \times D))$.

Bayes' theorem. In a clinical setting, a physician may estimate the probability that her/his patient has a defined disease by using the Bayes' theorem [26]. If one knows the prevalence of the disease in the population, the occurrence rate of a symptom or of a laboratory finding among the diseased and the sensitivity of a diagnostic test, one can estimate the occurrence of the disease (prevalence) in that population. According to the Bayes' theorem:

$$\text{Probability of the disease} = (\text{sensibility} \times \text{prevalence of the disease})/(\text{prevalence of the symptom}).$$

For example, what is the probability that our snoring patient has sleep apnea? We know from literature that about 90 % of patients with obstructive sleep apnea snore (sensibility). We also know that the prevalence of OSAS among men is about 4 % and that about 50 % of adult men, similar to our patient, snore at least sometimes. Hence, the probability of OSAS in our patient is $(0.9 \times 0.04)/0.5 = 0.072 = 7.2$ %.

Mortality rates. Mortality rate or death rate is the proportion of a population who die of a defined cause. The numerator is the number of persons dying, and the denominator is the total population in which the deaths occurred. The unit of time may be one calendar year or a longer period of time. In order to avoid bias arising from disproportions in age, gender, or race between the general (denominator; reference) population and the study population, the data are standardized. The indirect method is more popular than the direct method of standardization. As a result, *standardized mortality ratios* can be given. In long-term follow-up studies survival, mortality and also morbidity figures may be computed using different survival analyses.

Risk ratio and odds ratio. Risk is often used to describe rate of occurrence of a symptom or disease. Risk refers to probability that an event will occur within a defined period of time. A risk factor, or determinant of risk, is a factor or exposure that increases the probability of occurrence of a specified outcome. A risk factor may or may not be in causal relationship with the outcome.

Risk ratio (RR) or relative risk (also rate ratio) is the ratio of the probability (risk) of getting a disease (outcome) in a risk group (exposed subjects) divided by the probability (risk) of getting the same disease (outcome) in a reference group (non-exposed subjects). In the case of a rare disease, risk ratio approximates the odds ratio (OR). The OR is defined as the **odds** that an outcome will occur given a particular exposure, compared to the **odds** of the outcome occurring in the absence of that exposure. Instead of risk ratio, the odds ratio (cross-product ratio) and its 95 % confidence limits are widely used in epidemiological studies. Whenever possible (if meaningful prevalence or incidences are available), calculation of rate ratios (relative risks) is recommended because RRs are often easier to understand than ORs. OR always overestimates the RR. In addition, ORs are often misinterpreted as if they were equivalent to RRs [27]. If the lower limit of the 95 % confidence interval is greater than 1, the rate ratio is "statistically significant" with a P value less than 0.05, that is, the studied exposure is a "risk factor for the specified outcome." Similarly, if the upper 95 % confidence limit of a rate ratio is less than 1, the factor is "protective."

Normality and use of medians. What does "normal" mean in epidemiology? Sir Ronald Fisher regarded 95 % of the inner values of a distribution as common and the remaining 5 % as significantly uncommon. The outer 5 % of values is traditionally considered abnormal, but statistical or epidemiological theory does not support this view [3]. According to Feinstein, "Fisher's proposed boundary of uncommon occurrences was intended for inferential decisions about P values, not for descriptive decisions about normality. Nevertheless, after years of exposure to 0.05 as the magic level of stochastic significance, many clinicians have become thoroughly conditioned to accept the same boundary marker for abnormality" [3]. Many laboratories now use the term "customary range" instead of normal range. This term is more appropriate. It is also good for patients whose laboratory values are outside the customary range, because the values may be without any clinical significance even if they are out of the customary range.

Biological data do not always fit Gaussian normal curve. The distributions are often significantly skewed or bimodal. On such occasions, the usual mean ±2 standard deviations tactics is not appropriate. Unfortunately, one can still find that it is used in medical literature even if the data are not normally distributed. For example, one could read that the mean (± standard deviation) weight of children was

10 ± 12 kg. How does a child look if his/her weight is minus 2 kg (10 − 12 = −2)? One can have negative cholesterol or negative apnea index values, etc, if one gives means and standard deviations alone. Giving the confidence interval and range gives more information. In biological sciences and medicine, use of **medians** (the "middle value") and percentiles, even without means, is often better than means and standard deviations alone.

Median is easy to calculate and it describes the population better than the mean. It divides the population in two equal parts. To find the inner 95 % of the data, we need only to locate the 2.5 percentile point and the 97.5 percentile point. The procedure is simple, and by using it, we will never encounter impossible ranges.

Measures of effect size. Different measures may be used to have an idea about results of interventions and clinical trials. In particular, three measures are commonly used in evidence-based meta-analytical studies: **relative risk reduction (RRR)**, **absolute risk reduction (ARR)**, and the **number needed to treat (NNT)**.

Let us cite two examples. (1) Suppose that in a prospective follow-up study, 10 % of subjects treated with CPAP had a new cardiovascular event versus 20 % among the non-treated. These rates are also called risks of having a defined event; in other words, risk can be thought of as the rate of a defined outcome. (2) Suppose that in a randomized clinical trial on restless legs syndrome, 70 % of those with the active drug had significant amelioration of their symptoms versus 30 % in the placebo control group. In the same study, 1 % of those with active treatment and 0.3 % of those with placebo had hallucinations as an adverse effect.

Relative risk reduction. Relative risk measures how much the risk is reduced in the treatment group compared to the control group. In the first example above, 20 % of the control had a cardiovascular event compared to 10 % among those treated with CPAP. The CPAP treatment group had a 50 % (0.5) relative risk reduction. The formula is as follows: RRR = (CER − EER)/CER, where CER is the control group event rate and EER is the experimental group event rate. In the second example, the relative risk reduction of having hallucinations when using a placebo instead of the experimental treatment is 70 %, i.e., (1 − 0.3)/1. As we can see, the RRR is not a good indicator if the occurrence of an event is rare.

Absolute risk reduction. Absolute risk reduction is the absolute difference in outcome rates between the control and treatment groups, i.e., ARR = CER − EER. The absolute risk reduction does not confound the effect size with the baseline risk. In the first example above, ARR is 10 % (20 − 10% = 10 %). In the second example, ARR for hallucinations is 0.7 % (1 − 0.3) when using placebo. This figure is very small and easier to interpret than the large and not clinically significant relative risk reduction of 70 %. The ARR for having amelioration of symptoms is in this example, 70 – 30 % = 40 %.

Number needed to treat. Because the ARR is sometimes difficult to interpret, better indicators are needed. The **number of patients needed to treat (NNT)** in order to find a significant effect (e.g., cure and significant amelioration of symptoms) is a good indicator of a treatment effect [28]. The number needed to treat is simply another way to express absolute risk reduction. NNT = 1/ARR and it is the number of patients that would need to be treated to prevent one additional bad outcome. For the example of CPAP above, the NNT is 10 (1/0.1) and for the second RLS example, the NNT is 1/0.4 = 2.5. Thus, in the first example, 10 need to be treated and in the second example, only 3 patients. The number needed to have hallucinations, i.e., the **number needed to harm (NNH)** is in the second example 143 (1/0.007 = 142.8). If we compare 3 patients to 143 patients, we can clearly see that the benefits are much larger than harms in this respect. Of course, one must take all other adverse effects into account when the NNH is estimated. If the NNT is still larger than the NNH, then the treatment could be used. It is interesting to note already at this point that NNT of chronic insomniac patients with sedative hypnotics in a meta-analytic study of Glass et al. was 13 but the NNH was more than twice smaller than that number (NNH = 6). This means that the probability of doing harm to a patient was larger than that for doing good [29].

The NNT can be converted to an **NNT for a given patient** by estimating the **patient's susceptibility relative to an average control patient** in a trial report and dividing the reported NNT by this fraction F (i.e., susceptibility). For example, in the second scenario above, if a physician's 80-year-old patient is judged to be three times more susceptible as the average control patient to have hallucinations, then F = 3 and **NNT/F** = 143/3 = about 48. This means that one could still think about treating the patient with that drug, supposing that there is significant evidence about its effectiveness in old patients above 80 years of age. **The NNT can be computed also from the odds ratio and control group rate of events;** 95 % confidence limits for the NNT should also be given. Different tables and formulas exist in many statistical packages and also in the Internet, e.g., by searching "number needed to treat" using Google.

Effect size. Effect size (ES) is a commonly used index to measure the magnitude of a treatment effect. It is important to note that effect size indices are not statistical tests. Unlike significance tests, they are independent of sample size. ES measures are used especially in evidence-based meta-analytical studies that summarize the findings from a specific topic. Effect size (ampleur d'effet in French) is computed most commonly as the standardized difference between two group means. Originally, Cohen defined effect

size d as the difference between the means, $M_1 - M_2$, divided by standard deviation, s, of either group 1 or group 2, i.e., *effect size* $d = (M_1 - M_2)/s$.

This is an approximation of the theoretical formula for the standardized difference between two groups where the denominator should be the standard deviation of the population from which the groups are sampled. If it is unknown, it can be estimated in different ways. If the standard deviations of the groups are approximately the same, it can be assumed that they are estimating common population s. In this case, they can be pooled (s_{pooled}) to calculate Cohen's d index of effect size $d = (M_1 - M_2)/s_{pooled}$ [30, 31]. Usually, the subtraction of the means between the intervention (experimental) group and control group is done so that a positive difference means improvement and negative difference means deterioration. The pooled standard deviation is found as the root mean square of the two standard deviations. Modern statistical programs usually automatically compute also the pooled standard deviations, that is, the pooled standard deviation is the square root of the average of the squared standard deviations. When the two standard deviations are similar, the root mean square will not differ much from the simple average of the two variances.

Epidemiology of Sleep Disorders

The oldest epidemiological studies about sleep length are from the end of the eighteenth century. Among the most respected studies were those by Clement Dukes from England about the need of sleep of young children. Other well-known early studies are those by Hertel from Denmark, Bernhard from Germany, and Claparède from France [32, 33]. About 80–100 years ago, it was recommended that young children should sleep 10.5–13.5 h, 15-year-olds should sleep 9–10 h, and adults should sleep between 7 h 25 min and 8 h 23 min [34, 35], which does not differ significantly from present day self-reported figures of healthy adults having an average sleep length between 7 and 8 h. Women slept a little bit longer than men except in the case of mentally retarded subjects when the situation was reversed [36, 37].

Sleep disturbances increased with age as they do at present days. In the Laird's study [35] from 1931, at age 25, about 10 % of men were not satisfied with their sleep. At age 95, everybody reported some wakefulness each night. In the same study, more than 70 % of men reported some difficulty in going to sleep, and more than 40 % reported nightly awakenings. Different methods were used to help one to sleep. Reading was used by 25 %, and 18 % used relaxation techniques. Three percent of men used drugs to help them sleep. Two percent used alcohol to help them sleep [35]. The latter two figures differ significantly from those of present days.

Many epidemiological studies about sleeping habits have been done since 1960. In these studies, the average self-reported sleep duration varied between 7 and 8 h. In a questionnaire survey, 7.4 % of 1278 University of Florida students reported less than 6.5 h of night sleep, and 13.4 % reported more than 8.5 h [38]. In Scotland, 2446 subjects aged over 15 were inquired. Of the older subjects in the age group 65–74 years, 18 % complained of waking up before 5 a.m. The percentage decreased to 12 % after age of 75. Disturbed sleep was reported by less than 10 % of men aged 15–64. In the age group 65–74, disturbed sleep was a complaint in 25 % of men. In women, the respective percentage was 43 % [39]. In one classic study from 1979, Bixler et al. determined the prevalence of sleep disorders among 1006 households in the Los Angles metropolitan area [40]. The prevalence of past or current insomnia was 42.5 %. The prevalence of current insomnia was 32.2 %, and 7.1 % complained of excessive sleep.

Insomnia

The epidemiology of insomnia and insomnia-related symptoms is a bit blurred because of large variance in methods and case definitions used in different studies [41]. The view on insomnia is also changing in itself. Traditionally, insomnia was considered as "integrated into" psychiatric disorders. However, this view has changed. The current psychiatric DSM 5 as well as the 3rd International Classification of Sleep Disorders uses the term "insomnia disorder" as a distinction to "insomnia" as a symptom [42, 43].

Taking existing evidence together, about 2–18 % of adults usually complain of clinically significant persistent insomnia depending on the definition of insomnia and the population. Several studies suggest relatively consistently that about 10 % of middle-aged adults suffer from long-standing insomnia [40, 44–59]. Transient insomnia- and occasional insomnia-related symptoms are very common but prevalence figures vary greatly between studies from about 20–50 % [40, 55, 57, 60–64].

Chronic insomnia is often (in 35–69 % of cases) associated with psychiatric conditions. Most common comorbid condition in chronic insomnia is depressive disorder, which has been reported to be present in about 40–50 % of chronic insomniacs [49]. In one study, 93 % of depressed psychiatric inpatients had insomnia [65]. Among treatment seeking veterans of the 13 separate mental health diagnoses evaluated, all except dementia and schizophrenia were strongly associated with insomnia [41].

Insomnia and insomnia-related symptoms are associated with increasing age, at least up to the age of about 65 [53] and female gender particularly during the midlife years [66–68] being 1.4–2 times more common in women than in men.

About one-third of subjects older than 65 years have chronic insomnia. At very old age, the figures may be lower [46, 69]. In an Australian study, insomnia was persistent in 16.2 % of the community-dwelling population and in 12.2 % of institutional residents. Altogether 14.5 % of the elderly subjects living in the community used hypnotics regularly while the corresponding percentage was 39.7 among the institutionalized subjects [46]. However, while sleep problems may increase with age, active complaints to the physician may decrease with age [41]. Comorbidity and psychosocial influences are strong modifying factors underlying the association of insomnia and increasing age. Highest rates of self-reported insomnia symptoms have been reported for 18–24-year-old and 50–59-year-old men and women [70].

Aging process per se may not be the primary cause of insomnia among elderly people [71]. A 3-year longitudinal study [72] among 6899 men and women aged 65 and older suggested an annual incidence rate of insomnia approximately 5 %. Incident insomnia was associated with depressed mood, respiratory symptoms, fair to poor perceived health, and physical disability. Only 7 % of the incident cases of insomnia occurred in the absence of associated risk factors. Of the nearly 2000 survivors with chronic insomnia at baseline, almost 50 % did not report any symptoms after 3 years. The authors interpreted their results as not giving support to a model of incident insomnia caused by the aging process per se [72].

Among people complaining frequent or chronic insomnia and/or insomnia-related symptoms, the use of sleep medication is very common. It has been estimated that about 57–60 % of individuals complaining of frequent or chronic insomnia use sleep medication [73]. The association between medication use and insomnia is independent of other comorbidities [73]. The healthcare system is oriented to treat insomnia pharmacologically. Up to 60 % of adults seeking treatment for insomnia are prescribed sedative and/or hypnotic medications [73, 74]. This is reflected in recent prevalence figures of hypnotic medication use of 6–10 % among adult US population [75]. In US outpatient care, the number of office visits with insomnia increased by 13 % from 4.9 million visits in 1999 to 5.5 million visits in 2010. At the same time, however, the number of prescriptions for any sleep medication increased by 293 % from 5.3 in 1999 to 20.8 million in 2010 [76]. Somewhat older prevalence estimates among the general population have varied between 4 and 11 % [77–79]. Among 65–year-old or older, 9–15 % have been reported to use sleep medication nightly [80]. The use of hypnotic medication among insomniacs seems to be long standing [78]. The use of hypnotics in particular is associated with the use of psychotropic medication in general resulting in different multiuse combinations of hypnotics and sedatives with anxiolytics and psychotropic drugs [73].

Recently some studies have consistently reported that especially occasional self-reported insomnia symptoms, use of sleep medication, and perhaps also chronic insomnia in some countries show increasing long-term prevalence figures in the general adult population [55, 81–83]. An analogous trend was found also among adolescents in Finland [84]. In addition, the number and percentage of US outpatient office visits due to sleep-related problems and prescriptions for a sleep medication have also significantly increased [76]. The increasing trend of pharmacological treatment for insomnia has prompted warnings against possible overuse of medications among insomniacs [74]. In line with increasing prevalence figures, there is also an ongoing shift in prescribing sleep medication. There is some evidence that physicians have started to replace traditional hypnotics (benzodiazepines and their derivatives) by small doses of antidepressants and antipsychotics [85–87]. Theoretically, the latter medications may be more physiological as they may increase slow-wave sleep though their action on histamine-1 receptors [88]. Long-term epidemiological surveys of their benefits are, however, missing [89]. Self-reported insomnia-related symptoms have complicated underlying associations with individuals' socioeconomic status, general well-being, and quality of life as well as with different comorbidities [90, 91]. Different kind of information bias may complicate interpretation of various studies. However, it seems to be clear that something is happening in our time to which peoples' self-reported sleep quality is responding.

Efforts and official initiatives to reduce hypnotic use have been largely unsuccessful in healthcare system [92]. In particular in older individuals, adverse effects on cognitive and psychomotor functioning may result in increased risk of falls and traffic accidents [93]. Also, tolerance and dependence may develop. However, the interpretation of the established epidemiologic association between use of hypnotics and increased mortality has remained controversial. The association was reported first in the American Cancer Prevention Study [94]. Later, the follow-up data were reanalyzed and the "use of sleeping pills" and "tranquilizers" "often" associated with mortality with 1.5 hazard ratio when compared with non-users [66]. It is evident that "sleeping pills" at that time were different compounds and potentially more dangerous than those used today. However, the association has been later replicated approximately 20 times in different countries [75]. The association has been confirmed as regards total mortality [95, 96] and several specific causes of death such as cancer [75, 97, 98] and cardiovascular disease [99], among others. On the other hand, the strength of the association has usually not been especially strong. Median hazard associated with hypnotics among 24 studies was found to be <1.5 and only in four cases >2.0 after adjustments [100]. Negative findings have also been

reported [80, 101, 102]. Users and non-users differ from each other in several important ways as regards the comorbid conditions associated with insomnia itself, and it is practically impossible to control for all potential confounders. This makes the statistical analyses (or more accurately statistical inferences) of large observational studies complicated and difficult. The situation has created currently ongoing debate whether the association is causal or caused by confounding [103–106]. In any case, the clinicians should follow the principle of caution and the guidelines for temporary use of hypnotics.

Chronotype and insomnia. Interindividual variance in individuals' circadian preferences of the timing of their daily behaviors underly their phenotypical differences along a characteristic called chronotype. In parallel, different chronotypes differ in involuntary timing of physiological functions such as core body temperature, blood pressure, and hormonal secretion. Based on these behavioral and physiological differences, individuals can be classified into earlier timed morning types, the intermediate types, and the later timed evening types [107–110].

Epidemiology of chronotypes is new but currently rapidly evolving field of sleep epidemiology, although still in its beginning. Only few large epidemiological studies on chronotype have been so far published. Among the Finnish general adult population, the prevalence of clear morning types has been estimated to vary approximately from 29 to 47 %, and clear evening types from approximately 10–12 % [111–113]. A New Zealand study estimated approximately 10 % of 30–49-year-old population to be "definitely" morning types and approximately 40 % to be "moderately" morning types, 7 % "definitely" evening types and 5 % "moderately" evening types [114]. Evening type has been repeatedly shown to be associated with different health risks, for example, total mortality [113], cardiovascular disease and type 2 diabetes [115, 116], and depression [117, 118]. Of note, evening type is also associated with chronic insomnia complaints 2–3 times more often than morning type as well as use of sleep medication [112, 119].

Seasonal differences of insomnia. Occurrence of insomnia may vary depending on the season of the year. The results from the Nordic countries agree with each other [52, 120]. In Northern Norway, 41.7 % of women and 29.9 % of men had occasional insomnia. In general, complaints of insomnia are more common during winter than during other times of the year [121]. The reasons for this cannot be explained by the season (darker, colder climate, more rain, or snow) itself. Work and different lifestyle factors probably explain most of the variance, but we lack good evidence. In the Tromsø study, occurrence of insomnia during summer (summer insomnia) decreased with age, whereas the other seasonal types of insomnia increased with age [120]. Individuals also differ in their sensitivity or reactivity to seasons. Among high or moderate seasonality individuals, sleep problems suggesting insomnia as well as sleepiness have been shown to be more prevalent than among individuals of low seasonality group [122]. In clinical form, this is reflected in the association between depressive symptoms and seasons among patients suffering from seasonal affective disorder (SAD).

Insomnia in different occupations. Occurrence of sleeping problems varies by occupation and working times [123–126]. In a questionnaire survey of 6268 adults representing 40 different public sector occupations, 18.9 % of bus drivers complained of difficulty falling asleep. Among male directors and male physicians, the respective percentages were 3.7 and 4.9 %. Disturbed nocturnal sleep was complained most often by male laborers (28.1 % waking up at least three times a night) and female cleaners (26.6 %). Disturbed nocturnal sleep was rare among male physicians (1.6 %), male directors (7.4 %), female head nurses (8.9 %), and female social workers (9.4 %) [126]. The association of sleep and type of occupation are partly explained by working conditions, socioeconomic position, income, and probability of possible future unemployment [127, 128]. Accordingly, prevalence figures of insomnia-related symptoms are associated with great shifts in society's economic situation [129].

Psychiatric Disorders and Insomnia

Insomnia is associated with psychiatric disorders such as depression, anxiety disorders, alcohol dependence, and schizophrenia [130]. Traditionally, insomnia was considered a symptom of psychopathology. Until recently, insomnia was classified as a primary disorder if it was not related to mental disorders, and if it was, a diagnosis of secondary insomnia was given. These were the two most common DSM-IV insomnia diagnoses [131]. The differential diagnosis was, however, sometimes difficult. For example, in one study, 216 patients with insomnia were interviewed by one sleep specialist and one non-sleep specialist. By using DSM-IV criteria, 99 (46 %) were diagnosed as having insomnia related to mental disorders, and 48 (22 %) were diagnosed as having primary insomnia. A psychiatric disorder was rated as a contributing factor for 77 % of patients with a first diagnosis of primary insomnia [132]. It has been suggested that "comorbid" insomnia may be a more appropriate term than "secondary" insomnia [133]. Recently, DSM-V has divested the concept of primary/secondary insomnia and instead introduced "insomnia disorder" as the main diagnostic category for insomnia, leaving it possible to determine whether or not insomnia is comorbid with a psychiatric or somatic disorder [42]. In a large US community survey, the prevalence of insomnia without psychiatric comorbidity was 4.9 % [134]. Among those with comorbid insomnia in the past year, 25 % had major

depression, 19 % abused alcohol, 12 % had dysthymia, 9 % had panic disorder, 8 % abused drugs, 8 % had schizophrenia, and 2 % had somatization disorder [134]. In a World Health Organization (WHO) collaborative study, 25,916 primary healthcare patients were evaluated. Sleep problems were present in 27 % of the patients. Of the patients with insomnia, 51 % had a diagnosis of ICD-10 mental disorder, mainly depression or anxiety, abuse of alcohol, or a combination of different psychiatric disorders. 40 % of insomniacs reported using alcohol and over-the-counter medications to help them to sleep [135].

The relationship between psychiatric disorders and sleep is complex with bidirectional causation [136]. Insomnia is not only a symptom of psychiatric disorder but also a predictor of future incident depressive period, PTSD, and substance use. [10, 133, 137–140]. In a recent longitudinal study in 9683 young Australian women who were surveyed in 2000, 2003, 2006, and 2009, a new-onset depression and anxiety were predicted at each subsequent survey with two 2- to 4-fold OR estimates among those who reported sleeping difficulties "often" in 2000 [141]. In another study in 1584 adult patients seeking help from a private sleep medical center, suicidal ideation was consistently associated with different sleep complaints even when depressive symptoms were controlled for [142]. However, one placebo-controlled study in insomnia patients concluded that it may be the use of hypnotics, rather than insomnia itself, which is causal risk factor of future depression [143].

The overlapping of insomnia and psychiatric disorders results also in large mixed psychotropic drug use among insomniacs. In one telephone survey, it was estimated that among non-institutionalized French population 53 % of insomnia sufferers used at least one drug. Approximately, 20 % used hypnotics, 37 % anxiolytics, 7 % antidepressants, and 3 % other psychotropic drug [49]. Consequently, there is a potential risk of mixed drug overuse among insomniacs. Given that insomnia is associated with alcohol dependency one should remember that alcohol may have serious interactions with psychotropics, especially with hypnotics and sedatives. Among alcohol dependent patients, insomnia may also increase alcohol-related adverse psychosocial consequences [144].

Different stress factors belonging to more or less normal everyday life are also associated with insomnia and insomnia-related symptoms. Unemployment, being unmarried, separated, or widowed associate with higher prevalence of insomnia complaints in Japan as well as in other countries [145]. Different psychological complaints, psychological stress, symptoms of work-related stress, and mental exhaustion are associated with high prevalence of insomnia [47, 52, 77, 131, 146–149]. Simple methods, such as the five-item version of the Mental Health Index and some other questions, may be used to effectively screen workers with mental health and sleep problems [145, 150, 151].

Insomnia Among Patients with Neurological and Other Somatic Diseases

Parkinson's disease and dementia. Many neurological disorders are associated with disturbed sleep and insomnia. Parkinson's disease [152–161] and dementia [162–168] are typical examples. Sleep disorders occur in over 70 % of patients with idiopathic Parkinson's disease (PD), adversely affecting their quality of life. Among patients with Parkinson's disease, sleep disruption takes the form of sleep fragmentation with frequent and prolonged awakenings and daytime sleepiness. Nocturia, difficulty in turning over in bed, painful leg cramps, vivid dreams and/or nightmares, back pain, limb/facial dystonia, and leg jerks are the main causes of nocturnal awakenings in PD patients. Sleep disturbance gradually worsens with disease progression suggesting that it is related to the severity of the disease. Sleep disturbance may also be a complication of chronic levodopa therapy. In a survey of 100 PD patients, significant sleep complaints were found in 74 %. Sleep complaints were unrelated to patient age and the duration of disease but increased in prevalence with longer periods of levodopa therapy. Sleep abnormalities tended to increase in severity with continued treatment of PD. Dyskinetic side effects and on–off syndrome occur as well in patients with or without sleep complaints, but up to 98 % of patients experiencing psychiatric side effects also report sleep disruption [158]. A correlation with sleep disturbance and severity of PD exists [159–161, 169]. In an Indian case–control study, 149 PD patients and 115 age-matched healthy controls were asked about sleep disturbances using a questionnaire. Sleep problems were seen in 42 % of PD patients and 12 % of controls. Sleep disturbances included insomnia in 32 % versus 5 % of controls, nightmares 32 % versus 5 %, and excessive daytime sleepiness by 15 % versus 6 %. All sleep complaints were statistically more common in PD patients compared to controls and correlated with increased severity of the disease [154].

In a follow-up study, 142 of the initial 231 patients were re-evaluated after 4 years and 89 patients after 8 years [157]. Complaints of insomnia remained almost constant while problems related to turning in bed and vivid dreaming or nightmares increased during the follow-up. Insomnia was present in 54–60 % of the patients at each of the three study visits. Insomnia was related to disease duration, depression, and female sex [157].

Stroke and insomnia. Patients with stroke complain often of insomnia, and disturbed sleep may also be a risk factor of stroke or an indicator of other processes that are related to

stroke. Post-stroke depression is one such factor, but it does not explain everything. A sample of 277 stroke patients aged 55–85 had a psychiatric evaluation of 3–4 months after ischemic stroke. 56.7 % reported some type of insomnia complaint and 37.5 % fulfilled the DSM-IV criteria of insomnia. In 38.6 %, insomnia complaint had started before the stroke, and in 18.1 %, it started after occurrence of the stroke. Insomnia complaints correlated with increased disability, cognitive decline, anxiety, and increased use of psychotropic drugs [170]. In South Wales, 1986 men aged 55–69 completed a questionnaire on sleep patterns with help from their partners. They were asked about symptoms of disturbed sleep including insomnia, snoring, restless legs, obstructive sleep apnea, and daytime sleepiness (Table 28.1). During 10 years of follow-up, 107 men experienced an ischemic stroke and 213 had an ischemic heart disease event. About 1/3 of the men reported at least one symptom suggestive of sleep disturbance, and 1/3 reported daytime sleepiness. Compared with men who reported no such symptoms, the age-adjusted relative risk of an ischemic stroke was significantly increased in men with any sleep disturbance. The strongest association was with symptoms indicating sleep apnea (OR 1.97; 1.26–3.09) [171].

Other neurological and somatic disorders. Most subjects with mental retardation complain of some types of sleep disturbance [172, 173]. Insomnia is frequent among many other somatic disorders including different respiratory diseases [147, 174]. In a study by Dodge et al., the prevalence of insomnia was 31.8–52.4 % among adults with cough,

Table 28.1 Snoring as a risk factor of stroke

Study	Population	Methods; outcome	Stratification/adjustment	Type of snoring	OR (95 % CI)
Partinen and Palomäki [419]	50 male stroke patients and 100 hospital controls	Case–control, personal interview, neurological examination, CT/MRI; stroke versus others	Age, gender (men), BMI	Habitual snoring	10.3 (3.5–30.1)
				Often or always snoring	2.8 (1.3–5.8)
Koskenvuo et al. [406]	General population 4388 men, 40–69 years	Cohort study, 3 years follow-up, questionnaire, registry data; incidence of stroke or IHD	Age, gender (men), BMI, smoking, alcohol, HT	Often or almost	2.08 (1.5–3.77)
				Always snoring	(Stroke or IHD)
Palomäki [424]	177 Stroke patients and 177 hospital control patients	Case–control, questionnaire, neurological examination, CT/MRI; stroke versus others	Age, gender, alcohol, HT, IHD	Often or always snoring	2.13 (1.29–3.52)
Spriggs et al. [420, 423] others adj	326 IHD/stroke pat. and 345 community	Case–control, personal interview, neurological examination, CT/MRI; stroke versus others	Age, gender, BMI, smoking, alcohol, IHD, HT, AF, DM	Often or almost snoring	3.2 (2.3–4.4) adj for age and gender 1.7 (1.3–2.2) adj for all factors
Smirne et al. [420]	164 Stroke patients and 330 hospital control patients	Case–control, personal interview, neurological examination, CT/MRI; stroke versus others	Age, gender, BMI, smoking, alcohol, HT, DM, dyslipidemia	Often or always snoring	1.86 (1.20–2.87)
Jennum et al. [416]	804 70-year-old followed for 6 years	Cohort of 70-year-old men and women, snoring history and other information from medical records	Age, gender, BMI, smoking, alcohol, HT, social class, lipids, glucose, catechol	Often or always snoring	1.8 (1.1–3.6)
Neau et al. [417]	133 Stroke patients, and 133 non-hospital control patients	Case–control, personal interview, spouse present, neurological examination, CT/MRI, stroke versus others	Age, gender, BMI, DM, hypertension, cardiacarrhythmia	Habitual snoring	2.93 (1.28–6.75)
Hu et al. [283]	71,779 Female nurses, 40–65 years	Cohort study, 8 years follow-up, questionnaire, registry data; incident stroke versus no stroke	Age, smoking, BMI, hypertension, DM, hypercholesterolemia, familial IHD history and other covariates	Snoring regularly	1.88 (1.29–2.74) adjusted for age 1.35 (0.91–1.99) adjusted for all
				Occasional snoring	1.42 (1.07–1.89) adjusted for all

AF Atrial fibrillation, *DM* Diabetes mellitus, *HT* Hypertension, *IHD* Ischemic heart disease, *OR* Odds ratio

dyspnea, or wheezing. Among adults without respiratory symptoms, the prevalence was about 26 % [174]. In an older Swedish study, 18.8 % of men with obstructive pulmonary disease suffered from difficulties in maintaining sleep (DMS) and 12.4 % complained of excessive daytime sleepiness. Among diabetic men, DMS was complained by 21.9 % and difficulty initiating sleep was complained by 21.1 % [175]. In a large US telephone survey, nocturnal awakenings were complained by 41.5 % of patients with gastroesophageal reflux, 38.6 % of heart disease patients, and 27–38 % of patients with other somatic diseases [176].

Is Anticipation of Coming Health-Related Events Possible with Follow-up of Sleeping Pattern and Sleep/Wake Rhythm?

As mentioned above (see "psychiatric disorders and insomnia"), insomnia has been repeatedly shown to be a predictor of future incident depressive period, PTSD, and substance use. There is also increasing evidence that self-reported sleep duration is a statistically independent predictor of all-cause and cardiovascular mortality, and morbidity in large epidemiological follow-up studies in recent meta-analyses [177–179]. The association is U-shaped meaning that often both extreme ends of the self-reported sleep duration distribution are associated with increased risk. However, there is some variation among the results. For example, a U-shaped association was confirmed in some studies [180, 181], only among women but not in men [182], or only among men but not in women [183, 184]. In one study, only short sleep was associated with increased risk of stroke [185], and in some studies mainly long sleep was associated with risk of stroke [178]. A recent study suggested that use of sleep medication may be a strong modifier of the association between short sleep and health outcomes [186]. Also, negative findings have been reported as regards sleep duration and future health [187, 188]. One reason for the inconsistencies among findings may be that the interpretation of the association of self-reported sleep duration and adverse health outcomes is complicated [189, 190], and may be different in different populations or cultures.

Insomnia has been associated with future cardiovascular morbidity [191] and total mortality [192–194]. In one recent study, insomnia was associated with future diabetes but not with incident CVD [195].

Sleep Length; Natural Short and Long Sleepers

As described above, self-reported sleep duration is a statistical predictor of several detrimental future health outcomes. A U-shaped association of self-reported sleep duration and health outcomes suggests that among the general population there are two risk groups showing deviation from the population mean sleep duration. Within these groups, sleep-related health risks are supposed to be increased. The prevalence figure of these risk groups varies depending on the cutoff points used to determine short and long sleep duration. In Finland, it was estimated that among the general adult population there are 14.5 % (16.7 % of men and 12.5 % of women) short sleepers ($\leq$6 h) and 13.5 % (10.5 % of men and 16.1 % of women) long sleepers ($\geq$9 h) [196]. However, subpopulations of short and long sleepers are not homogenous. Cross-sectional studies have shown that in any time point in the general population, self-reported short and long sleep are associated with several health conditions (e.g., obesity, diabetes, hypertension, metabolic syndrome, and cardiovascular disease) and different lifestyle factors [181, 188, 192, 196–198]. In a cross-sectional study of 5419 adult men, a higher prevalence of diagnosed myocardial infarction was found among those who slept more than 9 h, while those sleeping less than 6 h per night had a higher occurrence of symptomatic coronary heart disease. This relationship remained after controlling for age, sleep quality, use of sleeping pills and tranquilizers, smoking, alcohol use, Type A score, neuroticism, use of cardiovascular drug, and arterial hypertension [199]. In a large population-based survey with 218,155 Australian adults aged 45 years and over 6 h versus 7 h sleep was associated with statistically significantly increased odds of heart disease (OR 1.11), diabetes (OR 1.159), stroke (OR 1.25), and high blood pressure (OR 1.08) (1.04–1.11). Long sleep ($\geq$9 h) was also significantly related to heart disease (OR 1.14), diabetes (OR 1.25), stroke (OR 1.50), and high blood pressure (OR 1.04) compared to 7 h of sleep [188]. In a meta-analysis of 12 prospective studies both long sleep (RR 1.45; 1.30–1.62) and in a lesser degree short sleep (RR 1.15; 1.07–1.24) were risk factors for stroke [178].

Consequently, probably relative large part of the sleep duration risk groups is at risk because of existing ill health (baseline comorbidities with deviation from the population mean 7–8 h of sleep duration). Therefore, it is important to adjust for comorbidities or individuals with a previous history of a given disease must be excluded from the analysis. Therefore, attention is paid to healthy short and long sleepers. Are they at risk?

In a given time point, healthy adults who sleep less than 6–7 h per night are called "natural short sleepers" and those sleeping more than 9.5 h of sleep "natural long sleepers" [189, 192, 200–203]. This concept makes an assumption that there is an underlying genetic factor which determines whether or not an individual is "a natural short or long sleeper" [189, 204, 205]. However, there are also individuals who have modified their sleep duration due to different external factors [204]. Consistent short sleepers may have a

smaller risk than average sleepers (7–8 h) who have become short sleepers or long sleepers later in their life [189]. Genetically, short or long sleepers are at higher risk than midrange sleepers [189, 192, 206].

The fact that an individual is capable, at least for some time, to modify his/her sleep duration and in this way possibly harm one's own future health has raised a question: Would it be possible that in our modern society sleep duration is gradually shortening among the general population either voluntarily or forced by external factors? It is clear that sleep is not just a biological phenomenon. Its behavioral execution differs in different cultures. For example, the practice of siesta (daytime napping) varies across different cultures [207]. A historian Roger Ekirch has published a fascinating study suggesting that in preindustrial era people in Western Europe experienced, on most evenings, two major intervals of sleep, bridged up to an hour or more of quiet wakefulness [208, 209]. During the past two centuries, the preindustrial segmented sleep pattern has been replaced by a consolidated nocturnal sleep in modern societies. Some studies have found a small long-term decrease in self-reported sleep duration among the general population, but the effect size is clinically meaningless [55, 210]. Recent reviews have concluded that there is no convincing evidence supporting the belief of a secular trend of sleep reduction in general population [211, 212].

Insufficient sleep is the most common cause of daytime fatigue and sleepiness. Insufficient sleep may be due to poor sleep with nocturnal awakenings, too short sleep, or due to some other cause. The lack of sleep may be due to "bad habits", or a discrepancy between biological and social circadian rhythms, or to some psychic or somatic pathology. In a Japanese study [202] among 3030 adult people, aged 20 or more, 29 % slept less than 6 h per night, and 23 % reported having insufficient sleep. Short sleep duration was the strongest predictor of excessive daytime sleepiness [202]. Similar figures have been published in Europe and USA [202, 213–215]. In Sweden, 12 % of adults had persistent chronic sleep loss, and 50 % of them also reported other concomitant sleeping difficulties. In subjects without sleeping difficulties, the most common cause of insufficient sleep was too little time for sleep [214]. In another study, the prevalence of insufficient sleep, defined as a difference of at least one hour between reported need of sleep and actual sleep length, was 20.4 % (16.2 % in men and 23.9 % in women). Almost half of those with insufficient sleep at baseline had it still 9 years later showing that the problem is often chronic. One-third of the liability to chronic insufficient sleep was attributed to genetic influences [215]. It should be, however, noted that "insufficient sleep" calculated as a difference between self-reported evaluations of one's need of sleep and self-reported usual sleep duration is not a direct measure of objectively determined sleep deprivation, and caution should be taken when interpreting the results of epidemiological studies on "insufficient sleep."

Daytime Sleepiness

Some prevalences of daytime sleepiness are shown in Table 28.2. Depending on the study and wording, the occurrence varies from very small 0.3 % to more than 30 % (see Table 28.2). As an average, the prevalence is between 5 and 15 %.

Sleepiness may be interpreted differently in different languages. The English word "sleepiness" is defined in the Random House Unabridged Dictionary and the Scribner-Bantam dictionary as "inclined to sleep, drowsy," and in Stedman's Medical Dictionary as "an inclination to sleep." Synonyms for "sleepy" include words such as tired and somnolent. Fatigue is a more general term describing, according to Stedman's, a state of lessened capacity for work and reduced efficiency of accomplishment, usually accompanied by a feeling of weariness, sleepiness, or irritability [216]. A more original description of fatigue is found in the highly appreciated French Dictionnaire des Termes Techniques de Médecine by Garnier and Delamare published in 1969, where fatigue is defined as "a state resulting from prolonged activity of an organ or system. It is translated as decrease of function and a particular sensation (feeling of fatigue) which is specific to each organ. The aim of training is to retard apparition of fatigue." Tiredness comes from the word tired, which is synonymous to weary, wearied, exhausted, fatigued, jaded, and bushed. In the Random House Unabridged Dictionary, "tired" suggests a condition in which a large part of one's energy and vitality has been consumed. One who is "tired" has used up a considerable part of his or her bodily or mental resources. One who is "fatigued" has consumed energy to a point where rest and sleep are demanded. Simple rest may decrease tiredness and feelings of fatigue but sleep is needed to relieve sleepiness. In sum, sleepiness is a preferred term to describe inclination to sleep or tendency to fall asleep.

Sleep-related breathing disorder is the second most common reason of excessive daytime sleepiness among adults after lack of sleep [201, 202]. Also, the use of hypnotic agents, other sleeping difficulties, and irregular sleep–wake schedule are related to daytime sleepiness. In most sleep laboratory populations, more than 75 % of patients with daytime sleepiness have sleep-related breathing disorders (most commonly obstructive sleep apnea syndrome), 20 % have narcolepsy, and 5 % have restless legs, periodic movements in sleep, or other sleep disorders. This does not reflect distribution in general population, where insufficient and/or poor quality of sleep explains most cases of sleepiness.

Table 28.2 Occurrence (%) of daytime sleepiness

Study	Size (*N*)	Population; age	Definition of sleepiness (wordings)	Methods	Percentage (%)
Sleeping too much					
Karacan et al. [520]	1645	General population; 18–70 years	Too much sleep	Questionnaire	0.3
Bixler et al. [40]	1006	General population; 18–80 years	Sleeping too much	Questionnaire	7.1 (current 4.2)
Ford and Kamerow [10]	7954	Population sample; 18–65+ years	Ever a period of two weeks or longer sleeping too much	Direct structured interview using Diagnostic Interview Schedule	2.8 (M), 3.5 (W)
Involuntary sleep attacks, sleeping episodes, irresistible sleep, chance of dozing					
Partinen [227]	2537M	Army draftees before military service; 17–29 years	Falls asleep at work	Questionnaire	6.4
Partinen and Rimpelä [521]	2016	Population sample; 15–64 years	Involuntary sleep attacks daily or almost daily	Phone interview	3.4 (M), 2.5 (W)
Billiard et al. [522]	58,162M	Army draftees; 17–22 years	Daily sleep episodes	Questionnaire	4.9
Klink and Quan [523]	2187	Population sample; 18–64 years	Falling asleep during the day	Questionnaire	12
Saarenpää-Heikkilä et al. [524]	574	Schoolchildren; 7–17 years	Sleeping during lessons often or always	Questionnaire (both subject and parents)	3 (B), 0 (G)

Narcolepsy

The prevalence of narcolepsy varies in population-based studies between 21 and 56 per 100,000 persons [217–235]. In some studies, sampling has been, for example, by newspaper advertisements and TV programs and these studies do not represent well-defined population samples. In addition, there are many unknown assumptions in some of the early studies and therefore these are not taken into consideration [226, 236–238]. The highest figures, around 160 or up to 590 per 100,000, are from Japan [219, 220, 230]. The lowest frequency, 0.23 per 100,000 population, is found in Israel [231, 239].

A simple screening method called the Ullanlinna Narcolepsy Scale (UNS) has been developed and validated [222]. The UNS consists of 11 items assessing cataplexy-like symptoms and tendency to fall asleep. The score varies from 0 to 44 and the cut point for diagnosing narcolepsy is 14. Using the UNS, the prevalence of narcolepsy with cataplexy was 26 per 100,000 population in adult Finns [223]. Very similar figures have been published from Hong Kong. Using the validated Chinese version of UNS, the prevalence rate of narcolepsy among southern Chinese was 34 per 100,000 (95 % CI 10–117). In Hong Kong, all narcoleptic subjects were HLA DRB1-1501 positive and 50 % were DQB1*06:02 positive [233]. Using the same methodology, the prevalence among Korean students is around 15 per 100,000 [240].

Cataplexy is one of the core symptoms of narcolepsy, but occasional cataplexy-like attacks may occur also in healthy subjects. Among young men, 16.5 % experience at least sometimes sudden weakness in some muscle groups that are associated with emotions. 3.7 % of young men had experienced such cataplexy-like symptoms often or almost during the past month [227]. In another study, 29.3 % of the people reported (at least once during his or her lifetime) feelings of limb weakness associated with emotions [223]. If this is considered as evidence of cataplexy and combined with the occurrence of daytime sleep episodes at least 3 days per week, 6.5 % of the population would have narcolepsy according to the minimal diagnostic criteria for narcolepsy of the ICSD. Clinical, polysomnographic, and CSF examinations of hypocretin allow more exact diagnosis and more precise occurrence rates [241–246].

In the current ICSD-3, narcolepsy is divided into narcolepsy type 1 (narcolepsy with certain cataplexy; narcolepsy with low CSF hypocretin; NT1) and narcolepsy type 2 (no cataplexy, CSF hypocretin normal; NT2). NT1 is

probably an autoimmune/autoinflammatory disease. NT2 is more heterogenous and iNT2, and idiopathic hypersomnia are very difficult to distinguish from each other. Using the new diagnostic classification, NT2, as well as idiopathic hypersomnia, seem to be much less common than NT1, but population-based epidemiological studies do not yet exist. Also, the existing prevalence studies, as shown in Table 28.3, must be interpreted with caution, as the criteria for diagnosis of narcolepsy have been variable. For example, in the Longstreth study only 50 % of the diagnosed narcolepsy with cataplexy were HLA DQB1*0602 positive [234], contrasting to almost 100 % positivity among NT1 patients in some recent studies [247–249]. Also, normal people may report of occasional cataplectic attacks and therefore it is uncertain if all subjects in that study, in fact, had true narcolepsy.

Incidence of narcolepsy. Studies on incidence of narcolepsy are scarce, but it seems that the incidence of narcolepsy is approximately 1 per 100,000 people per year [228, 248, 250, 251]. In Minnesota, the incidence of definite and probable narcolepsy with or without cataplexy was 1.37 per 100,000 persons per year (1.72 for men and 1.05 for women) [228]. In the same study, incidence of narcolepsy with cataplexy was 0.74 per 100,000 persons per year being highest in 10–19-year-olds (1.8/100,000/year) [228]. Computed from their data, the incidences of narcolepsy with

cataplexy were 1.0 per 100,000 persons per year in people aged less than 40 years and 0.1/100,000/year in people aged 40 years or more.

After the adjuvanted H1N1-vaccinations, the incidence of narcolepsy increased significantly, especially in those European countries, where Pandemrix® vaccination was the only vaccination used [247, 250, 252–259]. In Finland, all patients with Pandemrix-associated narcolepsy were HLA DQB1*06:02 positive and all patients who have had a lumbar puncture have been type 1 with low CSF hypocretin levels [247, 248]. After Pandemrix vaccination in Finland, the average incidence of narcolepsy increased in people aged under 17 years from 0.3 to 5.3 per 100,000 people per year [247]. In a retrospective cohort study, the incidence of narcolepsy was 9.0 in the vaccinated as compared to 0.7/100,000 person-years in the unvaccinated individuals, the rate ratio being 12.7 (95 % confidence interval 6.1–30.8) [252]. Reports from other countries have also shown a statistically significantly increased risk of developing narcolepsy after Pandemrix® vaccination [250, 253–259]. The incidence rate in children before vaccination campaign was lower, e.g., in Finland than in Minnesota [228], and it is possible that some children had remained undiagnosed before the vaccination campaign. The incidence rates in children, adolescents, and also in adults rose anyway to a much higher level than ever before indicating a relationship with the vaccination. Recent immunological studies provide a link between Pandemrix and narcolepsy. The results have moved the focus from adjuvants onto the H1N1 viral proteins [248, 249, 260].

There are some interesting associations with time of birth and narcolepsy. In southern China, an excess of winter births has been found in subjects with narcolepsy-cataplexy [261]. In a large multicenter (Montpellier, Montreal, and Stanford) study, birth dates of 886 patients with a clear-cut diagnosis of narcolepsy with cataplexy were compared with birth dates of the comparative general populations. The birth rate of narcoleptic patients was highest in March (OR 1.45) and lowest in September (OR 0.63 compared to general population). No gender or country of origin differences were observed [262].

Snoring and Sleep Apnea

Habitual Snoring

Snoring is an inspiratory noise (occasionally also occurs during expiration) caused by vibration of the soft upper airways tissues, mainly soft palate and posterior faucial pillars. Snoring corresponds to partial obstruction of the upper airways, and complete obstruction is followed by an apnea. Almost everybody snores sometimes especially when sleeping in a supine position. It is well known that alcohol increases snoring. Habitual (almost every night or every night) snoring is practically always present in patients with obstructive sleep apnea syndrome (OSAS). Children and elderly people may not snore loudly. Instead, they are breathing with their mouth open. In the first large-scale epidemiological study on snoring, about 24 % of San Marino men and 14 % of San Marino women were reported to habitually snore [263]. In Finland, 9 % of adult men and 3.6 % of adult women reported snoring always or almost always when asleep [264]. A recent Finnish study found that when individuals with prior history of cardiovascular disease were excluded from the Health 2000 sample of adult ($\geq$30 years of age) population among the remaining 5177 individuals 17.8 % (11.9 % of women and 25.2 % of men) reported to snore habitually [265]. Among Hispanic–American adults, the age-adjusted prevalence rate of regular loud snoring was 27.8 % in men and 15.3 % in women [266]. Snoring increases with age up to 60–65 years and decreases in older age [264, 266–273]. In many studies, prevalence of snoring has been higher but in such cases history of snoring has often been asked with only two or three possible response alternatives. Because almost everybody snores sometimes snoring figures are high. Occasional snoring or snoring as a dichotomous variable is not related to significant pathology [265, 274, 275]. On the contrary, habitual almost every night snoring seems to be a risk factor for cardiovascular and cerebrovascular diseases [265, 274, 276]. For a clinician, this is important. Having a positive response to snoring is not sufficient. One needs to know how often someone is snoring. When asking for frequency, semi-quantitative scales with defined time frames should be used. For example, “often” can mean once a month for someone but almost every day for another. Snoring history is significant if someone snores on at least 5 nights per week; in other words, someone is a habitual snorer. One can ask further also about presence of sleep apnea (breathing cessations) and snoring stertorousness.

If someone snores almost every night very loudly and intermittently and someone (a cohabiting person) has noticed breathing pauses on about 3–5 nights per week, the probability of obstructive sleep apnea is high. If the subject has been snoring for more than 13 years, it is almost certain that he/she has sleep apnea [277]. The probability of sleep apnea increases further if the clinical examination is suggestive of sleep apnea. Some of the best-known strong indicators of possible sleep apnea include thick neck, large waist circumference (visceral fat), increased fat under the chin, pathological Mallampati score with large tongue and/or large tonsils, and narrow upper airways with high ogival hard palate. If the snoring and apnea history are positive and the clinical examination is suggestive of sleep apnea, the prior probability can be higher than 90 %. In other words, the

diagnostic certainty is better than that of a screening sleep recording. It is also important to recognize false positive responses from screening recordings. Unfortunately, a good clinical history and clinical examination are sometimes overlooked trusting too much on the results of sleep recordings.

The main underlying mechanism behind the associations of sleep-disordered breathing (habitual snoring) and cardiovascular outcomes is obstructive sleep apnea (OSA). However, heavy habitual (every night) snoring (i.e., partial upper airway obstruction) may influence pulmonary arterial pressure even without apneas, and expose the heart and circulation to a cascade of detrimental stimuli such as increased intrathoracic pressure, autonomic dysregulation, platelet activation, oxidative stress, and endothelial dysfunction resulting in the development of cardiovascular disorders [278], daytime sleepiness, insulin resistance, metabolic syndrome, and other health consequences [277–295].

Sleep Apnea

Sleep-related breathing disorders (SRBD) and sleep-disordered breathing (SDB) refer mostly to sleep apnea. In a large population-based study, more than 2000 adults, aged 40–85 years, had a polygraphic sleep recording [296]. The median apnea-hypopnea index (AHI) was 6.9/h in women and 14.9/h in men. The prevalence of moderate to severe sleep-disordered breathing (defined according to AASM as AHI $\geq$ 15) was 23.4 % (20.9–26.0) in women and 49.7 % (46.6–52.8) in men [296]. Can these results be interpreted as meaning that almost 50 % of over 40-year-old men have SRBD, which should be treated by nasal CPAP as current medical textbooks are suggesting? Many questions remain open. Sleep apnea is very common and it is associated with many health-related outcomes. More prospective studies as well as randomized studies are needed anyway. Using the current "pathological limit" of AHI (AHI $\geq$ 5), even more than 80 % of men and 60 % of women could be defined as "patients with sleep apnea," if we use the recent Swiss figures [296]. The current definitions of sleep apnea using AHI indices must be revised, as the "original" historical limits of AHI (mild $\geq$5, moderate 15–30, severe $\geq$30) have been "taken from the pocket" and they have not originated from physiological background.

Currently, the generally accepted prevalence of symptomatic and clinically significant OSAS (SRBD with excessive daytime sleepiness) among adult men is probably somewhere between 3 and 7 %, and in women the prevalence of OSAS varies from 2 to 5 %. There is an age relationship. The prevalence of OSAS among men aged 40–59 may be greater than 4 % or even much greater than 10 %. Although sleep apneas are frequently found among elderly subjects, the occurrence of clinically significant sleep apnea is less common in older age groups than among people aged 40–65. In young women, OSAS is rare, but after menopause, up to the age of 65, it is almost as common as among men. Sleep apnea is not rare among children. Apneas with AHI > 5 may be found in more than 14 % but symptomatic sleep apnea syndrome is rare [267, 269, 297–304]. In the first population-based studies, the prevalence of OSAS varied between 1 and 4 %, but recent estimation have been higher. Men have higher figures than premenopausal women. Among adults, children, and also among subjects with mental retardation, OSAS is highly associated with central obesity [13, 14, 269, 270, 272, 273, 279, 298, 299, 304–321].

Obstructive sleep apneas are part of the complex of "heavy snorer's disease" as defined by Lugaresi et al [322]. As stated above, heavy snoring is as such, without sleep apnea syndrome, a risk factor for many health outcomes.

Sleep apnea should be properly quantified, not only by an apnea index (AI) (or apnea-hypopnea index; AHI) but also by the number of oxygen desaturations, limitation of air flow, degree of daytime sleepiness, and by cardiovascular function. An AI of 5 or AHI of 10 is commonly used as a criterion of OSAS. The diagnostic criteria should be adjusted for age [315–317, 323–325]. It may be that while the occurrence of sleep apnea increases with age the clinical meaningfulness of apnea decreases among elderly people. Hence, occurrence of clinically significant sleep apnea syndrome is rare among elderly people, who often have many other diseases that may be indirectly associated with sleep apnea [326–330].

Risk Factors for Snoring and Sleep Apnea

Central Obesity, Thick Neck, and Obstructed Upper Airways

Central visceral obesity is the most important risk factor for snoring and sleep apnea. Obesity is commonly measured by body mass index (BMI), which is calculated as weight in kilograms divided by square of height in meters [331]. According to the WHO criteria, adults with a BMI of 25 kg/m^2 and over may be considered as overweight and those with BMI of 30 kg/m^2 and over are considered as obese. According to WHO, in 2006, more than 60 % of US and UK citizens were overweight and almost 30 % of US citizens were obese with BMI over 30 kgm^{-2}. In the Nauru Islands almost 80 % and in the French Polynesia 36 % were obese (see, e.g., WHO Web pages on statistics of BMI/obesity [332]).

The frequency of snoring and sleep apnea increases with obesity in all published epidemiological reports. The same is true for heavy snoring and sleep apnea. For example, in the Katz's study habitual snoring was found to occur in 7 % of

men and 2.8 % of women with a BMI of less than 27 kg/m^2 and in 13.9 % and 6.1 %, respectively, of those above this level [203].

Using multivariable analysis, the Oxford group of John Stradling first reported that neck size is more closely related to severity of sleep apnea than BMI [303, 333–335]. Neck size may be easily measured, and it is a useful indicator of upper body obesity. Several lines of evidence show that central obesity (large waist circumference) is related to increased risk of cardiovascular disease, diabetes, and metabolic syndrome [336–342]. Other clinical markers that are risk factors for sleep apnea include high Mallampati score and small cricomental space [335, 341, 343–348]. If the cricomental space is more than 1.5 cm, obstructive sleep apnea is unlikely; in the study of Tsai et al., its negative predictive value was 100 % (95 % CI 75–100 %) [348].

Anatomically narrow upper airways. Lean people may have abnormal upper airways. Anything that obstructs upper airways is a risk factor for heavy snoring and sleep apnea. Among known risk factors are large adenoids or tonsils, and rhinitis [349–353]. Other abnormalities in upper airways are, e.g., those found in different dysmorphic syndromes, in mentally disabled people, in acromegaly, and familial amyloidosis [354–362].

In sum, obesity is linked with probability of snoring and sleep apnea, but BMI is not the best indicator of obesity. Therefore, at least, waist circumference, neck circumference, and cricomental space should be measured in all future clinical and epidemiological studies on snoring and sleep apnea. Waist- and neck circumference as well as the cricomental space may be estimated relatively well also in surveys that are based on questionnaires using different pictures of the head and neck. Responders can then choose the picture that resembles most their own faces. The collar size of a shirt correlates well with actual neck circumference.

Other Risk Factors for Snoring and Sleep Apnea

Among 2187 subjects representative of a general adult population in Tucson, major independent risk factors for snoring were male gender, age between 40 and 64 years, obesity, and cigarette smoking [363]. Snoring was more common in subjects who regularly used alcohol or hypnotics. The effect of smoking may be related to upper airway inflammation and edema caused by cigarette smoke.

Alcohol increases upper airway resistance and tends to induce obstructive sleep apnea in healthy people and especially among chronic snorers [349–353, 364–368]. This is probably due to the acute centrally depressing effects of alcohol. Among other risk factors, hostility is associated with habitual snoring [369].

Ethnic Differences in Occurrence of Snoring and Sleep Apnea

Prevalence and incidence of sleep apnea vary according to ethnicity (Table 28.4). In a study in Singapore comparing prevalence of snoring among Chinese, Malay, and Indian, the average prevalence of snoring was 6.8 % (53–83 %). The ethnic differences were significant. Among Chinese, 6.2 % (4.4–8.1), among Malay 8.1 % (6.1–10.2 %), and among Indians 10.9 % (85–13.4 %) snored. The minimum whole population prevalence by the most restricted symptom criteria for defining sleep breathing-related disorder was 0.43 % (0.05–0.8 %) [308]. In Singapore, some estimations have given a prevalence of 15 % for sleep apnea [370]. This figure is based, however, only on a small sample of people and it may not be representative of the whole Singapore population. Therefore, the figure is probably too high. The reasons may be related to differences in craniofacial anatomy and also to environmental effects. Examples of the latter include obesity which seems to be significantly more common, e.g., among African Americans and also among Saudi Arabian women than in people of Caucasian origin [308, 316, 371–374]. Reasons for higher occurrence of obesity are multiple, and socioeconomical factors should not be forgotten. Unemployment, alcoholism, and lack of financial security are known to be associated with higher figures of obesity. It must be emphasized that there is still a considerable lack of epidemiological data regarding the prevalence of OSA in Asian communities and consequently all inferences about the differences across Asian and European ethnicity should be made with caution [375].

Snoring and Sleep Apnea in Children

Snoring or obstructive sleep apnea is common in children of all ages. It must be noted that among children snoring may not be loud. A manifestation of obstructed upper airways may be that the child always sleeps with open mouth. Among 1615 Italian children, aged 6–13, 118 children (7.3 %) were habitual snorers. Children with rhinitis were more than twice as likely to be habitual snorers than others. There was a positive correlation between parental smoking and the presence of snoring in children [349]. In Iceland, 3.2 % of 555 children aged 6 months to 6 years snored often or always [270]. The estimated minimal prevalence of obstructive sleep apnea in that age group was 3.2 %. In one study among 4–5–year-old children, significant sleep and breathing disorders occurred in 0.7 % [376]. In a Spanish study, the prevalence of sleep-disordered breathing among

In order to diagnose obstructive sleep apnea syndrome, a subject must have verified sleep apnea and he/she must be symptomatic with EDS or other symptoms of OSAS. The highest figures above are in studies where the subjects may not have been symptomatic. In those cases, the prevalence figures represent only occurrence of apneas and not prevalence of OSAS

EDS Presence of excessive daytime sleepiness; *PSG* Polysomnographies were done; *Pre* Premenopause; *Post* Postmenopause; *HRT* Hormone replacement therapy

adolescents aged 12–16 was 1.9 % [377]. Adenotonsillar hypertrophy is the most common cause of upper airway obstruction in infants and children [352, 378, 379].

Sleep Apnea Among Elderly People

Habitual snoring seems to decrease after age of 65 or 70 years [380]. In a random sample of 5201 Medicare enrollees, 65-year-old or older, 33 % of the men and 19 % of the women reported loud snoring. Snoring was less frequent in people that were aged over 75. Observed apneas were reported by 13 % of men and 4 % of women [381]. In California, 19–24 % of people older than 65 years have an AI > 5, and 62 % of elderly people have a respiratory disturbance index (RDI) $\geq$ 10 [324, 325, 380]. The clinical significance of the high frequency of sleep apnea among elderly people remains to be seen. Presence of sleep apnea in an elderly subject does not mean that he/she has OSAS, and it does not mean that all elderly subjects with AHI or RDI over 10 should receive CPAP. In a cohort of 426 elderly people those with a RDI $\geq$ 30 had significantly shorter survival but the RDI was not an independent predictor of death among the elderly subjects during five years of follow-up when age, cardiovascular disease, and pulmonary disease were used as covariates [326]. The frequent occurrence of sleep apnea means, on the contrary, that we should perhaps use higher cut-point values of AI and AHI for elderly people [315].

Arterial Hypertension

Several cross-sectional and also prospective studies have shown that among middle-aged adults there is an association of habitual snoring, sleep apnea, and arterial hypertension. The causality is still not clear, but habitual snoring usually precedes development of hypertension. In other words, snoring and especially habitual snoring is a risk factor for developing hypertension [283–285, 288, 289, 326, 382–385]. The association seems to be independent of the effects of BMI, age, gender, smoking, use of alcohol, and physical activity. In case–control studies, the prevalence of sleep apnea among patients with essential hypertension is 25 % or higher [296, 386–393].

In practice, this means that if there is a history of habitual snoring and/or sleep apnea, and if the upper airways anatomy is suggestive of sleep apnea, a polysomnographic study must be done to verify or rule out clinically significant sleep apnea. According to many studies, the odds of having sleep apnea is significantly increased in presence of arterial hypertension [296]. In middle-aged adults with drug-resistant hypertension, the prevalence of OSA may be over 80 % [394].

In the study of Enright et al. among elderly people, loud snoring, observed apneas, and daytime sleepiness were not statistically significantly associated with hypertension or prevalent cardiovascular disease [381].

Heart Disease

There is an association between habitual snoring and/or obstructive sleep, and cardiac arrhythmias [395–402].

Coronary heart disease and myocardial infarction are more common among habitual snorers and untreated patients with sleep apnea than among non-snorers or people with sleep apnea. The average odds ratio for coronary heart disease of habitual snorers versus never or occasional snorers has been in most published studies about 1.9 or higher [266, 283, 285, 403–405]. The association remains after adjustment for arterial hypertension and BMI. In one of our studies, results were adjusted for BMI, history of arterial hypertension, smoking and alcohol, and the odds ratio decreased only slightly to 1.71 (95 % CI 0.96–3.05) [406]. However, in our recent study, the adjusted OR for stroke events was 1.65 (95 % CI 1.06–2.57) but for coronary events nonsignificant 1.13 [265]. In Australia, 101 male patients with myocardial infarction and 53 male control subjects were investigated [407] and a significant association of sleep apnea with myocardial infarction was found. The association was independent of age, BMI, arterial hypertension, smoking, and cholesterol level. Adjusted risk of myocardial infarction increased with increasing level of sleep apnea. Men with an AI > 5.3 had 23.3-fold (95 % CI 3.9–139.9) higher risk of myocardial infarction than did men with an AI < 0.4. The mean AI was 6.9 in patients with myocardial infarction versus 1.4 in the control subjects [407].

Also cardiac insufficiency/congestive heart disease seems to be more common among patients with sleep apnea and/or Cheyne–Stokes breathing than among subjects without sleep apnea [408–413].

Again, consistent with results that have been discussed above, these associations are found mainly among middle-aged subject and they are weaker among elderly people [414, 415].

Snoring and Stroke

Habitual snoring (snoring almost always or always when sleeping) is a significant and independent risk factor for cerebrovascular disease, but snoring per se, i.e., snoring rarely or sometimes, is not. In other words, there is an association between often or always snoring and ischemic cerebrovascular disease [265, 283, 406, 416–423].

The most important factors associated with brain infarction are age, male gender, arterial hypertension, various abnormal cardiac conditions, diabetes mellitus, and cigarette smoking. In addition to these established risk factors, however, there is evidence that suggests a link between habitual (almost every night or every night) snoring, OSAS, and stroke. In the first case–control study, 50 male patients with brain infarction were compared with 100 male hospital control subjects without any vascular diseases [419]. The risk ratio of brain infarction between often or always snorers and occasional or never snorers was 2.8 (95 % CI 1.3–5.8). The risk ratio was 10.3 (3.5–30.1) when habitual (every night or almost every night) snorers were compared with occasional or never snorers [419]. The independent contribution of habitual snoring as a risk factor for brain infarction was confirmed in another case–control study [424] of 177 male patients and control subjects matched for age and sex. After adjustments for several confounding variables, the independent odds ratio relating to often or always snoring and stroke remained at 2.13 (1.3–3.5) [424]. Spriggs and others [423] used community controls which may have altered the relationship. During the interview, another person from the household was present to increase validity of the history. In the Spriggs et al. study, 36 % of hospital controls snored often or always. Among community controls, 33 % of men and 28 % of women snored often or always. When admission to hospital because of stroke was compared, the odds ratio for often or always (regular) snorers versus non-regular snorers was 3.2 (2.3–4.4). After adjustment for BMI, smoking, alcohol drinking, previous history of cerebrovascular disease, ischemic heart disease, hypertension, atrial fibrillation, and diabetes, the adjusted OR for stroke in regular snorers was 1.7 (1.3–2.2), which was still statistically significant [423]. One important finding in the Spriggs study is that the prognosis after stroke was worse for regular snorers than for non-snorers. In the study by Smirne et al., the adjusted (age, gender, obesity, diabetes, dyslipidemia, smoking, use of alcohol, and hypertension) odds ratio for "often or always snoring" in relation to ischemic brain infarction was 1.86 (1.2–2.87) [420]. Neau et al. studied 133 patients, aged 45–75, and 133 control subjects matched for age and gender. During the interview, the spouse was present so that reliable history about snoring was obtained. Neau et al. used the same categorization for snoring as Partinen and Palomäki, according to which habitual snorers are those who reportedly snore always (every night). They defined as "snorers" those who snore often or always. "Non-snores" included never snorers and also occasional snorers, which is probably the correct way of categorization [417]. In that French study, the prevalence of habitual snoring was 23.3 % among patients with stroke and 8.3 % among their controls. The odds ratio for habitual snoring was 3.4 (95 % confidence interval, 1.5–7.6). The odds ratio for "often or always snoring" was 1.7 (95 % confidence interval 1.03–2.93). Even after adjustment for age, sex, arterial hypertension, cardiac arrhythmia, and obesity, the odds ratio of habitual snoring for stroke remained statistically significant (2.93; 95 % confidence interval 1.28–6.75). The risk of ischemic stroke was especially high among habitually snoring older men with arterial hypertension while the odds ratio did not reach statistical significance (OR 1.42; 95 % CI 0.51–3.99) [417] As a conclusion there seems to be a real association between habitual (defined as almost always or always snoring, i.e., snoring on at least 5 nights per week) snoring and brain infarction. Long-term cohort studies and more case–control studies are needed to confirm this.

The problem with cohort studies is that stroke is not as common as ischemic heart disease and large number of incident cases is needed. Therefore, until now there are few [275, 283, 406, 425] published prospective cohort studies looking for habitual snoring as a risk factor of stroke. We asked about snoring history in the Finnish Twin Cohort for the first time in 1981 and all subjects have been followed since then. This would allow us more than 30 years follow-up time and we aim to evaluate the situation during the coming years. In our first follow-up that was published in 1987, we did not have enough incident stroke cases so we had to pool the cardiovascular morbidity with cerebrovascular morbidity. At that time, the odds ratio for ischemic heart disease and brain infarction combined was 2.08 (1.5–3.77) [406].

The Nurses' Health Study includes 71,779 female nurses aged 40–65 at baseline in 1986, and it is the largest cohort study including questions about snoring and other sleep-related items [283]. Women with cardiovascular end points at baseline were properly excluded. The 398 incident strokes (60 never snorers, 288 occasional snorers, and 50 regular snorers) in that cohort during 8 years of follow-up allowed already some analyses. Snoring was asked as "Do you snore?" with three categories: "regularly," "occasionally," or "never." Although this classification differs from the preferred classification, the group "regularly" is probably quite close to the category of "often or always snoring" or the more strict "habitual snoring" that has been used in Finland and in France. Hu et al. [279] adjusted the results for age, BMI, smoking, menopausal status, history of myocardial infarction, consumption of alcohol, physical activity, sleeping time, diabetes, and hypercholesterolemia. The age-adjusted relative risk of stroke for regular snorers compared with never snorers was 1.88 (1.29–2.74). In a multivariate adjusted model, the relative risk remained significant for occasional snorers ($N = 288$) versus never snorers (1.42; 1.07–1.89). Because there were only 50 regular snorers, the adjusted relative risk was a little bit lower (1.35; 0.91–1.99). The relative risk of combined cardiovascular and cerebrovascular events for regular snoring was

1.33 (1.06–1.67) [283]. Recently, from the same Nurses' Health Study cohort, 935 women aged 43–69 years have been studied in more detail for the association between snoring history and cardiovascular disease [392]. In a multivariate analysis, more frequent snoring was directly associated with triglycerides ($P = 0.02$) and inversely with HDL cholesterol levels ($P = 0.03$) and adiponectin ($P = 0.03$). In the same study, longer sleep was associated with increased levels of C-reactive protein after adjusting for age, BMI, different lifestyle factors, family history of diabetes, glycemic control, and use of medications. The usually snoring women were as follows: older ($P = 0.03$), more obese ($P < 0.0001$), centrally obese with larger waist–hip ratio ($P = 0.005$), physically less fit ($P = 0.03$), using more alcohol ($P = 0.04$), more often hypertensives ($P = 0.0001$), more often users of insulin ($P = 0.006$), and premenopausal ($P = 0.02$) than never or occasional snorers [392]. These results suggest that snoring history and other sleeping history should be combined with other biomarkers of cardiovascular disease (CVD) risk.

In the MESA cohort, 5338 people of various ethnicities have been followed for an average of 7.5 years. In that study, habitual snorers had similar incident CVD and mortality rates compared with normal participants [425]. Habitual snoring was defined in that study as snoring at least on 3–5 days per week, which may be too low cutpoint, as habitual snoring should be defined as snoring on 6–7 days per week or as snoring every night or almost every night. Also, only 76 cases of stroke had occurred, and the authors discussed that their analyses may have been underpowered to detect a unique association between snoring and cerebrovascular events [425]. In Busselton, Australia, a community sample of 380 subjects was followed for 17 years. Snoring was not significantly related to all-cause mortality, incident cardiovascular disease, or stroke [275]. Both studies [421, 422] indicate anyway that snoring without presence of sleep apnea may be harmless. Therefore, one should ask separately also for the presence of sleep apnea as well as presence of sleep apnea that has been diagnosed.

Sleep Apnea and Stroke

Poza et al. [426] studied 79 consecutive patients of both sexes with cerebral infarction and 248 age and sex matched controls. They obtained data reflecting arterial hypertension, diabetes mellitus, hypercholesterolemia, smoking and drinking habits, coronary heart disease, cardiovascular disease, snoring, respiratory pauses during sleep and daytime sleepiness, by using a standard questionnaire to interview every subject and spouse. 34 % of the stroke patients and 27 % of controls were snorers and complained of apnea during sleep ($P = 0.19$). 19 % of patients and 11 % of controls presented snoring, respiratory pauses during sleep and daytime sleepiness simultaneously, suggesting obstructive sleep apnea syndrome ($P = 0.06$). The difference was statistically significant among subjects younger than 65 years. OSAS was found in 29 % of the patients and in 7 % of controls ($P = 0.006$). A multiple logistic regression analysis confirmed the independent effect of moderate to severe OSAS as a risk factor for ischemic stroke (adjusted OR 4.54). In people younger than 65 years, OSAS, regardless of its severity, was also an independent risk factor for ischemic stroke, with an adjusted OR of 5.78 [426]. Since then prospective studies have also shown an association between diagnosed sleep apnea and stroke. In the MESA cohort, 7.5 years follow-up study physician-diagnosed sleep apnea was associated with higher incidence of composite CVD including various cardiovascular events and stroke (hazard ratio 1.89 (1.22–2.93)) [425]. In a historical Canadian cohort study, sleep apnea was associated with CVD and mortality, and OSA-related factors other than AHI were shown as important predictors of composite cardiovascular outcome [427] pointing out that the severity of sleep apnea should not be judged only by respiratory indices.

Circadian Variation of Strokes and Snoring

Ischemic strokes occur most commonly in the morning before noon [428, 429]. In a study by Tsementzis et al., cerebral infarction was most common between 10 a.m. and noon, when the highest blood pressures are usually recorded [430]. In another study, most (57 %) of the 151 strokes occurred between 6 a.m. and noon [431]. In a meta-analysis of 31 publications, Elliott reported the circadian timing of 11,816 strokes [432]. There was a 49 % increase (95 % CI 44–55 %) in strokes between 6 a.m. and noon as compared with expectations that there is no circadian variation. All three studied subtypes of stroke had a significantly higher risk between 6 a.m. and noon (55 % for 8250 ischemic strokes, 34 % for 1801 hemorrhagic strokes, and 50 % for 405 transient ischemic attacks) [432]. Detailed information about circadian variation of different types of stroke is, however, still limited. Chaturvedi et al. [433] analyzed stroke onset using detailed classification of stroke subtypes. They analyzed data of 1272 patients who had a documented time of stroke symptom onset, and all stroke subtype determinations were made by a single specialist. Most atherothrombotic strokes (25.7 %), cardioembolic strokes (30.5 %), and strokes of other/unknown mechanism (27.1 %) occurred between 6:01 a.m. and 12:00 noon. The greatest portion of lacunar strokes (31.6 %) were present on awakening. More than one half of the infarcts in this series were either present on awakening or occurred in the mid- to late-morning hours [433].

Nocturnal and early morning strokes are related to habitual snoring and obesity. In one study, relation of the time of onset of stroke and snoring history was analyzed in 167 consecutive male patients. In 70 cases (41.9 %), cerebral infarction initiated during sleep or immediately after awakening [434]. Of the 70 infarctions with an onset at night or immediately after awakening, 48 patients had a history of snoring often or always (68.6 %). The respective percentage among the other 97 patients was 41.2 %. The difference was statistically significant, OR for often or always snoring was 3.1 (1.7–5.9; $P < 0.001$). The odds risk remained significant when age, arterial hypertension, BMI, smoking, consumption of alcohol, and diabetes mellitus were taken into account [434]. Changes in blood pressure after awakening in the morning may cause a breakthrough of the autoregulation of the cerebral blood flow. In normal conditions, nothing happens, but under unfavorable conditions, an infarction may follow.

Jimenez-Conde et al. [435] studied 813 patients with ischemic stroke. 127 them had a stroke during sleep (15.6 %). Obesity was a factor associated with sleep strokes. Adjustment for age and gender revealed that atrial fibrillation (AF) was less frequent in the group of sleep-related strokes. Sleep-related strokes were more severe and functional outcome at 3 months was worse than for strokes occurring at other times of day. The authors conclude that "while sleep could be associated with a lesser stroke occurrence, it could also be associated with a higher severity" [435]. The authors did not have specific data on snoring or sleep apnea, but the finding that obesity was more prevalent among subjects with sleep strokes is suggestive that habitual snoring and sleep apnea might explain at least part of that association.

Snoring, Sleep Apnea, and Dementia

In a study by Reynolds et al., AI > 5 was found in 42.9 % of demented patients, 17.6 % of depressives, and 4.3 % of controls. A significant association between sleep apnea and dementia of the Alzheimer type was found in women but not in men. Moreover, severity of dementia was significantly correlated with apnea index [436]. Vitiello and Prinz had the same finding that the association exists among women when 24 female patients with Alzheimer's disease were compared with 26 control subjects. The mean AHI among the female patients with Alzheimer's disease versus control subjects were 9 ± 3 and 2 ± 0.4, respectively [437]. In a case–control study of 46 patients with Alzheimer's disease, 37 patients with multi-infarct dementia, and a random sample of 124 elderly community residents, the demented patients snored twice more frequently than the controls. No difference in the occurrence of snoring was found between the two types of dementia [438].

Snoring, Sleep Apnea, and Sudden Death

In the first study analyzing relationships between history of habitual snoring and sudden death, an autopsy was performed in 460 consecutive cases of sudden death among 35- to 76-year-old men. The closest cohabiting person to each deceased was interviewed. The mean age of the deceased was 55.4 years, and the mean BMI was 26.3 kg/m^2. Among the obese snorers ($N = 82$), apneas had been observed "occasionally," "often," or "habitually" in 49 cases [439]. Death was classified as cardiovascular in 186 cases (40.4 %). Cardiovascular cause of death was more common among the habitual and often snorers than among occasional or never snorers. Habitual snorers died more often while sleeping. Habitually snoring was found to be a risk (odds ratio, 4.07; 95 % confidence interval, 1.45–11.45) for cardiovascular early morning death between 4 and 8 a.m. [439].

Subjects with obstructive sleep apnea (OSA) die often at night. Polysomnograms and death certificates of 112 Minnesota residents were reviewed [440]. Sudden death from cardiac causes occurred in 46 % of people with OSA, as compared with 21 % of people without OSA ($P = 0.01$). For people with OSA, RR of sudden death from cardiac causes from midnight to 6 a.m. was 2.57 (1.87–3.52). This is contrary to people without OSA, who had the highest RR (2.10) between 6 a.m. and noon. The higher the apnea-hypopnea index, the higher was the RR of sudden death between midnight and 6 a.m. [440].

Evolution of Obstructive Sleep Apnea Syndrome

Several studies have shown an increased risk of cardiovascular complications and death in patients with at least moderate (AI > 20) or severe (AI > 40) OSAS [441–444]. The increased risk is found especially among middle-aged people with sleep-disordered breathing, but not in elderly people when several other comorbidities and risk factors are present [288, 327, 445–447]. CPAP treatment reduces mortality [448, 449]. Two recent long-term follow-up studies have been published. In Australia, after a mean follow-up time of 13.4 years, subjects with moderate to severe sleep apnea had greater risk of all-cause mortality (fully adjusted hazard ratio [HR] = 6.24, 95 % CL 2.01–19.39) than subjects without sleep apnea. Mild sleep apnea with RDI 5–14.9 was not an independent risk factor for higher mortality

[450]. In an 18-year follow-up of the Wisconsin Sleep Cohort all-cause mortality risk, adjusted for age, sex, BMI, and other factors was significantly increased with severity of sleep apnea. The adjusted HR for all-cause mortality with severe versus no sleep apnea was 3.0 (1.4–6.3). After excluding persons who had used CPAP treatment, the adjusted HR for all-cause mortality with severe versus no SDB was 3.8 (1.6–9.0). The adjusted HR for cardiovascular mortality was 5.2 (1.4–19.2) [451].

CPAP ameliorates quality of life of the patients with OSAS [452–457]. In a 3-month randomized study of 71 patients using the Euroqol quality of life measurement, CPAP added 8 and a lifestyle treatment added 4.7 quality adjusted life years (QALYs) as compared to no treatment [457].

CPAP is effective in treatment of moderate and severe sleep apnea, but the effect is very small if there are no symptoms of daytime sleepiness [456, 458–462].

OSAS has also economic consequences. Untreated patients use significantly more healthcare resources than treated patients [452, 463–470].

Parasomnias

The parasomnias represent a group of undesirable physical events or experiences that occur during entry into sleep, within sleep, or during arousals from sleep. Parasomnias in children are quite common. Up to more than 60 % of people have experienced some parasomnias at least now and then in their childhood. One to ten percent of children have got often some parasomnias. In adults, parasomnias are rather uncommon. The prevalence of often occurring parasomnias is between 0.1 and 1 %. In this way, it is more likely that parasomnias are seen at sleep clinics than, e.g., narcoleptics. It is important to differentiate parasomnias from nocturnal epileptic phenomena.

Recently, a series of studies on nightmares in Finland had taken place. Across the cross-sectional time, series of eight National FINRISK study samples (1972; 1977; 1982; 1987; 1997; 2002 and 2007) frequent nightmares were reported in 4.6 % of women and 2.8 % of men. Of note, among war generation, the prevalence figures were 7.0 % in women and 7.2 % in men [471]. Symptoms of depression and insomnia were the strongest predictors of frequent nightmares in this data set. Also, several factors related to psychological and physical well-being were associated with nightmare frequency [472].

An interested reader should also consult other chapters in this book as well as other epidemiological studies and reviews on parasomnias [473–481]. Epidemiological studies of parasomnias are difficult because most often one must depend only on history. Thus, the ranges of occurrence are very variable, and the figures must be interpreted with caution. Parasomnias occur in close association with other sleep disorders. For example, patients with sleep apnea talk often in their sleep, and patients with restless legs syndrome may also have nightmares or other parasomnias. Genetic factors play an important role in different parasomnias [474].

REM Sleep Behavioral Disorder

The prevalence of REM sleep behavioral disorder (RBD) in general population is not known, but it may be close to prevalence of violent behavior during sleep which is about 1.6 % [482]. There is more and more evidence that REM sleep behavioral disorder (RBD) may be a preexisting symptom of a future synucleinopathy [483–485], and there is some evidence that in dementia disappearance or reversal of the day/night rhythm is associated with severity of dementia. For many reasons, there is a need to develop unobtrusive methods for long-term monitoring of sleep/wake and circadian activity patterns among neurological patients and among elderly people both in nursing homes and at home. Our group has monitored, using a small wrist-worn intelligent watch, demented and non-demented subjects living in a nursing home, and analyzed how changes in measured sleep correlated with the subjective assessment of sleep quality, daytime alertness, use of medications, and health. The activity signal data together with subjective assessments of sleep quality and daytime vigilance were collected from 42 volunteers (aged 56–97 years; 23 demented and 19 non-demented) for at least 10 days. The demented subjects had lower daytime activity and higher nocturnal activity than the non-demented subjects. Correlations between the activity parameters and self-assessments were weak but statistically significant. We also found correlation between functional ability and diurnal activity [164]. New methods of 24 h beat-to-beat monitoring of blood pressure should also be developed as, e.g., systolic blood pressure drop may be an early biological marker of future Parkinson's disease [485].

Restless Legs Syndrome

Restless legs syndrome (RLS) has been named Willis-Ekbom disease after Thomas Willis and Karl-Axel Ekbom. It is a common neurological disorder characterized by an urge to move associated with unpleasant sensory feelings mainly in the lower limbs. Rest—lying or sitting still—provokes the symptoms. In particular in premenopausal women, the syndrome is often associated with

abnormalities of iron transport and storage [486–488]. Many subjects with RLS have low levels of serum ferritin (<50 μg/l). Due to lack of tissue iron (ferritin), dopaminergic dysfunction may occur at cerebral or spinal cord level [488, 489]. Epidemiologic studies have shown that the condition is common in populations derived from northern latitude (e.g., from Northern Europe).

Restless legs syndrome is common (Table 28.5). Among adults, the prevalence of RLS symptoms is between 5 and 15 %. According to the REST study [490], the prevalence of clinically significant RLS is around 2.7 % varying between 1.3 and 4.2 %, the highest figure being from France. In a large (N = 10,263) French study [491], the average prevalence of RLS was 8.5 % (N = 870 fulfilled the IRLSSG criteria); 56.1 % of the 731 persons with complete information had at least moderate RLS having the International RLS Study Group severity score of at least 11 [491]. Using the Bayes' theorem, we can estimate that about 4.8 %

Table 28.5 Prevalence of RLS

Study, country	Population (N)	Methods, criteria	Prevalence (%)
Europe			
Ekbom [536], Sweden	Physician's practice, N = 500	Presence of restless legs (original criteria), interview and neurological examination	5
O'Keeffe et al. [537], Ireland	Acute care geriatric service patients, N = 317	Presence of restless legs, interview	5 (31 % of patients had ferritin <18 ng/ml vs. 6 % in controls)

Kim et al. [546], South Korea	General population *N* = 9939	IRLSSG criteria, interview	12.1 M: 8.5, W: 15.4

[a]In the rest study, the prevalences per country refer to symptoms occurring at least on two days per week and the figures in parenthesis refer to percentage of subjects who report having RLS symptoms at least twice weekly with moderate or severe impact on quality of life. The figures in parentheses reflect clinically significant RLS
M Men; *W* Women

of adults in France have at least moderate RLS. This figure is quite close to the 4.2 % figure from the REST study for French adults. 21.2 % of the French had at least severe RLS (IRLS score > 20) giving an estimated prevalence of 1.8 % for at least severe RLS. Similar or higher figures have been published from the Nordic countries [492–495].

The prevalence of RLS is significantly higher among women than men, and it increases by age. About 20 % or more of pregnant women suffer from RLS [496–498] especially during the third trimester with different degrees of severity. RLS during pregnancy is related to low ferritin and folate levels. Not only RLS often occurs during pregnancy, but also the risk of having RLS later in life increases by number of pregnancies. In a German study [499], the overall prevalence of RLS was 10.6 %. The prevalence among women was about two times higher than among men. The prevalence among nulliparous women did not differ significantly from that among men up to age 64, but the risk of RLS increased gradually with each pregnancy. Having one child increased the odds ratio (OR) to 1.98 (95 % confidence interval 1.25–3.13), 2 children increased the OR to 3.04 (2.11–4.40), and 3 or more children increased the OR to 3.57 (2.30–5.55) [499].

Restless legs syndrome symptoms are frequent in many diseases. Among European/Caucasian patients with end-stage renal disease [500–502], the prevalence may be much higher than 20 %. In one US study among 308 patients on hemodialysis, RLS symptoms were present during the past 6 months in 68 % of patients with Caucasian origin and in 48 % of patients with African–American origin [503]. This figure is very different from Indian figures. Only one patient from 65 patients (1.5 %) with chronic renal failure and none of the 99 control subjects complained of having RLS [504]. RLS is also frequent among patients with either juvenile or adult type 2 diabetes. The association is not found among young adolescent patients with diabetes [505], but it is found in older patients. The association may be explained by the increased frequency of small fiber sensory

neuropathy, which is known to be often present in patients with RLS. In a case–control study of 124 patients with type 2 diabetes and 87 controls, RLS was diagnosed in 17.7 % of the diabetics and in 5.5 % of controls. In a multivariate logistic regression, presence of polyneuropathy was the only statistically significant risk factor with an OR 7.88 (1.34–46.28) [506]. RLS has been associated also with attention deficit hyperactivity disorder (ADHD), fibromyalgia, rheumatoid arthritis, familial amyloidosis, those receiving an organ transplantation, other sensory polyneuropathies, multiple sclerosis, spinal stenosis, or other spinal pathology [488, 489, 507–517]. In a recent study, patients with RLS had higher lifetime prevalence of migraine than non-RLS controls (53.2 % vs. 25.5 %, $P = 0.005$; matched-OR 1.3 [$P = 0.019$]; and adjusted odds ratio (OR) 3.8 [$P = 0.03$]). No significant associations were found between RLS and active migraine with aura or inactive migraine [518]. The associations may be explained by either central or spinal dopaminergic pathophysiology that are probably related to iron metabolism or by peripheral neuropathic effects.

Although RLS is common, it is still poorly recognized. In UK General Practice Database, Van de Vijver et al found that only 3877 diagnoses of RLS had been done between 1994 and 1998 among almost 1.6 million persons, giving a prevalence of 0.25 %. Also, the incidence was small; 41 diagnoses of RLS per 100,000 person-years had been done [519]. In the REST study, 337 (81.0 %) of the 416 patients with clinically significant RLS (the RLS sufferers) reported discussing their symptoms with a primary care physician, and only 21 (6.2 %) were given a diagnosis of RLS.

Genetics of Sleep and Sleep Disorders

29

Stéphanie Maret, Yves Dauvilliers, and Mehdi Tafti

Introduction

After more than a century of modern scientific study of sleep, its biological function remains an enigma. In all mammals and birds and in some invertebrates such as drosophila, a substantial portion of life is spent in this behavioral state, and we know that lack of sleep or disturbed sleep has strong negative consequences on health and performance. Because of the conservation of this behavior during evolution (since its appearance), it is believed that sleep must fulfill a fundamental and vital biological need. As a complex behavior, sleep is influenced by both genetic and environmental factors as was demonstrated early on in familial and twin studies that assessed the role of genes in sleep and sleep disorders. The current progress in sequencing the genomes of species as different as human, mouse, zebrafish, and drosophila brought great expectation that genes related to sleep and sleep disorders could be identified. The discovery of a point mutation in the prion protein gene as the cause of fatal familial insomnia (FFI), followed by the discovery of the role of hypocretins in human narcolepsy, proved that through genetic approaches unexpected molecular pathways or new sleep-related genes could be discovered.

Genetics of Normal Sleep and the Electroencephalogram

Sleep and wakefulness are complex behaviors and thus are influenced by many genetic and environmental factors. Twin studies are of interest to determine the respective contribution of genetic and environmental factors to a given phenotype. The first study of genetics of sleep can be dated to a publication by Geyer in 1937 [1]. He reported a higher concordance of sleep habits of monozygotic (MZ) than dizygotic (DZ) twins. In 1951, Gedda [2] reported rare cases of concordant long sleepers (up to 15 h) in MZ twins. Gedda and Brenci [3] first estimated that the heritability of sleep duration is over 30 %. These authors later confirmed that sleep duration is highly similar even in twins living apart, discounting the influence of environmental effects [4]. Results from twin studies also showed that the waking electroencephalographic (EEG) patterns of MZ twins have a much higher resemblance than those of DZ twins or unrelated subjects, again confirming that this highly complex phenotype might be tightly controlled by genes and little affected by environment. In 1966, Zung and Wilson [5] performed the first polysomnographic sleep recordings in twins and found the temporal sequence of sleep stages to be almost completely concordant between MZ twins. More recent observations indicate that even the pattern of rapid eye movements (REMs) presents higher concordance between MZ than DZ twins [6] and that between 40 and 50 % of the variance in sleep duration and the presence of a sleep disorder can be accounted for by genetic effects [7, 8]. These and other studies have shown that a number of sleep aspects are strongly determined by genes.

Animal studies (mainly in mice and rats) show the presence of considerable interindividual variations in the different aspects of sleep even when animals are kept under identical environmental conditions from birth. Nevertheless, when several inbred strains of mice or rats are recorded, a far greater interstrain than intrastrain variability is reported for non-REM (NREM) and REM sleep, again indicating that environmental factors play a secondary role [9–17]. As

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_29

every aspect of sleep needs to be considered as a separate complex trait, a systematic approach is necessary to identify the genetic factors underlying each of these traits. In the early 1970s, Valatx [9] pioneered the experimental genetics of sleep by studying inbred, recombinant inbred, and hybrid mice. He reported that several aspects of sleep, including the amount of paradoxical sleep, are controlled by genetic factors [10, 11]. These studies, complemented with a diallelic study by Friedmann [12], clearly suggested that, although some aspects of sleep can follow a simple segregation, most other sleep traits cannot be predicted by classic genetic laws. Among many animal models [18], the fruit fly *Drosophila melanogaster* is a highly valuable one for dissecting the molecular mechanisms underlying sleep. This invertebrate shows all the features of sleep: It has a consolidated, circadian period of inactivity, which is characterized by increased arousal thresholds as well as a specific posture and resting place, and its rest is homeostatically regulated [19, 20]. Thus, rest in *Drosophila* is a sleeplike state. Moreover, this model organism is small, economical, and rapidly reproducing and has fewer genes, constituting an excellent tool for genetic analyses [21]. So far, nearly 20 genes have been identified in fruit flies that regulate sleep and some of these genes were also characterized in the mouse model [22].

One of the major advantages of animal models is the possibility of genetic manipulation by loss or gain of function of key genes. Based on the available knowledge in physiology and pharmacology, candidate genes can be identified and experimentally manipulated to assess their role in sleep. The first transgenic investigations in the field of sleep research included the cytokine pathway [23], with *Il1a*, *Il10, Tnf,* and *Tnf* receptors 1 and 2; the neurotransmitter pathway [24], with dopamine, histamine, and serotonin; and the clock genes [22, 25]. So far, hundreds of reports in transgenic animals suggest that in almost all cases, some significant sleep effects are observed confirming the involvement of the underlying genes. Therefore, the candidate gene approach is only valuable in verifying whether a gene of interest has any detectable effect and cannot help in identifying new genes.

Since sleep and wakefulness are very different in terms of brain activity, physiology, and behavior, it is reasonable to expect that there are differences also at the level of gene expression. Moreover, the temporal dynamics of sleep homeostasis, indexed as EEG delta power in NREM sleep, are compatible with the dynamics of gene expression, and sleep deprivation could thus lead to changes in gene expression. This should help to find genes functionally relevant to the homeostatic regulation of sleep, although it cannot be ruled out that the changes in expression of some of these genes are merely driven by the sleep–wake distribution instead of being functionally relevant.

In 1990, by using the substractive hybridization techniques in rats sleep deprived for 24 h, Rhyner and colleagues [26] were the first to isolate several messenger RNA (mRNA) clones with relative increased or decreased expression in the brain. Analysis of the structure of two of these clones identified neurogranin and dendrin [27]. Neuner-Jehle et al. [28] demonstrated that mRNA and protein for neurogranin and dendrin were differentially modulated in different regions of the rat brain by prolonged wakefulness. The laboratory of Cirelli and Tononi has continued this work to include changes in gene expression after spontaneous periods of sleep and wakefulness and long-term sleep deprivation in rats [29]. They have used several techniques such as mRNA differential display and complementary DNA microarrays to systematically screen brain gene expression. These authors have screened 10,000 of the 30,000 genes estimated to be expressed in the rat cerebral cortex, and their results indicate that approximately 5 % seem to be modulated by sleep and wakefulness [30]. The majority of genes are upregulated during sleep deprivation/spontaneous wakefulness relative to sleep. The same genes changed their expression during spontaneous wakefulness and sleep deprivation, but in the latter condition, the changes were more pronounced. A few genes are upregulated during sleep, but so far, their function remains mostly unknown (e.g., membrane protein E25). Similar results were reported by other groups in mice [31–33].

Modulated genes include a few functional categories [31–34] such as immediate early genes, transcription factors, growth factors, adhesion molecules, heat shock proteins, neurotransmitters, hormone receptors, metabolism and energy proteins, transporters, and enzymes.

Two major classes of genes are rapidly induced after only 3–6 h of wakefulness or sleep deprivation: the immediate early genes/transcriptional factors (*Homer1a*, *Arc*, *Fos,* and *NGF1-A*) and the mitochondrial genes. The immediate early genes are a specific class of genes that are rapidly induced by a variety of extracellular stimuli. The expression of *Fos* (a protein released during cellular or activation) is increased in the ventrolateral preoptic area during sleep, suggesting a sustained cellular activity in this area during sleep [35, 36]. After 6–8 h of wakefulness, there is an upregulation of genes related to energy metabolism such as those for glucose transporter (*Glut1*), glycogen synthase, and glycogen phosphorylase. The genes for several heat-shock proteins and chaperones, such as *HSP60, HSP70,* and *BiP,* are also upregulated [31, 37, 38]. These findings illustrate that the molecular genetics approach, complemented with other genetic techniques, is powerful in identifying new genes that are implicated in sleep homeostasis and that the mouse, rat, and drosophila models are appropriate models, especially when used in parallel.

Although these data demonstrate that the molecular approach is a valuable tool to find sleep genes, a gene that does not show transcriptional modification may nonetheless play an important role. New techniques are emerging to profile gene expression at the cellular level, such as laser capture microdissection [39], polyA-binding protein tagging [31], or

ribosome tagging [40] combined with high-throughput linear amplification of RNA and RNAsequencing [41, 42]. Nevertheless, these techniques are not suitable for the identification of constitutively expressed sleep genes, which can only be discovered by forward genetics.

Conceptually, the forward genetic approach is the most powerful strategy for the isolation of genes involved in any biological process, since it is the only approach that does not make any biased assumptions. In the genomewide search for genes affecting a particular phenotype, no a priori assumptions on the gene systems involved are made. Although this approach may lead to already known physiologic mechanisms, its strength is that systems previously unknown to be involved in sleep may be uncovered. Therefore, a genomewide search is the method of choice if we are to discover new "sleep" genes.

Mutagenesis

Whereas the quantitative trait loci (QTL) analysis (see later) aims at identifying "naturally" occurring allelic variants or gene mutations that modify sleep, mutagenesis is based on a randomly induced mutation approach. A strong mutagen such as ethylnitrosourea (ENU) is used to mutate spermatogonia. Assuming a mutation frequency of 0.0015 per locus per gamete [43], there is approximately a 50 % probability of finding a dominant mutation by screening a first generation of 650 offspring. With high-throughput screening for either dominant or recessive mutations, a major effect on a given trait can be identified. The individual mouse or fruit fly for which an aberrant phenotype has been identified has then to be crossed to establish the mode of inheritance of that trait. The isolation of *Clock* is an excellent example of the feasibility of this technique [44, 45]. After the treatment of mice with ENU, Vitaterna et al. [44] observed a mouse exhibiting a longer circadian period of approximately 25 h when kept in constant darkness. This mouse was crossed with a wild-type mouse to establish the mode of inheritance of the trait. The mutated animal carried a semidominant mutation in a locus required for the maintenance of normal circadian rhythmicity. Linkage analysis mapped this trait onto chromosome 5; a positional cloning was undertaken, and the mutated gene *Clock* (Circadian Locomotor Output Cycle Kaput) was identified [45]. Later, this technique allowed the discovery of *Rab3a,* with a mutation that altered both circadian period and homeostatic response to sleep loss, in the mouse [46].

The choice and success of each of the approaches are determined by the gene effect. Although some mutations can induce remarkable phenotypic changes, others produce only subtle effects that, in addition, can be confounded by gene–gene interactions (epistasis) and genetic background (modifier gene) [47]. Mutagenesis is therefore more successful for fully penetrant dominant or recessive mutations, whereas QTL analysis is more powerful in detecting natural allelic variations controlling complex traits [48].

QTL Analysis

QTL has been proposed as a powerful approach in the genetics of complex traits. A quantitative trait is a phenotype showing continuous variations in a population. Generally, complex phenotypes such as sleep are regulated by multiple genes, each of them having a small effect. The QTL technique is based on DNA natural polymorphisms, which are nonlethal mutations preserved in a population because of their neutral, subtle, or advantageous effect. As discussed in this section, QTL analysis can be successfully applied to the genetic dissection of both the sleep amount and the sleep EEG.

QTLs for Sleep Amount

The 24-h amount of sleep also shows highly significant differences between inbred mouse strains [9, 11, 15]. The two extremes regarding the amount of sleep over a 24-h period are AKR/J (AK) and DBA/2J (D2) strains. AK mice sleep 3 h more than D2 mice. Multiple genes may be found to be responsible for this difference, and therefore, a QTL analysis is appropriate. A first QTL analysis was performed in 7 CXB (BALB/cByJ × C57BL/6ByJ) recombinant inbred lines for the amount of REM sleep, and four QTLs were identified on chromosomes 5, 7, 12, and 17 [49]. Toth and Williams [50] studied sleep in a larger CXB recombinant inbred panel and found QTLs on chromosomes 4, 16, and 17. Both QTL studies reported different loci for the duration of diurnal and nocturnal and for total REM sleep time during 24 h, suggesting that different genes are involved in the expression and regulation of REM sleep. In both studies, none of the QTLs could satisfy a stringent statistical significance level certainly due to the small number of recombinant inbred strains (7–13).

A significant QTL was identified in 25 BXD recombinant inbred lines (C57BL/6 and DBA/2) on chromosome 1 for the amount of REM sleep in the 12-h light period [51]. Overall, between 40 and 60 % of the variance in sleep amounts and distribution can be explained by the additive effects of 6–15 genes in BXD recombinant inbreds, indicating, as for other complex traits, a polygenic basis for sleep. So far, no significant QTL has been found for the amount of NREM sleep [49, 51].

QTLs for Sleep EEG

In 1996, van Beijsterveldt et al. [52] recorded the waking EEGs of 91 MZ and 122 DZ twins during quiet resting with eyes closed. Spectral powers were calculated for the frequency bands alpha, beta, delta, and theta. The average heritabilities for all these frequencies bands were 76 % for delta, 89 % for theta and alpha, and 86 % for beta. In other

words, the rhythmic brain electrical activity is one of the most heritable traits in humans [52–54]. This important finding in humans was extended to the EEG activity during sleep in mice by using quantitative genetic analysis and in MZ twins in humans [14, 55, 56].

Quantitative analysis of the spectral EEG activity during sleep demonstrates an important variation between different inbred strains for both REM and NREM sleep [14]. The theta peak frequency (TPF) was found to vary greatly with genotype [14, 57]. The TPF was significantly different between C57BL/6J (B) and BALB/cByJ (C) mice during REM sleep, the first being slow (5.75–6.25) and the second fast (6.75–7.75). Over 80 % of the interstrain variability could be explained by genetic effects. In BXC F1 mice, the TPF was similar to that of B and significantly faster than C mice, suggesting that the C allele was recessive. By using 89 polymorphic markers, QTL analysis in 47 F2 mice identified a single highly significant locus on mouse chromosome 5, suggesting the presence of an autosomal recessive phenotype under the control of a single gene. This single locus could explain more than 65 % of the variance. After genotyping a backcross population, a strong linkage was found with the polymorphic marker D5Mit240. By genotyping 200 additional backcross mice and recording sleep in 31 selective recombinant mice, the region of interest was narrowed down to 2.4 cM. Different candidate genes were analyzed, and the short-chain acyl-coenzyme A dehydrogenase gene (*Acads*) within the region showed a spontaneous mutation in C mice. This finding suggests a major role for mitochondrial β-oxidation during sleep, which is fatty acid chain-length specific because long-chain acyl-coenzyme A dehydrogenase (*Acadl*) deficiency does not affect theta frequency. This finding constitutes the first identification of a sleep QTL [57].

It was also noticed that, during NREM sleep, DBA/2J (D2) mice show a reduced delta activity and have their EEG dominated by theta activity compared to most other inbred strains. The theta–delta ratio (TDR) on relative power spectra was determined for B6 and D2 mice and differed by more than 5 standard deviations [58]. The TDR of the F1 mice was similar to that of B6 mice and significantly different from D2 mice, suggesting that the D2 allele is recessive. A panel of 25 BXD recombinant inbred lines was recorded and QTL analysis was performed with more than 800 polymorphic markers on the whole genome. A single significant QTL was identified in the centromeric region of chromosome 14 that was responsible for more than 55 % of the total variance, clearly indicating the presence of an autosomal recessive gene. Fine mapping revealed a single-nucleotide polymorphism in the second untranslated exon of the retinoic acid receptor beta gene (*Rarb*). The different transcripts of this gene were amplified by reverse transcriptase polymerase chain reaction and sequenced. Seven polymorphisms including the biallelic marker were found between B6 and D2, one silent in the coding region and five in the untranslated 5′ regions. To test this candidate gene, we recorded different transcript knockout mice and their D2 hemizygotes. While the *Rarb* knockout had increased delta activity, a complete recovery of delta power was observed in *Rarb1,3*/D2, confirming the implication of this gene. *Rarb* transcripts were expressed at significantly higher levels in the brains of D2 compared to B6 mice, indicating that the polymorphisms in the gene had an effect on the transcription in vivo. By testing six other inbred strains, we noticed that only *Rarb1* varied with delta power. Retinoic acid, the active derivative of vitamin A, plays a major role during ontogenesis and particularly during the development of the brain through dopaminergic pathways. Sleep and the sleep EEG are also developmentally regulated. Whether it is through brain development and plasticity or through dopaminergic pathways that *Rarb* regulates the contribution of delta activity during slow-wave sleep (SWS) remains to be documented [58, 59].

QTLs for Sleep Homeostasis

Two main processes regulate sleep: a circadian and a homeostatic process. 122 Delta power, a measure of EEG activity in the 1 to 4 Hz range, in SWS is in a quantitative and predictive relationship with prior wakefulness. Delta power is negatively correlated with the response to arousing stimuli [60] and SWS fragmentation [61] and therefore can be seen as a measure of SWS intensity. Sleep loss evokes an increase in delta power during subsequent SWS that is proportional to the loss [62–64], whereas excess sleep results in an attenuation of delta power. [65] The time constant for the accumulation of a need for NREM sleep (increase in delta power), but not for its decline, varies greatly between inbred mouse strains [64]. QTL analysis was performed in 25 BXD recombinant inbred strains for the segregation of the rebound of delta power after 6 h of sleep deprivation. Results showed that additive genetic factors accounted for more than 67 % of the total variance [64]. By analyzing 788 polymorphic markers for a genomewide scan, a significant QTL was identified on chromosome 13 and a suggestive one on chromosome 2. The QTL on chromosome 13 explained 49 % of the total variance in delta power rebound, suggesting the presence of a major gene. Confirmation of the chromosome 13 QTL was obtained in baseline recordings of the same animals. This result suggests that sleep need is under strong genetic control and genes can be identified underlying NREM sleep homeostasis.

By using gene profiling in three inbred mouse strains differing in their sleep need, we have identified *Homer1a* as the best transcriptional marker of sleep need [31]. Interestingly, *Homer1a* maps exactly to the same chromosome 13 QTL that we had already identified for sleep need. We have also generated transgenic mice to investigate the transcriptional changes occurring in *Homer1a*-expressing neurons in the brain after sleep deprivation. Again, *Homer1a* was identified together with four other activity-induced genes, all

upregulated by glutamate. Homer1 proteins are postsynaptic density proteins linking metabotropic glutamate receptors to other intracellular effectors mediating the effects of *N*-methyl-D-aspartate and aminohydroxymethyl isoxazole propionate receptors as well as the intracellular calcium stores. Activation of Homer1a disrupts this signaling pathway and buffers the intracellular calcium. Our findings suggest a role for sleep in intracellular calcium homeostasis for protecting and recovering from the neuronal activation imposed by wakefulness. Since *Homer1a* is also induced by electroconvulsive therapy and antidepressants, we propose that its induction by sleep deprivation might correlate with the well-documented antidepressant effects of sleep deprivation.

Genetics of Sleep Disorders

Normal sleep is a highly complex behavior in its regulation and physiology, and a single defect at the molecular level of one of its component can cause a dysregulation and lead to a very disabling sleep disorder. As the molecular mechanisms of normal sleep are just beginning to be elucidated, the study of sleep disorders might be an alternative approach to understand the sleep function and to find new drug targets. With the recent discovery of the hypocretin deficiency in canine and human narcolepsy, the genetics of sleep and sleep disorders appears as a very promising avenue in our understanding of sleep disorders. Familial and twins studies indicate an important influence of genetic factors on sleep disorders, and the recent linkage analysis and candidate gene analysis on multiplex families resulted in the discovery of gene mutations, susceptibility factors, or linkage evidence in several sleep disorders. Three diseases are reported to result from a single-gene mutation: FFI, familial advanced sleep-phase syndrome (FASPS), and primary insomnia. A unique narcolepsy case has also been observed to be caused by a single-gene mutation. Most other sleep disorders have complex genetics with susceptibility genetic factors and environmental effects.

Disorders Caused by a Single Gene

Fatal Familial Insomnia

In 1986, Lugaresi et al. [66] described a 53-year-old man who suffered from progressive insomnia, dysautonomia (pyrexia, diaphoresis, myosis, and sphincter disturbances), dysarthria, tremor, and later myoclonus and coma, identifying the first sleep disorder for which a gene mutation has been identified: FFI. Two sisters of the patient and several relatives had the same symptoms leading to coma and death after 9 months. The major features of FFI include a progressive reduction of sleep duration, an early disappearance of sleep spindles, a loss of SWS, and the disintegration of the NREM-REM sleep cycle [67]. This autosomal dominant disease affects both sexes equally, with high penetrance, and leads uniformly to death. Parchi et al. [68] observed on postmortem tissues a massive neuronal loss and astrogliosis in the mediodorsal thalamic nuclei in association with relatively modest amounts of abnormal prion protein. Selective atrophy, loss of neurons, and astrogliosis of the anteroventral thalamic nucleus cause behavioral changes, whereas impairment of the mediodorsal thalamic nucleus disrupts sleep and wakefulness and is associated with the loss of EEG spindle activity [69]. The damage of serotonergic and γ-aminobutyric acid (GABA)ergic neurons leads to sleep–wake disturbance [66, 67]. The degenerations of the thalamic nuclei are caused by a point mutation at codon 178 of the prion protein gene (*PrP*) on chromosome 20 [70].

Familial Creutzfeldt–Jacob disease (CJD) is also associated with codon 178 mutation (substitution of asparagine for aspartate) and spongiform degeneration leading to dementia, but the two conditions differ at codon 129, with all FFI patients having a methionine and CJD patients having a valine at this position. Furthermore, homozygosity at codon 129 seems to have a clinical course of less than 1 year, severe insomnia, continuous motor overactivity, and severe dysautonomia [71]. The prion protein becomes protease resistant in the brain and is implicated in a group of disorders of the central nervous system termed *spongiform encephalopathies,* but the mechanism by which the mutant prion protein exerts its toxic effects remains unknown.

In 1999, Mastraianni et al. [72] described a patient with symptoms and lesions very similar to those of FFI but lacking the mutation at codon 178, suggesting a sporadic form of fatal insomnia. Parchi et al. [73] reached the same conclusion by studying five new patients. Mastraianni inoculated mice with brain homogenates from subjects having FFI or sporadic fatal insomnia and observed the same type and distribution of cerebral lesions [72]. Therefore, fatal insomnia can occur in the absence of the D178 N mutation.

Familial Advanced Sleep-phase Syndrome

FASPS is an abnormality of human circadian behavior that segregates in a highly penetrant autosomal dominant manner. Polysomnographic measurements of sleep and plasma melatonin and body temperature rhythms indicate that all measures are phase advanced by 4 h [74]. Genetic studies in drosophila, fungi, plants, and animals led to the identification and characterization of clock genes responsible for circadian behavior [75]. In mammals, several genes are determinant for circadian oscillation: *clock, bmal1, per,* and *cry.* Toh et al. [76]. found a four-generation family linkage between FASPS and the marker D2S395 on chromosome 2qter where the *PER2* gene maps. An *hPer2,* a human homolog of the *Drosophila period* gene, was found to be

mutated in affected members of one family with FASPS [76]. A mutation at position 2106 (A to G) of the hPer2 complementary DNA leading to a substitution of a serine at amino acid 662 for a glycine (S662G) is therefore responsible for FASPS in this family. The mutation affects the casein kinase I epsilon (CKIε)-binding domain of hPER2 protein and causes hypophosphorylation of CKIε in vitro. In a mammalian clock model, mPer2 is a positive regulator of the Bmal1 feedback loop, raising the possibility that phase advance of hPer2 could phase advance the feedback loop [77]. However, not all the families tested, and not all members of the same family, are linked with the hPer2 locus, suggesting a genetic heterogeneity in FASPS.

Another study identified a missense mutation (T44A) in the human CKIδ gene in a three-generation family affected by FASPS [78]. An A-to-G mutation was identified to be responsible for a threonine-to-alanine alteration at amino acid 44 in the CKIδ protein. This mutant kinase also decreases the enzymatic activity in vitro. When this mutated gene was introduced into *Drosophila,* it was found to lengthen the circadian period. Transgenic mice were also created with a human BAC clone containing the entire wild-type CKIδ gene with the T44A variant, and an opposite effect was observed: free-running periods were significantly shorter in these mutant mice. This suggests that the interactions of the clock components as part of the circadian network may be different or species dependent [78].

Short Sleep

Sleep length varies considerably and is normally distributed in most species. Nevertheless, short and long sleep durations run in families and might be genetically controlled. Short sleepers have been of interest to understand how sleep is regulated and seem to be under a higher sleep pressure [79]. Whether a single gene may regulate sleep duration was questioned but in some families, the trait seems to segregate in an autosomal dominant manner. He et al. [80] sequenced several genes involved in circadian rhythms in 60 short sleeper families and identified a point mutation in the transcription factor *hDEC2*. The exact function of DEC2 is not clearly understood but may act as a negative regulator of the circadian clock [81]. The identified mutation in hDEC2 (proline-to-arginine 385) was introduced into mice and caused a 1.2-h longer circadian period and shorter sleep. Similar experience with drosophila also resulted in shorter sleep, confirming that the mutation affects causally the sleep length [80]. Nevertheless, hDEC mutations seem to be extremely rare and so far only a single family with a mutation has been identified.

Primary Insomnia

Molecular studies of primary insomnias are very rare, but a study reported a missense mutation in a single patient with chronic insomnia. This mutation is a substitution of the amino acid arginine for histidine at position 192 (R192H) in exon 6 of the gene coding the $GABA_A\beta3$ subunit, altering $GABA_A$ receptor function in vitro [82]. The β3 subunit is suggested to be implicated in sleep processes by the observation that β3 knockout mice are not responsive to the hypnotic action of oleamide [83].

Narcolepsy

In 2000, Peyron and colleagues reported the first case of human narcolepsy caused by a point mutation, impairing hypocretin trafficking and processing [84]. A patient with severe symptoms and a very early age at onset (6 months) had a T-to-G transversion in the pre-prohypocretin gene, resulting in a leucine-to-arginine substitution in the signal peptide. Whether this mutation was a de novo or inherited could not be determined.

Familial forms of narcolepsy are very rare and probably represent less than 2 % of all narcolepsy cases. Available families suggest that narcolepsy might be caused by a single-gene mutation and two previous studies have localized two different loci on chromosome 4 and 21 but the underlying mutations were not identified [85, 86]. More recently, a large family with 12 affected members was identified in Spain. Linkage analysis in this family localized a single locus on chromosome 6. Exome sequencing in 3 affected members revealed a single mutation within the linkage region on chromosome 6 [87]. The missense mutation (a c.398C>G) was found in the second exon of myelin oligodendrocyte glycoprotein (MOG), only in affected family members. Transient expression of the mutant MOG in mouse oligodendrocytes showed aggregated subcellular localization, strongly suggesting an abnormal function [87].

Mutations in DNA methyltransferase 1 (DNMT1) were recently reported in several families with a rare condition known as cerebellar ataxia, deafness, and narcolepsy [88, 89].

Disorders with Human Leukocyte Antigen Association

REM Sleep Behavior Disorder

REM sleep behavior disorder (RBD) is a parasomnia that mainly affects middle-aged or older men. It occurs only during REM sleep and is characterized by the loss of skeletal muscle atonia related to REM, resulting in complex and vigorous dream-enacting behaviors [90]. An association with drug use, toxic exposure, and neurologic disorders is reported [91]. Gagnon et al. [92] reported that RBD was detected using polysomnographic recordings in about 33 % of patients with Parkinson's disease. RBD-type behaviors may be seen in up to 25 % of Parkinson's disease patients

[93] and may appear before the onset of motor symptoms of this disorder in approximately 40 % of older-onset RBD patients [94]. RBD is also associated with dementia with Lewy bodies [95]. These two associations reflect an underlying synucleinopathy. Genetically, RBD seems associated with the human leukocyte antigen (HLA) DQw1 allele, more precisely with DQB1*05 and DQB1*06 [96]. Replication studies are needed and should be facilitated by the increasing number of patients diagnosed with this disorder.

Sleepwalking

Sleepwalking is a frequent childhood parasomnia, affecting up to 20 % of children [97], but generally disappears at adulthood [98]. Sleepwalking is a disorder of arousal occurring during SWS [99], generally shortly after sleep onset, and resulting in complex movements including walking during sleep with a partial or complete amnesia the next day. Epidemiologic surveys, including familial and twins studies, suggest a strong genetic predisposition in sleepwalking [100–102], with over 50 % of concordance for MZ compared to 10–15 % for DZ twins [100, 101, 103]. The prevalence of sleepwalking in first-degree relatives of an affected subject is at least 10 times greater than in the normal population [100]. Two modes of inheritance have been proposed, multifactorial [103] and autosomal recessive with incomplete penetrance [104]. In a study in 60 caucasian subjects and their families, we have reported a positive association between the HLA DQB1*05 subtype [105]. The frequency of DQB1*05 was increased in sleepwalking patients, while DQB1*0602 (associated with narcolepsy) was slightly decreased. Detailed analysis in families indicated that the polymorphic amino acid Ser74, shared by all DQB1*04 and *05 alleles, is the HLA DQB1 polymorphism most tightly associated with this parasomnia. DQB1*05 has also been implicated in RBD [96]. A common genetic predisposition to sleepwalking and RBD may explain the coexistence of both disorders in some patients. Further replication and family studies are needed to confirm this association.

Kleine–Levin Syndrome

Kleine–Levin syndrome is a rare and mainly sporadic disorder characterized by periodic hypersomnia and different behavioral abnormalities such as cognitive and mood disturbances, compulsive hyperphagia, hypersexuality, and dysautonomics [106–109]. The etiology of Kleine–Levin syndrome is unknown, although an intermittent dysfunction at the diencephalic–hypothalamic interface was suggested [110, 111]. Another hypothesis is an imbalance in serotonergic or dopaminergic systems or an abnormality in the metabolism of these neurotransmitters [112, 113]. Familial forms are extremely rare but Katz and Ropper reported a familial case with two affected siblings [114]. The sister and brother shared the HLA DR2 and DQ1 antigens. In a study in 30 unrelated patients and their families, we have observed an increased frequency of the HLA DQB1*0201 allele (28.3 vs. 12.5 % in controls) [115]. Three of the patients but none of the controls were homozygous for this allele. In 17 heterozygous parents, 11 (64.7 %) had transmitted this allele, suggesting a preferential transmission. The recurrence of the episodes, the frequent infectious precipitating factors at onset, young age at onset, and the association with HLA DQB*0201 are in favor of an autoimmune etiology for this disorder [115].

Delayed Sleep-phase Syndrome

Despite normal sleep architecture, delayed sleep-phase syndrome (DSPS) is characterized by a persistently delayed sleep onset and offset. Shibui et al. [116] found that the melatonin rhythms of these patients were delayed compared to controls. However, the mechanism underlying this disease is still unknown, although different hypothesizes have been proposed: a prolonged intrinsic period beyond the range of entrainment to the 24-h day, a reduced sensitivity of the oscillator to photic entrainment, or an abnormal coupling of the sleep–wake cycle to the circadian rhythm [117–119]. Although DSPS seems to have a heterogeneous etiology, associations with HLA DR1 [120] and PER3 gene polymorphisms [121, 122] have been reported. The exact role of PER3 is not clearly established, but this protein heterodimerizes with PER1 and PER2 and CRY1 and CRY2 before entering the nucleus to inhibit the transcriptional CLOCK/BMAL1 complex [123, 124]. An alteration of PER3 phosphorylation could change its function and alter the cellular circadian machinery.

Narcolepsy

Narcolepsy is a rare and disabling disorder characterized by a tetrad of symptoms: cataplexy, excessive daytime sleepiness, sleep paralysis, and hypnagogic hallucinations [125, 126]. In Western countries, the prevalence is 0.03–0.1 % of the general population [127]; in Japan, the prevalence is the highest [128], and in Israel, the lowest [129]. The onset of the disease occurs between 15 and 30 years of age with a potential effect of the month of birth [130–132], generally with both sexes equally affected. The major abnormality in narcolepsy is an intrusion of REM sleep-like features during wakefulness, such as hypnagogic hallucinations, sleep paralysis, and cataplexy and an inability to stay asleep during the nighttime and awake during the daytime [133–135]. Less than 2 % of narcolepsies are familial but the risk for first-degree relatives is 20–40 times higher than for the general population [136]. This indicates a strong genetic influence on the development of the disease. However, twin studies reported only 25–31 % concordance, clearly indicating a major importance of environmental factors [137].

Numerous studies have demonstrated that narcolepsy has one of the tightest associations with a specific HLA allele. First an association with HLA class I Bw35 was reported in Japanese patients, whereas in caucasians, HLA Bw7 was associated [138, 139]. In the early 1980s, a 100 % association with HLA DR2/DQw1 was shown in Japanese patients [138] and up to 98 % in Caucasians [140]. Four alleles corresponding to DRB1*15:01, DRB5*01:01, DQA1*01:02, and DQB1*06:02 are associated with the disease. About 88–98 % of patients affected by narcolepsy with clear cataplexy are HLA DQB1*0602 positive, versus 40–60 % of narcolepsy patients with mild or atypical or no cataplexy [141]. The contribution of HLA is complex and recent results indicate that other DQB1 alleles increase or protect against narcolepsy [140, 142].

Although HLA DQB1*0602 remains the best genetic marker for narcolepsy, other genetic factors contribute to its susceptibility. Several studies have sought associations with non-HLA gene polymorphisms. A significant association between narcolepsy and the monoaminergic pathway involving monoamine oxidase A (MAO-A) and the catechol-*O*-methyltransferase (COMT) gene was reported [143–145]. A sexual dimorphism in the activity of the COMT gene as well as an effect on the severity of daytime sleepiness suggests a more critical alteration of the dopaminergic/noradrenergic than the serotonergic pathways in the pathophysiology of narcolepsy [144]. *COMT* genotype seems to influence sleep-onset REM periods together with sleep paralysis. Another study reported an involvement of tumor necrosis factor (TNF)-α promoter polymorphism in narcolepsy [146]. *TNFA* may be another susceptibility gene, particularly in association with HLA DRB1*15:01 [147]. Another association with TNF receptor 2 has been reported in Japanese patients, indicating the possibility of an additive effect [148]. Nevertheless, these candidate gene studies are commonly difficult to replicate and more recently are abandoned and replaced by genomewide association studies (GWAS) where hundreds of thousands of single-nucleotide polymorphisms (SNPs) are genotyped at once all over the genome. Thus, a first GWAS in Japanese patients found an association with variants in CPT1B and CHKB on chromosome 22 [149]. The first GWAS in Caucasians did not confirm the association found in Japanese but noted a new association with several variants within the T-cell receptor alpha locus (*TCRA*) [150]. This association was confirmed by us in European narcolepsy patients, and an additional but protective HLA variant (DQB1*06:03) was also discovered [142]. Another GWAs found evidence for association between narcolepsy and common variants in P2RY11 [151]. Given the implication of the immune system in the pathophysiology of narcolepsy, a large international study including 1886 narcolepsy patients and over 10,000 controls were carried out with a custom genotyping array that contained all variants within the genomic regions involved in all immune-related disorders (so-called immunochip study) [152]. This study discovered 2 new immune-related genes associated with narcolepsy: *TNFSF4* and *CTSH*, strengthening the immune origin of the disease [152]. However, in a recent study by us in 1261 European narcolepsy patients, only variants within the HLA and TCRA, could be replicated [140].

Narcolepsy is also found in dogs and is clinically and electrophysiologically similar to the human disease. Through linkage analysis and positional cloning, mutations in the hypocretin-2 receptor were identified as the cause of canine narcolepsy [153]. Simultaneously, a similar phenotype in mice was observed after a targeted deletion of the pre-prohypocretin gene [154]. The human 131 amino acid pre-prohypocretin is encoded by a gene on chromosome 17q21 and is synthesized by neurons located exclusively in the lateral, posterior, and perifornical hypothalamus [155]. A mutation in the pre-prohypocretin gene was identified in an atypical case of narcolepsy, but so far, no mutation has been found in hypocretin receptors genes. In a few post-mortem narcoleptic brains, an 85–95 % reduction in the number of hypocretin neurons has been reported, strongly suggesting that a selective destruction of hypocretin neurons in the hypothalamus is the most probable etiology for narcolepsy [84, 156]. Since 90 % of human cases of narcolepsy are sporadic and monozygotic twins show only partial concordance (25–31 %), the development of the disease should involve environmental factors directly interacting with genetic susceptibility factors. Therefore, because of the tight association with HLA, an autoimmune process could be the cause of an acute or progressive and selective degeneration of hypocretin-containing neurons in the hypothalamus. Environmental factors might trigger narcolepsy by inducing an autoimmune reaction that targets hypocretin-containing neurons.

Disorders with Other Gene Associations

Obstructive Sleep Apnea Syndrome

Obstructive sleep apnea syndrome (OSAS) is a common, chronic, and complex disorder characterized by repetitive episodes of upper airway obstruction that occur during sleep, usually associated with a reduction in blood oxygen saturation. OSAS typically leads to excessive daytime sleepiness, an increased risk of high blood pressure, and cardiovascular complications. Snoring is one of the main symptoms of OSAS, but while 30–50 % of the general population snores, only 4–5 % are affected by OSAS [157]. The concordance rates for snoring and OSAS are higher in MZ than DZ twins, with heritabilities of about 50 % [157, 158]. Numerous families of patients have been reported to be

at significantly higher risk. The segregation is explained by the fact that most of the risk factors involved in the pathophysiology of this condition are largely genetically determined. Body fat distribution and metabolism (especially upper body obesity), craniofacial dysmorphism, central regulation of breathing, and neural ventilatory control abnormalities predispose to the obstruction of the upper airways. Palmer et al. [159] performed a 9-cM genome scan on 66 white pedigrees and found linkage between the apnea–hypopnea index and chromosome 1p (lod score = 1.39), 2p (1.64), 12p (1.43), and 19p (1.4). Body mass index was linked to significant markers on 2p (lod score = 3.08), 7p (2.53), and 12p (3.41). After adjustment for body mass index, suggestive lod scores for OSAS persisted only on chromosome 2p (1.33) and 19p (1.45) [159].

Three other studies reported a possible link between apolipoprotein E ε4 and OSAS [160, 161, 162]. Apolipoprotein E is a polymorphic protein encode by three alleles at a single-gene locus on chromosome 19q13. The same allele has been associated with Alzheimer's disease and cardiovascular disease in the general population. The probability of moderate to severe sleep-disordered breathing is significantly higher in patients with apolipoprotein E ε4, independently of age, sex, body mass index, and ethnicity. This potential association is not, however, confirmed in older patients (>79 years old). A polymorphism in angiotensin-converting enzyme was also reported in moderate OSAS and was found to be tightly associated in hypertensive patients [163]. Finally, another study indicated an association between haptoglobin polymorphism and OSAS complicated with cardiovascular disease, suggesting that haptoglobin phenotype is an important susceptibility factor [164]. Several international GWASs are underway to find new association with different features of OSAS.

Restless Legs Syndrome

Restless legs syndrome (RLS) is one of the most common sleep and movement disorders, affecting 2–5 % of the general population [165]. According to the diagnostic criteria, RLS is characterized by an irresistible desire to move the limbs, usually associated with paresthesias and/or dysesthesias and motor restlessness, and results in nocturnal insomnia and chronic sleep deprivation [165]. RLS affects both sexes equally and the age at onset is variable, although early onset and anticipation phenomena have been reported in familial cases [166, 167]. Several studies reported that more than 50 % of patients with RLS had a positive family history and that an affected person is three to six times more likely to have a family history than an unaffected person [165]. The symptoms start or worsen at rest and improve with activity. In over 87 % of cases, RLS is associated with periodic limb movements in sleep (PLMS) [168]. The pathophysiology of RLS is still unknown, although dopaminergic dysfunction and brain iron metabolism abnormalities have been implicated [169].

Pedigree analysis in families of 12 pairs of monozygotic twins suggested an autosomal dominant mode of inheritance and 83 % concordance in monozygotic twins [170]. A genetic basis of this syndrome is supported by studies reporting a positive family history in 63–92 % of patients, strongly suggesting that a significant portion of the familial aggregation is due to genetic factors, proposed to be transmitted with an autosomal dominant mode of inheritance with incomplete penetrance and probable anticipation effect [171, 172]. An RLS susceptibility locus has been mapped on the short arm of chromosome 12 in a large French Canadian family (lod score = 3.59) [173]. Two main candidates in the region are the neurotensin gene (12q21), an important modulator of dopaminergic transmission, and the homolog of the *Drosophila* clock gene *timeless* (12q12-q13). However, another study could not confirm the susceptibility locus in either of the families studied [174]. Other mapping studies in different ethnic groups are needed because the RLS locus on chromosome 12 has been mapped based on a recessive mode of inheritance, while in most familial cases, a dominant mode of inheritance and variable expressivity is evident. This could suggest a genetic heterogeneity for the disease. Accordingly, in a large Italian family with RLS and PLMS, evidence for linkage was obtained on chromosome 14q based on an autosomal dominant mode of inheritance [166]. Another study identified 9p24-22a as a new susceptibility region in two American families, again with the assumption of an autosomal dominant mode of inheritance [175]. Finally, another linkage analysis in a large Italian family reported a suggestive locus on chromosome 19p13 [176]. A putative association between a polymorphism of MAO-A and RLS was reported [177], while another study indicated that a polymorphism of neuronal nitric oxide synthase, which maps to the RLS locus on chromosome 12q, is associated with RLS in whites [178]. As for narcolepsy, several large GWASs were also performed in RLS and/or RLS with PLMS. Five variants within MEIS1, BTBD9, PTPRD, MAP2K5 (SCOR1), and TOX3 were discovered [179–182]. Genetic variations of several of these genes were shown to be also associated with iron homeostasis [181, 183].

Primary Nocturnal Enuresis

Primary nocturnal enuresis is another common type of parasomnia in children, affecting 10 % of 7-year-old children and even 1–2 % of adolescents. Nocturnal enuresis is bed-wetting beyond the age of 5 years, when nocturnal bladder control would normally be expected. Enuresis is referred to as primary if the patient has not had at least 6 months of nocturnal continence. Familial and twins studies have suggested a genetic background for enuresis, although

psychosocial environmental factors have a major modulatory effect [184]. Backwin [185] showed that the incidence of the illness is highest in families in which both parents have been enuretic (77 %). In most cases, enuresis has an autosomal dominant mode of transmission with high penetrance (90 %) [186]. Four gene loci on chromosomes 8q, 13q, 12q, and 22q11 have been identified to be involved in primary nocturnal enuresis, suggesting its heterogeneity and the involvement of different pathways, including the bladder, the kidney, or the central control [184, 186, 187]. A Finnish study in twins reported a concordance rate of 0.43 for MZ versus 0.19 for DZ twins in childhood, whereas it was 0.25 versus 0, respectively, in adulthood [188]. A linkage analysis study reported a 2-point lod score of 4.2 in six families with dominant primary nocturnal enuresis around the aquaporin-2 (*AQP2*) water channel locus (12q) [189]. However, no mutation in the coding sequence was detected, excluding this gene in families in which the disease co-segregates with chromosome 12q.

Conclusions

The number of sleep disorders for which a genetic contribution can be established is expanding rapidly, and both genetic linkage and GWAS of large number of families and cases affected by a well-defined sleep disorder should be systematically undertaken to lead to the discovery of the genetic basis of the disorders and finally to their eventual evidence-based treatment. An interesting and striking feature of an important number of sleep disorders is that they are strongly associated with HLA, suggesting a hypothetical interrelationship between sleep and the immune system that still needs to be discovered. We know that microbial products and cytokines strongly influence sleep–wake behavior and the architecture of sleep, and we know that in humans the primary response to antigens following viral infections is associated with acute enhanced sleep amount, and also that growth hormone-releasing hormone and interleukin-1 have a sleep-promoting effect. However, no direct molecular mechanism has been identified that could link these observations. The relationship between the immune system and sleep–wake behavior may arise at different levels: immune-related molecules could play a role in the development of certain disorders, as hypothesized in narcolepsy, or sleep and brain immunity could be related through stress factors or may even have a regulatory effect on each other.

Finally, two new fields will need special attention in the near future: pharmacogenomics and pharmacogenetics. Pharmacogenomics involves genomewide analysis of the genetic determinants of drug efficacy and toxicity, while pharmacogenetics is the study of genetic causes of individual variations in drug response. Because evidence-based treatments for sleep disorders are rare, investigating the molecular bases of drug response might reveal new pathways where future drugs can be targeted.

Markku Partinen

Introduction

The worldwide epidemic of obesity is currently one of the greatest public health problems. Obesity with high body-mass index has increased globally, and it is the leading risk for the global burden of disease in many parts of the world [1]. Despite declines, tobacco smoking including second-hand smoke remained the leading risk in North America and western Europe. Dietary risk factors and physical inactivity collectively accounted for 10 % of global disability-adjusted life years in 2010, with the most prominent dietary risks being diets low in fruits and high in sodium [1]. Several lines of evidence have shown that disturbed sleep has harmful effects on health, and it may be hypothesized that insufficient sleep and other sleep disorders might be among the important risks in increasing the global burden of disease [2].

Obesity is a strong risk factor for cardiovascular diseases, and it is also an important risk factor for obstructive sleep apnea. New information about effects of nutrition in psychiatric and neurologic diseases has been published during the past 10–20 years. In clinical practice, many narcoleptics of excessive afternoon sleepiness after heavy lunches and especially after eating meals with high contents of carbohydrates. Effects of different types of meals on sleep have been investigated, particularly in the 1960s and 1970s, but amazingly little is still known about effects of food on sleep and alertness. Dietary factors most likely play a much more important role in the regulation of daytime vigilance than what is recognized. As early as the 1960s, Roberts and his collaborators [3] found that, especially in African-Americans, there was an association between diabetes and narcolepsy. They also found that eating carbohydrates during the daytime worsened sleepiness of narcoleptic subjects [3]. More recently, restless legs syndrome (RLS) has been associated with low ferritin levels, suggesting a possible dysfunction in iron metabolism [4–6]. Starting from revolutionary theories by Magistretti and Pellerin [7], there is increasing evidence that glial cells (mainly astrocytes) have a crucial role in brain metabolism [8, 9]. Much new information has also been published about the important role of the enteric nervous system (ENS) and the brain–gut relationship [10–12]. It is possible that nutrition is much more important in sleep–wake regulation, sleep disorders, and the global well-being of our brains than what is currently known.

The most important factors regulating sleep duration and vigilance levels are length and quality of sleep, duration of waking time, and different social and biological *Zeitgebers* (external cues). Also, various medications and nutritional factors have effects on sleep–wake regulation. The direct effect of foods on the central nervous system (CNS) may occur by different routes: direct nervous connections through the vagus nerve and nucleus tractus solitarius (NTS), cognitive processes, and humoral effects.

Enteric Nervous System and Sleep

Signals from different receptors in the gut are transmitted to the CNS by neural connections and humoral effects. The afferent fibers of the gut–brain neural connection run through afferent vagal and sympathetic nerves. The different sensors respond to mechanical stimuli (distention of the stomach, contractions of the intestine) and to chemical stimuli from nutrients in the lumen of the gut and from gut hormones, neurotransmitters, neuromodulators, cytokines, and inflammatory mediators produced by the bacterial flora in the gut (Table 30.1). Almost all if not all neuromediators of the ENS are involved also in sleep/wake regulation or regulation of circadian rhythms. The most studied transmitters are printed in **boldface** and some new transmitters with increased recent interest in sleep research are printed in *italics*. The neural stimuli travel from sensory neurons to interneurons. Different motor, secretory, and vascular reflex activities exist in the body. Information from different parts of the gut also passes to the brain stem for vasovagal reflexes and to the spinal cord

for different spinal reflexes. In the brain stem, most afferent vagal fibers terminate on the NTS. There is a viscerotropic representation of different parts of the enteric system in the NTS. From the NTS, information goes up to the hypothalamus and the amygdala; this information probably plays a role in satiety and emotional aspects of eating and may be

Table 30.1 Neuromediators in the enteric nervous system

• Acetylcholine
• **Adenosine**
• Agouti-related peptide
• Angiotensin II
• Calbindin
• Calcitonin gene-related peptide
• **Cholecystokinin**
• *Cocaine- and amphetamine-regulating transcript peptide*
• **Corticotropin-releasing hormone**
• Cortisol
• **Delta sleep-inducing peptide**
• **Dopamine**
• **GABA (gamma-aminobutyric acid)**
• *Galanin*
• Gastrin-releasing peptide
• **Glutamate**
• **Ghrelin**
• **Growth hormone-releasing hormone**
• Incretins gastric inhibitory polypeptide
• Glucagon-like peptide-1
• *Histamine*
• **Insulin**
• **Leptin**
• *MCH (melanin-concentrating hormone)*
• *α-Melanocyte-stimulating hormone*
• Neuromedin B
• *Neuromedin U and neuromedin S (in the SCN)*
• Neuropeptide Y
• Neurotensin
• *NO (Nitric oxide)*
• **Noradrenaline (norepinephrine)**
• Opioid peptides dynorphin
• Endorphins
• Enkephalins
• **Orexins** (hypocretin), especially orexin A
• Peptide YY (peptide tyrosine tyrosine)
• Pituitary adenyl cyclase activating peptide
• *Prostaglandins (in the gut, especially E and F)*
• Serotonin (5-HT), especially 5-HT_3, 5-HT_4, and 5-HT_{1p} receptors
• **Somatostatin**
• **Substance P**
• Thyrotropin-releasing hormone
• **Vasoactive intestinal peptide**

important in the regulation of alertness, sleepiness, and sleep–wake regulation.

Cholecystokinin and many other humoral factors have a role in the CNS-ENS network. The regulation of the sleep–wake cycle is complex, and there are different theories. The important brain transmitters in sleep–wake regulation include norepinephrine, acetylcholine, 5-hydroxytryptamine (5-HT), dopamine, glutamate, histamine, adenosine, γ-aminobutyric acid (GABA), and hypocretin. Also, prostaglandins and different peptides have an effect on regulation of alertness/sleepiness. In the past, the focus was on norepinephrine, acetylcholine, and 5-HT. They all play important roles, but do not explain "why we sleep." The role of adenosine and regulation of brain energetics is probably central. During wakefulness, extracellular adenosine increases; this increase in adenosine decreases wakefulness and causes sleepiness. Caffeine, the most common stimulant, is an adenosine receptor antagonist.

Role of Neuromediators

Peptides and Hormones

Cholecystokinin is a mixture of peptides, of which octapeptide is the most effective. It is secreted by duodenal and jejunal cells after eating food. Cholecystokinin acts on the gall bladder and the pancreas, stimulating bile production and the release of pancreatic digestive enzymes. It also acts on vagal neurons projecting to the brain stem, giving a signal of satiety that inhibits further need for eating.

Ghrelin is a peptide containing 28 amino acids. It is secreted mainly in the stomach, but its receptors (growth hormone secretagogue receptors) are present widely in the gastrointestinal (GI) tract, the ENS, and also in the CNS neurons around the arcuate nucleus. In the GI tract, ghrelin has prokinetic effects, and centrally it increases appetite. It acts on the hypothalamus to stimulate feeding, counteracting the inhibitory effects of leptin and peptide YY_{3-36} (PYY_{3-36}; see later). Through its actions on the GABA system, ghrelin inhibits pro-opiomelanocortin (POMC) and cocaine and amphetamine-regulated transcript (CART) neurons and decreases production of α-melanocyte-stimulating hormone (*α-MSH;* see later) in the arcuate nucleus area, inhibiting the anorexigenic effects of *α-MSH* (i.e., increasing food intake).

Leptin is a protein of 167 amino acids and is manufactured mainly in fat cells in adipose tissue. The amount of circulating leptin correlates positively with the amount of fat in the body. Leptin has many CNS effects. It counteracts the effects of neuropeptide Y (NPY), agouti-related protein (*AgRP*), and GABA containing neurons and activates production of α-MSH in the arcuate nucleus. As a consequence, leptin is catabolic. It decreases appetite and inhibits food intake, contrary to ghrelin. A decrease in leptin is associated with an increase in hunger and appetite.

The inhibitory effects of leptin last long time, in contrast to the rapid inhibition of eating behavior produced by cholecystokinin and the slow suppression of hunger between meals mediated by PPY_{3-36}. Both leptin and ghrelin have been investigated in several studies attempting to find a relationship between obesity, sleep apnea, and weight loss, but leptin does not seem to have significant effect in weight loss therapy [13–15]. Leptin is low among subjects with anorexia nervosa [16] Low levels of leptin are also associated with hyperactivity, and it has been hypothesized that leptin could have a role in the treatment of severely hyperactive patients [16].

Neuropeptide Y is a potent feeding stimulant secreted by cells in both the gut and the hypothalamic neurons. It causes increased storage of ingested food as fat. NPY inhibits transmission of pain signals to the brain.

Peptide YY_{3-36} is close in structure to NPY but, contrary to NPY, is a potent inhibitor of feeding. PYY_{3-36} is released by cells in the intestine after meals. The secretion increases with the amount of calories eaten, especially when these derive from proteins rather than from carbohydrates or fats. This may explain partly why people who eat a lot of carbohydrates are often hungry, developing obesity.

α-Melanocyte-stimulating hormone (*α-MSH*) is an anorexigenic melanocortin. Melanocortins are products of POMC gene in the arcuate nucleus in the mediobasal hypothalamus. Other melanocortins include ACTH, β-MSH and γ-MSH, β-endorphin and met-enkephalin. Alpha-MSH is responsible for production of melanin (tannin) by melanocytes in skin and hair in humans. The POMC cells are glucose-sensing cells [17]. They act to suppress appetite and food intake. In addition to central effects, melanocortins act on adipocytes by stimulating lipolysis and inhibiting leptin secretion. The melanocortins, α-MSH probably as the most important, are dominant anorexigenic peptides and important regulators of food intake.

AgRP blocks the action of α-MSH in the arcuate nucleus and is also involved in the regulation of food intake. The hypothalamic POMC and AgRP neurons are major targets of leptin and insulin action in the brain. As noted above, leptin stimulates POMC/CART and inhibits AgRP secretion [18].

Hypocretins (*orexins*) [19, 20] are produced by about 70,000 cells in the lateral hypothalamus. They were originally considered to be important particularly in central control of food intake. Hypocretin is an "orexigenic" neuropeptide, increasing food intake (N.B. interestingly in narcolepsy, with loss of orexin, weight gain is often observed), contrary to "anorexigenic" neuropeptides that decrease food intake. It is now evident that hypocretins have a much larger spectrum of action, including energy homeostasis, sleep–wake behavior, nociception, reward-seeking behavior, and drug addiction [10, 21, 22]. Hypocretin-producing cells can be directly modified by peripheral signals. They are sensing peripheral glucose, and they have receptors for leptin and

ghrelin [23]. Hypocretins are also widely present in the GI tract [10]. In the ENS, they have a role in regulation of GI motility, and also in gastric, intestinal, and pancreatic secretions. The relationships among enteric regulation, eating behavior, regulation of arousal, narcolepsy [24–26], and the orexin-hypocretin system remain to be further clarified. It is most probable that there are important interactions that explain many of the symptoms, including the effects of fasting and carbohydrate intake on the vigilance of narcoleptic subjects versus normal people.

Melanin-concentrating hormone (*MCH*) An important interaction exists between hypocretin cells and intermingling MCH cells in the lateral hypothalamus. Both hypocretin-producing cells and MCH cells are *glucose-sensing cells*—sensing blood glucose concentrations. Decrease in glucose stimulates hypocretin cells and inhibits MCH cells (increasing alertness and food intake) [23, 27–29]. Increase in blood glucose inhibits hypocretin cells and stimulates MCH cells (decreasing alertness and decreasing food intake). Both hypocretin and MCH projections are widely distributed. They are located close to each other, having synaptic interconnections, and modulating each other's cellular activity. According to these theories, the MCH–hypocretin interactions are crucially important in the regulation of food intake and energy balance. MCH cells are involved also in regulation of REM sleep and in narcolepsy and disturbed MCH and propiomelanocortin system may be related to development of obesity in narcolepsy [30, 31].

Anandamine is an endocannabinoide that is produced in the small intestine. It is "orexigenic," i.e., it increases appetite. Anandamine has a role especially in the hedonic regulation of eating. It is involved in removing unnecessary short-term memories. It is also responsible for slowing down movements, making people feel relaxed and calm [32].

Insulin is produced in pancreas by β cells in islets of Langerhans. The effects of insulin on glucose- and lipid metabolism are known better than those of the other mediators. Insulin increases satiety and decreases appetite. Insulin stimulates POMC/CART neurons in the arcuate nucleus, generating an anorexigenic signal [18].

Serotonin

Serotonin (5-HT) is an important neurotransmitter in the CNS with important effects on sleep–wake regulation. It also has an important role in regulation of GI function through an interaction with the ENS. The ENS can be considered the body's second brain, with more than 100 million neurons of different types. Up to 60–90 % of the total body amount of 5-HT is in the GI tract, and 2–20 % of all enteric neurons express 5-HT. The control of 5-HT's release from enterochromaffin cells is complex. Stimulatory receptors include β-adrenergic receptors, muscarinic and nicotinic acetylcholine receptors, and 5-HT_3 receptors. Inhibitory receptors include α_2-adrenergic, histamine H_3, $GABA_B$, adenosine A2, and 5-HT_4 receptors. In the GI tract, 5-HT is eliminated mainly by monoamine oxidase metabolism [11, 33].

An interesting element from the point of view of sleep and movement disorders is the 5-HT_{1p} receptor. This receptor is probably involved in the secretory and peristaltic reflexes of the GI tract. The molecular identification of this receptor is not yet clear. Lui and Gershon [34] suggested that this receptor is a heterodimer of the 5-$HT_{1B/1D}$ receptor and the dopamine D_2 receptor. Other studies have also shown that dopamine is involved in GI tract regulation. Gershon's group has also shown in knockout mice that intestinal motility is abnormal when D_2 is absent [35]. A dysfunction of the intestinal dopamine system probably explains many of the GI symptoms, especially problems of constipation that are usually present very early among patients with Parkinson's disease (PD). It remains to be seen whether there are some associations with symptoms of RLS, lack of iron, and dysfunction of the 5-HT–dopamine system of the GI tract.

Irritable Bowel Syndrome and Role of the Intestinal Microbiota

Irritable bowel syndrome (IBS) is one of the most common GI disorders. It is twice as frequent among women as among men. IBS is related to dysfunction of the enteral serotonin system. There are no published systematic epidemiologic studies about the occurrence of IBS among patients with RLS. In our own clinical database, GI symptoms had been tabulated from 141 RLS patients (unpublished observations). Of these patients, 17 (12 %) had GI symptoms that could be diagnosed as IBS type. Because we had not tabulated this history systematically, the true prevalence might be higher. On the other hand, about 29 % of patients with IBS have RLS [36].

Intestinal microbiota has a role as a regulator of autoimmune diabetes in animals, and probably also in humans [37]. The role of gut microbiota in other human HLA-associated autoimmune diseases, including narcolepsy, remains to be studied. Small intestine bacterial overgrowth (SIBO) is common in RLS. In a recent series, SIBO was found in almost 70 % of patients with RLS [38]. In a randomized study, all 20 patients with RLS had marked improvement in their RLS symptoms after treatment of SIBO [39]. The therapy of SIBO was based on rifaximin, which is a rifamycin-based nonsystemic antibiotic, meaning that the drug will not pass the GI wall into the circulation [39–41]. Although treatment with antibiotics may be

beneficial, the spectrum of gut microbes is changed, which may be followed by various adverse effects and symptoms that may last years. Changes in the gut microbiota may be involved in many neurological and psychological symptoms [42]. The intestinal microbes are also known to be able to produce many neurotransmitters such as GABA, serotonin, melatonin, catecholamines, histamine, and acetylcholine [42–44]. Different diets have been advised for patients with IBS. Some beneficial results have been obtained by use of probiotics and by FODMAP diet. That diet is low in fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (FODMAPs) that are poorly absorbed by the small intestine and fermented by bacteria in the large intestine [45].

Case Example

A 53-year-old male biochemist developed severe insomnia 3 weeks after returning from a congress in South America. He had difficulty falling asleep and he woke up repeatedly, sleeping only 2–3 h. After 3 weeks of insomnia, he became exhausted and consulted our sleep clinic. He was lean. One week before consultation, he had started zopiclone and fluoxetine because he was diagnosed to have depression, which he denied. There was no previous history of insomnia. The polysomnography at the laboratory was consistent with his history. Total sleep time was only 2.3 h, and there was no slow-wave sleep. No apnea or periodic limb movements were found.

In the clinical interview at the sleep clinic, it was found that he had diarrhea with a fever during his travel. He took ciprofloxacin for 5 days but, because he continued to have diarrhea, he consulted an internist. A variety of laboratory tests were done to exclude all potential bacterial, viral, and tropical diseases. Nothing specific was found, but he was given two more antibiotics, including metronidazole. The diarrhea became much better, and his body temperature was between 37.0° and 37.3 °C. Insomnia developed one week after the last antibiotics had been taken. The problem was discussed with the patient. The internists concluded that he had had either bacterial or viral enteritis but no serious disease had been found. He speculated that the strong antibiotics had destroyed the entire bacterial flora, including healthy saprophyte bacteria.

Because his general condition was quite good, we decided to stop further laboratory examinations and start down-titrating zopiclone and fluoxetine. He also started to take omega-3 fatty acids, and *Lactobacillus casei/Enterococcus faecium* to normalize his intestinal flora. We encouraged him to restart exercise. After three weeks, he began to sleep normally as he had done before. His insomnia was of a psychophysiologic type, and anxiety (fear of some severe disease) probably also played a role. It is possible that his insomnia could have been caused by a change in the intestinal flora, and hence changes in the ENS-CNS regulation. The amelioration of his insomnia by reintroducing bacteria in the diet, without any other treatment, is in favor of this theory.

Role of Neurosteroids

Neurosteroids are synthesized in astrocytes, oligodendrocytes, Schwann cells, Purkinje cells, hippocampal neurons, and retinal amacrine and ganglion cells [46, 47]. Cholesterol is transported to glial mitochondria, where it is converted to pregnenolone. In the cytosol, pregnenolone is then converted to different neurosteroids such as allopregnanolone and dehydroepiandrosterone (DHEA). DHEA is a precursor of testosterone, which is converted to estradiol by an aromatase [46, 47]. Vitamin D is also an important neurosteroid [48]. Synthesis of neurosteroids is regulated by interactions between neurons and glial cells.

Neurosteroids have many important actions. Allopregnanolone activates neuronal $GABA_A$ receptors having anxiolytic, sedative, sleep-inducing, and anticonvulsant effects. Benzodiazepines, alcohol, and γ-hydroxybutyrate increase brain levels of allopregnanolone. Thus, these drugs may potentiate GABAergic transmission directly and also by increasing allopregnanolone. Pregnenolone sulfate, DHEA, and DHEA sulfate (DHEA-S) are inhibitory, noncompetitive modulators of $GABA_A$ and positive modulators of *N*-methyl-D-aspartate (NMDA) receptors by facilitating calcium influx. Estradiol inhibits NMDA receptors. Neurosteroids acting on NMDA are implicated in cognition, neuroprotection, and neurotoxicity. While pregnenolone sulfate is excitotoxic to cortical and retinal cells, DHEA and DHEA-S have neuroprotective effects against glutamate toxicity. However, the exact mechanisms of such neuroprotective effects are not clear.

Neurosteroids have been implicated in many neurologic and psychiatric disorders, including epilepsy, neurodegenerative diseases, schizophrenia, and depression. For example, depression is associated with reduced levels of allopregnanolone in cerebrospinal fluid. Antidepressant treatment with fluoxetine increases allopregnanolone levels [49]. There is also some evidence that DHEA helps in the treatment of depression. The beneficial effect of DHEA correlates with a decrease in glucocorticoids, which are increased in depression.

There is increasing evidence about many important roles of neurosteroids in regulation of vigilance as well. It remains to be studied whether nutritional factors could also play some role in this. DHEA is marketed in pharmacies and health shops. Little is known about possible positive (and, perhaps, also negative) long-term neuropsychiatric effects of nutritional factors that may cause changes in brain neurosteroids.

Role of Neurohormetic Phytochemicals

Several lines of evidence have shown that diets rich in fibers, vegetables, and fruits are associated with reduced risk of cardiovascular disease and many neurologic diseases [50]. There is also evidence that a vegetarian diet helps in weight control, and in this way prevents obesity and occurrence of obstructive sleep apnea. As stated previously, rapidly absorbed low-fiber carbohydrates induce sleepiness. Therefore, a vegetarian diet with a lot of fiber and slowly absorbing "good" carbohydrates is better for staying alert during waking time. Some of the positive effects are explained by antioxidant effects of different phytochemicals, but there is also evidence that some effects may be due to subtoxic effects of some neurotoxic molecules in the gut.

Hormesis refers to a paradoxical process in which low doses of a given toxic substance, or radiation, induce beneficial effects while larger doses of the same substance are toxic to cells and organisms [51–53]. Examples of endogenous molecules with neurohormetic actions are nitric oxide, carbon monoxide, glutamate, and calcium. Neuroprotective natural substances include α-tocopherol, lycopene, resveratrol (red grapes, red wine, peanuts, and soy), sulforaphanes (broccoli), catechins (green tea), allicin and allium (garlic), curcumin (turmeric), hypericin (in St. John's wort), and many others. In randomized clinical trials, hypericin (*Hypericum* extracts) has shown clinical efficacy comparable with the efficacy of some commonly used antidepressants, including citalopram, paroxetine, and fluoxetine [53–60]. This is of interest to sleep specialists because antidepressants are also used in treating insomnia, especially if it is thought to be associated with underlying depression. Much more research is needed to find out if natural substances affect sleep–wake behavior.

Hot spices may disturb sleep, perhaps by a neurohormetic action. In one study on six young men, tabasco and mustard in the evening reduced slow-wave and stage 2 sleep, reduced total time awake, and prolonged sleep onset. The spicy food in the evening elevated body temperature during the first sleep cycle. It is possible that capsaicin affects sleep by its effects on body temperature [61].

Caffeine, Adenosine, and Sleep

Caffeine, used mainly in the form of coffee, is the world's most common psychoactive drug. Caffeine is present in coffee, tea, cola, energy drinks, and chocolate, and it induces wakefulness. Its stimulant properties depend on its ability to reduce adenosine transmission in the brain. Caffeine acts as an antagonist to adenosine A1 and especially to adenosine A2 receptors [62]. Huang and collaborators found in knockout mice that caffeine increased wakefulness in both wild-type mice and A1 receptor knockout mice, but not in A2a receptor knockout mice. Thus, caffeine-induced wakefulness may be due mainly to its effects on adenosine A2a receptors [63]. Porkka-Heiskanen and her collaborators [64–66] have also recorded human sleep electroencephalograms (EEGs). The longer the previous wakefulness period is, the longer and deeper is the following sleep. The inhibitory neuromodulator adenosine is one promising candidate for a sleep-inducing factor. Its concentration is higher during wakefulness than during sleep, it accumulates in the brain during prolonged wakefulness, and local perfusions as well as systemic administration of adenosine and its agonists induce sleep and decrease wakefulness. The hypothesis is that adenosine accumulates in the extracellular space of the basal forebrain during wakefulness, increasing the sleep propensity. The increase in extracellular adenosine concentration decreases the activity of the wakefulness-promoting cell groups, especially the cholinergic cells in the basal forebrain. When the activity of the wakefulness-active cells decreases sufficiently, sleep is initiated. During sleep, the extracellular adenosine concentrations decrease, and thus, the inhibition of the wakefulness-active cells decreases, allowing awakening and a new wakefulness period [65].

In addition to coffee, caffeine is found in tea, cola drinks, energy drinks, and chocolate. Theobromine is also present in large quantities in chocolate. Dark chocolate is stimulating; 100 g of 70 % chocolate corresponds to 1–2 cups of coffee depending on strength of the coffee and size of the cup. Caffeine is a CNS stimulant. Its actions are variable among different people. Caffeine is absorbed rapidly, and peak activity is achieved in 30–60 min. The duration of action is usually 4–6 h, but in elderly subjects with slower metabolism, the duration may be up to 16–20 h. Insomniacs are usually advised to avoid coffee after 6:00 PM, but in some sensitive persons with insomnia, coffee at noon may disturb falling asleep in the evening.

One cup of coffee contains 75–125 mg of caffeine. A large amount of caffeine, usually over 300–500 mg (depending on individual sensitivity), causes restlessness, anxiety, trembling, tinnitus, and feelings of euphoria/delirium. Everyday use of more than 500 mg of caffeine leads to caffeinism with insomnia, fatigue, and different psychosomatic symptoms. It has been estimated that perhaps 10–20 % of coffee drinkers have caffeinism. Chronic coffee drinkers have often developed tolerance to caffeine, and some people may drink more than 10 cups of coffee daily. They have withdrawal symptoms if they do not have their coffee. Coffee is a well-known factor disturbing sleep [67–69]. Two or three cups of coffee (or in sensitive persons just one cup) before bedtime is followed by difficulty falling asleep and restless sleep.

Landolt et al. [70] administered 200 mg of caffeine in the morning and analyzed the sleep stages and EEG power spectra during the subsequent night in nine healthy men.

They also measured caffeine levels in saliva, which decreased from a maximum of 17 μmol/L 1 h after intake to 3 μmol/L at 23:00 in the evening. Compared to placebo, sleep efficiency and total sleep time were significantly reduced after the morning intake of caffeine [70]. Slow-wave sleep decreases and amount of stage 1 sleep usually increases after drinking coffee. Insomnia and RLS are more frequent among habitual coffee drinkers than among others. Paradoxically, in some persons, one or two cups of coffee may ameliorate quality of sleep. The reason can be behavioral conditioning, but it is also known that caffeine has a stimulating effect on both breathing and cardiac function. In patients with RLS, symptoms worsen by drinking a lot of coffee. Missak postulated that the human body—in cases of iron deficiency and chronic renal failure—may produce a substance similar to caffeine [71].

Epidemiologic studies have provided evidence that caffeine, an adenosine receptor antagonist, reduces the risk for PD [72–75]. There are indications of specific interactions between striatal adenosine A2a and dopamine D_2 receptors. In one study, the dopaminergic effects of caffeine were examined with [^{11}C]raclopride positron emission tomography in eight healthy habitual coffee drinkers after 24 h of caffeine abstinence. Compared to oral placebo, 200 mg of oral caffeine induced a 12 % decrease in midline thalamic binding potential ($p < 0.001$). These findings indicate that caffeine has effects on dopaminergic neurotransmission in the human brain, which may be different in the striatum and the thalamus [73]. Caffeine and other A(2A) receptor antagonists are also potentially neuroprotective, which may explain some of their favorable effects [74–76].

Glucose, Lactate, and Glial Cells

The main sources of energy for the brain are glucose and lactate. According to Magistretti's theory, lactate may be the most important source of neuronal energy [7, 9, 77]. Most of the glucose from brain capillaries enters glial cells through the blood–brain barrier. In astrocytes, glucose is metabolized into lactate by glycolysis. The rate of lactate metabolism depends on brain activity and use of oxygen. Mitochondrial function should be intact for proper functioning.

Besides the heart, the CNS is the only part of the body that may have both functional and structural changes after hypoglycemia. However, the brain resists fasting better than other organs. The brain uses glucose at a rate of about 70 mg/min and contains about 1–2 g of glucose, which is sufficient for about 90 min if no more glucose is obtained from circulation. There are no strong associations between behavioral symptoms and plasma glucose levels, but fatigue and other symptoms usually occur when glucose levels are below 1.5–2 mmol/L. Common reasons for hypoglycemia are overdose of diabetic medications, high insulin levels, and severe malnutrition.

Glutamate, adenosine, and GABA have crucial roles in controlling brain energetics and lactate formation in the astrocytes. Monocarboxylate transporters (MCT1 and MCT4 in astrocytes and MCT2 in neuronal cells) are needed in the transfer of lactate from astrocytes to neurons [9, 78]. It is important to note that alpha- and beta-adrenoceptors exist in the surface of astrocytes [79]. Norepinephrine activates these adrenoceptors and stimulates glycogenolysis in astrocytes, which then produce lactate from glucose and release it to provide necessary energy for neurons [9, 80].

These theories also fit findings of Haydon and collaborators about the importance of glial cells in control of synaptic transmission, neuronal activity, and sleep [81–83]. Also Newman, Montana et al., and Zhang et al. have pointed out the role of astrocytes in regulation of synaptic activity [84–86], and, as Hertz and Zielke have written, astrocytes may be the "stars of the show" [87]. All functions of glutamate are regulated by astrocytes. Glutamate is the most important excitatory brain transmitter, and all is dependent on the ability of astrocytes to produce glutamate and glutamine [87]. The studies by Aubert and his collaborators of CNS lactate kinetics support these findings, indicating that neurons are lactate-consuming cells, whereas astrocytes are lactate producers [88]. Lactate production by the astrocytes increases with enhanced glutamatergic activation, and consumption of lactate by neurons also increases as a result of glutamatergic activity [8, 88]. It may well be that many neurologic and psychiatric diseases will turn out to be mainly glial diseases. This may also be true for fatigue and sleepiness. One of the main roles of sleep is to ensure sufficient energy for waking brain activity. To understand this better, the glial–neuronal network should be investigated, rather than concentrating our research efforts on neuronal synaptic relationships. If neurons do not have enough food (energy) of proper quality, they may starve and will not function normally [9].

In sum, the astrocyte-neuron lactate shuttle (ANLS) model, as Pellerin and Magistretti call it, can now be recognized as a major theory of brain energetics. The ANLS model helps to understand also neuronal plasticity, neurodegeneration, memory consolidation, and functional brain imaging [9]. The relations of sleep disturbances (sleep deprivation, fragmented sleep) and in the regulation of the ANLS need to be studied in more detail.

Meals, Dietary Nutrients, and Sleep

Effect of different nutrients on sleep has been studied in a large survey of 4500 people. Use of the following nutrients was associated with shorter sleep latency: alpha carotene,

selenium, dodecanoic acid, and calcium. For example, the following nutrients were associated with better sleep and less awakenings during sleep: avoiding excessive salt, eating carbohydrates, use of vitamin D, dodecanoic acid, and lycopene [89]. Nonrestorative sleep was associated with butaneoic acid, lack of calcium, lack of vitamin C, lack of water, excess moisture, and excess cholesterol. Daytime sleepiness was associated with increased moisture, more caffeine/theobromine, less potassium, and less water [89]. These different elements will be handled in more detail below.

Rapidly Absorbing Carbohydrates, Large Meals, and Tryptophan

The hedonic regulation of food intake is powerful and it may be a key element in development of obesity. In normal weight subjects, the hedonic eating behavior is in balance with the homeostatic control of energy intake [90]. In obesity, the hedonic drive for eating may outweigh the homeostatic control of eating, leading to excess of energy intake. In a French study, rats were allowed to choose between water sweetened with saccharin and intravenous cocaine. Almost all (94 %) rats preferred saccharin water instead of cocaine. Rats preferred also natural sugar (sucrose) over cocaine. In order to abolish this finding, high doses of cocaine, causing intoxication, were needed [91]. Sugar and sweet food can induce reward and craving in humans that are at least comparable in magnitude to those induced by addictive drugs [92].

Clinicians treating narcoleptics know that rapidly absorbing carbohydrates induce sleepiness in the afternoon among their patients. What about the effect of carbohydrates in normal subjects? Most studies in which different foods have been compared with each other show that carbohydrates at lunch induce afternoon sleepiness more than proteins. In a study by Spring et al. [93], normal adults consumed either a high-protein or high-carbohydrate meal. Two hours later, their mood and performance were tested. Women, but not men, reported greater sleepiness after a carbohydrate as opposed to a protein meal. Men, but not women, reported greater calmness after a carbohydrate as opposed to a protein meal. Age of subjects had an effect on the response to meals. When meals were eaten for breakfast, persons older than 40 years felt more tense and less calm after a protein-rich than after a carbohydrate-rich meal. Older subjects did not like a morning protein meal as much as a carbohydrate meal, but objective performance was impaired more after a carbohydrate-rich lunch than after a protein-rich lunch. Sustained selective attention, as measured by dichotic shadowing, was impaired in the afternoon after consuming a high-carbohydrate lunch. In sum, these findings suggest negative effects on concentration after a high-carbohydrate, low-protein lunch [93].

In another study, fatiguing effects of lunch after carbohydrate-rich meals were compared to other types of meals [94]. Observed behavioral changes were correlated with changes in plasma glucose, insulin, and amino acids. Only the carbohydrate meal significantly increased fatigue, which could not be attributed to hypoglycemia because plasma glucose remained elevated. The afternoon fatigue began when the carbohydrate meal elevated plasma tryptophan but ended even though the ratio remained elevated. According to Christensen, fatigue after a high-carbohydrate lunch cannot be explained only by reactive hypoglycemia or sweet taste and could partially be explained by the hypothesis that fatigue parallels an elevation of tryptophan and effects endogenous opioids [95]. Associations among a carbohydrate-rich meal, an increase of tryptophan, and feelings of fatigue have also been confirmed in other studies [96].

Rapid increase in insulin and its effect on tryptophan are related to symptoms of fatigue. In particular, after rapidly absorbing carbohydrates as well as after a glucose intolerance test, insulin is rapidly increased. This rapid increase in insulin is associated with an increase in the ratio of tryptophan to large neutral amino acids (LNAAs) causing abnormal neuroglycopenic symptoms. In practice, this may be seen as “sugar drunkenness” [96]. These findings have been confirmed by Cunliffe et al., who found that subjects consuming a pure carbohydrate meal were more tired with feelings of fatigue and had had slower reaction times. A general feeling of mental or central fatigue was noticed after a pure isocaloric fat meal. The ratio of tryptophan to LNAAs was decreased after a pure fat or mixed meal and rose after a pure carbohydrate meal. The authors concluded that central and subjective fatigue after carbohydrate intake may be related to an increase in tryptophan relative to other competitive amino acids. Pure fat intake may also have a negative influence on CNS arousal [97].

Wheat, Starch, Amylopectins, and Postprandial Sleepiness

Celiac disease is well-defined autoimmune disorder. It occurs in genetically predisposed people. In celiac disease, ingestion of gluten leads to damage of the small intestine. Gluten is a protein that is found in rye, barley, wheat, and foods made with these grains. Patients with celiac disease suffer from abdominal bloating, pain, gas, diarrhea, pale stools, and weight loss. They may have skin rash due to dermatitis herpetiformis, iron deficiency anemia, and tingling sensations in the legs. They may mimic symptoms of restless legs. The prevalence of celiac disease is about one

percent. Celiac disease may be a cause of a sleep disorder, but gluten may not be the most important factor in grains, that may cause sleepiness.

Wheat, other grains, potatoes, and other sources of starch may cause sleepiness also directly by increasing blood glucose and insulin levels. It is to be noted that wheat bread may cause a faster and higher increase in blood sugar than ingestion of sugar. The amylose-amylopectin ratio is one of the factors explaining glucose- and insulin-response differences. Foods with higher amylose content are accompanied by a lowered metabolic response and lower increase in glucose and insulin than foods with higher amylopectin content. Of the starchy foods, legumes with high fiber content elicit a much lower postprandial response of glucose and insulin, and hence less postprandial sleepiness than food rich in starch [98, 99]. Legumes are also good sources of high-quality proteins. The amount of amylose and amylopectins depends on many factors. For example, macaroni has a lower amylose-amylopectin ratio than spaghetti, and it increases blood glucose more than spaghetti.

The amount of food eaten is also related to feelings of sleepiness. Solid foods cause more sleepiness than liquid foods. Valuable studies have also shown that the larger the meal, the sleepier the person is afterward [100]. It may be that filling the stomach with plenty of food might have a stronger effect than different constituents of food per se [101].

Eating in the Evening and Night Sleep

Sleepiness and fatigue after lunch are usually unwanted. For this reason, people wanting to avoid postlunch sleepiness should avoid rapidly absorbing carbohydrates and large meals. Needless to say, alcohol during lunch increases sleepiness. On the contrary, in the evening, the sleep-facilitating effects of carbohydrates may be beneficial. Recently, Afaghi et al. [102] explored the effect of the glycemic index (GI) on sleep in 12 healthy men. Their subjects were administered standard, isocaloric (3212 kJ; 8 % of energy as protein, 1.6 % of energy as fat, and 90.4 % of energy as carbohydrate) meals of either Mahatma (GI = 50 [low]) or Jasmine (GI = 109 [high]) rice 4 h before their usual bedtime. On another occasion, the same high-GI meal was given 1 h before bedtime. Sleep onset latency shortened significantly after a high-GI meal compared with a low-GI meal. The high-GI meal given 4 h before bedtime had better action on sleep latency than the same meal given just 1 h before bedtime (9.0 ± 6.2 vs. 14.6 ± 9.9 min; $p = 0.01$) [102]. This finding confirms earlier studies showing that a (light) carbohydrate-rich diet during dinner may be beneficial for sleep.

Adding tryptophan may enhance the action of carbohydrates. A controlled double-blind study lasting five weeks evaluated whether eating of cereals enriched with nutrients facilitating sleep could help to improve infants with sleep disorders. A "sleep facilitating cereal" product containing 225 mg tryptophan, 5.3 mg adenosine-5′-P, and 6.3 mg uridine-5′-P per 100 g of product. As compared to similarly tasting cereals without added nutrients, the administration of enriched cereals led to an improvement in sleep [103]. In another study, the same group found that cereals enriched with tryptophan (60 mg tryptophan in 30 g cereals per dose) eaten at both breakfast and dinner increased actigraphically measured sleep efficiency, actual sleep time, immobile time, and decreased total nocturnal activity, sleep fragmentation index, and sleep latency [104].

According to common knowledge, heavy meals late in the evening disturb night sleep. Driver and collaborators studied effects of different types of evening meals and of a 10-h fast (no evening meal) on body temperature and night sleep. Seven healthy people participated. Meals of varying energy content and episodes of sleep influence body temperature. Lower rectal temperatures were measured during the fast than following the meals. Higher energy content of the evening meal associated with higher body temperatures at night. No differences were observed in the subjective or polysomnographic sleep measures [105]. A transient heavy evening meal, 2–3 h before going to bed, or a 10-h fast may not alter significantly sleep of previous good sleepers. However, the higher body temperature after heavy meal reflects higher autonomic activity, and there is evidence for example in insomniacs and in patients with narcolepsy that higher core body temperatures (and lower peripheral temperatures) are associated with less sleepiness and lower quality of night sleep [106, 107].

Contents of meals may also be related to the circadian type. In a Japanese study, evening-type persons, as compared to morning-type persons, had significantly lower energy-adjusted intake of protein, calcium, magnesium, zinc, vitamins (D, riboflavin, B6), and vegetables and with a higher intake of noodles [108]. In other words, evening chronotype may be associated with inadequate dietary habits such as low vitamin and mineral intake.

Postlunch Fatigue

A siesta after lunch is still common in some parts of the world, although it has disappeared from most developed countries. Also in developed countries, a feeling of tiredness in the afternoon is common. According to Bell [109], 71 % of narcoleptics and 9 % of healthy adults suffer often or always from postprandial sleepiness. The vigilance level has a bimodal pattern: Alertness is at its lowest level after midnight, and there is another dip in alertness occurring during the afternoon independent of whether one has been

eating or not. The effects of different types of meals have been studied. There is evidence that heavy meals cause more fatigue than light meals. There is also agreement that alcohol during lunch causes sleepiness in the afternoon. In clinical settings, there is some evidence that rapidly absorbing carbohydrates in particular cause more sleepiness and fatigue after lunch than slowly absorbing carbohydrates and proteins. Eating carbohydrates at breakfast, on the contrary, may not increase daytime sleepiness. In another study, subjects also tended to feel more sleepy and fatigued 2–3 h after a high-fat, low-carbohydrate breakfast than after low-fat, high-carbohydrate breakfast [110].

Obesity and Sleep

Obesity is an epidemic, especially in Western countries. It is believed that the epidemic is a consequence of eating too much food with energetic value combined with a decrease in physical activity. This is probably true, but it does not explain everything. In the medical world, research on cardiovascular diseases has been one of the primary foci. High-cholesterol levels are associated with an increase in cardiovascular morbidity. Therefore, the food industry has been developing foods with no cholesterol, and people are advised to avoid butter and fats. However, the food industry has also been developing more and more foods and soft drinks with high sugar content (e.g., Coca-Cola, Pepsi-Cola). Despite eating less, fat people become more and more obese, suggesting that other factors must be involved.

From a physiologic standpoint, body fat is deposited in excess amounts when caloric intake exceeds caloric expenditure [111]. Most of our calories are expended in a resting state. We know that obese patients with sleep apnea have difficulty losing weight. It has been questioned whether obese people have a lower resting metabolism than lean people. Are obese people like diesel motors? Using whole-body direct calorimetry and other methods that enable measurement of basic metabolism, researchers have shown that obese subjects often have lower resting metabolic rates that persist after weight reduction, that people with a high genetic propensity for obesity often show this decreased resting metabolism before they become obese, and that these people are more likely to regain their weight after weight reduction. The mechanism of the low resting metabolic rate in many obese people is not known [111]. Eating less food with high energy content is needed to lose weight. Also, avoiding rapidly absorbing carbohydrates should be an element in weight reduction. Avoiding fats and increasing exercise do not help if an obese subject continues to drink sweet soft drinks and eat a lot of potatoes, white bread, or sweets. It is important to note that, with excess caloric intake, carbohydrates convert to fat. Citrate from the citric acid cycle diverts from mitochondria into cytosol for fatty acid synthesis. After a meal rich in carbohydrates, insulin release from the pancreas causes a 30-fold increase in glucose transport into adipocytes.

Several prospective epidemiological studies have shown that there is a relationship between sleep length, sleep quality, and obesity. Both short sleep (too short sleep relative to individual need of sleep) and poor sleep quality increase the risk of developing obesity, and consecutively type 2 diabetes and metabolic syndrome [112–117]. In experimental studies, sustained sleep fragmentation in mice affects brain temperature, food intake, and glucose tolerance [118]. Different neuronal networks and transmitters are involved as discussed earlier in this chapter.

Dietary Patterns and Sleep

Effect of Fasting on Sleep

Effects of fasting on sleep length differ depending on the study. Fasting was associated with shorter sleep in some human studies and with increased sleep in others. Results of studies on the effect of fasting on sleep architecture are somewhat divergent. Fasting, resulting in decreased energy intake, seems to be associated with an increase in slow-wave sleep, and a decrease in rapid eye movement (REM) sleep and sleep stages 1 and 2. In the earlier studies, this was explained by the restorative function of slow-wave sleep [119, 120]. In the 1980s, it was thought that sleep was mainly for the brain and had little restorative value [121]. It is now known that sleep not only is important for the brain, but also has a restorative function [13, 122]. The relationship is complex. In experimental studies, caloric restriction protects the brain against aging and disease, while restriction of sleep has an opposite effect. Markers of oxidative stress were lower in cultured neuronal cells treated with caloric restriction serum compared with those treated with ad libitum serum [123].

Muslims fast during the ninth month (Ramadan) of the Islamic Hijra calendar. Hijra is a lunar calendar, and Ramadan occurs at different times in the seasonal year over a 33-year cycle. Fasting during Ramadan occurs daily from sunrise to sunset. The effects of the intermittent type of fasting during Ramadan differ from those of continuous fasting. In one study, the main finding was that during Ramadan, evening sleep latency was increased and nocturnal sleep architecture was modified. Slow-wave sleep and REM sleep decreased during Ramadan. The effects of Ramadan fasting on nocturnal sleep have been explained by changes in drinking and meal schedule, rather than an altered energy intake, which may be preserved [124]. In another study, Ramadan diurnal fasting induced an increase in subjective

and objective daytime sleepiness, measured by MSLT, associated with changes in diurnal rectal temperature [125]. Later bedtime during Ramadan shortens consistently night sleep by about an hour or more, which explains probably a part of the increased daytime sleepiness [126, 127].

Ketogenic Diet and Sleep

The ketogenic diet has been used for a long time in the treatment of severe epilepsy. It is efficient but it is usually only a temporary solution. Some efforts have been made to develop other diets that are based mainly on lowering amounts of carbohydrates in order to lower blood sugar levels without inducing marked metabolic ketosis. Early results have been promising. Again, these diets are based on Magistretti's theories and on theories about the role of astrocytes [7, 9, 85, 128]. Hypocretin and MCH cells are sensing glucose levels. Lower blood glucose is associated also with higher hypocretin and lower MCH levels increasing alertness [23]. It is possible that in fact brain cells, especially glial cells, perform better when glucose levels are lower. This is followed also by better synaptic function and less paroxysmal activity.

According to theories on brain energetics, the ketogenic diet could help people to sleep better and have better alertness during the daytime. Hallbook et al. [129] have published first results supporting this idea. They examined 18 children with treatment-resistant epilepsy. All children had polysomnography studies before starting a ketogenic diet and after three months on the diet. Eleven children were evaluated after staying on the diet for one year. Seizures were controlled with the diet, and it was associated with decreased total sleep and total night sleep. There was no change in amount of slow-wave sleep, and REM sleep was increased. Stage 2 sleep was decreased ($P = 0.004$), and sleep stage 1 was unchanged. There was a significant correlation between increased REM sleep and improvement in quality of life.

Brown has formed an interesting hypothesis to explain the positive mental effects of a low-carbohydrate diet [130]. Better vigilance, feelings of well-being, and feelings of mild euphoria have been attributed to increased production of ketone bodies, which can replace glucose as an energy source for the brain, as Magistretti has postulated [7, 9]. Brown noted that one of these ketone bodies, β-hydroxybutyrate (BHB), is an isomer of γ-hydroxybutyrate, which is used as treatment for alcohol and opiate dependence and also for narcolepsy with cataplexy. Brown hypothesized that the positive mental effects with fasting and a low-carbohydrate diet may be due to shared actions of BHB and GHB on the brain. BHB, like GHB, is a weak partial agonist for $GABA_B$ receptors [130].

Ketogenic diet has many adverse effects, and it may not even be necessary to achieve clinical results. In a study by Johnson et al., ketogenic and nonketogenic low-carbohydrate diets were equally effective in reducing body weight and insulin resistance, but the ketogenic diet was associated with significantly more adverse effects [131].

Power Naps

Short naps preceded by intake of caffeine or "power naps" have shown to be an efficient way of increasing alertness in the workplace or when driving a car. First, 100–150 mg of caffeine is taken in the form of coffee or an energy drink. This is followed by a 15- to 30-min-long nap. During short naps, caffeine is absorbed and postnap drowsiness (sleep drunkenness) may be avoided. Alertness is increased for 3–6 h [132–134]. Some physicians advise elderly people to avoid daytime naps. There is, however, no good evidence showing that a nap in the afternoon would be harmful for night sleep, providing that the nap has been short enough (<1 h) [135]. According to some recent information, frequent long daily naps may be related to underlying medical pathology [136], but according to Naska et al. [137] naps of any duration may be healthy. Clearly, more studies are needed on the health effects of daily naps.

Alcohol and Sleep

Excessive use of alcohol is associated with complaints of insomnia. Alcohol shortens sleep latency, but it may also disturb sleep later at night. Two or more drinks of whiskey or other liquors increase snoring and are a strong risk factor for obstructive sleep apnea [138–141]. There is also evidence that heavy drinking of alcohol is associated with smoking, obesity, poor physical condition, ill health behavior, and insomnia. One or two glasses of alcohol may help a person to fall asleep, but more than two glasses worsen the quality and architecture of night sleep [142–144], in addition to causing snoring and sleep apnea. Larger amounts of alcohol (0.5–1 g/kg body weight) diminish REM sleep during the first third of the night, but there is often a rebound of REM sleep later at night. This correlates with awakenings early in the morning. If alcohol is used in larger quantities, REM sleep is diminished during the whole night. The blood alcohol level at the time of going to sleep correlates with a decrease in REM sleep [145]. According to many studies, alcohol decreases slow-wave sleep, but according to other studies, slow-wave sleep, especially during the first third of the night, may increase. In any case, the normal sleep architecture is easily disturbed with larger

doses of alcohol. Alcoholics sleep poorly. Even worse, the sleep of alcoholics may be disturbed for many years after drinking has stopped [146]. This must be taken into account when treating insomniacs with a history of alcoholism since they may need psychological support for many years.

Could alcohol be used as an alternative to hypnotics? There is evidence that one glass of wine or spirits in the evening may help in falling asleep both among working adults and elderly people. There have been some studies in residential facilities for the elderly, where use of hypnotics has been compared with use of wine or sherry. In a randomized study, one glass of alcohol was better than one tablet of a hypnotic [147]. Use of hypnotics is a problem in geriatric institutions, because use of hypnotics among elderly people is associated with increased mortality. There is very little evidence of benefits for long-term every-night use of hypnotics, but many studies have shown risks of routine hypnotic use [148–153]. Alternatives to hypnotics are needed, especially for elderly people. One of them is a social hour. In some residential facilities for the elderly, one glass of wine or sherry, served in a day room/living room, is offered during a social hour in the evening. It is possible that most of the beneficial effects are explained by behavioral factors [147, 154]. The elderly people who are given a glass of sherry do not usually drink it immediately, but stay in the day room/living room for some time. This results in a delay in going to bed, which is associated with fewer awakenings during early morning hours after midnight.

Essential Fatty Acids and Sleep

The polyunsaturated fatty acids (PUFAs) such as linoleic acid, α-linolenic acid (α-LA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) are essential fatty acids in many mammals, including humans (see *Nutrition and Development of the Central Nervous System* later). α-LA is a precursor of DHA, and EPA is converted to DHA in the body. A sufficient amount of PUFAs from food is necessary for health and well-being. Both DHA and EPA are omega-3 acids, and both may be obtained by eating fish oils. The American Heart Association has recommended that the amount of long-chain omega-3 fatty acids should exceed 650 mg/day. In Britain, more than 1000 mg/day has been recommended by the British Heart Association [155]. Fatty fish is the best source of omega-3 fatty acids. One hundred grams of salmon contains about 1000 mg of omega-3 fatty acids and 100 g of herring contains about 2000 mg. White fish meat contains much less of these essential fatty acids than fish with fatty meat. There is increasing evidence that a reduced amount of ingested omega-3 fatty acids is associated with fatigue, depression, and problems of attention. Omega-3 fatty acids have been tested in the treatment of subjects with attention deficit disorder and in subjects with depression, female subjects with borderline personality disorder, fatigue in multiple sclerosis, memory disturbances, dementia, and some other neuropsychiatric diseases. Some randomized controlled studies have shown that omega-3 acids help, but there are also conflicting results and more well-conducted randomized studies are needed [155–169].

There is some evidence showing that essential fatty acids may modulate sleep. Fagioli from Italy studied eight children who were fed by total parenteral nutrition without essential lipids and seven other children who received a daily supplement of essential lipids in their parenteral nutrition. Slow-wave sleep was significantly decreased in the group of children who did not receive fatty acids as compared to those who did [170]. Omega-3 fatty acids are also necessary for early brain development and infant sleep. Cheruku et al. [171] measured plasma DHA from 17 women at parturition. They found a significant positive correlation with concentration of DHA and quality of the newborn infants' sleeping patterns as measured by a sleep mattress method. This is thought to relate to more mature brains of the newborn infants. Lack of omega-3 fatty acids may be related to sleep disturbance in depressives [172]. Palmitoleic and oleic acid are precursors of a sleep-inducing oleamide [173, 174]. Linoleic and eicosadienoic acid could be helpful for maintaining sleep also because they are precursors of the sleep mediator prostaglandin D2 [175].

Narcolepsy and Meals

In the 1960s, Roberts and his collaborators studied 326 narcoleptic patients. They reported that, of 40 African-Americans in their narcolepsy population, 70 % had recurrent hypoglycemia without diabetes mellitus [176]. In routine clinical practice, many patients with narcolepsy often complain of excessive sleepiness in the afternoon, particularly if they have eaten a lunch rich in carbohydrates and especially if they have eaten a sweet dessert. Avoiding a heavy, carbohydrate-rich lunch and desserts helps them to be more alert in the daytime. Based on this experience, patients with narcolepsy should be routinely advised to avoid rapidly absorbing carbohydrates, especially at lunchtime. On the contrary, as noted already above, a light evening meal with carbohydrates may ameliorate night sleep.

In spite of clinical experience, there is very little scientific knowledge about the effects of different types of meals on symptoms of narcolepsy. Bruck et al. [177] studied 12 narcoleptics and 12 matched controls in a double-blind crossover study. They measured behavior after a light lunch supplemented with a drink of either 50 g of glucose or placebo (in the form of an artificially sweetened drink). In the narcoleptic subjects, glucose was associated with

decreased wake duration, reduced latency to sleep onset, and more spontaneous and induced sleep stage changes during a Wilkinson auditory vigilance task. The subjects also had a sleep EEG during a 45-minute nap. In a polygraphic score of sleepiness (PSS) [178], more slow-wave sleep stages were observed after glucose than after placebo. Eleven of the 12 narcoleptics had significantly more REM sleep after glucose as compared to the placebo drink [177]. The authors discussed their results in relation to serotonin synthesis and an increase in insulin after glucose.

Sodium oxybate, a pharmacologic compound related to GHB, is considered today as one of the best treatments for narcolepsy with cataplexy. Sodium oxybate also ameliorates nocturnal sleep. The mechanisms of action are not fully understood. Its effect on the GABA system is considered to be important, but it is tempting to think that some of the effects may be similar to the effects of a ketogenic diet. Brown noted that BHB, a ketone, is an isomer of GHB; both are also partial agonists of $GABA_B$ receptors [130].

In a study by Husain et al. [179], the effects of a low-carbohydrate, ketogenic diet on sleepiness and other narcolepsy symptoms were studied among nine patients with narcolepsy. The patients with narcolepsy were asked to adhere to the Atkins diet plan, and their symptoms were assessed using the Narcolepsy Symptom Status Questionnaire (NSSQ). The NSSQ-Total score decreased by 18 % from 161.9 to 133.5 ($P = 0.0019$) over 8 weeks. Subjectively, patients with narcolepsy experienced modest improvements in daytime sleepiness when they were on a low-carbohydrate, ketogenic diet [179].

Obesity among narcoleptics is common [180–183]. One could assume that lack of hypocretin in narcoleptics could be associated with increased feeding behavior, overeating, and obesity. Arnulf and her collaborators studied 13 narcoleptics and 9 healthy age/sex/ethnicity-matched controls [184]. Their patients with narcolepsy (both typical narcolepsy-cataplexy syndrome and narcolepsy without cataplexy) tended to be overweight. There was no significant difference in the basic metabolic balance. Overweight narcoleptics had lower resting energy expenditure and food intake than patients with normal weight and controls, indicating calorie restriction. Plasma glucose, cortisol, thyroxine, thyroid-stimulating hormone, prolactin, and sex hormone levels did not differ between groups. Narcoleptic patients had more problems in eating behavior, and they also had more signs of bulimia compared to controls. In sum, in this study, low hypocretin values were not associated with obesity per se, but the narcoleptic subjects tended to eat more than needed, causing them to be overweight. The overweight narcoleptics tended to have lower energy consumption at rest, as do many other overweight people compared to people of normal weight [26, 111]. This makes weight loss more difficult.

Narcolepsy without cataplexy, idiopathic hypersomnia, and attention deficit hyperactivity disorder (ADHD) has some similarities in their symptomatology. According to a theory by Russell and Killian, ADHD may be caused by disordered brain energetics with insufficient astroglial production of lactate [185, 186]. Modafinil and methylphenidate are used in treatment of narcolepsy and CNS hypersomnias. Their action in ADHD may be explained also by stimulation of the glial cell surface adrenoceptors, and hence by stimulated production of lactate in astrocytes, leading to better energy balance in the brain [186].

Dietary Minerals and Sleep

Iron

Iron has an important role in many enzymatic processes. Sufficient iron in the CNS is necessary for normal functioning of dopamine receptors. Tyrosine hydroxylase regulates dopamine synthesis. Iron and tetrahydrobiopterin are cofactors of tyrosine hydroxylase. Iron is also linked to functions of GABA, serotonin, and opioid peptides. In experimental cell cultures, dopaminergic cells of the substantia nigra can be destroyed by chelation of iron by desferoxamine. Adding opioids in these cell cultures is protective. Iron also has a catalytic effect in oxidative mechanisms of the CNS. Measuring serum ferritin and soluble transferring receptor from a venous blood sample allows estimation of tissue iron levels. In RLS, S-ferritin is often low, in which case giving iron per os, or intravenously in more severe cases, should be part of the treatment.

In patients with disturbing symptoms of RLS (Willis–Ekbom disease), 50–70 μg/L is commonly used as the lower limit at which one should consider giving iron supplementation, even if hemoglobin is normal. Usually the soluble transferrin receptor values are also low. Iron should be given as Fe^{2+} (bivalent iron) together with vitamin C to increase absorption of iron from the gut. If ferritin levels do not rise and the symptoms are bothersome, intravenous iron might be considered. Nondextran formulations such as Ferinject® or Venofer® are shown to be safer than older dextrans. Several studies have already shown the benefits of intravenous iron [187, 188], beginning with the early experiences from Sweden in the 1950s [189].

Yehuda and Yehuda [190] noted that in young children, sleep disturbances, fatigue, and possible learning disturbances may be related to iron deficiency early in life. A relationship between sleep disturbance, restless legs, and iron deficiency in children with autism spectrum disorder has been reported [191].

Kuhn and Brodan studied the effects of 5 days of sleep deprivation on the circadian rhythm of serum iron in a group

of six healthy male volunteers. Sleep deprivation markedly reduced the mean level of iron, diminished the absolute and relative amplitude of oscillations, disturbed the shape of the daily course of serum iron, and gradually decreased the computative acrophase (i.e., shortened the period of rhythm). Forty-eight hours of recovery resulted in only a partial normalization of all the observed changes [192].

Symptoms of ADHD are often reported by patients with narcolepsy, and some of the symptoms of narcolepsy resemble those of ADHD. RLS is significantly associated with ADHD and both conditions have been associated also with low levels of ferritin [191, 193, 194]. RLS is frequent also in narcolepsy. About 15 % or more of patients with narcolepsy seem to have RLS [195, 196]. Accumulation of iron in the brain, mostly in the form of ferritin, is associated with an elevated risk of developing neurodegenerative diseases such as PD [197]. High ferritin levels have been associated also with some autoimmune diseases, such as multiple sclerosis [197, 198]. In patients with RLS, serum ferritin levels are often low, but in patients with narcolepsy and concomitant RLS, serum ferritin levels were higher than in narcolepsy patients without RLS [195].

Copper, Zinc, and Other Minerals

Copper acts as a cofactor in many enzymatic processes, including those mediated by ceruloplasmin, monoamine oxidases, cytochrome oxidase, and superoxide dismutase. The largest part of dietary copper (96 %) is bonded into ceruloplasmin and ferroxidase, which are needed in many phases of iron metabolism. Lack of copper can manifest as neutropenia, microcytic anemia, growth disturbances, or slowing of erythropoiesis. Copper deficiency also may present as myeloneuropathy resembling vitamin B_{12} deficiency. Menkes' syndrome is an example of a genetic disturbance of copper metabolism causing deficiency of copper. Wilson's disease is an autosomal recessive disease that causes accumulation of copper in the liver and brain. It is practically impossible to take in too much copper from a normal diet. Intake of large amounts of vitamin C, zinc, iron, and cysteine worsen the absorption of copper from the gut. Lack of copper may also occur after poor diet, excessive consumption of zinc tablets, and bariatric surgery [199].

Zinc is also required in many enzymatic processes (carbonic anhydrase, alkaline phosphatases, many different dehydrogenases, etc.). In the CNS, zinc is abundant in the so-called zinc-containing synapses of glutamatergic neurons. Such neurons are located mainly in the prefrontal lobe; frontal dysfunction may result from lack of zinc. Conversely, bivalent zinc may cause excitotoxic damage. Other minerals (e.g., magnesium, manganese) are also important for proper functioning of the CNS.

Nutrition and Development of the Central Nervous System

Malnutrition affects development of the brain. One of the pioneers in this field has been Myron Winick, a pediatrician specializing in embryology and growth development [200]. In the 1960s, he spent several months in Chile, where he noticed at the time of autopsy that malnourished children had a reduced number of brain cells. Later his group published similar results from Jamaica. Studies among Korean orphans less than 1 year old with adequate nutrition or malnourishment have shown that malnourishment is associated with poor functional outcome at the age of 12 years. In developed countries, the most important nutritional factor for early disturbance of brain development is alcohol (i.e., fetal alcohol syndrome). Children with fetal alcohol syndrome have low birth weight, retarded growth, dysmorphic facial features, and learning deficits. In developing countries, many other types of significant intrauterine and early postnatal malnutrition may affect brain development. In these countries, malnutrition is usually associated with poor living conditions, poor hygiene, and poor socioeconomic status.

Nutrition plays an important role in the development of the human CNS. Prenatal malnutrition affects the developing brain in many ways. Adequate intake of proteins, minerals, and vitamins is necessary for proper brain development, including brain growth, neurogenesis, cell migration, and cell differentiation. Are some nutrients more important than others? Folate deficiency is associated with disturbances of neural tube development during early gestation. There is evidence that malnutrition may result in various types of minimal brain dysfunction, disorders of attention, and learning disabilities [200]. There is also evidence that malnutrition during pregnancy is associated with an increased incidence of some behavioral and psychiatric problems, including mental retardation and schizophrenia. Studies have shown that malnutrition may cause diffuse lesions and functional disturbances in connections between neurons and glia, axonal and dendritic circuits, and the development of various neurotransmitter systems [201]. Fortunately, the human brain is plastic, and the effects of malnutrition may be at least partly reversed by proper nutrition later in childhood [200]. In addition, genetic effects, living environment, possible infections, and many other factors are important. Pascual and collaborators have published their results on neuroglycopenia, a syndrome caused by insufficient glucose availability during brain development in the early years of life [202]. The cause of neuroglycopenia may be nutritional energy deficiency or a genetic mutation of the cerebral glucose transporter type 1 (*GLUT1*). In the latter case, children with neuroglycopenia may suffer from a combination of epilepsy, motor dysfunction, and neuropsychological abnormalities.

During gestation and early postnatal life, the PUFAs linoleic acid, α-LA, EPA, and DHA are necessary for proper development and functioning of cell membranes. DHA is present in high concentrations in retinal and cerebral cortical brain lipids. It is particularly necessary for development of the brain and retina and is normally supplied via the placenta and milk. By which mechanism do omega-3 fatty acids act in the CNS? Neuronal cell membranes contain phospholipids, and dietary omega-3 fatty acids are needed for proper constitution and functioning of these membranes. There is evidence that a sufficient amount of dietary omega-3 relative to omega-6 fatty acids is needed for proper CNS function. Too much omega-6 relative to omega-3 fatty acids may be harmful. Omega-6 fatty acids are metabolized to prostaglandins with higher inflammatory potential compared with those generated from omega-3 fatty acids. Sufficient tryptophan and tyrosine intake are needed for production of the serotonin and catecholamines. The omega-3/omega-6 ratio is also linked to proper functioning of serotoninergic and catecholaminergic neurotransmission. Several studies have shown that the ideal ratio of omega-3/omega-6 fatty acids is about 1:4. In many countries, this ratio is close to 1:30, which means that people have much more omega-6 acids relative to the important omega-3 acids. The ratio of membrane omega-3 to omega-6 PUFAs can be modulated by nutrition. This is also probably true for proper sleep–wake regulation, but more studies are needed to prove this. These results do not directly prove that malnutrition during early childhood causes problems in the development of the sleep–wake cycle. It is, however, very possible.

Sleep Duration, Morbidity, and Mortality

31

Shawn D. Youngstedt, Daniel F. Kripke, and Shelli James

Introduction

Over a span exceeding 50 years, more than 50 epidemiologic studies have demonstrated a U-shaped association of sleep duration with mortality, with the lowest mortality associated with approximately 7 h of self-reported sleep [1–4]. Figure 31.1 illustrates data from the Cancer Prevention Study I, perhaps the first study to clearly demonstrate the U-shaped mortality association with sleep duration [5, 6]. Similar U-shaped epidemiological associations have been found between sleep duration and multiple morbidities, including cardiovascular disease [7, 8], stroke [8], hypertension [9], diabetes [10], depression [11], metabolic syndrome [12], dyslipidemia [13], and inflammation [14].

The pressing questions today are whether these associations are causal and whether they are remediable through sleep interventions. If short or long sleep are truly causal factors in mortality and morbidity, then modest changes in time in bed (TIB) or total sleep time (TST) might have significant benefits for health and possibly for survival.

This review will begin by discussing how epidemiologic data provide evidence of causality. Then, we will briefly review epidemiologic studies linking sleep duration with mortality and morbidity. We will also briefly discuss experimental sleep restriction studies and implications for health. Since the epidemiologic evidence linking mortality with long sleep is stronger and more consistent than that associated with short sleep [15], yet long sleep is not addressed as much in the literature, we will focus more on long sleep. We will discuss possible mechanisms mediating risks associated with long sleep. Finally, we will consider future research which could begin to resolve the causal elements of sleep duration in morbidity and mortality.

Epidemiologic Principles and Designs

Epidemiologic research involves studies of associations of risk factors with mortality or morbidity, for example, the associations of short or long sleep with mortality and disease. Epidemiologic data cannot entirely prove a causal association between risk factors and mortality or disease. However, various designs provide stronger evidence of a possible causal association. Moreover, in some literatures, such as that linking smoking with mortality, associations are so strong and consistent that assumptions of causality are virtually beyond dispute.

Cross-Sectional Studies

Cross-sectional studies measure risk factors and the presence or absence of disease simultaneously. For example, many cross-sectional studies have shown a higher prevalence of various diseases among short and long sleepers compared with average-duration sleepers [15]. An advantage of cross-sectional studies is that they can be performed relatively rapidly and inexpensively.

Potentially confounding factors (e.g., age, demographics, diet, medications, exercise, other diseases) which might explain the association of interest are typically statistically controlled in the analyses. However, in cross-sectional

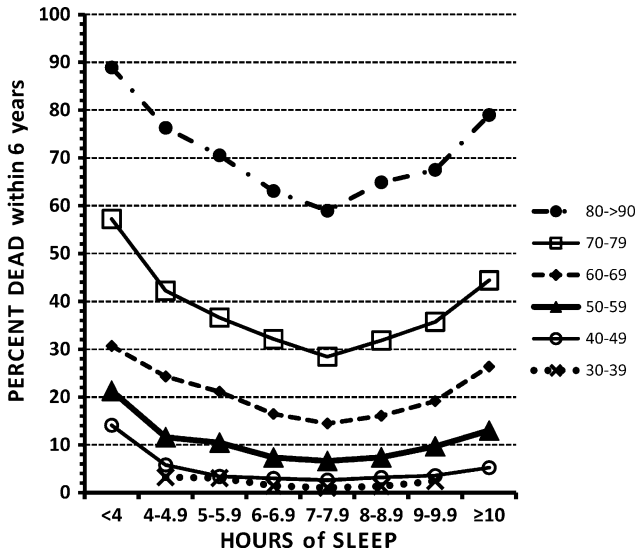

Fig. 31.1 Percent mortality (within 6 years) versus hours of sleep for different age groups, showing U-shaped distributions in every age group. Data were for over 400,000 participants in the Cancer Prevention Study 1 (Redrawn and adapted from Fig. 6 of Kripke et al. [6])

studies, the adequacy of control of confounders is often questionable. Even when dozens of factors are controlled, doubts can remain about whether the associations between risk factors and disease might still be explained by other factors which were not assessed or by complex interactions between potentially confounding factors, which are rarely assessed.

There are also limitations to the measurement of confounders. For example, questions pertaining to health could be limited to self-reports, and information about health-related behaviors such as diet and physical activity could be limited to brief questions for which validity has not been adequately established.

Another limitation of cross-sectional studies is an inability to show a temporal sequence between the risk factor and disease. For example, cross-sectional studies showing associations of depression with short sleep and long sleep cannot delineate whether a deviant sleep duration preceded depression or vice versa. Thus, cross-sectional studies do not provide strong evidence of causality.

Case–Control Studies

In case–control studies, a sample of subjects is selected for developing a disease or for dying, and a control sample, matched on age, sex, and other factors presumed to be relevant, is also selected. Then, the degree of exposure to potential risks factors and the odds of having the risk factor are compared retrospectively between the case sample and the control sample. Risk factors are determined from medical records and/or interviews of the participants or perhaps family members. For example, a recent case–control study identified infants who had died of sleep-related deaths (e.g., sudden infant death syndrome) and a control group and compared potential socioeconomic risk factors between the groups [16].

Case–control studies are most suitable for diseases which are rare and for diseases for which there is a long time period between exposure to a risk factor and onset of death or disease. One disadvantage of case–control studies is the difficulty in finding a control group which is adequately matched to the case group in factors which could influence the association. Another limitation is that interviews are susceptible to recall biases in case subjects or family members. For example, if poor sleep were assessed as a risk factor, case subjects might be biased to report that they had experienced poor sleep prior to the disease, a serious problem in studies of sleep duration.

Prospective Cohort Studies

Prospective cohort studies involve the selection of a group at random from a defined population, or the selection of groups exposed or not exposed to a risk factor, e.g., long or short sleep, versus 7 h sleepers. At baseline, the groups are carefully assessed on multiple potential risk factors for disease and mortality. The cohort and control group are then followed over time, and the incidence of disease or mortality is assessed.

An advantage of the prospective design is that risk factors can be carefully assessed at baseline, which leaves less potential for bias compared with retrospectively assessing risks after disease status is known. Prospective studies also allow for assessments of changes in risk factors over time, and for assessment of disease more accurately as it occurs. Temporal sequences between the risk factor and disease or mortality can also be assessed. Thus, prospective studies are generally regarded as the strongest epidemiologic evidence that a risk factor might cause a disease. However, causality can still not be definitively established in studies for which risk factors are not experimentally manipulated. There could be unrecognized or inadequately controlled confounders which could explain the association of interest, for example, a factor that was not adequately assessed at baseline.

Disadvantages of the prospective approach include its relatively high cost and time required to complete the study. However, a large proportion of studies that report prospective associations of risk with disease have involved retrospective analyses using baseline data that were previous collected, often many years beforehand, e.g., using electronic medical records.

Epidemiologic Evidence Linking Short and Long Sleep with Mortality

Associations of short and long sleep with mortality have been demonstrated in prospective studies involving >1 million participants, statistical control for over 30 potential covariates, and follow-up durations as long as 10–20 years [15]. Moreover, the patterns have been noted for men and women and all adult age strata. As reviewed elsewhere, there have been a large number of studies from all over the world demonstrating morbidity and mortality associated with long and short sleep. Although the possibility of confounding factors in these associations can still not be rejected, statistically, the chances that the associations are random are vanishingly small.

Kurina et al. [17] have provided an excellent critique of the literature. They highlight inconsistencies among studies: Of 55 findings, 30 supported an association of mortality risk with long sleep (including the largest studies), but only 16 supported an association of mortality risk with short sleep (including the two largest studies). Only two smaller studies reported scattered contrary findings. Despite the inconsistencies, in our view, the large consensus of studies encompassing millions of participants provides quite strong evidence that long sleep is associated with elevated mortality risks, and short sleep is less consistently associated with mortality as well. As reported several times previously, the evidence for association of long sleep with increased mortality is considerably stronger than the evidence for association with short sleep, but both are indicated by overwhelming trends among the results.

As noted by Kurina et al., the definitions of reported "long sleep" and "short sleep" durations have varied across studies, but we would think that such inconsistencies would be more likely to produce false negatives than false-positive findings of association. One suspects that many of the inconsistencies of definition arose from the use of samples too small to examine sleep durations in units of 1 h or less. Smaller samples also would have lacked adequate data and power for the extremes of short and long sleep. Smaller samples may require longer follow-ups to record enough deaths for statistical power, and the test–retest reliability of reported sleep durations drops off as the intervals between ascertainments increase. Over intervals as long as 20 years, the reliability of a single ascertainment of sleep duration decreases, so one might expect regression to the mean sleep duration to become increasingly important, tending to cause false-negative results.

Kurina et al. noted that sleep durations estimated from polysomnography or actigraphy are consistently shorter than those reported by questionnaire surveys. Moreover, questionnaires frequently neglect to distinguish between usual sleep durations on work days versus weekends and off-work times and frequently neglected the issues of napping and shift work. Although objective sleep durations are indeed usually shorter than questionnaire reports, the two are very significantly correlated. There is also evidence for a U-shaped associated of mortality with objective actigraphic sleep duration, however, with actigraphic recording, the optimal survival seems associated with 5.0–6.5 h [18], not with the 7.0 h (±0.5 to 1.0 h) frequently described as associated with optimal survival in questionnaire data. Accordingly, in actigraphic studies, we anticipate that both long sleep and short sleep will encompass ranges of duration shorter than the consensus from questionnaire studies, but that will in no way obviate the associations of sleep duration with mortality and morbidity. We do not find it plausible that widespread objective recording will negate the enormous evidence relating sleep duration to mortality and disease. Fortunately, just recently, low-cost wrist actigraphs with cloud-based data storage have become available to millions of customers, who purchase these actigraphs largely to keep track of exercise. As yet, we have seen no validation of sleep estimation algorithms for these popular consumer actigraphs, but surely it is only a matter of time until objective multi-year sleep recording will become available for tens of thousands of research participants, simply by analyses of data already being collected. Because modern polysomnography (especially with the intrusive instrumentation used for clinical apnea assessments) is well known to disturb sleep, and because multi-day and multi-year polysomnographic monitoring of tens of thousands of research participants is currently inconceivable, we do not anticipate that polysomnography will offer a superior objective measurement methodology compared to actigraphy.

In summary, although several wise critiques by Kurina et al. remind us of needed refinements of epidemiologic studies of sleep duration, we regard it as unlikely that better methodologies will negate the associations of sleep duration with mortality and various morbidities. However, it is important to concede that confounding which may not negate observations of association may negate association as definitive evidence of causation.

Arguments Advanced Against the Idea that Long Sleep Is Harmful

In epidemiologic studies, the risk of long sleep has typically been at least as great, and often greater than, the risk of short sleep, and more likely to persist following control for various confounds. Nonetheless, in contrast with the vast literature devoted to studying the risks of short sleep and speculation regarding potential underlying mechanisms, the risks of long sleep have been largely overlooked or dismissed as some type

of artifact. Several lines of arguments against the notion that long sleep is harmful are addressed below.

An "Epidemic" of Insufficient Sleep?

Limited data from selected epidemiologic studies have indicated that sleep duration has declined by about 1 h over the last few decades [19]. Such data, combined with evidence of risks of experimental sleep restriction (see below), have led to speculation—at times reaching hysterical proportions—that there is a modern epidemic of insufficient sleep. In particular, some scientists [20] as well as public relations advocates for sleep-focused businesses have been reluctant to accept evidence that 8 h sleep and beyond are associated with more mortality risk than 7 h. Such advocates of long sleep look back to a mythical time in the past when everybody slept 8 h, when women did not have to awaken to care for infants in the night, men did not have to guard the home, farmers did not have to tend to their livestock and fields, and nobody had to feed the fire. Of course, historical records fail to support these myths [21]. To the contrary, recent comprehensive reviews have indicated that there is no consistent temporal decline in nighttime or 24-h sleep duration, nor is there compelling evidence of increased prevalence of short sleep (<6 h/night) [22–24].

It is often also argued that the common phenomenon of sleeping extra amounts on weekends and holidays represents compensation for cumulative sleep debt during the week [25]. However, surveys suggest that sleeping extra amounts on weekends might be analogous to holiday overindulgence in food [26], and not necessarily indicative of harmful sleep debt. It makes no more sense to argue that people should always sleep to satiety than to argue that they should always eat to satiety. Just as being a bit hungry at times may be good for us, some daytime sleepiness could have had an adaptive role in evolution. In particular, midday napping in hot climates may be adaptive. Remarkably, both contemporary national questionnaire surveys and actigraphic studies indicate that since the year 2000, the U.S. adult population has had a median weekday sleep duration of about 6.0 h, consistent with the optimal actigraphic sleep duration associated with survival [18]. Since life expectancy has been increasing and health improving as sleep durations allegedly decrease, it requires a bold disrespect for evidence to insist that most of the population is sleeping too little.

Association of Long Sleep with Risks Could Be Explained by Other Factors

As discussed above, epidemiologic evidence cannot prove causality because of potential confounding of causes. Multiple psychobiological and sociobehavioral factors have been associated both with long sleep and health problems, including sleep apnea [27], depression [28], low socioeconomic status [29], unemployment [30], race [31], and low physical activity [4]. It is important to note that the same might be said of the risks of short sleep. Although epidemiologic studies have controlled for all of these factors, doubts still remain about how well these factors have been controlled or whether other factors have been overlooked.

Two lines of evidence resist concerns with a reverse direction of causality, i.e., moribund state or illness causing long sleep. First, epidemiologic studies that have excluded mortality data for the first several years to exclude moribund subjects at baseline have observed similar association of long reported sleep with excess mortality [15]. Second, associations of long sleep with risk have been found in prospective studies, including studies in which good health of subjects was apparent at baseline [32]. Indeed, a recent study of healthy children at baseline found a clear increased incidence of lifetime mortality among the long and short sleeping children at baseline [33].

Long Total Sleep Time or Long Time in Bed?

Research suggests that self-reported long sleepers [34], as well as average sleepers [35], tend to overestimate their TST by about 60 min compared with objective data. Thus, reported sleep durations tend to be closer to objective TIB than TST [35]. Mortality and morbidity risks associated with self-reported long sleep might be at least partly attributable to long TIB, which would have advantages for both research and therapeutic modification since TIB is far more modifiable than TST. However, given the high correlations of TIB with TST, reported long sleep is likely to be indicative of long physiologic sleep in epidemiologic studies. Recent research has confirmed risks associated with objectively long sleep [18, 36]. Studies that have discriminated between TIB and TST have found very similar mortality associations with both measures [18, 37, 38]. Moreover, studies which consider 24-h sleep report similar associations of sleep duration with risks.

Plausible Mechanisms of Risks of Long Sleep

Skeptics have argued that there is not a biologically plausible mechanism to explain how long sleep could cause negative health effects [20]. Yet, many healthy behaviors are hazardous in excessive amounts, including exercise, water intake, and sunlight exposure. Abundant self-report evidence suggests that sleep is not unique in this respect. People often feel lethargic after sleeping extra amounts on holidays or weekends [39] or following experimental sleep extension [40].

Clearly, there are hazardous effects of the extreme condition of excessive sleep produced by bed rest. Indeed, just 2–5 days of bed rest can elicit significant impairments in insulin sensitivity and cardiovascular function [41, 42]. More prolonged bed rest elicits profound deficits in bone density [43], muscle function [43], and mood [44]. In view of these findings, hospitals have increasingly attempted to minimize patient bed rest. During bed rest, young healthy adults display fragmented sleep patterns similar to that of nursing home residents, with extreme amounts of napping throughout the day and night [45], which might partly mediate the risks.

A similar hazard associated with habitual long sleep (or long TIB) is plausible via several potential mechanisms. First, extra TIB or sleep represents more completely sedentary time, and even an extra hour per day of other sedentary behaviors (e.g., television watching) has been associated with mortality and morbidity [46]. Long sleep has been associated with low levels of daytime physical activity [4], which could be explained by feelings of lethargy associated with long sleep [39, 40], as well as simply having less time available for physical activity [47]. Second, as with bed rest, long sleep is associated with increased sleep fragmentation, which has been significantly associated with poor health outcomes both in epidemiologic research [48] and in studies of experimentally induced fragmentation [49]. Third, long sleep duration could elicit metabolic changes that could lead to dyslipidemia [13]. Fourth, long TIB is associated with less exposure to light, which could result in depressed mood [50] and less robust synchronization of the circadian system. Fifth, lethargy and malaise, noted after acute sleep extension and in long sleepers, could potentially reflect cytokine imbalance elicited by long sleep.

Experimental Sleep Deprivation and "Short Sleep"

Negative effects of experimental sleep restriction have been well documented in dozens of short-term studies spanning over a century. Continuous sleep deprivation kills animals in a matter of weeks [51]. In humans, sleep restriction can elicit impairments in glucose tolerance [52], resistance to illness [53], mood [54], alertness [55], and cognitive performance [56]. Nevertheless, most sleep deprivation studies have had several limitations which make it difficult to draw definitive inferences with respect to relevance to public health. First, studies have mostly involved profound sleep deprivation, which might have little relevance to population variation in sleep duration. Second, most sleep deprivation studies have involved short-term manipulations (e.g., usually ≤ 5 days). Although negative effects might accumulate chronically, it is also plausible that people can adapt to sleep restriction. Indeed, several earlier studies found that TIB in young 8-h sleepers could be reduced to 4.5–5.5 h over several months with no impairments in performance or mood [57–60]. Third, double-blind designs are nearly impossible to accomplish in human sleep deprivation studies. Usually, the research observers are aware of the treatment, which could lead to subtle expectantly influences and interpretative biases. Participants invariably also know whether or not they are receiving sleep restriction. Fourth, laboratory sleep deprivation studies also tend to have almost-abusive aspects sensed by the participants and thus are susceptible to biases of participant expectancy and demand pressures related to easily deducible research hypotheses. Sixth, laboratory studies have examined participants subjected to exceptionally boring and meaningless tasks while deprived of bright light, caffeine, and usual levels of ambulation.

Some elegant laboratory studies have demonstrated cognitive deterioration when participants were randomized to spending 4 h in bed (i.e., sleeping less than 4 h) versus 6 h in bed (i.e., sleeping less than 6 h) versus 8 h in bed (i.e., sleeping less than 8 h). The dramatic disparity was between 8 versus 4 h in bed, with the deterioration associated with 6 h TIB being statistically marginal [56]. The relevance of such laboratory sleep deprivation studies to ordinary life is undocumented; they have not realistically simulated the variety of causes of short sleep found in the population.

Nonetheless, a recurrent illogic in discussions of short sleep is indiscriminant use of the term "sleep deprivation." In the laboratory, research participants may indeed be deprived of sleep. Nevertheless, it would appear that the short sleep associated with morbidity and mortality in most epidemiologic studies is usually not frankly coerced. Voluntary social factors may also be an element, as well as family demands. Sometimes a person restricts his/her sleep to comply with a bed partner's pattern. It is unknown to what extent short sleep in the population is attributable to external "deprivation," forms of voluntary self-restriction, genetic influences, insomnia, delayed and advanced sleep phase disorders, restless legs syndrome, or other medical disorders.

Genetic Causality

As much as 50 % of reported variation in sleep duration may be heritable [61, 62]. Two interesting genetic polymorphisms associated with sleep duration are a potassium channel variant [63] and short telomere length [64]. There are presumably other polymorphisms, such as those associated with delayed sleep phase disorder, which may also cause variations in sleep duration. The extent to which genetic variations might produce increased mortality mediated by variant sleep durations per se or alternatively by independent causal pathways is unknown.

Recently, a form of epidemiologic and genetic analysis utilizing Mendelian randomization has presented a new strategy for evaluating causal effects of short and long

sleep. Presumably, when one or both parents are heterozygous, Mendelian inheritance of a genetic polymorphism is essentially random. To the extent that a genetic polymorphism may cause lifelong habitual sleep duration to vary, the causal effects mediated by sleep duration can be evaluated by assessing the genetic association with sleep duration and thus with the outcome compared with the genetic association with the outcome directly. For example, if a potassium channel polymorphism is associated with short sleep (usually genetic associations are assumed causal because reverse causation cannot occur) and short sleep is associated with excess mortality, we determine the association of the potassium channel polymorphism with excess mortality. We could then estimate the association of the potassium channel polymorphism with control for the mediation by short sleep. From these data, it would be possible to determine the percentage of potassium channel polymorphism causal effect on mortality mediated by short sleep, and from this, the causal component of short sleep upon mortality could be inferred.

An increasing number of databases combining genome-wide association data with mortality data are being developed. As whole-genome sequencing becomes rapidly more widely utilized, whole-genome databases will be similarly developed. If data on sleep duration (whether questionnaire-based or objective) can be added to these databases prospectively, then follow-up for mortality and morbidity will permit Mendelian randomization analyses to be computed at the small cost of obtaining questionnaire or actigraphic records of sleep duration. The Mendelian randomization strategy will offer a highly feasible and efficient method of exploring the causality of sleep duration effects on mortality and upon various morbidities.

The Need for Controlled Trials

Ultimately, the causal element of sleep duration in mortality and morbidity must be explored through controlled trials, the gold standard experimental method of determining causality and treatment benefits. If sleep duration per se is a causal element in morbidity or mortality, then it should be demonstrable through the experimental method by randomly relieving the deviation from optimal duration. The problems of controlled trials of extending short sleep and curtailing long sleep are quite different. Ultimately, these problems must be mastered, if we are to have controlled-trial data to justify clinical interventions upon sleep duration.

The majority of controlled trials of extending short sleep have used hypnotic drugs. It is noteworthy that there are no controlled trials of hypnotic drugs which demonstrate objective long-term improvements in major health parameters, much less prolongation of survival. To the contrary, a large epidemiologic literature has demonstrated that use of hypnotics is associated with increased mortality and morbidity, as summarized by Kripke et al. [65] and Weich et al. [66]. Available controlled trials on hypnotic drug effects have generally been limited to studies of a year or less in duration and fewer than 1000 participants, study sizes which are too small to evaluate major hypnotic effects upon morbidity or mortality. The pharmaceutical industry is perfectly capable of performing trials of tens of thousands of participants followed for years, which should be adequate to assess major morbidity and mortality risks, but the industry has not yet made the effort to evaluate major risks of hypnotics, nor has government contributed with its regulatory role or by performing such studies with governmental support.

Fortunately, we do have useful data available from shorter term trials combined in meta-analyses by research groups without financial interests in hypnotics. In perhaps the most comprehensive meta-analysis to date, Buscemi et al. [67] found that hypnotics do not increase sleep durations even 1 h subjectively, and the objective sleep increments are much less. Indeed, the analysis questioned whether the "z" drugs (including zolpidem) produce any significant objective increase in sleep at all, certainly not enough to favorably impact mortality or morbidity. Were hypnotics able to relieve morbidity, we might expect to see fewer adverse medical effects reported in the hypnotic-administered groups than in the controls, but to the contrary, the randomized hypnotic groups had significantly more morbidity. Similar conclusions were reached in an independent meta-analysis of hypnotic effects on elderly patients (among whom most mortality associated with short sleep is concentrated) [68].

A couple of examples may be instructive. Mayer and colleagues reported a randomized controlled trial of ramelteon in which, at the end of 6 months, the ramelteon group was objectively found to be sleeping only about 1 min more than the placebo group [69]. The placebo group slept better than the hypnotic group after drug withdrawal.

In another randomized controlled trial of eszopiclone given to older insomniacs, the placebo group improved about 3 min more in actigraphic sleep duration than the eszopiclone group after 12 weeks, and the eszopiclone group slept slightly worse for three weeks after drug withdrawal [70], as reported on the ClinicalTrials.gov web site (http://www.clinicaltrials.gov/ct2/show/results/NCT00386334?term=eszopiclone&sect=X015_0b#outcome42 accessed February 19, 2014). In summary, the clinical trial literature does not suggest that hypnotics are a useful approach to reducing morbidity and mortality associated with short sleep. It remains to be seen whether exhortation is an effective method of lengthening self-restricted sleep durations, and whether such an approach can relieve the associated morbidity and mortality.

In the converse problem of curtailing long sleep, moderate changes are being proven feasible. Youngstedt et al. [71] completed an 8-week randomized controlled trial of willful self-restriction of long sleep with some objective improvements in sleep quality and no significant adverse effects, and a multi-center group is now expanding this strategy with objective monitoring [72]. Expanding preliminary iterations of this approach further will be needed before willful self-restriction could be tested in a randomized controlled trial large enough and long enough to explore whether restricting long sleep reduces the associated morbidity and mortality.

Summary

A strong epidemiologic literature has reported a U-shaped association of self-reported sleep duration with mortality and various morbidities. There is room for much extension and improvement in epidemiologic studies, but it appears that the epidemiologic findings encompassing millions of participants on several continents make a strong case for association of reported sleep durations with mortality and morbidity. The epidemiologic questionnaire findings are to a limited extent supported by objective sleep measurements, but larger objective studies are needed and now feasible. Unfortunately, causality cannot be inferred from the associations in these data, nor can it be inferred that extending short sleep will improve health or that restricting long sleep will improve health. The need for studies focused on causality is becoming more evident. Since sleep duration is to a considerable extent heritable, a genetic strategy based on Mendelian randomization offers a new pathway to exploring causality. To obtain a gold standard of causal evidence and to supply a basis for clinical interventions to modify sleep durations, we will need to develop large controlled trials which might demonstrate the possibilities of clinical benefit in modifying sleep durations.

Obstructive Sleep Apnea Syndrome

32

Rachel Korson and Christian Guilleminault

Introduction

Obstructive sleep apnea syndrome (OSAS) is a common, often under recognized, medical disorder characterized by repeated episodes of upper airway closure during sleep. The Wisconsin Sleep Cohort data listed prevalence figures of moderate-to-severe OSAS (defined by an apnea-hypopnea index of ≥ 15 events per hour all accompanied by excessive daytime sleepiness) at 10 % in men and 3 % in women among the ages of 30–49 years but 17 % in men and 9 % in women among the ages of 50–70 years) [1]. OSAS is associated with a constellation of symptoms and objective findings [2]. The most common presenting complaints are loud, disruptive, interrupted snoring, associated with unrefreshing sleep and excessive daytime sleepiness (EDS), or fatigue. OSAS may long remain undetected because the breathing disturbances occur at night, but the consequences are reflected in impairment of daytime function. Amazingly, many patients with even severe sleep apnea of many decades duration remain unaware of the cause of their difficulties. Bed partners are invaluable informants, describing frightening long pauses of breathing, choking sounds, and stridorous gasps when breathing resumes. The course is a slowly progressive one. Thus, the patient's daytime performance becomes insidiously more impaired, until the patient eventually decompensates and presents to the healthcare system, either volitionally or as a result of one of the complications of sleep apnea. Sleepiness is typically misperceived as a natural consequence of aging. There is a disparity between the prevalence of OSAS in the community and recognition among medical professionals of the frequency and impact of OSAS; this disparity is particularly sizable among primary care providers and health system managers [3].

Complete obstruction of the upper airway is termed *obstructive apnea* and partial closure is referred to as a *hypopnea.* When measured by polysomnographic (PSG) recording, obstructive apneas are defined as a total cessation of airflow at the nose and mouth, lasting at least 10 s, associated with ongoing thoracic and abdominal efforts to inspire. As per the American Academy of Sleep Medicine (AASM) Guidelines, last updated in October of 2012, hypopneas are defined as a greater than 30 % decrease in nasal airflow, lasting at least 10 s, associated with continued respiratory efforts, and either a 3 or more second arousal or with a drop in blood oxygen saturation of 3 % or greater [2, 4, 5]. In a recent modification of the manual, the AASM confirmed the 3 % or more desaturation (cg). More advanced technology has shown that a small decrease in tidal volume (V_T) may involve only one breath (or respiratory cycle) and lead to a transient, electroencephalography (EEG)-defined arousal, when associated with increased respiratory efforts while asleep. The current, noninvasive method of measuring oxygen saturation in arterial blood (Sao_2) does not indicate a recognizable drop in Sao_2 in association with this V_T decrease. If repeated, however, the short arousal will have an impact on sleep continuity—that is, lead to sleep fragmentation. In the strictest sense of the term, a reduction of airflow with a short arousal is a hypopnea, and some sleep specialists do not limit the term *hypopnea* to the definitions outlined earlier. This may be appropriate, given that very short events can have pathophysiologic consequences and impair well being, as with upper airway resistance syndrome (UARS) [6–9]. Both apneas and hypopneas are terminated with a large inspiratory breath.

Central apneas are seen on PSG as episodes of cessation of thoracic and abdominal respiratory efforts as well as nasal-oral airflow, lasting at least 10 s. Long-standing obstructive apnea may result in disturbances of central and peripheral respiratory reflexes, in turn causing central apneas. Moreover, the presence of inspiratory effort that distinguishes obstructive from central apneic events may be detectable only with esophageal manometry. Because this diagnostic tool is not in common use in sleep laboratories, these events are often misinterpreted as central apneas. Mixed apneas are composed of both central and obstructive components. The term *complex* or treatment-emergent central apnea refers to central apneas that are induced by the introduction of positive airway pressure (PAP) therapy. Treatment-emergent central apneas may dissipate with time as the body's chemoreceptors are thought be become readjusted to the normalized oxygen concentrations. Treatment-emergent central apneas, however, may persist.

The number of apneas and hypopneas are separately totaled and then divided by the hours of total sleep time to yield an apnea index (AI) and hypopnea index (HI). The AI and HI are summed to determine the apnea-hypopnea index (AHI), which is the average number of apneas and hypopneas per hour of sleep [10].

The minimum AHI and AI required to constitute a mild disorder is debated [11]. The symptomatology that is produced by a given objective amount of respiratory disturbance varies from individual to individual. Some people with severe OSA complain of very few symptoms, while other individuals with very mild OSA have severe symptoms. The correlation between AHI severity and long-term morbidity is not precisely delineated. This complex relationship is confounded by nightly fluctuations in the AHI, the amount of oxygen desaturation, and the percentage of time spent with reduced oxygen saturation. For clinical purposes, an AHI higher than 5 events/h is most commonly considered to be in the pathologic range [12, 13]. The term sleep-disordered breathing (SDB) has been given multiple definitions that render usage of this term difficult. It was initially created to report on the presence of abnormal breathing events that did not qualify for the definition of "hypopnea" that requires SaO_2 drop or visual EEG arousal and a set decrease in airflow. It became obvious over time that patients may have an impairment without having the required Sao_2 drop or that the visually scored EEG arousal was difficult to recognize. Also, introduction of the nasal cannula pressure transducer mode of recording led to recognition of flow limitation, and usage of an esophageal pressure (P_{es}) sensor to detect the presence of abnormal respiratory effort has changed the way breathing events are scored. Tabulation of these extra events led to calculation of a respiratory disturbance index (RDI) that includes respiratory event-related arousals (RERAs) as well as apneas and hypopneas. Others used "sleep-disordered breathing" as equivalent to AHI, rendering the value of the term at that time very questionable.

Obstructive sleep apnea syndrome lies along a continuum of SDB. There are controversies about the linearity of this continuum: It appears from recent data that there could be a point of "no return" where lesions in the upper airway leave permanent traces that may continuously impact on upper airway motor control during inspiration. Some (and we are part of this group) want to subdivide this reported "continuum" in two segments: First stage of chronic snoring and upper airway resistance (and there is no clear demonstration that chronic snorers do not always present some degree of upper airway resistance) with limited symptoms and usually no daytime sleepiness, and finally entering second stage through an increasing clinical severity, with progressive degrees of obstructive apnea based on RDI and oxyhemoglobin desaturations with clear sympathetic activation (cg). (This second stage has for some been always associated with a variable degree of upper airway neurologic lesions that may leave permanent sequelae.) Upper airway resistance syndrome (UARS) may be present without associated snoring but with associated daytime sleepiness or fatigue [6, 7].

The specific pathophysiology of these syndromes is discussed later in this chapter. As the incidence and prevalence of UARS have not been well characterized up to very recently, most of the presentation focuses on the well-known OSAS.

Epidemiology

The risk of developing OSAS increases with age, and the PSG pattern of obstructive apnea is strongly correlated with abdominal and neck obesity and male gender (however, when android obesity is present, subjects present with a combined syndrome: upper airway impairment and restrictive chest bellows impairment due to obesity) [14–17]. Prevalence of OSA reaches a maximum between the fifth and seventh decades [18]. Menopausal women develop OSAS at a rate similar to that of men. The Wisconsin Sleep Cohort Study evaluated the association between premenopause, perimenopause, and postmenopause and SDB in a group of 589 women. Using multivariate regression analysis adjusted for age, body habitus, smoking, and other potential confounding factors, Young et al. calculated the odds ratios for an AHI greater than 5 events/h of sleep to be 1.2 for perimenopause, and 2.6 (range 1.4–4.8) for postmenopause [19]. These results suggest that the menopausal transition is significantly associated with an increased risk of SDB independent of known confounding factors. However,

a recent study comparing younger (<30 years old) to older premenopausal women, found that with increasing age alone, came an increased risk of severe OSA (11 % vs. 21 %) [20]. Another important finding of this study was that, of the younger women, 20 % had UARS and 50 % had mild OSA. These mild presentations, although not often accompanied by the classic symptoms of snoring, witnessed apnea, and nocturnal gasping, did lead to significant daytime complaints of excessive daytime sleepiness, depression, and unrefreshing sleep [20].

Some minority populations appear to have a higher prevalence of SDB, indicating that race may be a risk factor. Three such populations are Pacific Islanders [21, 22], Hispanic Americans [23, 24], and Far East Asian [25], though there have been no studies that control for comorbid conditions found more frequently in these populations than in whites. As data from the Cleveland Family Study indicate, African-Americans may be at increased risk for sleep apnea [23]. In this study, the increased prevalence was not accounted for by differences in exposure to alcohol or tobacco or differences in body mass index (BMI). Moreover, this effect was most apparent in individuals younger than 25 years of age. Variable age of puberty, speed of development of secondary sexual characteristics, and mucosal enlargement associated with hormonal surge may have biased these findings. In contrast, a study in New Zealand comparing sleep apnea severity among Maoris, Pacific Islanders, and Europeans reported that race was not an important predictor of severity when adjusted for factors such as neck size, BMI, and age [24]. Familial aggregates of OSAS clearly indicate that risk factors for the development of this condition may exist very early in life [26–29].

Initial studies that attempted to define rates of OSAS were limited by biases that tended to underestimate actual prevalence. Early studies by Lavie [29] in Israel and Gislason et al. [30] in Sweden assessed the prevalence of OSAS in the adult male population to be 7 and 1.3 %, respectively. More recent studies of large, comprehensive population samples suggest a prevalence rate of OSAS at least two times higher than those early estimates [1, 31, 32]. In 1993, Young and colleagues published a large community-based study of adults 30–60 years of age that calculated, if OSA was defined as having an AHI greater than 5 events/h, a prevalence of 9 % in women and 24 % in men [13]. If the AHI of greater than 5 events/h was associated with symptoms of excessive sleepiness, however, the prevalence was 2 % and 4 % in women and men, respectively [13]. These studies are limited as they looked mainly at whites.

Obstructive sleep apnea syndrome has been associated with mortality both from vascular complications and from highway and industrial accidents. Two retrospective studies by Partinen et al. [33] and by He and colleagues [34] found an increased mortality rate for patients with OSAS, particularly in those younger than 50 years of age. As previously stated, OSAS is underdiagnosed. Untreated OSAS is a cause of death, as already shown by the study of Partinen et al. [33], and serious injury on the road and in the workplace [35–38]. Work by Findley et al. [38] suggests that the accident rate for OSAS patients is seven times that of the general population. Other studies have shown similar findings [39, 40].

Morbidity: Cardiovascular System

Over the past several decades, obstructive sleep apnea (OSA) has been shown to play a central role in hypertension, cardiovascular and cerebrovascular risk, metabolic syndrome, and longevity.

Hypertension

Systemic and pulmonary hemodynamics undergo acute and chronic changes as a consequence of obstructive apnea, most of which reverse on successful treatment of the upper airway obstruction. During normal sleep, blood pressure dips as compared to that during wakefulness. In subjects with OSA, nocturnal blood pressure remains elevated during sleep, with significant fluctuations in systemic arterial pressure occurring cyclically with episodes of apnea. During obstructive apneic events, there is an initial decline of blood pressure followed by an elevation that becomes maximal after ventilation resumes. In a study of 10 moderate-to-severe apneics, systolic and diastolic pressures rose approximately 25 % from their baseline values during apneas (i.e., from 126 to 159 mm Hg systolic and from 65 to 83 mm Hg diastolic) [41]. When apneas occur continually throughout the night and are associated with very severe oxygen desaturations, elevations may be extreme, exceeding 200 mm Hg systolic and 120 mm Hg diastolic [42].

Evidence implicates several mechanisms that contribute to cyclic increases in blood pressure. A fall in partial pressure of arterial oxygen and an increase in acidosis signal the carotid chemoreceptors to trigger vasomotor center-mediated arteriolar constriction, which leads to increased systemic vascular resistance. Increased ventilatory effort against a closed upper airway in the face of air trapping leads to significant right-to-left bowing of the interventricular septum and decreased cardiac output [43, 44]. Left ventricular collapse can occur with very negative inspiratory pressures [43]. With resumption of ventilation, and the abrupt shift from sleep to wake, there is a release of vagal parasympathetic predominance and heightened sympathetic tone.

Pulmonary stretch reflexes induce tachycardia, which increases cardiac output. Changes in preload and afterload due to repetitive Müller's and, at times, Valsalva maneuvers also contribute to the changes in cardiac output. Evidence of elevated sympathetic nervous system activity can be measured by increased urinary catecholamine levels, which return to normal after treatment of apnea [45, 46].

Investigation of OSA subjects using microneurography on the peroneal nerve in the popliteal fossa during wake and sleep has further enhanced our knowledge about sympathetic activity in people with OSA. In healthy individuals, muscle sympathetic nerve activity (MSNA) at the popliteal level shows low sympathetic activity, particularly at rest during daytime wakefulness in experimental conditions. OSA patients have elevated MSNA during wakefulness, with a very significant increase in discharge rate [47–49]. It is believed that the repetitive hypoxemia associated with apnea and hypopneic events leads to important changes in the autonomic nervous system neuronal network, with a resetting of the sympathetic receptors [49]. This resetting leads to the continuous discharges that persist during the daytime when hypoxemic events are not present. The abnormal waking sympathetic activity is thought to lead to vascular changes, including progressive endothelium impairment involving the nitric oxide system [50, 51], which has been strongly implicated in the development of plaques and atherosclerosis [52, 53]. These are some of the mechanisms believed to be responsible for developing hypertension with OSA.

Independent of the associated mechanisms, OSA is a risk factor for hypertension [54]; other factors are difficult to tease out as, unfortunately many studies have been performed on obese OSA patients and it is impossible to completely dissociate the role of obesity from the role of upper airway obstruction during sleep. Hypertension is also a frequent comorbid condition with sleep apnea [54–57]. Approximately 30 % of patients with systemic hypertension have sleep apnea, whereas 50 % or more of patients with sleep apnea have systemic hypertension, and the percentage of those with refractory hypertension is even higher. The Sleep Heart Health Study, in a cross-sectional analysis of over 6000 subjects, showed an independent association between OSA and hypertension. The most compelling evidence that OSA is an independent risk factor for hypertension comes from the Wisconsin cohort group. This population study involved over 700 government employees and collected medical and sleep data via detailed questionnaires, physical examinations, and PSG. Peppard et al. found that having OSA (diagnosed by PSG) significantly increased the risk of developing hypertension 4 years later compared to the risk in subjects without SDB, independent of known confounding factors [57]. This increased risk was greater in those subjects with more severe disease. Subjects with mild obstructive sleep apnea (AHI of 5–14.9 events/h) were 2.03 times (95 % confidence interval [CI], 1.29–3.17) more likely to have hypertension than normals, and subjects with an AHI of 15 events/hr or more were 2.89 times (95 % CI, 1.46–5.64) more likely to have hypertension. Even those with mild SDB (AHI of 0.01–4.9 events/h) were not immune from the negative effects of disordered sleep and were more likely to develop hypertension 4 years later, with an odds ratio of 1.42 (95 % CI, 1.13–1.78) compared to subjects without SDB [57].

Hypertension may be generated by sympathetic overactivity triggered by intermittent hypoxemia, large negative fluctuations in intrathoracic pressure, and repetitive arousals from sleep [56, 58, 59]. Hypertension may improve after treatment of apnea [60]. The ameliorative effect of treatment has been found after upper airway surgery [61] and nasal continuous positive airway pressure (CPAP) [62]. Moller et al. [63] performed 24-h blood pressure monitoring and measured plasma levels of vasoactive hormones in 24 OSA patients and 18 control subjects. Compared with the controls, OSA patients had significantly higher blood pressure and heart rate, and the sleep-related nocturnal blood pressure drop was reduced [63]. Thirteen OSA patients re-examined after 14 months of CPAP therapy demonstrated reduction in blood pressure, which correlated with a decrease in both plasma renin and plasma angiotensin II concentrations [63]. However, many patients with hypertension and OSA do not go back to normal blood pressure.

Sin et al. reported that 40 % of 301 patients with congestive heart failure had OSA and systemic hypertension. After controlling for other risk factors, OSA patients were 2.89 times (95 % CI, 1.25–6.73) more likely to have systolic hypertension than those without OSA. The degree of systolic blood pressure elevation was directly related to the frequency of hypopneas and apneas [64].

In OSA patients, there is evidence the body tries to compensate for hypertension. Increased release of atrial natriuretic peptide (ANP) during sleep has been found in sleep apnea, with concomitant increases in urine and sodium output [65]. ANP suppresses the renin–angiotensin–aldosterone system, and plasma renin activity curves have been found to be abnormally flattened in apneics during sleep [66]. These changes lower blood volume and blood pressure and may play a protective or compensatory role against blood pressure elevations in OSA. Treatment of apnea normalizes ANP, thereby diminishing diuresis and natriuresis, and increases renin and aldosterone release.

Accumulating data indicate that OSA is an independent risk factor for gestational hypertension and preeclampsia contributing to adverse maternal and fetal outcomes.

High-risk pregnant women should be screened and treated appropriately for any sleep-disordered breathing given the possible benefit that CPAP use may have on health outcome.

Heart Failure

Heart failure also appears to occur as a consequence of OSA. The Sleep Heart Health Study reported that OSA is associated with a relative odds ratio of 2.38 for heart failure independent of other known risk factors [67]. OSA is also prevalent in patients with heart failure. Javaheri et al. [68] performed PSG in 81 ambulatory men with stable, treated systolic heart failure. Fifty-one percent of the patients had moderate-to-severe sleep apnea with an AHI of 15 events/h, and the group had an average of AHI of 44 events/h [68]. Chan et al. reported in a series that about 50 % of patients with isolated diastolic heart failure had an AHI of at least 10 events/h [69].

Whether heart failure patients with SDB benefit from CPAP treatment is unclear. Several studies have shown that short-term use of CPAP in patients with heart failure and obstructive sleep apnea improved left ventricular ejection fraction, blood pressure, and ventricular systolic volume [70, 71]. CPAP is recommended for heart failure patients with clear-cut OSA [70, 71]. However, in addition to obstructive events, heart failure patients may present with a variety of abnormal respiratory activities while sleeping. They may have central events; mixed events, Cheyne–Stokes respirations, and repetitive diaphragmatic pauses; or a combination of mixed, obstructive, and rare central events. This last subgroup may derive some benefit from nasal or bilevel CPAP. However, a careful analysis of the PSG pattern is needed, and an in-laboratory titration for pressure is mandatory, evaluating the appearance of dyspnea reported during the titration night. Bradley et al. reported the first studies and concluded that nasal CPAP is not a recommended treatment for heart failure patients who suffer from central sleep apnea (defined as >50 % of apnea episodes central in etiology) as treatment did not improve quality of life, number of hospitalizations, or survival [72]. Kasai et al. reported that following CPAP therapy patients with heart failure and moderate-to-severe OSA were less likely to die or be hospitalized than untreated patients, though those who were poorly compliant with CPAP were most likely to reach these unwanted end points [73].

Pulmonary Hypertension

Moderate-to-severe increases in pulmonary arterial pressure occur with each apneic episode. Maximal pulmonary pressures are generated during rapid eye movement (REM) sleep. They coincide with maximal hypoxemic and hypercapnic values [60] and probably reflect hypoxic pulmonary vasoconstriction. When pressure gradients between the pulmonary artery lumen and thoracic cavity are evaluated, transmural pulmonary arterial pressure decreases during the first 25 s of apnea and then increases until breathing returns and transiently rises more rapidly [74]. Another hemodynamic change consists of reductions in cardiac output of up to one-third of baseline values in apneas longer than 35 s [43].

The development of persistent pulmonary hypertension during wakefulness and cor pulmonale may be caused by severe hypoxemia during sleep [73, 74], but is more likely in daytime hypoxemia [75]. There has again been controversy regarding the persistence of daytime pulmonary hypertension. Earlier studies estimated the prevalence of pulmonary hypertension in OSA patients to be as high as 20–41 % [76–78]. However, these studies were small and did not control for other risk factors for pulmonary hypertension. There is, however, agreement that a subgroup of OSA patients present with pulmonary hypertension, usually moderate, during the day associated with their sleep-related problem. The American College of Chest Physicians recommends that evaluation for OSA should be part of the initial workup in patients with pulmonary hypertension [79]. Possible mechanisms thought to cause pulmonary hypertension include hypoxemia-induced endothelial cell dysfunction and pulmonary artery remodeling [80]. The reversal of pulmonary hypertension in OSA patients is reported to be poor after treatment [81].

Cardiac Arrhythmias

Cardiac arrhythmias that occur exclusively during sleep are common in apneics. Sinus arrhythmia accompanies each obstructive respiratory cycle, in which rate diminishes with the cessation of airflow and accelerates when breathing resumes. These changes can be mild or severe, resulting in repetitive cycles of bradycardia and tachycardia fluctuating from fewer than 30 to more than 120 bpm [82]. Severe sinus bradycardia (fewer than 30 bpm) affects approximately 10 % of sleep apneics and is usually seen with severe hypoxemia [83–85]. These aberrations of rate combined with hypoxemia predispose to conduction defects, malignant arrhythmias, and perhaps sudden death. Asystoles of up to 13 s, second-degree atrioventricular (AV) block, premature ventricular contractions (PVCs), and runs of ventricular tachycardia are among documented apnea-related abnormalities [86]. A prospective study of 147 consecutive patients demonstrated significantly higher prevalence of nocturnal paroxysmal asystole in OSA patients and increased episodes of bradycardia and pauses that correlated with the severity of the sleep apnea [87].

Proposed mechanisms for bradycardia, Mobitz type I AV block, and asystole involve vagal nerve activation due to both Müller's maneuver and hypoxemic carotid body stimulation. Electroencephalographic arousal with airway reopening and lung expansion triggers cardiac acceleration. Increased sympathetic tone due to hypoxemia and acidosis may be expressed after vagal influence is withdrawn, leading to PVCs, sinus tachycardia, and ventricular tachycardia. PVC frequency and other ventricular arrhythmias have been shown to correlate with severity of oxygen desaturation, increasing threefold with desaturations lower than 60 % (as compared to 90 %) [87].

From a global perspective, many of these physiologic changes in response to asphyxia may be viewed as an attempt to preserve perfusion to the critical cerebral and coronary systems. Increased systemic pressure selectively perfuses these critical central vessels, whereas bradycardia decreases myocardial oxygen consumption. As bradycardia becomes more profound, however, myocardial perfusion may become more impaired, because the perfusion gradient drops as diastole is prolonged. Coronary ischemia may result in ventricular arrhythmia. On return of ventilation, cardiac rate and output rise in the setting of sympathetic dominance and decreased systemic resistance. The demand for myocardial oxygen to accomplish this work outweighs the supply of reperfused blood, rendering the myocardium vulnerable to malignant arrhythmias [87].

Obstructive sleep apnea may increase one's risk of developing atrial fibrillation (AF) and its recurrence after cardioversion. In one study, consecutive patients who underwent cardioversion for AF were compared to patients without AF who were referred for management of cardiovascular disease at a tertiary medical facility. The prevalence of OSA was statistically higher in patients with AF (49 %) compared to those without AF (32 %) [88]. Kanagala et al. showed that the recurrence rate of AF at 12 months after cardioversion in patients with untreated OSA was nearly twice that of untreated OSA patients (82 % vs. 42 %, respectively) [89].

Coronary Artery Disease, Myocardial Infarction, Stroke, and Early Death

Sleep apnea and even snoring have been epidemiologically linked to increased incidences of myocardial infarction and stroke [90, 91]. Spriggs and coworkers [92] looked at risk factors for stroke in approximately 400 individuals with OSAS who had been matched with controls for sex and age and found an odds ratio of 3.2 for symptoms of snoring. Another study found an increased odds ratio even after adjustment for ethanol use, hypertension, and heart disease. The ratio increased approximately fourfold if obesity, observed apneas, and a subjective sense of EDS were present [90]. A study of over 1000 patients showed an increased hazard ratio in OSA patients of 2.24 for stroke or death from any cause over a several-year period [93]. After adjustment for multiple risk factors (age, sex, race, obesity, hypertension, etc.), the hazard ratio remained significant at 1.97 (95 % CI, 1.12–3.48). Furthermore, analysis indicated that those with more severe OSA were more likely to reach these end points. Though this study strongly suggests OSA increases the risk of stroke or death, it may statistically underestimate its risk in the development of these end points as many of the OSA patients were treated surgically or with CPAP during the study period [93].

The increased incidence of stroke is likely secondary to multiple reasons. During apneic events, there is a greater chance of hypoxemia, hypercapnia, increased frequency of cardiac arrhythmias, increased coagulation, and paradoxical embolism through a patent foramen ovale. Cerebral blood flow may be variable during apneic events as evidenced by transcranial Doppler studies. However, Yaggi et al. [93] presented convincing data indicating that OSA is an independent risk factor for stroke.

Stroke and transient ischemic attacks are also a risk factor for OSA. Over half of patients with acute strokes or transient ischemic attacks have OSA [94, 95]. Stroke patients who have OSA appear to have higher mortality as well [94]. One study has shown that successfully treating stroke patients who have OSA with CPAP significantly decreased the risk of subsequent vascular events [96]. However, larger studies suggest that only a minority of stroke patients with OSA are able to tolerate CPAP [97].

Obstructive sleep apnea may be a predisposing factor to atherosclerosis and plaque formation, as discussed earlier, due to its action on the arterial endothelium and the nitric oxide system. Kaynak et al. [98] preformed ultrasonographic examination of both carotid arteries to evaluate intima-media thickness and the presence of plaque in 114 male patients referred for evaluation of SDB. Patients with OSA had significantly increased intima-media thickness compared with habitual snorers. Age and BMI were significantly associated with intima-media thickness, whereas age and RDI were most predictive for plaque [98].

Obstructive sleep apnea has been linked to other risk markers for cardiovascular disease, including increased levels of leptin, C-reactive protein, and homocysteine, and insulin resistance syndrome [99]. However, some of the abnormalities observed have been determined not to be related to OSA but to the frequently associated obesity; as an example, C-reactive protein is not elevated in OSA patients with a maximum BMI of 25 kg/m^2 despite a mean AHI of 30 events/h [100]. Abnormal levels of leptin and ghrelin seen in these subjects seem to be related more to the severity of the sleep fragmentation (or total sleep loss) induced by the

syndrome that directly results from apnea and hypopnea [101]. Leptin and ghrelin levels can normalize in patients once their sleep apnea has been treated [102].

Several studies have shown decreased mortality associated with OSA patients treated with tracheostomy or CPAP [33, 103]. He et al. [34], comparing cumulative survival after 5 years of untreated versus treated patients with an AI greater than 20 events/h, showed that cumulative survival was approximately 75 % in the untreated group as compared to almost 100 % for the treated group was criticized due to the large number of subjects lost at follow-up. A study by Partinen et al. comparing mortality in OSA subjects 5 and 8 years following tracheostomy or no treatment showed decreased mortality in treated subjects [33]. A large study from Spain involving over 800 patients showed that OSA patients compliant with CPAP, compared to those who were not treated, were more likely to survive over a several-year period. The survival rate was positively associated with increased CPAP usage [103]. Marin et al. [104] published a study involving several hundred Spanish men and showed that fatal and nonfatal cardiovascular events occurred more frequently in untreated OSA patients compared to treated OSA patients. Furthermore, treated patients with sleep apnea had a frequency of fatal and non-fatal cardiovascular events similar to that of simple snorers [104].

Earlier studies showed an increased incidence of proteinuria in OSA patients [105, 106]. However, more recent studies have not shown this correlation [107, 108].

Pathophysiology

Sleep-disordered breathing is caused by increased resistance while breathing secondary to narrowing at one or more sites of the upper airway. Locations of narrowing include the nose, retropalatal region, retroglossal region, or, less commonly, the hypoglossal region.

The size of the pharyngeal upper airway is dependent on a balance of forces between the upper airway dilators, which maintain upper airway patency, and the negative pharyngeal intraluminal pressure created during thoracic expansion as a result of inspiration. Skeletal factors also play a role. Bernoulli's principle dictates that narrowing of any segment while airflow is maintained causes an increased velocity of airflow in that segment. This decreases intraluminal pressure and further narrows the segment, favoring upper airway collapse. In sleep, the stage (REM vs. non-REM [NREM]) also influences upper airway patency as REM sleep is associated with atonia. Lack of coordination between inspiratory muscles and upper airway dilators leads to upper airway occlusion during sleep. This was reported as early as 1978 by Guilleminault and Motta [109] in an investigation of patients with postpoliomyelitis syndrome who had been treated with a cuirass ventilator. These patients developed a negative intrathoracic pressure that could not be counteracted by the upper airway dilators and that led to the development of OSAS. These findings were later confirmed by Hyland et al. [110] and by Simmonds and Branthwaite [111].

More recent studies have shown abnormal activity of the dilatory pharyngeal muscles (genioglossus and tensor palatine) in OSA patients. During the waking state, the activity of these muscles is increased compared to controls [112]. With sleep onset, there is normally an increase in resistance due to a decrease in upper airway muscle tone. In OSA patients, there is a greater diminution in muscle tone compared to controls as measured by electromyography (EMG) [112, 113]. A working model for OSA may be that, in the presence of a susceptible airway (one that is already narrowed by obesity, a small chin, enlarged tonsils, etc.), the factors that act to maintain upper airway patency and minimize increases in upper airway resistance during sleep are inadequate, with consequent SDB. Recent studies have suggested that a potential upper airway stabilizing mechanism may be initiated by the flow of air into the pharynx during inspiration. Although the complete details of this reflex have not been described, it appears that a reflex loop is activated once inspiration starts causing a flow of air into the upper airway with the following sequence of events: (1) Sensory neurons in the upper airway are activated; (2) sensory afferents travel to the brain stem, which subsequently activates the efferent hypoglossal nerve that innervates the genioglossus and geniohyoid; and (3) genioglossus and geniohyoid contraction keeps the pharynx open during inspiration. This reflex may be altered in OSA patients because of damage to the muscle and nerves from the vibratory trauma of snoring. This theory is supported by the findings of abnormal sensory nerves and nerve function seen in both histologic preparations and neurophysiologic studies of upper airway muscles in OSA patients [114–116].

At sleep onset, there is an increase in resistance due to a decrease in upper airway muscle tone [113, 117]. This increase in upper airway resistance has no known consequences in normal subjects. In snorers, however, there is a further increase in each snore. In response to this increased resistance, many subjects are able to increase their inspiratory effort and maintain normal V_T. Increased effort is demonstrated by P_{es} monitoring, which may reach peak inspiratory nadirs of −12 to −15 cm H_2O. The effort is constant over time, and in some patients does not negatively impact sleep architecture or oxygen saturation. However, in other cases, the upper airway dilators are unable to oppose the negative pharyngeal intraluminal pressure sufficiently to maintain minute ventilation and normal gas exchange [118].

In these cases, inspiratory effort is increased as reflected by an increase in P_{es} nadir. With increasing inspiratory efforts, there is a decrease in the width of the upper airway, as upper airway dilators are unable to exactly match the inspiratory negative pressure. At some point, an abnormally negative P_{es} pressure is reached, V_T is reduced for one to three breaths due to the further narrowing of the upper airway passage, and an arousal response is triggered. This response is transient and short lived (as short as 2 s with visual EEG scoring). Changes in sympathetic and parasympathetic tones vary depending on the degree of adjustment done by the upper airway muscles in relation to the increase in inspiratory efforts. The results of this delicate balance may lead to a chronic low blood pressure and even some small physical signs of chronic hyperactivity of vagal tone (cold hands, cold feet, slight dizziness when abruptly getting up particularly when getting out of bed just after waking up) [119].

It is notable that a large percentage of OSAS patients have subtle craniofacial abnormalities, such as a highly arched hard palate, a long soft palate with low placement and redundant tissues, and moderate retroposition of the mandible [120, 121]. It has been suggested that these abnormalities are responsible for obstructive apnea during the first weeks of life in certain subjects [122]. These abnormalities are related to genetic factors, and we have investigated several families in which a small upper airway has been passed down for generations [123].

As stated previously, the upper airway begins at the nares and includes the nasal vestibule, nasopharynx, oropharynx, and hypopharynx. The pharynx is an especially vulnerable portion of the upper airway because it serves both digestive and respiratory functions. It must be sufficiently floppy to contract and guide food into the esophagus, while alternately maintaining sufficient muscle dilation to keep from being sucked closed.

Nasal obstruction from any cause, including allergic congestion, inflamed lymphoid tissue, or septal deviation, can initiate obstructive nocturnal respiratory pathology by converting breathing from the nasal to the oral route. Oral breathing predisposes to abnormal airway dynamics favoring pharyngeal collapse and backward displacement of the base of the tongue. The dilating genioglossus and geniohyoid muscles become mechanically disadvantaged, and airway resistance is increased.

The next potential level of obstruction arises at the nose and oropharynx due to enlarged adenoidal, tonsillar, and soft palate tissues. Enlargement of these tissues is secondary to hereditary and acquired factors. Allergies and recurrent upper respiratory infections can cause hyperplasia and scarring of lymphoid tissue. Snoring renders the uvula more edematous due to suction and trauma, which further compromises the small oropharyngeal space. Macroglossia may be due in part to obesity and is implicated in OSAS [119].

A constellation of jaw malformations is associated with OSAS, including a highly arched hard palate and class II dental occlusion (overjet). The position of the mandible relative to the maxilla determines the posterior extension of the tongue. Because the genioglossus muscle inserts on the mandible, with retrognathia or micrognathia, the genioglossus originates on a backwardly displaced mandible and thus extends further posterior, predisposing to hypopharyngeal obstruction. During sleep in the supine position, gravity pulls the tongue further into the pharyngeal lumen, and varying degrees of decreased muscle tone additionally relax the tongue dorsally.

Chronic nasal obstruction during childhood that results in oral breathing may induce craniofacial changes predisposing to sleep apnea later in life. This has been shown in rhesus monkeys with experimentally partially occluded nostrils that developed mandibular deficiency relative to paired controls. Oral breathing changed EMG activity in facial muscle groups, leading to altered forces on the developing facial skeleton [124–126]. Partial improvement in these changes occurred if the obstruction was relieved early enough. Upper airway obstruction from enlarged adenoids in children has been shown to lead to decreased mandibular size and retrognathia, among other craniofacial changes (see below) [127–131].

Pathological hypotonia of the tongue muscles has been shown to lead to the development of a high and narrow hard palate which is associated with increased risk of sleep-disordered breathing. Understanding the continuous interaction between muscle activity of the tongue and the development of a normal palate and other anatomical structures supporting the upper airway highlights the role of myofunctional therapy in the treatment of sleep-disordered breathing [132].

Adiposity compromises the upper airway not only because the “double chin” externally compresses the pharynx in the supine position, but also through internal infiltration of parapharyngeal structures (i.e., the adipose tissue alters and reduces airway space). Pharyngeal dilator muscle mechanics may be compromised by this loading [133]. Additionally, upper airway imaging studies have shown that patients with OSA have narrow airways due to adipose tissue in the lateral walls of the pharynx.

Testosterone may contribute to obstruction by inducing more parapharyngeal muscle bulk and more centripetal fat distribution. This might explain the fact that snoring often begins at puberty or during the immediate postpubertal period. Even a few kilograms of excessive weight can tip the balance toward upper airway obstruction in anatomically vulnerable patients.

Morbid obesity degrades waking and sleeping ventilation in addition to its impact on upper airway dynamics. Adipose deposition around the abdomen, diaphragm, and ribs reduces

thoracic cage compliance, requiring increased work of breathing [134]. Functional residual capacity is decreased, and atelectasis of dependent airways may create ventilation-perfusion mismatch with hypoxemia [135]. In the supine position, the abdominal weight creates additional load, which increases hypoxemia [136]. During REM sleep, muscle atonia renders accessory respiratory muscles such as the intercostals and upper airway dilators functionally paralyzed. Thus, the diaphragm contributes mostly to inspiration against the load created by the heavy chest mass, leading to the profound oxygen desaturations seen during REM sleep in some obese patients.

Summary

Partial or complete upper airway occlusion is related to the development of greater subatmospheric intrathoracic pressure during inspiration. This subatmospheric pressure is transmitted to the pharyngeal region, creating "suction" on the soft tissues, which are the major constituents of the pharyngeal airway. To prevent closure, reflexes are normally activated at least 500 ms before the beginning of inspiration to activate the contraction of upper airway dilator muscles in opposition to this subatmospheric intrathoracic pressure.

During sleep, many of the upper airway dilator muscles have much less contractile power than the diaphragm. The genioglossus and geniohyoid muscles are particularly affected. The motor activity of these muscles is abnormal in OSA patients, with heightened contraction during the daytime and decreased contraction at sleep onset. This physiologic change allows the development of abnormal inspiratory upper airway resistance, which may result in partial or complete occlusion. If abnormalities of the upper airway due to anatomic, physiologic, or neurologic causes reduce size to a level lower than critical or limit the capabilities of upper airway dilator muscles, a more or less pronounced collapse will occur during sleep in this very flexible region. The obesity hypoventilation syndrome with increased arterial partial pressure of carbon dioxide (P_{CO_2}) has been described during the awake state. It is thought to result from reduced hypoxic and hypercapnic ventilatory drives and is not attributed to weight-related mechanical factors [137].

Neural factors that relate to state changes from wakefulness to sleep, as well as changes across sleep stages, play an adjunctive role in the anatomic considerations of the genesis of OSAS. During sleep, the wake-related contribution to ventilatory drive is lost. This wakefulness stimulus [138] consists of factors that are independent of metabolic and voluntary components. With sleep onset, autonomic integration of acid-base and oxygen homeostasis is believed to occur in the medulla. Inputs to this regulator include peripheral chemoreceptors for PCO_2 and partial pressure of oxygen (PO_2); central chemoreceptors for pH and PCO_2; and stretch receptors in the lung, thoracic wall, and upper airway. Ventilatory responses to both hypercapnia and hypoxia are decreased in all stages of sleep [139, 140], with more profound decrements usually occurring during phasic REM than in NREM sleep states. REM sleep-related decrements in muscle tone leading to changes in thoracoabdominal mechanics with distortion of the thoracoabdominal wall will be further increased in obesity. During sleep, PO_2, V_T, and minute ventilation are decreased, whereas PCO_2 increases by 2–6 mm Hg. These changes are attributed to a resetting of the CO_2 set point and a depressed ventilatory drive per given level of PCO_2 compared to wakefulness. For unknown reasons, males have a reduced ventilatory response to CO_2 compared to females [141].

With sleep onset, sensitivity of the central CO_2 set point to the peripheral chemoreceptors is reduced. This results in a central apnea or a reduction in diaphragmatic effort and a decrease in tidal volume (central hypopnea), which allows P_{CO_2} to rise. If resumption of breathing induces obstruction by the mismatched timing mechanism discussed earlier, or if the dilatory muscles of the oropharynx have decreased tonicity, then a brief arousal may be triggered. Arousal resets the P_{CO_2} to the awake set point and increases ventilation. With the resumption of sleep, a cycling of central apnea, obstructive apnea, and arousal will occur [142]. This is commonly observed in the mixed apneas typically seen in obstructive sleep apneics. Any cause of sleep fragmentation, such as periodic limb movements, may bring about the unstable respiratory state in predisposed individuals that produces this common type of sleep onset apneas.

In addition to the chemoreceptor influences described earlier, pressure-sensitive reflexes exert a more rapid influence on upper airway patency. Located throughout the upper airway [142], pressure-sensitive reflexes coordinate the interplay of forces between inspiratory pump muscles and dilator muscles in a breath-to-breath fashion. When suction pressure produced by the diaphragm is registered, these reflexes increase genioglossus muscle activity, moving the tongue anteriorly and prolonging the duration of inspiration. Longer inspiratory times reduce the peak suction pressure, facilitating patency of the airway.

These reflexes are normally reduced during sleep but may be defective or ineffective in patients with sleep apnea. Issa and Sullivan [143] found upper airway closure to occur at abnormally low inspiratory pressures in patients with sleep apnea during a study in which the nasal airway was occluded. Even when peripheral chemoreceptor drive was added, which should facilitate patency, there was no augmentation in activation of the dilator muscles, as measured by closing pressure.

The degree of hypercapnia in sleep apnea is influenced by input from the peripheral chemoreceptors on upper airway

dilators and the inspiratory pump as well as the ability of these reflexes to trigger arousal with resumption of ventilation. Most OSAS patients are normocapnic while awake. However, a limited population of severe sleep apneics displays hypercapnia while awake that is not attributable to pulmonary disease or obesity. The hypercapnia in these patients indicates hypoventilation due to downward resetting of chemoreceptor reflex sensitivity. Sullivan's group [144] showed that these patients had decreased carotid body responses to hypoxemia and failed to develop normal augmentation of response to superimposed arterial hypercarbia. Elevated levels of CO_2 were required to produce a ventilatory response. These patients demonstrated long periods of obstructive apnea or hypopnea, concomitant with sustained arterial oxygen desaturations and arterial CO_2 elevations.

Resetting of chemoreceptors may allow the endurance of longer apneic events while asleep without producing arousals. Because the chemoreceptor responses are depressed, they do not lead to increased inspiratory efforts—as would normally occur with sensitive reflexes—thereby preventing the partially occluded upper airway from being sucked entirely closed. Diminished inspiratory efforts through a narrow upper airway cause reduced total ventilation, with oxyhemoglobin desaturation and CO_2 elevation. Tracheostomy or nightly treatment with nasal CPAP normalizes awake hypercapnia, suggesting that sleep apnea is a major factor in its development.

Snoring

Snoring is a noise produced when vibration occurs at several levels of the upper airway. It may be associated with various degrees of upper airway resistance. It may be heard after a complete airway obstruction; with a significant hypopnea; or with hypoventilation, leading to a cohort of symptoms. It may be associated with a limited and intermittent drop in V_T and be associated with isolated sleepiness. It may cause sleep fragmentation or present with no other clinical symptoms. The notion that snoring itself may engender cardiovascular risk is in question. Studies that suggested this probably failed to separate out subpopulations with UARS (discussed later), or situational apneics based on such behavior elicitors as alcohol or sedative use. Although more research is required, it is likely that chronic heavy snorers eventually become patients with clinically significant syndromes of obstruction. The diagnosis of "benign snoring" may not truly exist, as data from the Wisconsin cohort study showed that people that snored and did not have obstructive sleep apnea (an AHI below 5 events/h) had an elevated risk of developing hypertension over several years [57].

Vibration from snoring may damage the tissue and nerves of the upper airway, decreasing compensatory mechanisms that maintain airway patency. Snoring, however, is not a prerequisite for partial upper airway occlusion leading to clinical symptoms.

Upper Airway Resistance Syndrome

Upper airway resistance syndrome [6–9] may cause a chronic complaint of EDS that is objectively confirmed by abnormal scores on the Multiple Sleep Latency Test (MSLT). It was first described in patients who suffered from EDS. A retrospective study selected 54 patients previously diagnosed at Stanford University with idiopathic hypersomnolence based on pathologic MSLT scores, who were also snorers [6]. The mean group MSLT score was 6.1 min, with abnormal scores defined as less than 8 min. These patients did not fit standard criteria for OSAS in terms of RDI, significant oxygen desaturations, or both.

In 14 patients (9 women, 5 men), nocturnal sleep showed fragmentation with repetitive 3- to 14-s alpha rhythm EEG arousals, with a mean of 49 ± 11 arousals per hour of sleep. When studied by esophageal balloon manometry (a technique reflecting intrathoracic inspiratory efforts as negative "suction" pressure) and a pneumotachometer with face mask to quantify airflow, a pattern emerged. Increasing inspiratory efforts were demonstrated by excessively negative P_{es} nadirs between -13 and -51 cm H_2O (normal is greater than -8), accompanied by decreasing peak flows and V_Ts one to three breaths before the arousals. These sequences were punctuated by repetitive arousals. Because the arousals and snoring would have been the only abnormalities identifiable by standard PSG recordings, these patients would not have met standard criteria for OSAS based on oxygen desaturation or apneas and hypopneas as measured by nasal–oral thermistor.

These 14 patients underwent CPAP titration to eliminate the snoring and alpha arousals. At a 3-week follow-up, subjective complaints of EDS were eliminated in all 14 patients, MSLT scores normalized to a group mean of 13 ± 3 min, and arousals were reduced to eight per hour of sleep.

In a series of 93 UARS patients, Guilleminault and Chowdhuri [9] reported that 56 % were women, 32 % were of East Asian origin, and the mean age was 38 ± 14. Thus, sex, race, and age distribution differs from the typical OSA patient demographics. UARS patients frequently complain of insomnia, sleep fragmentation, and fatigue. Their psychological profile often reveals high anxiety. Other clinical features of UARS patients include cold extremities, postural hypotension, history of fainting, a low systemic arterial blood pressure (below 105 mm Hg), orthostasis on tilt-table testing, myalgias, and functional somatic complaints [9]. During sleep, UARS patients demonstrate an increase in

alpha rhythm and a relative increase in delta sleep, unlike OSA patients, who show a predominance of stages 1 and 2 NREM sleep with a decrease in delta sleep. Additionally, NREM sleep has been shown to be more disturbed in UARS patients than controls, with an increase in EEG cyclic alternating pattern (CAP) rate that correlates to symptoms of fatigue and sleepiness [145]. Despite the recognition of UARS as a distinct disorder, many patients remain untreated and experience worsened symptoms of insomnia, fatigue, and depressed mood over time [146].

The difference between UARS and OSA patients is hypothesized to be caused by genetically predetermined and environmentally altered pharyngeal receptors, particularly mechanoreceptors. Patients with UARS may have intact, sensitive, peripheral pharyngeal function, or hyperfunction, whereas OSA patients may have primary pharyngeal receptor dysfunction. Patients with UARS awaken in response to relatively small increases in respiratory effort compared to OSA patients, whose arousal threshold requires much higher inspiratory pressures (up to −40 to −80 cm H_2O).

Secondary Apnea

A variety of medical conditions and craniofacial malformations are commonly associated with OSAS. Patients with congenital conditions including micrognathia, such as Pierre Robin, Hunter's, and Treacher Collins syndromes, and Crouzon's disease, present in childhood; children with cleft palates repaired by a pharyngeal flap have developed iatrogenic obstruction. Cranial base abnormalities associated with OSAS include achondroplasia and Klippel-Feil syndrome malformations. Down syndrome patients have large tongues and retrognathia, predisposing to upper airway obstruction. Children with Prader–Willi syndrome may suffer OSAS due to morbid obesity. Treatment of Prader–Willi syndrome with growth hormone may worsen OSA, which may even lead to death [147]. Endocrine abnormalities causing OSAS include hypothyroidism with myxedema, which causes macroglossia and parapharyngeal tissue infiltration. Acromegaly is a known cause of macroglossia.

Neurologic disorders associated with OSAS include the Shy-Drager syndrome of multisystem degeneration (central and obstructive apnea) and neuromuscular diseases involving facial and thoracoabdominal musculature such as poliomyelitis and myotonic and muscular dystrophies. Patients with acquired or hereditary neuropathies (such as Charcot–Marie–Tooth disease) and those with amyotrophic lateral sclerosis are also at a higher risk for developing OSA. History of stroke or transient ischemic attacks significantly increases risk of OSA. Secondary kyphoscoliosis will worsen nocturnal respiratory function. Lesions of the temporomandibular condyle leading to retrognathia (developmental or acquired due to rheumatoid arthritis, osteomyelitis, or trauma) may predispose to OSA.

Evaluation

History: Nighttime Symptoms

Pertinent symptoms of OSAS fall into daytime and nocturnal categories. Loud guttural snoring, at its worst in the supine position, punctuated by choking sounds and followed by cessation of breathing, is virtually pathognomonic. Although snoring commonly starts around the time of puberty, presentation to a physician is typically prompted by a recent increase in snoring intensity associated with weight gain. The sleep of the bed partner is compromised by the patient's high-amplitude snoring and restless sleep. The volume may be so loud as to exceed standards set by the Occupational Safety and Health Administration for workplace safety [148]. The apneic phase can last from seconds to more than a minute. These respiratory cessations may frighten bed partners, who often remain vigilant to wake the patient to resume breathing. Commonly, partners begin sleeping in separate rooms, which may create stress in the relationship.

Restless sleep in large part stems from sleep fragmentation caused by airway obstruction. Repetitive EEG arousals lasting seconds may terminate apneic episodes, thereby causing a regain of "wakeful" muscle tone observed on the chin EMG. This facilitates a restorative breath, allowing the cycle to repeat. Behavioral arousals accompany some of these EEG arousals, resulting in position changes, abrupt rising of the upper torso from the bed, and large flailing limb movements. Some of these movements appear to be agitated, with concomitant groaning or crying out of short dysphoric phrases. The vast majority of brief arousals are not consciously recalled on awakening, although the patient may appreciate that the quality of sleep has been poor. Clues to restless sleep are obtained by asking the patient how disturbed are bedcovers by morning, and how many times he or she awoke during the night.

It is surprisingly infrequent for the patient to awaken with actual awareness of an asphyxial sensation such as choking or gasping. When this does occur, it may be accompanied by a "feeling of dying," and the patient may run to the window or sit up at the edge of the bed. Rarely, patients are still unable to draw an inspiratory breath upon awakening, but usually can do so after coughing. It is believed that this may be due to adhesion of the uvula to the posterior pharynx.

There appears to be a subpopulation of sleep apneics in whom the presenting complaint is sleep maintenance insomnia. Some of their arousals trigger full awakenings that last at least several minutes. Because they remain unaware of

the respiratory antecedents of these awakenings, OSAS should be considered among the differential diagnoses in evaluating patients with chronic difficulties maintaining sleep.

The clinician should ask about symptoms related to snoring, such as the presence of a dry mouth or sore throat on awakening. Asking the patient if he or she drinks water overnight may also elicit information on a dry upper airway. Morning headaches that resolve within an hour of awakening should also be asked about, as they may be clues to nocturnal hypercarbia and increased intracranial pressure. These headaches are typically generalized or bifrontal in nature. The occurrence of nocturnal confusional spells, such as watering the houseplants with milk, may be due to either hypoxemia or slow-wave sleep (SWS) parasomnias triggered by respiratory-induced arousal.

Multiple episodes of nocturia have been related to elevated plasma levels of ANP and catecholamines [149, 150]. After the first night of treatment with nasal CPAP, a return to normal levels with concomitant decrease in urinary volume to approximately 50 % of pretreatment amounts has been reported. This helps explain why enuresis is more common in children with OSAS and was reported in 7 % of 120 apneic adults seen successively at Stanford in 1992 [151]. Confusion and increased intra-abdominal pressure from inspiratory attempts against a closed upper airway may also contribute to enuresis.

Symptoms of nocturnal esophageal acid reflux and heartburn are facilitated when excessively negative intrathoracic pressure exerts upward suction on abdominal contents, and increased abdominal pressure expels the contents. The patient may also complain of nocturnal aspiration. Bruxism may be noted and may be a clue to dental malocclusion resulting from the common jaw misalignment etiologically related to OSA. A history of orthodontic treatment to correct an overjet is common. The patient may have a history of wisdom tooth extraction secondary to impaction. These individuals may also manifest morning headaches or dysfunction of the temporomandibular joint.

History of seasonal or environmental allergies should be sought, as these are common causes of nasal obstruction in adults and adenotonsillar enlargement in children. Studies of rhesus monkeys with chronic and temporary nasal obstruction suggest that nasal obstruction with mouth breathing during childhood is etiologically related to subsequent mandibular growth insufficiency [126, 127]. We have documented craniofacial abnormalities with cephalometric radiography that were not appreciated on clinical examination [128].

Nocturnal diaphoresis of the face and chest may be seen in association with the increased effort required to inspire against resistance during the night. Increased caloric expenditures to breathe may also account for a subpopulation of sleep apneics who have difficulty gaining weight.

Ethanol or other sedatives used before bedtime worsen OSAS by at least two mechanisms. They greatly diminish the contraction of the upper airway dilators, as well as interfering with the organization of reflexes coordinating upper airway dilators with the contraction of inspiratory muscles [152]. They may also increase the cortical arousal threshold, allowing more prolonged apneas and severe oxygen desaturations. A history of increased snoring or development of any of the symptoms discussed earlier in association with sedating substances should raise the index of suspicion for OSAS. In elderly patients with AI greater than 5 events/h, sedative use or sleep deprivation may escalate the AI into the pathologic range [153].

History: Daytime Symptoms

The cardinal daytime symptom of OSAS is EDS, which manifests as a tendency to inadvertently fall asleep during quiet or passive activities, to take intentional naps, or to experience short but repetitive attention lapses while doing monotonous tasks. Such sleepiness is the consequence of sleep fragmentation. Patients usually misperceive the act of dozing off as being caused by the characteristics of the situation (i.e., boredom), rather than by their abnormal intrinsic degree of somnolence. It helps to inform patients that quiet settings do not produce sleepiness, but merely unmask it. Patients often forget or deny episodes of daytime sleepiness, which may better be elicited from household members who frequently observe the patient dozing while watching television or reading. Momentary lapses into sleep while driving are a potentially lethal consequence of somnolence, and history of these lapses should always be sought by inquiring about motor vehicle accidents due to sleepiness or inadvertently dozing at the wheel or swerving into another lane. Such incidents are particularly likely on long or monotonous trips. Affirmative answers require rapid treatment interventions.

Symptoms of fatigue, tiredness, and lack of energy are frequently reported by patients with OSA and must be enquired about during the clinical interview. These symptoms are more frequently reported and emphasized by OSA patients than sleepiness [154].

Cognitive complaints resulting from EDS are common and may be the only clue to OSA in those who misperceive their sleepiness. Automatic behavior, when an action is performed without subsequent recall, is an extreme manifestation of such cognitive impairment. Increased errors and poor judgment may place patients at risk of losing their jobs [12]. Severe morning confusion and disorientation, termed *sleep drunkenness,* may be a sequela of preceding hypoxemia. Studies have shown OSA patients have problems with attention, executive behavior, visuospatial learning, motor

performance, and constructional ability [155]. A meta-analysis showed a trend for improved performance of cognitive outcomes in OSA patients treated with CPAP compared to placebo [156]. Larger studies are currently underway evaluating the impact CPAP has on cognitive performance.

Sleep fragmentation may produce personality changes that are often first noted by family members. These include moodiness, irritability, anxiety, aggression, and depression. More marked personality changes involving irrational behavior, jealousy, and paranoia have been reported. Sleepy patients report less enjoyment from previously engaging activities. They are typically misperceived as unmotivated or lazy, descriptors they come to believe if the underlying etiology remains undiscovered.

Diminished libido or impotence is not an uncommon complaint, even in nonelderly OSA patients. Fanfulla et al. reported abnormal bulbocavernosus reflex in 68 % of 25 male OSA patients with AHI greater than 10 events/h [157]. These abnormalities correlated significantly with the severity of OSA and the severity of gas exchange alterations, but did not vary with age. With treatment of OSA, sexual function may improve [158–164].

In taking the medical history, inquiries regarding systemic sequelae must be sought. These include the existence and duration of borderline or elevated blood pressure; angina; symptoms of right heart failure, including peripheral edema; and transient cerebrovascular ischemic symptoms.

Physical Examination

Patient evaluation begins with observing the patient in the waiting room for sleeping or snoring. Obesity (BMI $\geq$ 30 kg/m^2) and neck circumference greater than 40 cm have shown a sensitivity of 61 % and specificity of 93 % for OSA regardless of gender [165]. The distribution of weight should be noted, as more midline depositions favor nocturnal respiratory pathology. In particular, adiposity or muscularity of the neck predisposes to upper airway obstruction, and severe abdominal obesity may also predispose to alveolar hypoventilation. A nasal voice is a clue to nasal obstruction, and mild hoarseness is often noted in heavy snorers. The lateral facial profile should be inspected for retrognathia or micrognathia, keeping in mind that the relevant site is the indentation below the lip that identifies the genial tubercle, where the tongue makes insertion on the mandible. The patient should bite down to demonstrate dental occlusion. Overjet is recorded in millimeters, and underbite should be noted as well. Palpate the temporomandibular joint while the patient opens the jaw widely for subluxation or a click as evidence of jaw misalignment. The oral cavity is inspected for dental prostheses, size of tongue, and soft palate tissue size and appearance. Soft palate edema and erythema may be due to snoring. A soft palate inferiorly positioned behind the tongue may be due to stretching from chronic excessive suction as a result of snoring. Tonsillar hypertrophy is noted. The hard palate is checked for a high arch, which has been found to correlate with OSAS.

Evidence of upper airway obstruction is obtained by evaluating breathing in the supine position with the jaw slackened slightly open and the nares occluded, to simulate oral breathing during sleep. If snoring or labored breathing results, this is good evidence that even greater difficulties will occur during sleep. The nose should be assessed for septal deviation, polyps, flaring of the nostrils, collapse of the internal valves, and patency of either vestibule with the opposite naris occluded. The thyroid should be examined for evidence of enlargement.

Blood pressure and pulse are measured and a general physical examination is performed, bearing in mind signs of dysrhythmia or heart failure. Lung auscultation provides clues of pulmonary pathology that would exacerbate oxygen desaturation caused by upper airway obstruction. A complete neurologic evaluation may uncover neuromuscular disorders impacting on upper airway patency and respiratory muscle function. A complete physical examination can eliminate the presence of generalized diseases, particularly those causing lymph node enlargement or mucosal infiltration, which may reduce the upper airway lumen.

The history and examination should reveal secondary causes of OSAS, including searching for a local tumor in the upper airway. Suspicion is raised in the presence of rapid emergence of obstructive symptoms not associated with weight gain, throat pain, constant hoarseness or other vocal cord dysfunction, prominent difficulties swallowing, or nasal regurgitation. Such symptoms should prompt otolaryngologic evaluation.

Laboratory Evaluation

Polysomnography

A full-night PSG study in the sleep laboratory is the main method of evaluation (level 1 study). The study devotes various channels to the recording of the EEG (i.e., F3–M1, C4–M1, C3–M1, 01–02), electro-oculogram (EOG), chin and limb (usually anterior tibialis) noninvasive EMG, qualitative measurements of oral-nasal airflow, thoracic and abdominal respiratory efforts, electrocardiogram (ECG), and pulse oximetry. An entire night of study is generally recommended, as opposed to a partial night, because substantial changes in respiratory disturbance typically occur from one sleep cycle to another across the night. Because REM sleep

predominates toward the end of the night, REM sleep-related respiratory disturbances might easily be missed without a full night of study.

However, in some circumstances, a split-night study can be considered. The split-night study requires the recording and analysis of the same parameters as a standard diagnostic full-night PSG. Recent guidelines from the American Academy of Sleep Medicine (AASM) state that a split-night study may be considered in patients if four criteria are met [156]. The first is that an AHI of at least 40 events/h be documented during a minimum 2-h diagnostic PSG. Split-night studies may be considered at an AHI of 20–40 events/h, based on clinical judgment (e.g., if there are also repetitive long obstructions and major desaturations). The second criterion is that CPAP titration be carried out for more than 3 h as respiratory events can worsen as the night progresses. The third criterion is that PSG documents that CPAP eliminates or nearly eliminates respiratory events during REM and non-REM sleep, including REM sleep with the patient in the supine position. The last criterion is that a second full-night PSG with CPAP titration be performed if the diagnosis of a sleep-related breathing disorder is confirmed but the second and third criteria are not met [165, 166].

A monitored level 1 PSG allows quantification of various factors that are disturbed in sleep apneics, including the RDI, oxygen desaturation, sleep stage percentages, and sleep efficiency. Sleep fragmentation can be assessed as variable-length awakenings or EEG arousals lasting only several seconds. CAP can be sought in non-REM sleep as a subtle indication of cortical arousals [167]. PSG helps determine whether the arousals are due to apnea or unsuspected factors such as periodic limb movements or primary insomnia. Associations between sleep stage and positional influences on respiratory disturbance can be made. Cardiac arrhythmias and their relationship to oxygen desaturation and sleep stage can be identified. Relatively invasive techniques to measure upper airway pressure may have circumscribed clinical usefulness. UARS (discussed earlier) may only be suspected based on transient alpha rhythm EEG arousals on the standard PSG, warranting additional investigation using esophageal manometry. Catheter systems allowing measurement of differential pressures at different levels of the upper airway may also help in determining the level of collapse at which surgical intervention should be addressed [168–170].

Pulse transit time measures the transmission time for the arterial pulse pressure wave to travel from the aortic valve to the periphery; it increases during arousal-induced increases in blood pressure. Pulse transit time has a high sensitivity and specificity in distinguishing between central and obstructive apnea-hypopnea and may be used if P_{es} monitoring is not available on attended PSG [171].

Technologies that allow in-home sleep monitoring are rapidly emerging. Portable units range from study levels 2–4. Level 2 units contain a minimum of seven channels, including EEG, EOG, chin EMG, ECG or heart rate, airflow, respiratory effort, and oxygen saturation. Level 3 units contain a minimum of four channels, including ventilation or airflow (with at least two channels of respiratory movement, or respiratory movement with airflow), heart rate or ECG, and oxygen saturation. Level 4 units measure a single parameter or two parameters, such as oxygenation and heart rate.

Although portable studies are a more convenient and less expensive alternative to standard PSG, there are significant limitations. The absence of trained personnel to intervene in the event of technical difficulty or medical emergency is one of the primary shortcomings. Concern has also been raised about the precision and accuracy of some portable units for the evaluation of more subtle cases of SDB, such as those with a predominance of hypopneas or UARS [172]. The most recent practice parameters published by the AASM approve the use of level 3 unattended portable monitoring units for the diagnosis of OSA in a limited setting [173, 174]. The guidelines state that these unattended studies can be performed only in conjunction with a comprehensive sleep evaluation by a board-eligible or board-certified sleep medicine specialist. A sleep medicine specialist must also interpret the study. Portable testing should only be performed on adult, nonelderly patients with a high pretest probability of having moderate-to-severe OSA without other sleep disorders, including central sleep apnea, periodic limb movement disorder, insomnia, parasomnias, circadian rhythm disorders, or narcolepsy. Furthermore, patients are not eligible for portable testing when they have comorbid medical conditions that may degrade the test accuracy, such as chronic obstructive pulmonary disease (COPD) or peripheral vascular disease. These recommendations further state there is insufficient evidence to use level 2 or 4 devices in an unattended setting [174].

Multiple Sleep Latency Test

The MSLT [175] is considered to be an objective measure of EDS. A series of daytime naps (usually five) of 20-min duration at 2-h intervals is performed to determine time to sleep onset. These sleep latencies are averaged. Scores under 8 min in the absence of confounding factors (e.g., insufficient preceding nocturnal total sleep time, use of hypnotic medication) are generally regarded as abnormal. REM occurrences during naps are also noted.

Because the demonstration of EDS is not required for the diagnosis of OSAS, MSLTs are not mandatory in the

evaluation of OSAS. If a PSG for suspected OSAS is negative, however, MSLT performed the subsequent day may help diagnose a different sleep disorder of excessive somnolence, though 5–15 % of OSA subjects can have MSLT findings consistent with narcolepsy. When complaints of sleepiness persist after adequate treatment is instituted, an MSLT may reveal an unsuspected second sleep disorder, requiring a separate treatment approach.

In large clinical populations, the severity of OSA based on AHI was not particularly predictive of sleepiness as objectively measured by the MSLT [175, 176].

Imaging Studies

As an adjunct to clinical evaluation, particularly when surgical treatment is contemplated, various imaging procedures can help identify the site(s) of upper airway obstruction. For a comprehensive review, the interested reader is referred to papers by Shepard et al. [177] or Faber and Grymer [178]. Imaging is also imperative when the history raises suspicion of a mass lesion as the cause of upper airway obstruction. It should be kept in mind that procedures performed on an awake patient do not reveal the actual anatomy during sleep, when postural and state-related changes in muscle tone alter the awake relationships.

Cephalometric radiographs provide a midline view of relevant cranial base and facial bones with their soft tissue appendages. Maxillary or mandibular deficiency can be calculated, and awake posterior airway space measured as the distance between the base of the tongue and posterior pharyngeal wall. Soft palate and lymphoid tissue extent is identified.

Fiberoptic endoscopy of the upper airway down to the vocal cords performed in the seated and supine positions provides further assessment of the possible sites of collapse. The patient can perform Valsalva and Müller's maneuvers to elicit collapse, although the predictive value for identifying candidates for surgical success after uvulopalatopharyngoplasty (UPPP) is limited [179–181]. Fiberoptic endoscopy should be systematically performed to eliminate secondary causes of upper airway obstruction if signs and symptoms are consistent with them.

Computed tomography (CT) scanning provides detailed surveys of cross-sectional levels of the upper airway, and magnetic resonance imaging (MRI) can be used to image multiple planes. CT and MRI have mainly been used as research tools due to their expense. Newer techniques such as fast CT scanning may prove to have prognostic clinical usefulness in selecting candidates for successful surgical outcomes. The 50-m s scan time, as compared to 2–5 s for conventional CT, is sufficiently rapid to show dynamic dimensional changes across various levels of the upper airway during the respiratory cycle. It can potentially be used in a sleeping patient.

Videofluoroscopy of the pharynx in anteroposterior and lateral directions offers another means for observing dynamic anatomic changes in the upper airway during ventilation. It is of limited clinical usefulness in view of its significant radiation exposure.

Other Studies

Pulmonary function tests, including spirometry and arterial blood gases, are a useful adjunct in investigation. Diminished vital capacity has been identified as a risk factor for SDB both in the Cleveland Family Study and in the elderly [22, 182]. Although associated with excess cardiovascular morbidity, a lowered vital capacity may be a marker for central obesity or an indicator of the presence of OSAS [183, 184]. Patients with daytime hypoxemia or CO_2 retention due to intrinsic lung disease might be expected to show severe oxygen desaturations with the addition of obstructive sleep pathology and may require cautious addition of low-flow oxygen to nasal CPAP. Those with restrictive pulmonary dynamics based on morbid obesity might require special treatment with bilevel positive airway pressure (BIPAP) or intermittent positive pressure ventilation delivered by nasal mask. Arterial blood gases provide the most relevant information for a sleep evaluation if obtained after the patient remains supine for 20 min. This aids in detection of insufficient ventilation associated with the supine position.

Thyroid function screening will exclude hypothyroidism as a cause of apnea and daytime somnolence. Polycythemia without known lung disease should lead to a consideration of sleep apnea.

Treatment

Behavioral Recommendations

Once OSAS is diagnosed, treatments can be suggested based on evaluation of contributing factors and disease severity. It has long been known that weight loss in obese patients is effective in the reduction of the number of apneas, sleep fragmentation, and the extent and number of desaturations. In overweight patients without obvious fixed anatomic considerations such as retrognathia, weight loss may result in eventual cure. For most patients, nasal CPAP should be instituted along with weight loss measures. These measures include weight reduction surgery, diet with or without pharmacologic intervention, and exercise. When applicable,

a program of exercise may be facilitated after daytime somnolence is ameliorated by CPAP. For those who are not completely cured by weight loss, the significant reduction in weight often allows a lower CPAP pressure requirement or increases the likelihood of a surgical cure. Patients with large losses should be re-titrated to the lowest effective pressure.

Elimination of central nervous system depressants such as ethanol or sedatives from the bloodstream at bedtime decreases the severity of OSAS. If a strong positional relationship is discovered, with obstruction limited to the supine position, recommendation to remain in a lateral or prone position can be made. A sock filled with a golf or tennis ball and sewn onto the back of the pajamas or T-shirt may help patients learn to avoid the supine position. A full-length wedge pillow may also be helpful in this respect. In mild cases, attention to position may suffice.

Pharmacologic Treatment

Currently, there are no US Food and Drug Administration (FDA)-approved medications that treat OSA. Tricyclic antidepressants such as protriptyline have been used to increase muscle tone and diminish REM sleep time in cases of mild or REM sleep-related OSAS. Progesterone acts as a respiratory stimulant in obese patients but has no impact on an obstructed airway. Paroxetine has been shown to mildly decrease apneas during NREM sleep [185]. Provigil has an FDA approval to treat residual daytime sleepiness of treated OSA patients, with statistical improvements in Maintenance of Wakefulness Test, Epworth Sleepiness Scale, and quality-of-life scores compared to controls [186]. Unfortunately, to date, pharmacologic approaches designed specifically to treat SDB have been largely unsuccessful.

Continuous and Bilevel Positive Airway Pressure (See also Chap. 34)

An enormous advance in the treatment of OSAS began in the early 1980s with the first commercially available continuous positive pressure generators. These bedside machines compress room air and channel it through a soft vinyl or silicone nasal mask, a full-face (nasal-oral) mask, or endonasal cushions at a given pressure. CPAP serves as a pneumatic splint to keep the upper airway patent. Pressure requirements must be established during sleep for each patient. Optimum pressure is the lowest one that completely eliminates obstructive apneas, hypopneas, snoring, and mask flow limitation and normalizes arterial PO_2. Patients who routinely consume ethanol in the evening are most accurately titrated to CPAP after consuming their usual intake, which raises the pressure requirement.

BIPAP differs from CPAP by using separate inspiratory and expiratory pressures. BIPAP machines time themselves to patient-initiated breathing. By reducing the pressure on expiration, BIPAP lowers the resistance against which the patient must exhale. This is advantageous for patients with severely restrictive pulmonary dynamics, such as those with emphysema, the morbidly obese, and those with neuromuscular weakness. Patients with normal lungs who could not tolerate CPAP might feel more comfortable on BIPAP, especially those requiring higher CPAP pressures (approximately 13 cm H_2O). Those with severe discomfort due to drying of the mucosa could benefit from BIPAP because of the overall decrease in airflow relative to CPAP. BIPAP also offers a higher range of inspiratory pressures than CPAP, with maximum pressures of 30 cm H_2O. The newer devices with extended pressure range also have the ability to control inspiratory time (flow) and are therefore more appropriate for patients with isolated neuromuscular disease. Intermittent positive pressure ventilation may be more useful in some patients with sleep-related hypoventilation who cannot be maintained on bilevel units.

A PSG study to titrate CPAP or BIPAP pressure should be performed for one entire night to allow adequate assessment. A second titration night can be done if an adequate pressure was not identified the first night. Ideally, the optimum pressure is checked for adequacy throughout all stages and positions. It is especially critical to evaluate the patient in the supine position, when the maximum pressure requirement occurs. Unfortunately, financial constraints increasingly dictate that split-night studies be performed. This method of diagnosis and treatment tends to underestimate the severity of disease because treatment takes place in the latter half of the night when apnea is usually at its worst. In patients with severe apnea, a rebound of unusually long REM sleep and SWS that may be out of circadian phase occurs once adequate airway patency is attained. REM sleep rebound shows unusually prominent phasic activity, whereas the SWS episodes may show exceptionally high voltage EEG activities. Rare but dangerous sequelae of REM rebound have been seen in severe apneics with CO_2 retention under slightly suboptimal pressure. Arousal is suppressed during a long rebound, and if partial upper airway closure persists, dangerous hypoxemia may result [182].

Auto titrating positive airway pressure (APAP) devices offer a theoretical advantage of foregoing a traditional CPAP titration study by delivering the lowest pressure needed to prevent respiratory disturbances. These devices may decrease side effects of traditional CPAP such as air swallowing and abdominal bloating and are theoretically able to accurately record flow leaks, hypopneas, and apneas. They detect snoring, apneas, hypopneas, flow limitation, and changes in airway resistance or impedance, which are then interpreted by a central processing unit based on specific

diagnostic algorithms to determine the resultant voltage for the APAP blower in response to these signals [187]. Studies have shown significant variability between different APAP devices, with undertreatment of 13–60 % of patients using the devices (residual RDI > 5 during treatment) as usually the APAP device is set between 4 and 20 cm H_2O, a setting that should not be used: Based on clinical evaluation, a minimum setting should be selected by the specialist [188]. There is insufficient evidence to use these devices to diagnose OSA [189].

The 2007 AASM practice parameters on APAP devices give sleep specialists the option to use these devices in an unattended setting to treat uncomplicated OSA patients [189]. Potential patients include those with moderate-to-severe OSA without significant comorbidities such as congestive heart failure, COPD, central sleep apnea syndromes, or hypoventilation syndromes. Sleep specialists have the option of treating these OSA patients with APAP devices either left in the self-adjusting mode or set at the prescribed 90th or 95th percentile pressure and utilized during a several-week trial period. Patients prescribed APAP devices should be closely followed by a sleep medicine specialist to ensure adequate treatment. A standard CPAP titration should be performed in patients whose symptoms do not resolve with APAP [189].

A severe limitation of APAP devices is that they determine pressures differently, and there are few studies comparing various APAP devices to each other and to set CPAP devices. APAP is not superior (and many would argue not even equivalent) to a fixed CPAP pressure determined by an attended titration. Therefore, AASM guidelines state "polysomnography directed CPAP titration is still the standard method for determination of effective CPAP pressure" [189]. With improvements in technology, greater clinical experience, and growing literature on the subject, APAP devices will likely be more widely used in the future.

Treatment with nasal CPAP or BIPAP offers advantages of safety and assured efficacy over surgical approaches. They offer immediate and complete treatment for OSAS and are less costly than extensive surgical approaches. They can be used temporarily while weight loss is pursued or surgery is pending. Positive pressure eliminates risk factors for associated morbidity along with daytime somnolence. Modern CPAP units are small, portable, and quiet. Most have a ramp feature that gradually adjusts the pressure upward to the preset pressure, allowing sleep onset to occur at more comfortable lower pressures.

Disadvantages of CPAP lie in psychological resistance to ongoing nightly reliance on a machine. Poor compliance is the main obstacle to this treatment modality. Patients may feel claustrophobic and intolerant of the restriction of their movement and may perceive the treatment as an obstacle to intimacy with their bed partner and as a reminder of their mortality. The devices are annoying to some patients, although they are continually improved. Those traveling frequently may find it inconvenient. Generally, young adults and patients who are dating find this treatment to have an unacceptable social impact.

Common physical difficulties encountered include reactive nasal congestion or rhinitis, sinusitis, epistaxis, drying of the nasal-oral mucosa, discomfort or skin trauma from a poorly fitting mask, and an allergic reaction such as contact dermatitis from the mask interface. Nasal symptoms usually subside after the first few months and can be ameliorated with heated humidification, daily nasal rinses, and a nasal steroid inhaler. Comfort issues and dermatitis should be closely supervised and addressed with trials of various mask adaptors and styles or by altering the mode of delivery via nasal pillows or other mask types. Psychological distress is minimized by support from the entire sleep laboratory team, with reassurance and understanding at the time of initiation and close follow-up. Sleep apnea support groups exist in many areas to help with coping and compliance. Occasionally, a brief course of bedtime hypnotics is required, with the patient's full understanding that the severity of apnea will worsen if the medication is used without the CPAP device. Flow leaks through an open mouth can be minimized by use of a chin strap.

Long-term compliance has been only fair, with an estimate of 60–85 % of patients using their machines regularly after one year [190, 191]. Compliance has been associated with the severity of daytime hypersomnolence before CPAP, but not with pretreatment disease severity as indicated by the RDI or oxygen saturation nadir. Intellectual understanding of the benefits of nightly use (i.e., to decrease cardiovascular risk factors) appears insufficient to motivate long-term compliance. Cognitive behavioral interventions may improve compliance [192]. In one study, use of a C-flex device was shown to significantly increase patient compliance [193].

In patients who do not wish to undergo the extensive surgeries that might be required to produce a complete cure, selective surgery to relieve nasal obstruction can reduce pressure requirements and improve CPAP tolerance. In patients with more than mild oxygen desaturation on diagnostic testing (i.e., <85 %) who choose surgical treatment, CPAP initiation may be contemplated preoperatively to decrease the postoperative risk of further desaturation due to edema. Preoperative CPAP also reduces soft palate edema due to snoring and improves overall health status. Weight

loss before surgery while using CPAP increases the chance of successful cure by creating more airway space through parapharyngeal tissue reduction.

Surgical Approaches (See also Chap. 36)

The first surgical treatment for OSAS was tracheostomy. This intervention is rarely needed now, because of the pervasive use of positive pressure therapy. Although used infrequently, tracheostomy provides immediate profound improvement for some individuals with severe OSAS. Maintenance of a tracheostomy is associated with some morbidity and psychosocial implications.

Surgery is individually tailored to overcome upper airway obstruction after a thorough analysis of the three main levels of potential obstruction: the nose, soft palate, and base of the tongue or hypopharynx. Often, more than one level must be treated, either sequentially or simultaneously. Patients must understand that surgical treatment is an extensive and more costly process with greater risks than medical treatment. In addition, surgery carries no guarantee of cure in an individual patient, with only statistical cure rates available.

Nasal obstruction can be corrected with septoplasty, polypectomy, or radiofrequency turbinate reduction. Though these procedures can improve nasal breathing and SDB, nasal surgery alone successfully treats only a minority of OSA patients.

Soft palate resection via UPPP or uvuloflap surgery has an approximately 40 % response rate in individuals but is much less successful in obese patients [194–203]. However, the success rate can be as high as 80 % in properly selected patients [195–201]. Depending on how "success" is defined, these rates may be altered considerably. Most surgeons consider OSA surgery as success if a 50 % reduction of the AHI achieved. The most common postoperative adverse sequelae include severe pain for approximately two weeks, transient nasal reflux and nasal speech due to palatal incompetence, minor loss of taste, and tongue numbness. Major complications involve permanent nasal reflux or nasal speech due to permanent velopharyngeal incompetence and scarring with retraction leading to palatal stenosis.

Because UPPP ameliorates snoring due to vibration of the uvula without addressing potential obstruction behind the base of the tongue, a major sign of ongoing residual obstruction may be masked. It is therefore imperative to follow up all surgeries with a postoperative sleep study. Ideally, this study should be delayed at least four months after surgery to allow thorough resolution of edema and readjustment of respiratory reflexes. Those patients with moderate-to-severe apnea can be maintained on CPAP in the interim and withdrawn two weeks before study to allow expression of airway changes from potential residual obstruction.

Genioglossus advancement via inferior sagittal osteotomy is a technique pioneered at Stanford University [204] that addresses the retroposition of the tongue by advancing the insertion point of the genioglossus, the geniotubercle. The surgeon makes a small mandibular incision at the geniotubercle, pulls the bone segment through the jaw, and allows the fracture to heal. This is usually performed in conjunction with UPPP. The success rates have been variable, ranging from 23 to 77 % [204–210]. Common complications are minor and consist of transient dental nerve anesthesia. Mandibular fracture may occur if the incision extends into the alveolus.

Hyoid advancement can expand the airway by moving the tongue base and pharyngeal musculature forward. This is achieved by attaching it to the thyroid cartilage. This procedure is usually performed in conjunction with genioglossus advancement to improve OSA, but some surgeons will combine it with UPPP alone [207, 209, 211]. The success rate of hyoid advancement is variable and ranges from 17 to 65 % [210, 211]. This surgery requires an external incision on the neck.

Maxillomandibular advancement (MMA) is another surgical option to improve OSA. It is generally reserved for patients for whom other treatments have failed and who do not want to be treated with nasal CPAP. This procedure expands the entire airway, including the nasopharyngeal and hypopharyngeal airway. Patients undergoing MMA who have previously undergone the earlier discussed surgeries can have excellent improvement of OSA. Generally the jaws must be advanced 8–14 mm for adequate treatment of OSA. MMA is currently the most effective sleep apnea surgical procedure, with success rates generally between 75 and 100 % [206, 212–215]. MMA shows promising cure rates long term, but weight gain is associated with the recurrence of OSA [215].

Tongue base suspension suture is thought to reduce the collapsibility of the tongue during sleep [213]. It is often performed in conjunction with UPPP, with variable success rates reported [217, 218]. Radiofrequency reduction of the base of the tongue may also improve OSA by increasing the retropharyngeal airway space. Though this procedure does improve OSA when performed alone, it does not appear to be as successful in the long run [219]. Many surgeons perform this procedure in conjunction with UPPP or MMA.

Bariatric surgery with significant weight loss has been shown to improve and even cure OSA in morbidly obese patients [220–222].

Oral Appliances (See also Chap. 36)

Various types of dental devices have been used to treat OSA. They work by increasing airway space, providing a stable

anterior position of the mandible, and advancing the tongue or soft palate, and possibly by changing genioglossus muscle activity [223]. The devices are worn only during sleep. There are a variety of oral appliances; some are prefabricated and are relatively inexpensive, while others are custom-made by dentists. The advantage over surgery is that there is no permanent change of anatomy and no surgical risk involved.

The most effective devices are those that cause the mandible to protrude forward. A meta-analysis concluded that oral appliances mildly improved subjective daytime sleepiness and SDB compared with controls, but less well than CPAP [224]. Though patients tend to be more compliant with wearing oral appliances than using CPAP, these devices tend not to be as effective in treating OSA [189]. Patients are more likely to achieve success with an oral appliance if they have less severe OSA, are nonobese, have positional OSA, and are able to significantly protrude their jaw from baseline [225, 226].

According to AASM guidelines, oral appliances can be used in patients with mild-to-moderate OSA who prefer them to CPAP therapy, or who do not respond to, are not appropriate candidates for, or fail treatment attempts with CPAP [227]. The success rate of oral appliances often mirrors the severity of OSA, with patients with mild OSA more likely to achieve success than those with severe OSA. Referral to a dentist who is adequately trained and has understanding of SDB is paramount. Minor tooth movement and cg changes in occlusion can develop in some patients after prolonged use 212a.

Obstructive Sleep Apnea in Children

Obstructive sleep apnea occurs in premature and full-term infants as well as in children (see also Chap. 52). Although this disorder in children was neglected for a long time, it is a common disorder affecting 3 % of children 2–8 years of age [228–232]. In very young patients, the apnea usually becomes apparent as a result of color change and bradycardia. In most children, a constellation of daytime and nighttime clinical symptoms signals the condition. At different ages, different symptoms are more common. Postpubertal teenagers do not differ from young adults, but younger children often present a different clinical picture.

Clinical Features

Obstructive sleep apnea syndrome can be associated with a series of daytime and nighttime signs and symptoms that may not be obvious at an initial evaluation [229, 230]. The daytime symptoms include EDS so severe that school authorities suggest medical consultation, and abnormal daytime behavior ranging from aggressiveness and hyperactivity to pathologic shyness and social withdrawal. Children may exhibit more subtle symptoms including inattention, daytime fatigue, learning problems, morning headaches, frequent upper airway infections, failure to thrive, and obesity. Nocturnal symptoms seen at all ages include difficulty breathing while asleep, heavy snoring, apneic episodes, restless sleep, nocturnal sweating, nightmares, and SWS parasomnias. The absence of normal growth or failure to thrive can be seen at most ages [227, 230–237].

Reasons for seeking consultation vary with age. Before 12 months of age, children may present with noisy nocturnal breathing, disturbed nocturnal sleep, and repetitive crying, or a poorly established day–night cycle may be the presenting features of OSA. OSA may also contribute to the occurrence of an apparent life-threatening event due to abnormal autonomic cardiovascular control and an increased arousal threshold [238, 239].

In toddlers, nocturnal crying spells or sleep terrors may prompt an evaluation for OSA. Grouchy or aggressive behavior, daytime mouth breathing, and difficulty waking up may be seen. Difficulty breathing while asleep, heavy snoring, apneic episodes observed by parents, restless sleep, nightmares, and night terrors are the most frequent reasons for consultation. This may be partly due to the parents' ability to evaluate a young child's sleep often and the fact that young children fall asleep early, allowing parents to note abnormal sleep behavior.

In children older than 5 years, EDS (associated with complaints of tiredness and daytime fatigue), abnormal daytime behavior, learning disabilities, frequent morning headaches, nocturnal enuresis, and major discipline problems are common reasons for consultation. A few children are referred at a late stage of the syndrome [240]. These children not only present significant failure to thrive but also may have been hospitalized for unexplained acute cardiac failure or unexplained development of systemic hypertension. The cardiac failure often will have occurred after the child had contracted a cold or bronchopneumopathy, which may not have been severe but, in combination with the chronic nocturnal problem, nevertheless led to the acute failure.

Symptoms of attention-deficit/hyperactivity disorder (ADHD) have been positively associated with SDB in children. Chervin et al. showed that children diagnosed with ADHD had a threefold increase in snoring compared with controls [237]. Other studies have shown similar findings [230, 235, 236]. What is even more interesting is that snoring on its own has been shown to be a strong risk factor for future emergence or aggravation of ADHD symptoms [237].

Classically, the pediatric patient presenting with OSA has large tonsils and is underweight and having difficulty increasing his or her weight, despite a normal appetite. He or she also may be shorter than expected. Nocturnal secretion of growth hormone in children with repetitive apneas has been shown to be abnormally low. We have noted a similar decrease with heavy snoring, due to decreased growth hormone levels released during sleep and elevated caloric expenditure from increased work of breathing. In addition, childhood obesity is becoming an epidemic, more obese patients are presenting with OSA and the incidence of pediatric OSA will likely rise. It is estimated that up to one-third of obese children have OSA [231, 241].

The clinical evaluation of children should be as thorough as for adults, and suspicion of OSAS should lead to PSG monitoring during sleep.

Polysomnographic Testing

Although repetitive apneas may be seen in children with equal frequency as in adults, most commonly the PSG indicates only intermittent apneas. Sometimes no apneas are monitored, even when a florid symptomatology exists [242]. A pediatric sleep study is evaluated differently than an adult record. The criterion for an apnea or hypopnea duration is equal to two breaths for the patient or 10 s, whatever is shorter. An AHI greater than 1/h is considered abnormal in the pediatric population [243]. Pediatric OSA patients have fewer cortical arousals with breathing events and their sleep architecture tends to be better preserved compared to adult OSA patients.

Prepubescent children have a greater tendency to present complete apneas during REM sleep. During NREM sleep, prepubescent children with OSAS present as loud snorers. Documented by a sonogram, snoring is commonly associated with an increase in respiratory rate. The degree of tachypnea is variable within a given age group and sometimes within a given subject during the night. The increase in breathing frequency compensates for the decrease in V_T and allows maintenance of normal minute ventilation with an appropriate level of oxygen saturation. However, partial upper airway obstruction leads to great enhancement of respiratory efforts, which is obvious when one observes the laborious, noisy mouth breathing during sleep. P_{es} measures demonstrate the increase in respiratory efforts. P_{es} nadir may reach −35 to −40 cm H_2O without induction of a complete collapse of the upper airway in children 5–6 years old. Increased efforts may also be demonstrated by monitoring of intercostal-diaphragmatic EMG. Surface electrodes placed 10 mm apart near the eighth right intercostal space, between the anterior and posterior axillary lines, permit collection of the EMG activity of the inspiratory muscles. The signal can be integrated, and, depending on the calibration procedures used, semi-quantitative or quantitative measurements may be obtained. Measurement with surface electrodes and integration of abdominal muscle activity during expiration may demonstrate the degree of active expiratory effort that some of these children have to perform.

Despite the increase in respiratory efforts associated with snoring and increased upper airway resistance, children may not present with very fragmented sleep. The short alpha rhythm EEG arousals seen with increased upper airway resistance in adults may be uncommon in children. Breathing may appear laborious, however, and increased efforts are often demonstrated by perspiration (at the head and neck or generalized). This suggests that the daytime sleepiness observed in these children despite near-normal sleep structure and the absence of microarousals cannot be explained by sleep fragmentation alone. Polygraphic monitoring must thus focus not only on the presence or absence of apnea (with the knowledge that the absence of apnea may be very misleading) but also on increase in respiratory effort and breathing frequency, as well as the importance of thoracoabdominal mechanical changes.

The repetitive inspiratory efforts expended during complete or, more often, partial upper airway obstruction lead to abnormal septal motion with leftward shift of the interventricular septum and the development of pulsus paradoxus [244]. Cardiac arrhythmias, particularly asystole and secondary AV block, may be seen, and intermittent increase in systolic blood pressure may be noted. Finally, systemic hypertension has been observed in association with OSAS. Systemic hypertension in prepubertal children completely disappears with tracheostomy. The only cases of systemic hypertension found to be clearly idiopathic and for which treatment of OSAS led to complete and long-term normalization of blood pressure were in prepubertal or pubertal children [245].

Asthma and Upper Airway Obstruction During Sleep

In children, a relationship exists between asthma and upper airway obstruction. Allergic reactions very early in life lead to mucosal swelling and enlargement of the pharyngeal region. There is a well-known interaction between the size of the upper airway and craniofacial development, particularly development of the mandible, during early childhood. The presence of upper airway allergies will thus limit maxillomandibular growth and cause a decrease in the size of the upper airway. Small upper airways are often associated with increased upper airway resistance during sleep, leading to increased respiratory efforts and the development of snoring during sleep. Increased upper airway resistance and

nocturnal snoring worsen asthma, causing increased risk of a nocturnal asthma attack.

Orthodontic Complications and Upper Airway Obstruction During Sleep

Children with partial or complete upper airway obstruction during sleep frequently have maxillomandibular growth retardation. Abnormal orthodontic features are common. Class II malocclusion is frequently seen but is not the only orthodontic problem. As 60 % of facial development is complete by 4 years of age and 90 % by 11 years of age, it is important to recognize orthodontic involvement. It is also important to understand that inappropriate orthodontic treatment that further impairs maxillomandibular growth may catalyze the appearance of snoring and significantly increase upper airway resistance during sleep. Abnormal maxillomandibular development may be responsible for the nocturnal occurrence of snoring and bruxism. Further understanding of the development of abnormal breathing during sleep came from studies of children submitted to adenotonsillectomy, the most common treatment in childhood OSA (see below).

Treatment

Nasal obstruction is rarely the only factor in the development of apnea in children, but it can be a contributing factor. In rare cases, correcting the obstruction can alleviate, if not cure, the OSAS.

Tonsillectomy and Adenoidectomy

Tonsillectomy alone or tonsillectomy with adenoidectomy is standard treatment of pediatric OSA. Early studies showed that this procedure can cure over 80 % and improve the vast majority of pediatric OSA cases. However, later studies suggest that OSA may persist in up to 70 % of postoperative patients [246–249]. Too often not enough attention is paid to problems that may be associated with enlarged tonsils and adenoids (i.e., abnormally long soft palate, retroposition of the mandible, or soft tissue infiltration behind the base of the tongue), which may explain residual apnea after tonsillectomy. Furthermore, if tonsillectomy and adenoidectomy are performed during the prepubertal years in boys, there is a chance that the extensive soft tissue growth that occurs during puberty may cause a reappearance of OSAS in those whose airway space is already compromised by a malocclusion such as a mild-to-moderate retro-position of the lower mandible [250]. A recent study comparing cephalometrics in children with OSA previously cured with tonsillectomy and adenoidectomy showed that there was a significant reduction in posterior airway space that developed at a mean age of 14 years compared to the same patients at a mean age of 11 years. This was associated with a return in sleep-disordered breathing [251]. Fiberoptic endoscopy must be performed systematically in association with one imaging test to determine the extent of soft tissue surgery needed to treat OSA. Systematic follow-up of OSA children post-T&A between 6 months and 3 years shows that abnormal breathing during sleep reoccurs [252]. The reasons why there are re-occurrences are not fully understood. It is known, however, that increased patient age at time of T&A, obesity, and the initial severity of the OSA are all factors associated with increased risk of reoccurrence. Some recurrences occur during puberty. Others occur at an earlier age, particularly in children who do not undergo myofunctional reeducation.

Factors that increase the risk of developing sleep-disordered breathing include prematurity, [252] a positive family history of OSA, [24–28] and cartilage lesions as seen in Ehlers Danlos Syndrome [253]. Other risk factors include infantile rheumatoid arthritis involving temporal mandibular articulation, posttraumatic lesions of the same articulation, and heritable neuromuscular disorders, such as Myotonic Dystrophy, that induce abnormal growth of the maxilla and mandible, a short anterior frenulum, and abnormal tongue positioning.

Research from 1972 to 1980 on a monkey model with experimentally induced increased nasal resistance largely contributed to our understanding of how increased nasal resistance may lead to abnormal craniofacial growth and to the development of sleep-disordered breathing. The infant monkeys showed changes in EMG firing, mouth breathing associated with abnormal muscle tone, oral facial hypotonia, and secondary changes in maxillary-mandibular growth [124, 126, 130]. In children, any cause of increased nasal resistance may lead to sleep-disordered breathing through these same mechanisms.

Orthodontic and Maxillomandibular Surgery

Pediatric OSAS is a complex problem. Changes in maxillary and mandibular growth, including retroposition of the mandible, a steep mandibular plane, and an abnormally narrow, high-arched palate, often result from abnormal mouth breathing. These features are not always obvious. No one can overlook Pierre Robin syndrome, but specialists do not always appreciate a mandibular problem, and orthodontists may not be aware of the negative impact that a moderately abnormal mandible has on the upper airway. Relatively noninvasive orthodontic approaches using rapid maxillary expansion in conjunction with traditional orthodontic treatments have been shown to effectively treat sleep apnea in children with lasting positive results [254, 255]. Maxillary distraction results in widening of the palate

and the nose, thereby improving nasal occlusion. Rapid maxillary distraction is usually preformed in pediatric patients whose OSA persists despite tonsillectomy and adenoidectomy. Bi-maxillary distraction is also performed depending on the orthodontic findings and degree of involvement of the mandible. Novel orthodontic techniques may be used when maxillary retrusion is important.

Recent investigations analyzing the results of post-T&A alone and post-T&A followed by orthodontic cases have shown that the above treatments may not be sufficient to prevent recurrence of SDB. This may be in part because these therapies do not address upper airway muscle activity and do not re-entrain normal nasal respiration in the place of mouth breathing. Myofunctional therapy has been used in conjunction with orthodontic treatment since the 1960s in different countries particularly western Europe and Brazil [256]. The efficacy of such associated treatments has been well documented since the 1990s. But it is only recently that myofunctional therapy has been used in adults with OSA with limited results [257]. In children, this treatment, in combination with the other treatment modalities, has been shown to result in a return of normal breathing 3–4 years post-treatment [132]. The advantage of myofunctional therapy is twofold. First, it leads to a noticeable improvement in upper airway muscle tone, and second, in many cases, it eliminates mouth breathing [257]. Mouth breathing in and of itself can be symptomatic. In a recent evaluation [258], children with residual symptoms of sleep-disordered breathing despite T&A ± orthodontics and aggressive allergy management were shown to have mouth breathing during polysomnography for more than 1/3 of the total recorded sleep time, while children without symptoms had less than 5 % of mouth breathing.

In addition to consideration of T&A, pediatric OSA patients should have an evaluation of their oral facial growth and tongue and lip muscle activity. The simple exercises indicated at http://www.myofunctionaltherapy.blogspot.com [257] should normally all be easily performed. Limitation of response indicates functional muscle impairment of the oral facial region that should be corrected with myofunctional rehabilitation. Post-treatment polysomnography with usage of a mouth thermistor protected from nasal flow by a "cup" cg [24] should demonstrate absent or based on Stanford data less than 5 % of mouth breathing. The presence of functional regional muscle impairment and/or a large amount of mouth breathing at post-treatment recording with mouth thermistor with cup should lead to systematic myofunctional therapy and nasal breathing reeducation. This should be done in conjunction with aggressive nasal allergy management and appropriate correction of any high-arched palate and narrow nasal cavity with rapid maxillary expansion.

At times, such approaches are insufficient and a more aggressive treatment approach is needed. Maxillofacial abnormalities are clearly related to the presence of OSAS in children. When present, maxillofacial surgery may be considered. Piecuch [259] reported a child treated with maxillofacial surgery for OSAS. Kuo et al. [260] have reported two cases and Bear and Priest [261] reported three cases of OSAS that were resolved by maxillofacial surgery. Bell et al. reported a 50 % success rate in treating eight cases of OSA with maxillomandibular advancement (MMA) [262]. The most extensive series of patients (teenagers and adults) treated with maxillofacial surgery was reported by Riley et al. [213] and Holty and Guilleminault did a meta-analysis of all published MMA cases including teenagers [263]. It is recommended that MMA is performed only after facial growth and development has peaked. Prior to this, allergy management, myofunctional therapy, and the orthodontic approaches described above are recommended to obtain as much benefit as possible. If symptoms persist, nasal CPAP may be used while awaiting MMA.

Ethnicity may render surgical protocols different. Taiwanese surgeons have proposed a specific protocol for Chinese individuals. The meta-analysis performed has shown that MMA success is significantly lower if at least a 12 mm advancement of the maxilla measured at the cut-point is not achieved. Given the ethnic differences in facial anatomy between Far East Asians and Caucasians, maxillary advancement will usually have a larger impact on Asian facial esthetics. Masking techniques such as counter-clockwise rotation may not be as successful in Far East Asians as in Caucasians if no other approach is taken at the time of surgery. MMA will always involve changes in facial presentation, but computer simulation based on cranio-facial CT of the subject can provide information on the post-surgical presentation. In the hands of well-trained surgeons, this procedure is often quite successful. However, adults after 40 years of age have a 30 % decrease in MMA success rates. Excessive weight gain and the development of lung diseases are two additional health problems that clearly decrease efficacy of MMA surgery at long-term follow-up [263].

Maxillomandibular advancement drawbacks include the assumption of surgical and anesthesia risk, a possibly esthetically displeasing facial outcome, as well as a prolonged postoperative recovery time of 8–12 weeks [262–264]. Again nasal breathing re-learning may be needed. It is recommended that all other treatment modalities be investigating prior to consideration of this major surgery.

Mandibular distraction osteogenesis, used in conjunction with orthodontics, has also been used to successfully treat six pediatric OSA patients [265]. Distraction osteogenesis has been used regularly in infants and young children with syndromic presentations such as Pierre Robin, Crouzon, and other cranial-facial syndromes. Its application is different here as individuals are not syndromic and usually the

sleep-disordered breathing has been diagnosed during the peri-pubertal period and orthodontic approaches such as rapid maxillary expansion cg or bimaxillary treatment have not been sufficient.

European orthodontists will often perform further maxillary widening through the use of palatal implants. This allows for avoidance of applied molar forces in addition to facilitation of nasal passage opening by more posterior implant placement. Such an approach allows re-opening of the palatine suture in teenage individuals most commonly 14–17 years of age. By making a surgical cut in the mandibular bone and applying a distractor, mandibular widening may also be performed. Such an approach is reserved for patients with lateral narrowing and no antero-posterior involvement, an uncommon presentation. The cost of implants in some countries limits its use.

Tracheostomy

In the past, tracheostomy was a frequent treatment when tonsillectomy and adenoidectomy were insufficient. Tracheostomy resolves the OSAS, but often causes secondary problems such as unexpectedly challenging stoma management, devastating psychosocial effects, and infection. Nevertheless, tracheostomy is clearly beneficial in many cases. The need for tracheostomy can be alleviated by the use of other treatment modalities.

Nasal Continuous Positive Airway Pressure

Children as young as 6 months old have been treated with nasal CPAP at Stanford since 1984, and long-term treatment has been successful [265, 266]. Several manufacturers currently supply nasal CPAP for young children, and Respironics provides masks for infants and very young children.

The complications and problems associated with this treatment have been related to (1) the fact that the children (many of whom were mentally handicapped) had difficulty understanding how the mask and CPAP equipment functioned; (2) problems with the parents' collaboration with the medical team to train the child to keep the nasal mask on his or her face; (3) air leaks at the edge of the mask causing reappearance of apnea and eye irritation; and (4) skin allergy to the masks in small children. The first two problems resulted in some children abandoning nasal CPAP treatment; the other problems, although occasionally bothersome, never led to interruption of therapy. The theoretical risk of stomach dilation due to incorrect administration or other problems has never been reported. In very young children, hand restraints during sleep may be necessary to adapt the child to the apparatus.

Pediatric patients using CPAP should be re-evaluated for mask fit every 6 months because of rapid craniofacial growth. An annual visit with a craniofacial specialist should occur to affirm that the headgear and mask do not worsen a maxillary growth deficiency [9, 26].

Summary

Obstructive sleep apnea syndrome is surprisingly common and must be recognized as a disease with diverse, adverse, systemic consequences, including cardiovascular risk. The associated sleep fragmentation, excessive daytime sleepiness, and fatigue can be disabling and degrade quality of life. As such, inquiries regarding symptoms of snoring and excessive daytime sleepiness should be routinely screened for as part of preventative health care. A high index of suspicion for this condition must be maintained, as the sequelae of the disease can be devastating. Fortunately, OSAS is easily treatable, with CPAP therapy being the gold standard of care. Recommendations can also be tailored to the patient's problems, taking into consideration individual preference, age, personality, lifestyle, and objective findings with PSG.

Advances in awareness of the presence and pathophysiology of pediatric SDB along with new understanding of reasons for incomplete or transient treatment success give hope that routine screening, early recognition, and aggressive treatment early in life will be performed. Evaluation will require systematically checking that nasal breathing has truly been restored. This is rarely performed today due to the limited understanding of many specialists of the impact of "loss of usage" of an organ such as nasal breathing during sleep. Functional therapies taught by a trained specialist to regain nasal breathing and proper muscle tone should be employed. This is only done in some limited places around the world today. However, such systematic approaches may decrease the frequency of OSA. In Brazil, a state law has made it mandatory for neonatologists to evaluate for the presence of an abnormal frenulum at birth. At Stanford, retrospective analysis of 6 years of pediatric referrals revealed that 1 out of 30 children with SDB has a short frenulum on ENT evaluation.

Some final considerations include the following: Ehlers Danlos syndrome, which is a risk factor for OSA, is quite common, yet under recognized. Symptoms such as abnormal tendencies for twisted ankles and knee or shoulder dislocations need to be more aggressively screened for. Also, aggressive treatment of nasal allergies, including desensitization shots, is also required to avoid intermittent and incomplete treatment of a chronic problem. Furthermore, early recognition of abnormal oral facial growth in young infants needs to be evaluated. Bottle-feeding with soft nipples that do not require the same strong sucking action as breast-feeding, or the same continuous effort from the upper airway muscles and tongue further predispose infants to

SDB and should be avoided. Such simple screening and precautions could dramatically impact pediatric SDB. Lastly, pediatric obesity is a growing epidemic and major cause of OSA. It leads to fatty infiltration of the tongue and other soft tissues of the upper airway. Abnormal adipocyte secretions of many peptides including leptin and obesin induce further metabolic and inflammatory consequences. Obesity and OSA may both cause some of the same symptoms, such as fatigue, and both can lead to major negative cardiac consequences later in life. In conclusion, when treating OSA, it is important not to forget to treat the underlying contributing factors such as obesity, which may have independent devastating health consequences. Recognition early in life of risk factors that may lead to abnormal breathing during sleep requires screening by not only pediatricians, but also by allergists, pediatric dentists, and orthodontists. Early intervention may halt disease progression, improve outcomes, and change lives.

Central Sleep Apnea, Hypoventilation Syndrome, and Sleep in High Altitude

33

Bernardo J. Selim, Virend Somers, and Sean M. Caples

Introduction

The International Classification of Sleep Disorders (ICSD-3) has grouped the sleep-related breathing disorders into central sleep apnea syndromes (CSAS), obstructive sleep apnea (OSA) disorders, sleep-related hypoventilation disorders, and sleep-related hypoxemia disorder [1]. This nosological classification encompasses a heterogeneous group of sleep-related breathing disorders with diverse pathophysiological mechanisms, which can be divided into two groups based upon their effect on CO_2 concentration, those with and those without elevated arterial carbon dioxide tension ($PaCO_2$). Sleep-related hypoventilation disorders are associated with hypercapnia ($PaCO_2 \geq 45$ mm Hg), and they are the result of either increased respiratory load (chest wall and lung elastic loads), decreased respiratory drive (ventilator control abnormalities), or inadequate respiratory muscle strength (neuromuscular unit impairment and neuromuscular disorders). In contrast, central sleep apnea (CSA) associated with eucapnic or even hypocapnic arterial carbon dioxide tension levels, during wake and sleep time ($PaCO_2 \leq 40$ mm Hg), are characterized by intermittent reduction (central hypopnea) or cessation of airflow concomitant with the absence of respiratory efforts (central apneas) (Table 33.1).

Some of these diverse disorders could be primary (e.g., congenital central hypoventilation syndrome [CCHS]), or secondary to medications (e.g., opiates) or medical conditions. When the underlying condition is reversible, the associated sleep-related breathing disorder may improve or resolve. However, when the correction of the underlying medical illness is not possible, long-term supportive treatment options are available.

General Considerations in CSA and Alveolar Hypoventilation Pathophysiology

Neurophysiologically, a central apnea event is the result of absent pontomedullary pacemaker activity to generate a neural output with subsequent activation of the inspiratory thoracic muscles. Considering the mechanism(s) and the resulting tension of carbon dioxide in blood ($PaCO_2$), central apneic events can be grouped into the following: (1) physiologic CSA, (2) non-hypercapnic CSA, and (3) hypercapnic sleep apnea. These mechanisms are explained below with subsequent emphasis later in each disorder (Table 33.2).

1. Physiologic central apnea: sleep-onset and post-arousal central apneas.

When falling asleep, the usual influence of wakefulness on the drive to breathe is lost, facilitating the subsequent development of sleep-onset apneas. These are considered physiologic, and they are observed in healthy individuals during the transition from awakening to superficial stages of NREM sleep (e.g., N1 and N2). This transition shows highly sensitive dependence of the respiratory control system on $PaCO_2$-driven chemoreceptor input during the shift of eucapnic levels from awake to sleep state and vice versa [2, 3]. When falling asleep, a new eucapnic level (2–6 mm Hg) above awakening $PaCO_2$ level is set as a result of a physiologic decrease in tidal volume [4, 5]. During sleep, the previous awake eucapnic $PaCO_2$ level will become the new apneic threshold ($PaCO_2$ level below which a central apnea will occur). The apnea will endure until the $PaCO_2$-level increases back to the sleep eucapnic level, with subsequent reinitiation of breathing. Therefore, breathing instability at sleep onset is commonly observed (Fig. 33.1). In contrast to

Table 33.1 Etiologies of central sleep apnea syndromes and alveolar hypoventilation

(I) **Physiologic central apneas**
1. Sleep-onset central apneas
2. Post-arousal central apneas
3. Phasic REM sleep
(II) **Sleep-related disorders associated with normal nocturnal carbon dioxide**
(A) *Central sleep apnea syndromes*:
1. Primary central sleep apnea
2. Central sleep apnea with Cheyne–Stokes breathing
3. Central sleep apnea due to high-altitude periodic breathing
(III) **Sleep-related disorders associated with high nocturnal carbon dioxide**
(A) *Ventilatory control abnormalities with normal pulmonary function test*:
1. Congenital central alveolar hypoventilation syndrome
2. Idiopathic central alveolar hypoventilation
3. Central sleep apnea due to a medication or substance (narcotics)
(B) *Neuromuscular disorders with abnormal pulmonary function test*:
1. Cervical spinal cord injury
2. Amyotrophic lateral sclerosis
3. Guillain–Barre syndrome
4. Myotonic and Duchenne dystrophies
(C) *Chest wall and lung disorders with abnormal pulmonary function test*:
1. Kyphoscoliosis
2. Thoracoplasty
3. Chronic obstructive lung disease
4. Advanced restrictive lung disease
5. Obesity hypoventilation syndrome

NREM, REM sleep is less dependent on the $PaCO_2$-driven chemoreceptor input, likely related to an increase in the central inspiratory neural drive as the main driver of respiratory function [6].

During cortical arousals, the chemoreceptor sensitivity is reset back to the awake eucapnic level, making the sleeping eucapnic $PaCO_2$ relatively hypercapnic in comparison with the awake eucapnic level. This will trigger an increased ventilatory response, facilitated by the increase in flow from dilation of upper airway muscles. When the sleep resumes, the recently reached arousal $PaCO_2$ level will cross the sleep apneic threshold with subsequent development of a central apnea, commonly called post-arousal apnea [7].

2. Non-hypercapnic CSA:

This is typically characterized by awake $PaCO_2$ less than 45 mm Hg. Apneic events are the result of over-response or under-response of the respiratory control system to minimal changes in nocturnal $PaCO_2$ (high "loop gain") [8]. The loop gain is an engineering term that describes the degree of response, in this case of the respiratory control system, after a ventilatory disturbance. The higher the loop gain, the higher the overventilation or underventilation response. Loop gain is comprised of three components: (1) the controller gain, the chemoreceptor-driven ventilatory response to changes of $PaCO_2$ and PaO_2 above and below the eucapnic level; (2) the plant gain, ventilatory response to changes in pulmonary capillary $PaCO_2$ and PaO_2; and (3) the mixing gain which is the circulatory time needed for changes in $PaCO_2$ and PaO_2 in pulmonary capillaries to be detected by the chemoreceptors (effective circulatory time) [9]. Disorders such as idiopathic CSA, Cheyne–Stokes breathing (CSB), and CSA due to high altitude are considered to be the result of this high "loop gain" of the respiratory control system. Because of the dependence on $PaCO_2$ described above, these breathing disorders are generally exclusive to NREM sleep.

3. Hypercapnic CSA:

This group of disorders is generally known as "alveolar hypoventilation" and is defined by an elevated nocturnal $PaCO_2$ level (>45 mmHg), which may extend during the daytime. The main respiratory abnormality resides anywhere along the brainstem respiratory control center (e.g., congenital central alveolar hypoventilation syndrome), throughout the respiratory motor output unit, from the motor neuron to the innervated respiratory muscle.

Overlap exists between obstructive sleep apnea and CSA in the obesity hypoventilation syndrome (OHS). In obese patients (body mass index >30 kg/m^2), an extension of nocturnal alveolar hypoventilation into daytime defines OHS. The pathophysiology is not completely understood, but it may include the interaction of the following: (1) high upper airway tone, (2) impaired respiratory mechanics (increased work load), and (3) decreased ventilatory drive (blunted respiratory response) [10–14].

Specific Considerations by Disease Entity

Central Sleep Apneas Syndromes

Primary Central Sleep Apnea

In the group of non-hypercapnic CSAs, primary CSA is an idiopathic disorder (ICSA) characterized by recurrent central apneas associated with polysomnographic criteria of 5 or more events of central apneas and/or central hypopneas per hour of sleep, representing more than 50 % of the total number of apneas and hypopneas. There are common complaints of sleep fragmentation (e.g., excessive daytime

Table 33.2 Central sleep apnea syndromes and alveolar hypoventilation

Categories	Disorders	Pathophysiology
Central sleep apnea syndromes associated with normal nocturnal carbon dioxide	*Primary central sleep apnea*	Idiopathic. Probably, the combination of increased ventilatory response to $PaCO_2$ changes by chemoreceptors (high loop gain system) and a failure of expiratory to inspiratory switch in central respiratory controllers
	Central sleep apnea with Cheyne–Stokes breathing (*CSB*)	Commonly seen in systolic and diastolic heart failure. CSB is the result of an increased ventilatory response to $PaCO_2$ changes (high loop gain system), a narrow difference between the apnea threshold and the sleeping eucapnia, as well as an impaired cerebrovascular reactivity to CO_2
	Central sleep apnea due to high-altitude periodic breathing	Periodic breathing is the result of hypoxia-mediated increase in controller gain, with subsequent narrowing of the difference between eupneic PaCO2 and apneic threshold, as well as the oscillation in cerebral blood flow
	Central sleep apnea due to a medication or substance (narcotics)	Cluster or ataxic breathing is the result of opioid effects on the pre-Bötzinger complex with subsequent suppression of respiration rate and respiratory drive
Sleep-related hypoventilation disorders associated with high nocturnal carbon dioxide	*Ventilatory control abnormalities:* • Congenital central alveolar hypoventilation syndrome (CCAHS) • Idiopathic central alveolar hypoventilation	For CCAHS, ventilatory control is blunted by mutations in the PHOX2B gene For idiopathic central alveolar hypoventilation, the etiology is unknown
	Neuromuscular disorders: • Spinal muscular atrophy • Myotonic dystrophy • Cervical spinal cord injury	Ventilatory control blunted by inability to translate ventilatory center output into appropriate neuromuscular action
	Chest wall abnormalities: • Kyphoscoliosis • Thoracoplasty • Obesity hypoventilation syndrome	Increased work of breathing due to thoracic cage abnormalities with subsequent chronic respiratory failure
	Lung disorders: • Chronic obstructive lung disease • Advanced restrictive lung disease	In obstructive and restrictive disorders, ventilatory drive remains high, but effectiveness is reduced by gas exchange abnormalities secondary to increased airway resistance and pulmonary parenchymal damage

sleepiness, frequent nocturnal awakenings, or insomnia). By this definition, the presence of an alternative diagnosis, such as Cheyne–Stokes breathing or evidence of sleep-related hypoventilation would automatically exclude the diagnosis of ICSA [1].

Epidemiology:

ICSA is a rare disease, with an estimated prevalence reported to be 4–7 % of patients referred to a sleep center [15].

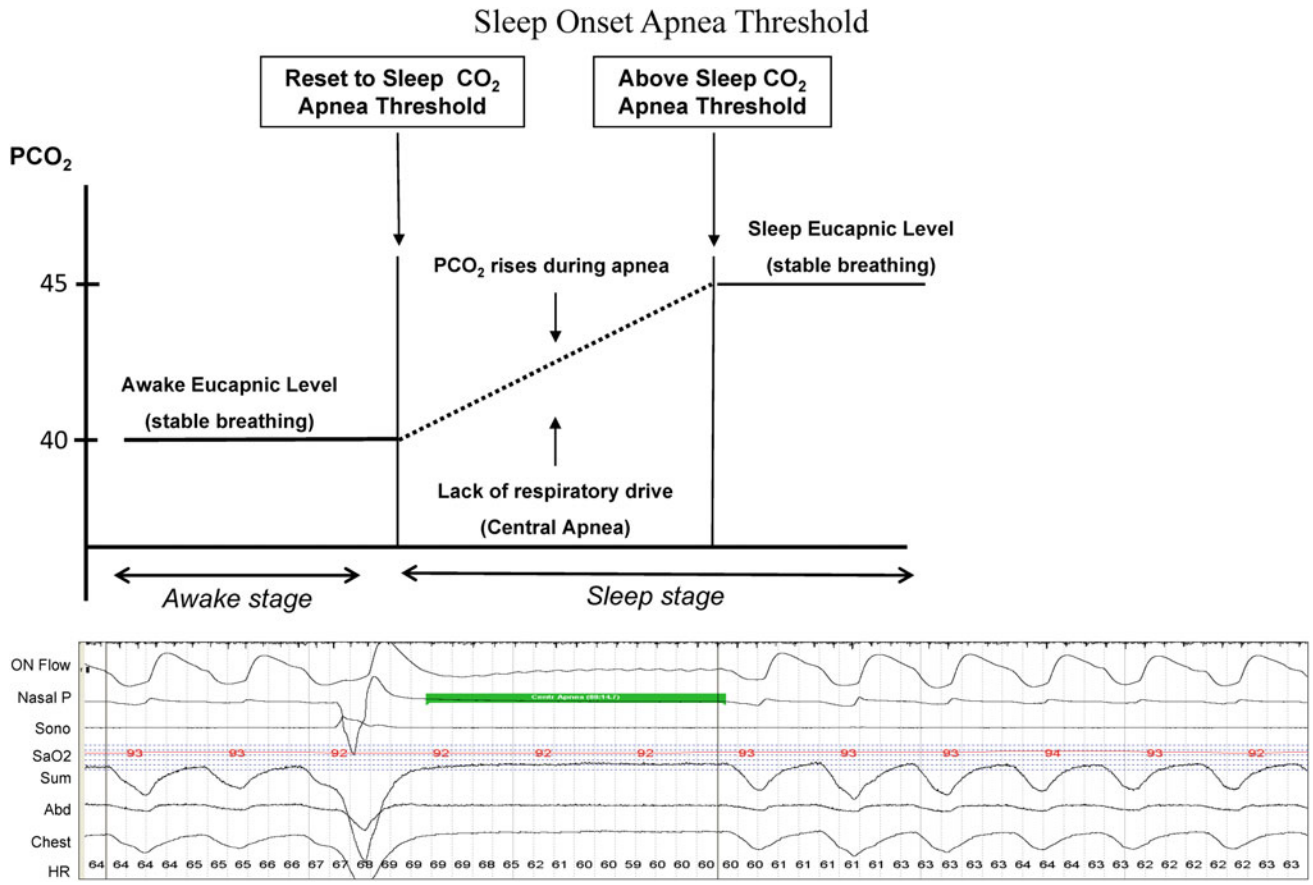

Fig. 33.1 At sleep onset, there is breathing instability, often in the form of central sleep apnea. The set point of the apnea threshold is different in wakefulness and sleep. When falling asleep, the awake eucapnic level falls below the set point sleep apneic threshold resulting in lack of respiratory drive (apnea) until the new sleep eucapnic level is reached and the respiratory drive is reinstituted

Clinical characteristics:

ICSA patients may present with complaints of snoring, witnessed apneas, restless sleep, insomnia, and/or excessive daytime sleepiness [15, 16]. It is more common in older males and in patients with cardiovascular disease [17, 18].

Pathophysiology:

The underlying mechanism is not well understood. Like in Cheyne–Stokes breathing due to congestive heart failure (CSB-CHF), idiopathic CSA patients have an increased hypercapnic ventilatory response during arousals, likely the result of high controller and plant gain, facilitating the crossing of the apnea threshold [7, 8, 19]. This mechanism can be supported by the clinical response of ICSA to acetazolamide, with the subsequent increase in systemic $PaCO_2$ [20]. However, the absence of the crescendo–decrescendo ventilatory pattern in ICSA and a shorter breathing cycle length, likely from the absence of effective circulatory time delay, may point to alternative pathways from those of CSB.

Polysomnography:

Idiopathic CSA is characterized by repetitive episodes of CSA frequently found during N1 and N2 sleep (NREM). Different from CSB, the periodic breathing cycle length in CSA is shorter (20–40 s), and the apnea event terminates with a large breath, concomitant with the presence of an arousal. No crescendo–decrescendo ventilatory pattern is present in this periodic breathing pattern [1, 21] (Fig. 33.2).

Management:

1. *Pharmacological treatment*:

Limited data support a trial of acetazolamide, zolpidem, and triazolam in ICSA treatment. In a non-randomized treatment study, DeBacker and colleagues have found that the

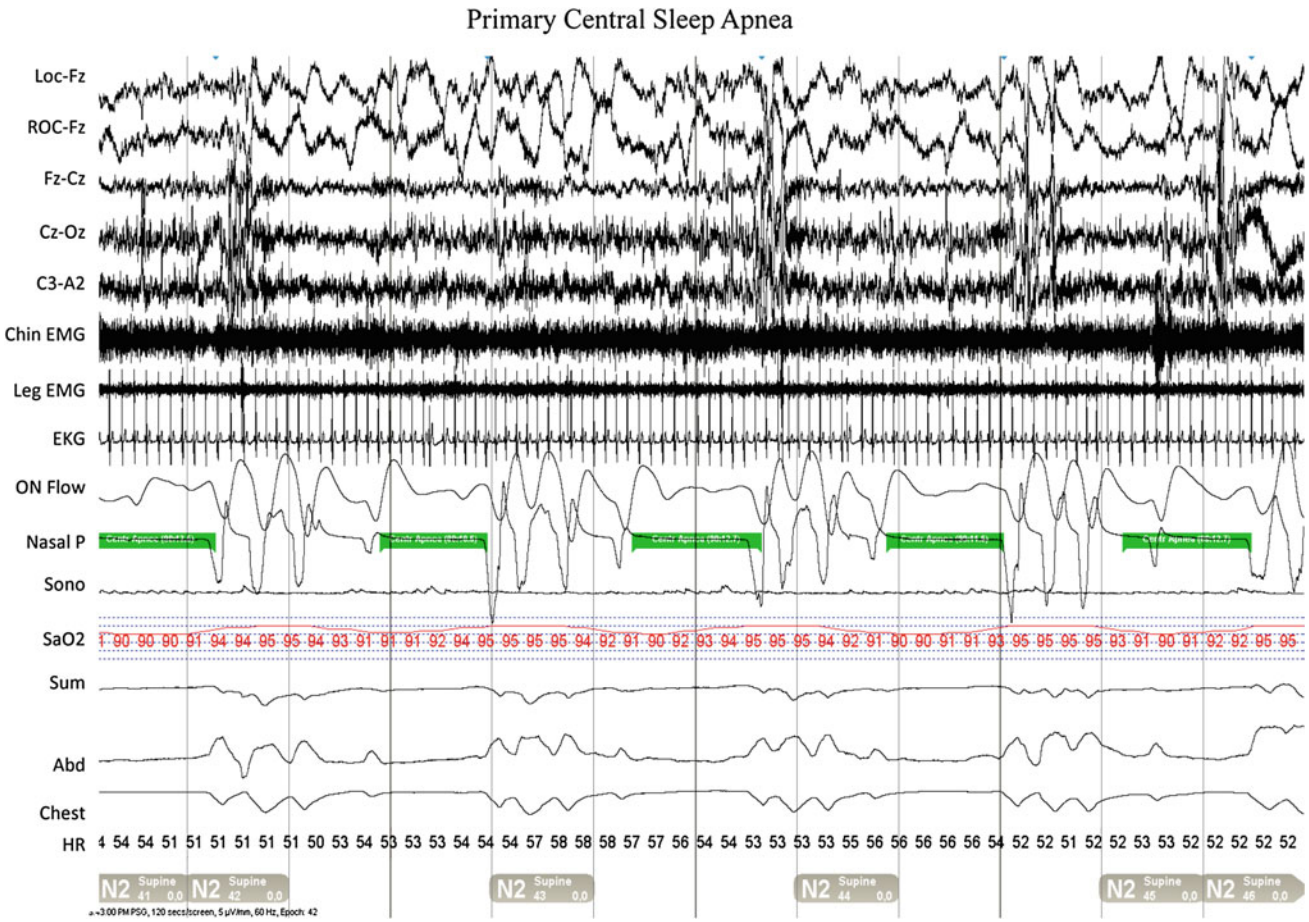

Fig. 33.2 This polysomnographic segment obtained from a patient with primary central sleep apnea shows 4 epochs of 30 s with cyclical central apneic events. Each heavy vertical line demarks 30 s. The thermal sensor channel (ON flow) shows a drop of ≥ 90 % of peak thermal sensor signal from baseline. The nasal pressure signal (Nasal P) denotes episodes of central apneas (*green bars*) separated by a normal ventilation with a cycle length of 20–40 s

administration of acetazolamide at low doses can decrease the apnea–hypopnea index (AHI) at one-month follow-up, with concomitant decrease in daytime sleepiness [15, 20]. Effective reductions of AHI and central apnea index (CAI) were also reported with administration of zolpidem, and triazolam, with the improvement in daytime sleepiness in the zolpidem intervention group [22, 23]. Due to limited available evidence and the potential of side effects, pharmacological intervention in ICSA should be individualized until further studies are available.

2. *Assistive devices*:

There is also limited supporting evidence regarding the use of positive airway pressure (PAP) in the form of Continuous PAP (CPAP), Bilevel PAP with backup rate (BPAP-ST) or Adaptive servo-ventilation (ASV) in patients with ICSA [24]. Current CSA practice parameters recommend a trial of positive airway pressure therapy for the treatment of ICSA until further studies define the best treatment strategy [25].

Central Sleep Apnea Due to Cheyne–Stokes Breathing Pattern in Congestive Heart Failure (CSB-CHF)

Epidemiology:

Congestive heart failure (CHF) is a highly prevalent chronic disease, affecting around 2 % of the general population (5–6 million Americans) and up to 10 % of those above age 65 [26]. CHF is the most commonly recognized cause of CSA. Although the existing literature is limited by referral and participatory bias, it is estimated that in heart failure patients with reduced left ventricular ejection fraction (<45 %), as

much as 31 % have CSA [27–29]. In those patients with preserved ejection fraction (diastolic dysfunction), the prevalence of CSA may reach up to 23 % [30].

Clinical characteristics:

Classic signs and symptoms such as paroxysmal nocturnal dyspnea (PND) and orthopnea in those with heart failure might be explained in many instances by CSA-CSB. Even though patients with heart failure and sleep-disordered breathing do not commonly report sleep-related complaints such as excessive daytime sleepiness, presenting clinical characteristics of patients with CSA-CSB may be otherwise undistinguishable from those with OSA [31]. Patients in CHF with CSB are more likely to have atrial fibrillation and poorer functional status (NYHA class), supporting the notion that CSB is a consequence of progressive heart failure and possible indicator of higher morbidity and mortality [29]. Although found more frequently in CHF patients, CSB is not pathognomonic as it can also be observed in stroke and in chronic renal failure patients [32].

Pathophysiology of CSB due to heart failure with/without preserved systolic function:

Non-hypercapnic central apnea in heart failure patients with ventricular dysfunction are the result of the interaction of the following factors: (1) low awake steady state of $PaCO_2$, (2) lack of increase of $PaCO_2$ at sleep onset, with subsequent reduced difference between the apnea threshold and the sleeping eucapnic level (reduce PCO_2 reserve), (3) increased response to $PaCO_2$ changes (high loop gain system), and (4) impaired cerebrovascular reactivity to CO_2.

- In heart failure patients, a low awake steady state of $PaCO_2$ has a direct correlation with severity of the heart failure and high wedge pulmonary pressure in comparison with eucapnic heart failure patients. By stretching J-receptors (afferent C fibers), minute ventilation is increased with subsequent low steady level of wake $PaCO_2$ [33–35].
- The awake $PaCO_2$ does not increase at sleep onset as expected by the physiological development of sleep-related hypoventilation in eucapnic individuals. In these patients, the increase venous return while in supine position translates into an elevated capillary pulmonary pressure with subsequent increase in respiratory rate and ventilation. This will prevent the expected rise in $PaCO_2$ during sleep stage, narrowing the difference between the sleep eucapnic level and the apnea threshold $PaCO_2$ level, with propensity to develop central apneas [36, 37].
- Increase response to $PaCO_2$ changes (high loop gain system) is the result of increased gain in the three components of the respiratory control system: controllers, plant, and mixing gain. In heart failure, the controller gain is increased by acute lung vascular receptor stimulation of the atrial and pulmonary vasculature and by increased carotid chemoreceptor sensitivity. The plant gain is increased mainly by a low functional residual capacity. Finally, the mixing gain is increased by a prolong arterial circulation time as a result of pulmonary congestion, ventricular enlargement, and decreased stroke volume [37, 38] (Fig. 33.3).
- Impaired cerebrovascular reactivity to CO_2 has been noted in CSA patients with CHF, affecting the stability of the breathing pattern by causing ventilatory overshooting during hypercapnia and undershooting during hypocapnia [39].
- *Polysomnography*:

The classification of sleep disorders as obstructive sleep apnea (OSA) or CSA is important when determining treatment options in CHF. In CSA with CSB, the polysomnography during diagnostic or positive airway pressure titration should show at least 5 or more central apneas and/or central hypopneas per hour of sleep, representing more than 50 % of the total number of apneas and hypopneas. The characteristic periodic breathing pattern of heart failure, known as Cheyne–Stokes breathing, is defined polysomnographically by cycles of ≥ 3 consecutive central apneas and/or central hypopneas separated by a crescendo–decrescendo shape tidal volume [40]. It is commonly found during transition

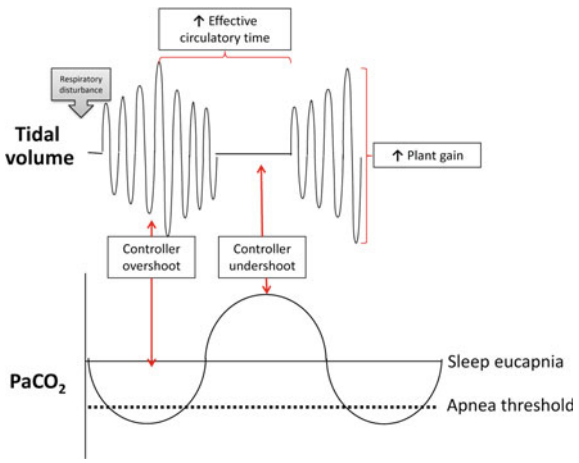

Fig. 33.3 Schematic of respiratory control response in Cheyne–Stokes breathing (CSB). The loop gain is the respiratory control system's degree of response to a ventilatory disturbance. It is comprised of (1) the controller gain, (2) the plant gain, and (3) the mixing gain (effective circulatory time)

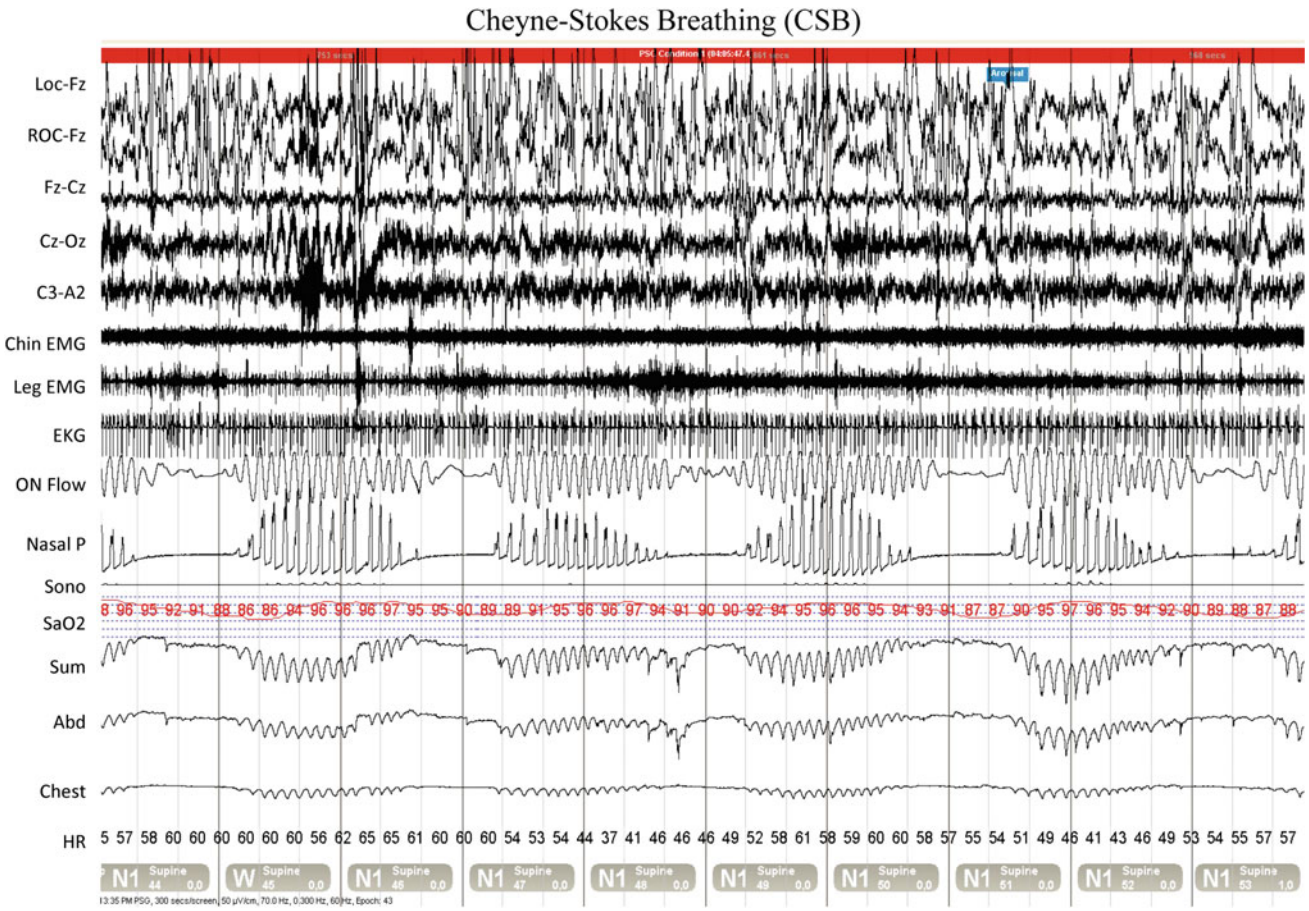

Fig. 33.4 This polysomnographic segment obtained from a patient with compensated systolic heart failure shows 10 epochs of 30 s. Each heavy vertical line demarks 30 s. The thermal sensor channel (ON flow) shows the presence of apneic events as a drop of ≥ 90 % of peak thermal sensor signal from baseline. The nasal pressure signal (Nasal P) denotes episodes of ≥ 3 consecutive central apneas separated by a crescendo and decrescendo change in breathing amplitude with a cycle length of ≥ 40 s

from wakefulness to NREM sleep (N1 and N2), dissipating in N3 and REM. The cycle length, measured from the beginning of a central apnea to the end of the next crescendo–decrescendo respiratory phase, averages ≥ 40 s, and it likely reflects a prolong circulatory time (high mixing gain) [8]. Central apneas that occur within a run of CSB are reported to be associated with less marked oxygen desaturation than similar obstructive and mixed apneas [41]. Arousals, usually located during the ventilatory period, have not shown to have any critical role in termination of apneas or protective mechanism as in obstructive sleep apnea [42] (Fig. 33.4).

Management:

1. *Cardiovascular pharmacological therapy*:

Optimization of cardiovascular pharmacotherapy should be the first intervention in the management of CSA due to CHF. The use of beta-blockers, ACE-inhibitors, angiotensin II receptor blockers (ARB), aldosterone antagonists, and diuretics will have a salutary effect in the neurohormonal physiopathology of heart failure, with potential benefits in Cheyne–Stokes breathing. For example, β-blockers are known to influence hypoxemic chemosensitivity (controller gain) [43]. Also, ACE-inhibitors and diuretic therapy may influence the occurrence of CSB by lowering the intracardiac filling pressures [44]. Despite current efforts to optimize cardiovascular therapy in severe CHF, no significant change of Cheyne–Stokes prevalence could be appreciated in small observational studies [29, 45, 46].

Even though not commonly used, other pharmacological therapies are theophylline and acetazolamide. Acetazolamide, by respiratory stimulation and diuretic effect, may decrease the plant gain and widen the difference between the sleep eucapnic levels and the sleep apneic threshold [47]. Clinically, this translates into a reduction in AHI and improvement in patient's perception of sleep quality [48, 49]. However, side effects associated with acetazolamide, such as paresthesias, tinnitus, metabolic acidosis, electrolyte

imbalance, and dizziness, should be considered at time of prescription. Theophylline, by competing with adenosine at a central level, stimulates respiratory centers resulting in a 51 % reduction in the apnea–hypopnea index, mostly because of a reduction in the number of episodes of central apnea. It also shows a decrease in the duration of arterial oxyhemoglobin desaturation during sleep [49–51]. However, the benefits of theophylline should be weighed against the narrow therapeutical range and stimulant effect.

2. *Gas therapy*:

CO_2 supplementation and dead space therapy:

Because the pathophysiology of Cheyne–Stokes breathing is thought to be related to increase chemosensitivity to $PaCO_2$ at the central controllers (high controller gain), avoiding relative hypocapnia may stabilize the respiratory system. This can be reached by CO_2 supplementation (gas modulator) or by increasing anatomic dead space (DS). Low CO_2 supplementation can be bled from a positive airway pressure gas modulator into a positive airway pressure device. However, limitations relate to cost of the gas modulator, supply of CO_2, and side effects of treatment have affected the practical application of this therapy in the clinical field [52]. Increasing physiologic dead space during positive pressure therapy has been reported to control CSAs in those with CHF [53, 54]. Low levels of CO_2 inhalation mildly raise the sleep eucapnic level, increasing the difference with the $PaCO_2$ apneic threshold. This is achieved by the sequential connection of a non-vented oronasal mask to 4–6 in. of tubing (rebreathing space), an exhalation valve, and a conventional positive pressure circuit. This expiratory rebreathing reservoir represents an increase of $PaCO_2$ in the order of 2–3 mm Hg. Unfortunately, pressure leaks and sleep fragmentation are common [55]. When compared to ASV therapy (discussed later) in patients with CHF, DS and ASV caused a similar reduction in the apnea–hypopnea index (AHI), but total sleep time was significantly decreased by DS, attributed to a high arousal index and disruption of sleep architecture [56].

Oxygen therapy:

Uncontrolled studies of oxygen supplementation via nasal cannula report a decrease in the AHI, as well as an increase the left ventricular ejection fraction (LVEF) at 3–12-month follow-up without clinically significant adverse effects [57, 58]. These effects may be achieved by different pathways: (1) by reducing the controller gain, (2) by increasing the difference between the eucapnic $PaCO_2$ level and the $PaCO_2$ at apneic threshold, and 3) by increasing cerebral CO_2 levels [59, 60]. Even though oxygen supplementation cannot replace CPAP treatment benefits, oxygen supplementation could be considered in those patients with poor compliance with noninvasive ventilation [25].

3. *Assistive devices*:

Several assistive devices modalities have been studied in patients with CHF. Continuous positive airway pressure (CPAP), bilevel positive airway pressure without backup rate (BPAP-S) and with respiratory backup rate (BPAP–ST), and adaptive servo-ventilation (ASV) have been investigated.

Continuous positive airway pressure (CPAP) therapy:

There are a number of beneficial effects on the cardiovascular system when continuous positive airway pressure is applied to the patient with CHF. CPAP can affect the response of the respiratory control system by several pathways. It may decrease the circulatory time (mixing gain) and increase the difference between the eucapnic sleep levels and the apneic threshold. Positive airway pressure may also increase the functional residual capacity (decrease in plant gain) and overcome resistance to airflow in the congested upper airway.

Despite these effects, a large multicenter controlled trial named the Canadian Continuous Positive Airway Pressure for Patients with CSA and Heart Failure Trial (CANPAP), failed to show survival benefit with CPAP treatment in advanced HF and CSA at interim analysis, leading to early termination of the study. Worth noting in this study, CPAP implementation showed attenuation of CSA, improvement in nocturnal oxygenation, and an increase in the ejection fraction [61]. This negative result in survival benefit might be attributed to a lack of PAP titration to achieve a therapeutical reduction in AHI or limited compliance with the device. The authors suggested the lower than expected prevalence of CSA led to under-powering, possibly as a result of better medical management in the era of beta-blockers. However, in a subsequent subgroup analysis, CPAP showed positive effect on LVEF and transplant-free survival when CPAP therapy was able to normalize the apnea–hypopnea index to less than 15 events per hour [62, 63]. Subsequent studies have also shown CPAP to increase the LVEF by 6 % and decrease the AHI between 21/h [95 % CI 17–25] and 30/h [95 % CI 23–37] [25]. In conclusion, CPAP may be appropriate therapy for selected patients in whom respirator events are controlled [25].

Bilevel positive airway pressure (BPAP) therapy:

There is paucity of publications regarding the impact of bilevel positive pressure ventilation in patient with CHF. The data available up to now discourage the use of BPAP-S mode in this population, as it may aggravate central apneas/periodic breathing by hyperventilation. It has been shown that CPAP and BPAP-ST are equally effective in lowering the AHI and NYHA class [64]. BPAP-ST could be an effective alternative to those patients with high residual AHI while on CPAP, benefiting from an increase in LVEF of up to 12.7 ± 10 % [65].

Adaptive servo-ventilation (ASV) therapy:

The adaptive servo-ventilation is a feedback control system targeting minute ventilation or peak respiratory flow, adding a component of ventilation that is anticyclic to the patient's own respiratory drive periodicity. Short-term studies have shown ASV to effectively suppress the Cheyne–Stokes breathing pattern seen in CHF patients with CSA, with improvements in some sleep-related outcomes, as outlined below. When compared to CPAP, compliance may be better with ASV [66]. However, as final results of ongoing large clinical trials are awaited, and in the context of an unexpected increase in mortality associated with ASV as detailed below, the role of the device in the management of CSA in patients with CHF remains to be defined.

Patients with systolic CHF-CSB on treatment with ASV show improvement in polysomnographic parameters (normalization of number of respiratory events), cardiac function (left ventricular ejection fraction, LVEF, and N terminal pro B-type natriuretic peptide NT-proBNP), NYHA functional class, and cardiopulmonary exercise tolerance parameters (VO_2-ATOxygen consumption at anaerobic threshold or peak exercise, VO_2 peak, and 6-min walking distance) [67]. One observational study reported a decrease in the number of cardiac events (cardiac death and rehospitalization) at 6-month follow-up [68, 69]. Even in cases of coexistence of obstructive sleep apnea (OSA), CSA, and Cheyne–Stokes breathing (CSB) in patients with and without heart failure, ASV reduced the central apnea hypopnea index and BNP levels significantly more effectively as compared with CPAP over an eight-month and twelve-month follow-up period [70, 71]. A similar profile of improvements has also been shown in patients with diastolic CHF-CSB on ASV, as well as CHF patients with obstructive and CSA occurring concurrently within the same night, independent of the severity of the sleep-disordered breathing [72–74]. Limited published data are available to infer the impact of ASV on mortality [69, 74]. Recently, preliminary results of the SERVE-HF trial, which assessed the effects of treatment of CSA with ASV on mortality and morbidity in patients with symptomatic chronic heart failure (NYHA 2–4) with reduced ejection fraction (LVEF $\leq$ 45 %), showed an increased risk of cardiovascular mortality for those treated with ASV in comparison with those with best medical care alone. The increased risk appears to be greatest in those with pure CSA with more severe ventricular dysfunction. However, additional analysis of the phase IV SERVE-HF data and further longitudinal studies are needed to accurately identify the long-term impact of ASV in CSA-CHF patients with varies left ventricular ejection fractions, as well as those with preserved ejection fraction.

There are few published studies with direct comparison of ASV with CPAP, BPAP-ST, and oxygen supplementation. At one night study, ASV suppresses CSA and/or CSB (CSA-CSB) in heart failure and improves sleep quality better than CPAP or 2 L/min of oxygen supplementation. In comparison with BPAP-ST, ASV performs better in CSB-CHF but equivalent to CPAP [75, 76].

Other devices and interventions:

Some smaller case series show improvement in the AHI when atrial overdrive pacing (AOP) is used to improve cardiac function in patients with CSA-CHF in comparison with those without AOP [77]. This may be attributed to an increase in cardiac output with subsequent decrease in pulmonary wedge pressures and circulatory time. Similar to AOP, cardiac resynchronization therapy (CRT) reduces the AHI without altering sleep stages [78]. When both AOP and CRT are combined, a minor additional improvement in the AHI is obtained by decrease in the central AHI [79]. Of note, preliminary data from unilateral transvenous phrenic nerve stimulation in patients with CSB–CHF showed a trend toward stabilization of breathing and improvement in oxygen saturation [80].

In those patients with CSA secondary to impaired cardiac function from valvular disease, surgical treatment has been shown to improve sleep-disordered breathing. Even though improved, CSB may persist even after post-transplant normalization of cardiac function [81].

Central Sleep Apnea Due to a Medication or Substance, Opioids

Epidemiology:

A projected 201.9 million opioid prescriptions were dispensed in the USA in 2009 [82]. As the quantity of opioid prescription in the USA has grown rapidly in recent years, the number of patients on opioids presenting to the sleep

clinic for evaluation of sleep-related breathing disorders has also increased. It is estimated that the prevalence of CSA among opioid users, on at least six months therapy, is about 24 %. In methadone maintenance therapy, CSA is identified in up to 30 % of patients [83]. A direct relationship between the total daily dose of opioid and the AHI is found only among methadone users and not among other opioid users including oxycodone, hydrocodone, morphine, hydromorphone, and tramadol [84]. Sleep-disordered breathing has been reported to be reversed with discontinuation of methadone [85].

Clinical characteristics:

Opioid-related breathing disorders in sleep can present in the form of obstructive sleep apnea, CSA, alveolar hypoventilation, or a combination of them. Although symptoms of excessive daytime sleepiness, sleep fragmentation, and insomnia are common complaints, it is difficult to disentangle independent effects of the sleep disorder from the influences of the underlying pain syndrome and non-sleep-related influences of narcotics.

Pathophysiology:

Opioids are naturally occurring or synthetic agents which bind to a class of four G protein-coupled receptors in the central and peripheral nervous systems and respiratory tract, leading to decreased neuronal excitability [86]. These receptors fall into four classes: δ, μ, nociception/orphanin, and the κ receptor. Opioid medications, mimicking endogenous ligands (endorphins, enkephalins, dynorphins, etc.), act through these receptors at different levels of the peripheral and central nervous system. Ligands that stimulate μ and κ receptors particularly suppress central respiratory pattern generation, resulting in decreases in respiratory rate and tidal volume. Both naturally occurring and synthetic opioids may exhibit preferential receptor affinity and may act as agonists, mixed agonists/antagonists, or antagonists.

Animal research, supported by limited work in humans, describes opioids acting on medullary respiratory neurons with the suppression of respiration rate and respiratory drive (pre-Botzinger complex), central chemoreceptors' response to hypercapnia, peripheral response to hypoxemia (glomus cell of carotid body), and depression of the arousal system. Generally, in humans, opioids tend to decrease hypoxic and hypercapnic ventilatory responsiveness. Opioid agonists, particularly fentanyl, tend to decrease upper airway muscle tone and the compensatory response to resistive loading. In addition, some agents have been associated with increased rigidity of accessory respiratory muscles, further limiting ventilation.

These influences suggest that opioids may increase susceptibility to sleep-related breathing disorders. The effect of opioids on human ventilatory control is influenced by dose and ligand specificity. At lower doses, respiratory depression occurs secondary to a decrease in tidal volume, and at higher doses, secondary to a decrease in respiratory rate [86]. A decreased ventilatory response to hypercapnia/hypoxia also occurs [83].

Polysomnography:

Polysomnographic effects on sleep during acute opioid administration include decreases in slow-wave and REM sleep with decreased sleep efficiency and increases in arousals and N1 and N2 sleep. Other studies have shown a decrease in slow-wave sleep with increased N2 sleep and no change in sleep efficiency or total sleep time in patients receiving either morphine or methadone during polysomnography [87]. During chronic opioid administration, the decreases in slow-wave and REM sleep may normalize with improvement in sleep efficiency [88].

As mentioned in the pathophysiology section, a decreased ventilatory response to hypercapnia/hypoxia will develop CSAs in two characteristic patterns of breathing: the cluster period breathing pattern and the ataxic/Biot's breathing pattern. The cluster breathing is characterized by cycles of hyperventilation with tidal volumes of stable amplitude, separated by central apneas of variable duration. The ataxic/Biot's breathing pattern is characterized by variable amplitude and rate of tidal volume as well as variable central apnea duration (Fig. 33.5)

Management:

The literature assessing treatment of CSAS due to drugs or substance is limited. As the effect of opioids on central apneas is probably dose-dependent, discontinuation or a decrease in opioid dose to the lowest tolerated by the patient is recommended [89]. Only limited data support use of PAP devices. CPAP may reduce the AHI, generally by controlling obstructive respiratory events, but not CSAs. In fact, the use of CPAP may aggravate CSA [90]. Regarding intervention with ASV, there are conflicting data from small studies about its role in this group of patients. Further study is needed before routine use of PAP devices can be recommended in the setting of chronic opioid use [90, 91].

Central Sleep Apnea Due to High-Altitude Periodic Breathing

After a high-altitude ascend to approximately 3500 m above sea level or greater, most healthy individuals will develop a

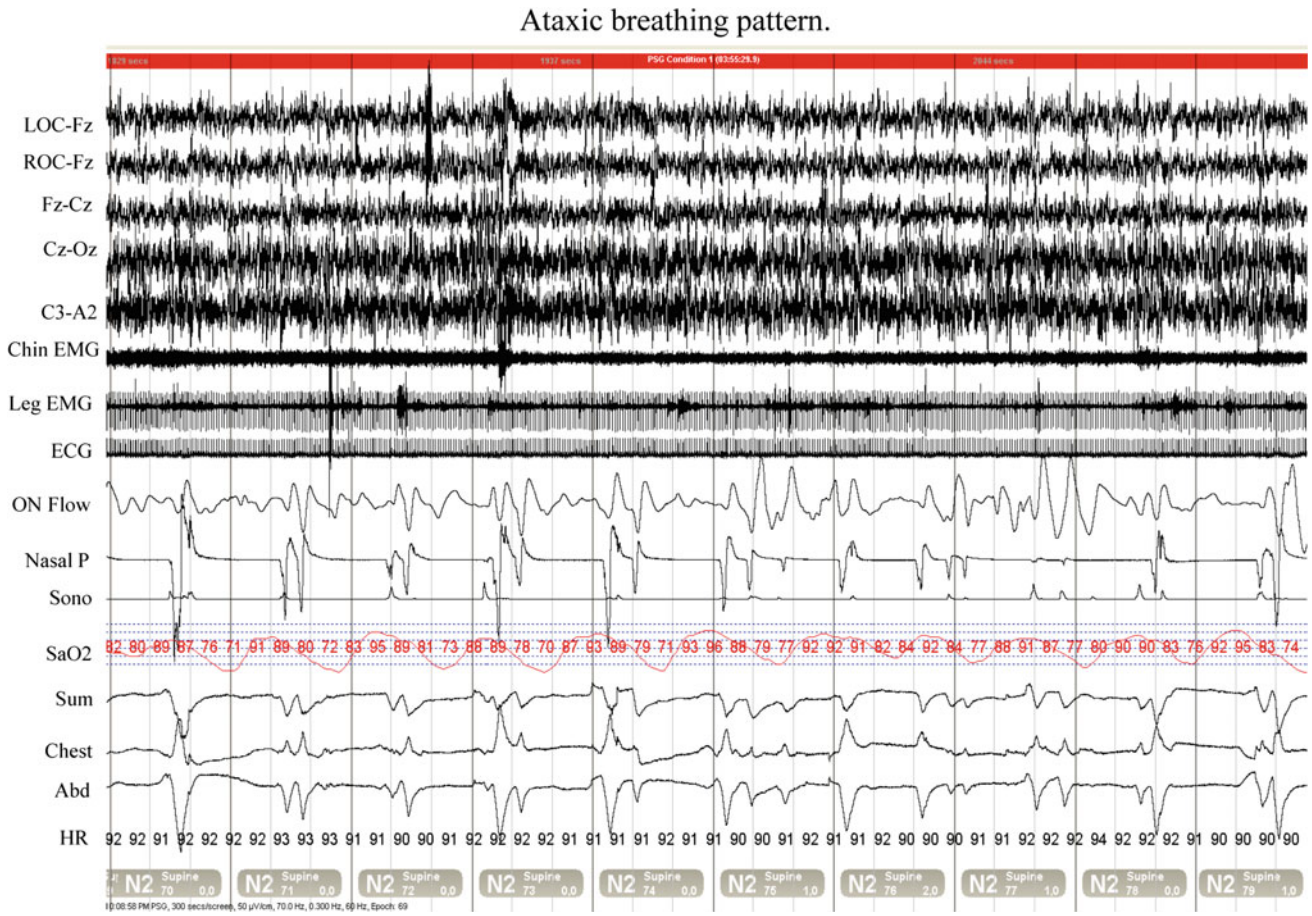

Fig. 33.5 This polysomnographic segment obtained from a patient on chronic opioids shows 10 epochs of 30 s. Each heavy *vertical line* demarks 30 s. The thermal sensor channel (ON flow) and the nasal pressure signal (Nasal P) denotes ataxic or irregular breathing

periodic breathing pattern driven by acute alveolar hypoxia [92–94]. This typically develops during ascension itself, immediately after or during the acclimatization period. Development of CSA due to high altitude will depend not only on altitude itself, but also on speed of ascension as well as on individual variability to hypoxic responsiveness.

Clinical characteristics:

Arousal events increase with altitude. This increase in total arousals will translate into sleep fragmentation which may result in subsequent complaints of fatigue and excessive daytime sleepiness [95, 96]. Despite the fact that the number of arousals is higher in periodic breathers at different altitudes, periodic breathing pattern itself is not associated with a poorer subjective sleep quality when compared to non-periodic breathers [92, 97].

Pathophysiology:

The major effects of high altitude on humans relate to the changes in barometric pressure (PB) and its consequential changes in the ambient pressure of oxygen (O_2). Since the fraction of inspired oxygen remains constant at approximately 20.93 % during ascension, the most important determinant of inspired PO_2 and subsequent arterial PO_2 (PaO_2) at any altitude is the barometric pressure. For example, at an altitude of 3000 m, the barometric pressure and inspired PO_2 are only about 70 % of that at sea level. During ascension, as arterial PO_2 falls due to a low atmospheric pressure (hypobaric hypoxia), ventilation will be stimulated, with resultant hypocapnia and respiratory alkalosis. Despite high individual variability in acclimatization to the increasing hypoxia at high altitude, sustained hypoxic stimulus during ascension will trigger a periodic breathing

pattern in clusters during the night [97]. It is the hyperventilation triggered by hypoxia, with subsequent fall in $PaCO_2$ below the apneic threshold, that results in central apneas [98]. With breathing cessation, $PaCO_2$ increase will trigger a subsequent hyperventilation period based on high tidal volumes, in which the PaO_2 rises and $PaCO_2$ falls to near wakefulness level. In high altitude, periodic breathing is the result of the hypoxia-mediated increase in controller gain, with subsequent narrowing of the difference between eupneic $PaCO_2$ and apneic threshold, as well as the oscillation in cerebral blood flow, which elevates the cerebrovascular responsiveness to hypercapnia and hypocapnia [99–101]. Even though acclimatization to high-altitude results in an overall increase in saturation of oxygen, periodic breathing may increase in duration and persist in time, consistent with progressive increase in loop gain of the respiratory control system [96, 102, 103].

Polysomnography:

In healthy individuals, sleep architecture changes at high altitude with concomitant development of periodic breathing. When altitude starts increasing from 3500 m above sea level, duration in N1 stage increases, at the same time slow-wave sleep decreases. However, the time spent in REM sleep is well preserved along ascension up to 5000 m above sea level. Total arousal events increase as altitude increases, as a result of an increase in spontaneous arousals, as well as an increase in arousal related to periodic breathing and/or obstructive sleep apnea [95, 97, 104]. A periodic breathing pattern can develop at any altitude above 3500 m. In comparison with those individuals without periodic breathing, periodic breathing subjects experience an increase in the total arousal index, without a disruption of sleep architecture or sleep oxyhemoglobin saturation [92, 97].

At high altitude, periodic breathing is characterized by recurrent central apneic events in cycles of 12–34 s. It is usually associated with mild oxygen desaturation. Worse in NREM sleep, it stabilizes during REM sleep. As noted in different studies, there is high individual variability in intensity of periodic breathing to hypoxia at any certain altitude [94]. Because it is considered an adaptation to high altitude, there are no established polysomnographic criteria regarding the frequency of apneic events above which it is considered abnormal.

Management:

Slow ascension and acclimatization are crucial interventions to ameliorate the development of sleep and breathing disorders. By physiologic adaptation of oxygen content and carrying capacity to high altitude, slow ascent can decrease respiratory drive triggered by hypoxia. Unfortunately, at elevations above 3500–4000 m, acclimatization does not restore normal sleep, even for healthy individuals born at high altitude [96, 105].

At this time, limited data support pharmacological interventions, such as theophylline, temazepam, and acetazolamide for the prevention and treatment of high-altitude periodic breathing. If pharmacological intervention is contemplated, side effects and limitations of the intervention should be cautiously considered. Theophylline and acetazolamide have being shown to normalize the sleep-disordered breathing at high altitude. Different from theophylline, acetazolamide significantly improves basal oxyhemoglobin saturation during sleep, with no major side effects. The effect of temazepam on periodic breathing, overnight SaO_2, and next-day cognitive performance has also been studied. Even though temazepam has shown to reduce periodic breathing, it has also been associated with a small but significant decrease in overnight SaO_2. If pharmacological intervention is considered, theophylline and acetazolamide are recommended to be started 3 days before ascension [106]. On the other hand, temazepam is recommended to be taken on two consecutive nights soon after arrival at 5000 m [107].

Since all of the deleterious effects of high altitude are caused by the low inspired PO_2, supplementary oxygen can improve the inspired PO_2, thereby decreasing respiratory drive and ensuing central apneas. Unfortunately, implementation of this intervention is challenging at high altitude, and data in oxygen supplementation are limited to intervention in acute high-altitude illness such as acute mountain sickness [108, 109].

Sleep-Related Hypoventilation Disorder, Central in Origin Versus Due to Medical Disorder

Classification:

In pulmonary physiology, arterial tension of carbon dioxide ($PaCO_2$) is calculated by the alveolar equation, in which alveolar tension of carbon dioxide (Pa CO_2) is proportional to CO_2 production (VCO_2) divided by alveolar ventilation.

$$PaCO_2 = K \times \frac{VCO_2}{\left(V_t \times RR \times \left(1 - \frac{V_d}{V_t}\right)\right)}$$

In this equation, the alveolar ventilation results from the product of tidal volume (V_t), respiratory rate (RR), and the dead space-to-tidal volume ratio (V_d/V_t) Assuming a constant

CO_2 production from our body, hypoventilation is mainly the result of decrease in minute ventilation ($V_t \times$ RR) or the increase of dead space volume (V_d), as a volume of gas that does not eliminate CO_2, or a combination of both [110]. Because the causes of alveolar hypoventilation are multiple, a clinical classification based on the patient's pulmonary function can help to differentiate abnormalities of the ventilatory drive (autonomic/metabolic respiratory control system) associated with normal pulmonary function versus abnormalities of pulmonary mechanics with subsequent abnormal pulmonary function. Pulmonary function is commonly evaluated based on the information obtained in a pulmonary function test (PFT), further narrowing the differential diagnosis in hypoventilation. Pattern of volume and flow changes observed in the spirometry and lung volumes can support an obstructive (e.g., COPD) or restrictive physiology (e.g., interstitial lung disease and neuromuscular-skeletal diseases). Information from the diffusion capacity of carbon monoxide (Dlco) can point to changes in the surface of gas exchange (e.g., emphysema) or vasculature (e.g., pulmonary hypertension). When neuromuscular diseases are in question, a maximal respiratory pressures test can reflect changes in inspiratory and expiratory respiratory muscles' strength (Table 33.1).

Alveolar Hypoventilation Syndrome with Decrease in Ventilatory Drive (Normal Pulmonary Function)

This group of disorders is characterized by nocturnal chronic alveolar hypoventilation and hypoxemia despite normal neuromuscular and pulmonary function. Either idiopathic (e.g., non-obstructive alveolar hypoventilation), genetic (e.g., CCHS), or acquired disorders (e.g., lesions in brainstem, respiratory depressant medications) share the common feature of nocturnal failure of the autonomic/metabolic breathing pathway with subsequent profound nocturnal hypoventilation. In general, these conditions may be attenuated during the daytime when the wakefulness/voluntary drive to breathe is dominant.

(a) Congenital Central Alveolar Hypoventilation Syndrome

Congenital central hypoventilation syndrome (CCHS), formerly referred as Ondine's curse, is a rare disease identified by an autosomal dominant genetic mutation in the PHOX2B gene located in the chromosome 4p12, the role of which in the disease has yet to be identified [111–114].

Epidemiology:

Reports of incidence of CCHS vary widely from 1 in 10,000 to 1 in 200,000 live births [115]. The spectrum of hypoventilation severity is varied, and although most cases present in newborns, mild phenotypes can also be identified in adults (primary hypoventilation syndrome) [116]. Unfortunately, the mortality rate is calculated to be around 38 % and median age of death is about 3 months [117].

Clinical characteristics:

During wakefulness, non-respiratory behavioral influences will modulate the ventilatory activity. However, during sleep, nocturnal shallow breathing, or cyanosis and apnea, is commonly found in perinatal sleep. Apart from alveolar hypoventilation, with subsequent signs and symptoms of profound nocturnal hypercapnia and hypoxia, this disease has been associated with Hirschsprung disease (aganglionic megacolon), neural crest tumors (e.g., neuroblastomas), and ocular abnormalities (e.g., strabismus) [118]. If untreated, death may occur as a complication of cor pulmonale and severe hypercapnia-hypoxemia.

Pathophysiology:

Even though the pathophysiology of the abnormal control of breathing in CCHS remains unclear, a unifying hypothesis is that the abnormality is located in areas of the brain involved in integration of chemoreceptor afferent pathways for ventilation. Patients with CCHS typically have adequate ventilation while awake followed by profound alveolar hypoventilation during sleep ($PaCO_2 > 45$ mm Hg), mainly due to decreased tidal volume and respiratory rate [119]. Depending on the severity of the disease, hypoventilation may extend into wakefulness.

Polysomnography:

After NREM sleep is established, failure of automatic–metabolic control of breathing will manifest as a severe hypoventilation, with or without central apneas, associated with sustained desaturations. Contrary to NREM sleep, ventilatory function becomes more stable during REM sleep [120].

(b) Brain stem, diencephalic regions, and spinal cord disorders

Independent of the mechanism of brainstem lesion, namely compression, edema, ischemia, infection, or infiltration, the

compromise of central chemoreceptors as well as the respiratory centers in the brain stem will result in hypoventilation and sleep apnea. Also, lesions of the descending pathways associated with the respiratory center, such as anterior cervical spinal artery syndrome or cervical cordotomy, will also translate into an ultimate failure of the autonomic/metabolic breathing pathway with subsequent profound hypoventilation. In these patients, the respiratory mechanics are normal with consequent normal pulmonary function.

Alveolar Hypoventilation Syndrome with Abnormal Respiratory Mechanics/Gas Exchange

Neuromuscular Disorders and Chest Wall Syndromes

Based on the neuroanatomical location of these lesions, from the upper motor neurons down to the neuromotor axis and up to the respiratory muscles, they can be grouped into motor neuron disorders (e.g., amyotrophic lateral sclerosis (ALS), post-polio syndrome), demyelinating disorders (e.g., multiple sclerosis, Guillain–Barre syndrome), neuromuscular junctional disorders (e.g., myasthenia gravis, Eaton Lambert syndrome), and respiratory muscle disorders (e.g., muscular dystrophies, mitochondrial myopathies). They are associated with hypercapnia ($PaCO_2 \geq 45$ mm Hg) as a result of increased respiratory load (chest wall and lung elastic loads). Functionally, these altered mechanics will not only reduce the minute ventilation but will also increase the dead space volume (higher V_d/V_t). In general, these disorders have an abnormal pulmonary function test characterized by restrictive physiology, with concomitant decrease in maximum inspiratory pressures as a marker of inspiratory muscle weakness.

Lower Airways Obstruction, Pulmonary Parenchymal Disease, and/or Vascular Pathology

Lower airway obstruction diseases, of which chronic obstructive pulmonary disease (COPD) is the most common, will limit the airflow with constraint of maximal minute ventilation. Alveolar hypoventilation will occur when the reduced maximal minute ventilation falls below the minimal minute ventilation threshold needed to maintain eucapnia. On the other hand, advanced stages of intrinsic restrictive pulmonary diseases, such as interstitial lung disease (ILD), will impair minute ventilation by reducing tidal volumes (V_t) and increasing dead space fraction (V_d/V_t). Finally, disorders that obliterate pulmonary vascular flow, such as pulmonary hypertension, will decrease the number of alveolar units able to participate in gas exchange (gas exchange disorders), with subsequent increase in dead space volume (V_d/V_t) and hypoventilation. Abnormalities in the pulmonary function test are characterized by obstructive physiology, a restrictive physiology, or a combination of both. Concomitant decrease in diffusing capacity of carbon monoxide (DLco) in the pulmonary function test may support a pulmonary parenchymal and/or vascular pathology.

Polysomnography:

If upper airway tone is not compromised, the polysomnographic study is characterized by sustained nocturnal desaturations without significant presence of respiratory events. The diagnostic criteria for scoring hypoventilation requires that a polysomnography or a sleeping arterial blood gas should be performed, showing at least one of the following criteria: (1) an overnight oximetry with less than 90 % for more than five minutes with a nadir of at least 85 %, and/or (2) more than 30 % of total sleep time at a saturation of oxygen less than 90 %, and/or (3) $PaCO_2$ that is $\geq$45 mm Hg or higher than during wakefulness [1]. It is worth noting that with diaphragmatic compromise (e.g., diaphragmatic paralysis), ventilatory efforts will be maximally affected during REM, with subsequent generation of "pseudo" central apneas.

Management:

Noninvasive ventilation (NIV), in the form of positive airway pressure ventilation (PAP), is the first-line therapy in nocturnal alveolar hypoventilation independent of etiology. In patients with neuromuscular diseases such as amyotrophic lateral sclerosis (ALS) with preserved bulbar function, BPAP-ST has been shown to improve median survival as well as quality of life at 1 and 6 months. Unfortunately, in those ALS patients with moderate-to-severe bulbar dysfunction, NIV may improve sleep-related symptoms, but has not been shown to prolong survival [121].

Limited data exist in average volume assured pressure support in alveolar hypoventilation. However, it could be an alternative to BPAP-ST for alveolar hypoventilation in progressive neuromuscular diseases due to its ability to self-adjust pressures for a target tidal volume.

The role of oxygen therapy in cases of alveolar hypoventilation syndrome is limited to those cases with persistent oxygen desaturations despite optimal control of hypercapnia by PAP devices. Its implementation as monotherapy should be avoided in patients with alveolar hypoventilation due to neuromuscular diseases or chest wall deformity as it may facilitate carbon dioxide retention [122].

Alveolar Hypoventilation Due to Obesity Hypoventilation Syndrome

Obesity hypoventilation syndrome (OSH) is defined as a body mass index >30 kg/m^2 combined with findings of daytime hypercapnia ($PaCO_2$ > 45 mm Hg at sea level) and hypoxemia (PaO_2 < 70 mm Hg at sea level), not otherwise explained by other known causes of alveolar hypoventilation, such as neuromuscular, restrictive, or obstructive pulmonary disorders (e.g., COPD) [123]. In the current obesity epidemic, this entity is often unrecognized and treatment is frequently delayed without a high clinical suspicion, despite the increased morbidity and mortality associated with this disease. While blood gas analysis is confirmatory, clues to the diagnosis may come from pulse oximetry and serum bicarbonate levels. In one study, a calculated bicarbonate cutoff of more than 27 m mol/L provided a sensitivity of 85.7 %, and a specificity of 89.5 % for the diagnosis of OHS, with 68.1 % positive and 95.9 % negative predictive value [124].

Epidemiology:

Large population-based studies are lacking, but the estimated prevalence of OHS is about 0.15–0.3 % in the general population, 11–20 % in sleep clinic referral cohorts for suspicion of OSA, and 8 % in bariatric surgery clinics with an increase up to 50 % of those hospitalized patients with BMI greater than 50 kg/m^2 [125–127].

Clinical characteristics:

OHS patients tend to be extremely obese and often present with complaints indistinguishable from OSA patients, such as excessive daytime sleepiness, morning headaches, and poor concentration [128]. Pulmonary function tests are characteristics of a restrictive physiology. Different from OSA patients, OHS patients have a lower SaO_2 during the daytime, peripheral edema, and pulmonary hypertension [125–127, 129]. In comparison with OSA, pulmonary hypertension is more common and more severe probably due to more chronic hypoxemia with concomitant endothelial dysfunction [125, 130].

Unfortunately, there is a significant delay in the diagnosis of this disorder with subsequent higher numbers of hospitalization and intensive care admission, in comparison with those obese patients without OHS [127, 131–133]. In general, the mortality rate in patients with untreated OHS is high [134]. Mortality is also elevated in this population in comparison with non-OHS obese individuals (23 and 9 %, respectively, at 18-month follow-up), as most patients are discharged without therapy [127]. Cardiovascular morbidity is also higher than non-OHS obese individuals, and OHS patients are more likely to develop CHF, angina pectoris, and cor pulmonale [133, 135].

Pathophysiology:

Daytime hypercapnia separates OHS from OSA. In approximately 90 % of patients with OHS, the sleep-disordered breathing is obstructive in nature [125]. The remaining 10 % of patients with OHS have an AHI of less than 5 events per hour, and their sleep-disordered breathing consists of sustained nocturnal hypoventilation, defined as a nocturnal increase of $PaCO_2$ of at least 10 mm Hg over wakefulness levels. In these patients, the predominant abnormality is a sustained hypercapnic–hypoxemic state ($SaO_2 \leq 90$ %), which extends during daytime. The physiopathology of OHS is not completely understood, but it may relate to interactions of the following: (1) impaired respiratory mechanics (increased work load), (2) reduced upper airway tone, and (3) decreased ventilatory drive (blunted respiratory response) [136].

Impaired respiratory mechanics:

In comparison with obese individuals without daytime hypercapnia, OHS patients have more impairment of respiratory mechanics based on low lung volumes (e.g., vital capacity and functional residual capacity), with the reduction in respiratory system compliance, increased airway resistance, and subsequent increased work of breathing associated with reduction in inspiratory muscle strength [10, 12, 137–139].

Reduced upper airway tone:

In patients with predominant upper airway obstruction, hypercapnia is considered to be the result of a combination of an elevated AHI with prolonged apnea duration and a short ventilatory duration between respiratory events. The subsequent development of metabolic compensation with high bicarbonate levels may further blunt the chemoreceptor-mediated ventilatory response to CO_2, resulting in the extension of hypercapnia into the daytime [13, 140–142].

In those OHS patients without upper airway obstruction, alveolar hypoventilation with sustained hypoxemia may occur and is strongly associated with development of awake hypercapnia [140]. In these patients, minute ventilation decreases by the reduction in tidal volume of approximately 21 % during NREM sleep and 39 % during REM sleep [143].

Decrease in ventilatory drive:

To compensate for the increase in respiratory load, obese individuals without OHS maintain eucapnia by increasing respiratory drive. Leptin, a circulating protein produced mainly by adipose tissue (adipokine), may contribute to this adaptation [144]. However, in OHS patients, despite increases in leptin levels, the respiratory drive and the responsiveness to hypoxia and hypercapnia are diminished [14, 145, 146]. It is suspected that a "central leptin resistance" may play a role in this phenomenon [14].

Polysomnography:

OHS patients may present different polysomnographic patterns. Those with predominant obstructive sleep apnea physiology will present cyclical airflow limitation (e.g., obstructive apnea and obstructive hypopnea) and desaturations indistinguishable from other non-OHS OSA patients. The second typical respiratory abnormality taking place during sleep in OHS patients is REM sleep hypoventilation. REM sleep hypoventilation is aggravated in OHS, as impaired respiratory mechanics combined with REM-related respiratory drive reduction will result in the absence of compensatory increases in work of breathing [128]. After adequate CPAP therapy with resolution of upper airway obstructive physiology, persistent central sustained hypoventilation may be present with sustained oxyhemoglobin desaturation [123, 147].

Management:

Weight loss is an important goal in the management of obesity hypoventilation syndrome (OHS). Bariatric surgery is an effective intervention to achieve substantial weight loss; however, obstructive sleep apnea and the need for PAP therapy for this may still be considered after surgery [148, 149].

Together with weight loss, positive airway pressure is considered the first-line therapeutic modality for nocturnal hypoventilation [25]. In most cases of OHS, when obstructive apnea–hypopnea is predominant, CPAP is highly effective in improving gas exchange and sleep-disordered breathing at ≤ 3 months, as well as improving lung volumes and central respiratory drive ≥ 4 weeks [150–152].

If sustained desaturation and elevated $PaCO_2$ levels persist despite the elimination of respiratory events by CPAP therapy, BPAP therapy is indicated. Even though it is estimated that 20–50 % of patient with OHS will fail CPAP with requirement of BPAP therapy, BPAP is not superior to CPAP if titration is successful [151]. During bilevel therapy, the difference between the inspiratory positive airway pressure (IPAP) and expiratory pressure (EPAP) should be targeted to improve ventilation by increasing tidal volume. Although BPAP treatment in OHS patients significantly improves blood gases (reduction in hypercapnia and hypoxemia), as well as sleep architecture, it does not show changes in inflammatory (IL and cytokines), metabolic (glucose and lipid metabolism), and cardiovascular (endothelial function and arterial stiffness) markers at one-month follow-up [153]. Although improved mortality has been shown with noninvasive positive pressure ventilation treatment when compared with historical controls, no prospective controlled trials are available at this time [135].

Limited data are published regarding average volume assured pressure support devices (AVAPS). In stable OHS patients on AVAPS, even though nocturnal hypoventilation is better controlled, their objective and subjective sleep quality and comfort of ventilation are slightly lower in comparison with those on BPAP [154, 155].

In addition to PAP therapy, and despite effective nocturnal ventilation, up to 40 % of OHS patients may need oxygen supplementation [147]. Even though supplemental oxygen therapy may worsen respiratory status of uncontrolled hypercapnic respiratory failure, persistent daytime hypoxemia after initiation of PAP therapy has been shown to be an independent predictor of poor survival in OHS patients [156, 157].

If noninvasive mechanical ventilation fails, tracheostomy for mechanical ventilation may be required without guarantee of complete daytime CO_2 normalization [158].

Treatment-Emergent Central Sleep Apnea

Treatment-emergent CSA, formerly known as complex sleep apnea syndrome (CompSAS), has been a topic of considerable controversy. It has been recently added into the group of CSAS by the International Classification of Sleep Disorders Task Force [1]. The diagnosis is based on the presence of 5 or more predominantly obstructive respiratory events during a diagnostic polysomnography, followed by a positive airway pressure titration polysomnography showing significant resolution of obstructive events and emergence or persistence of CSA events. The CAI should be more or equal to 5 events per hour, and the number of central events should represent more or equal to 50 % of total number of apneas and hypopneas. However, the presence of any alternative diagnosis associated with CSA, such as heart failure (CSA-CSB) or opiate use, would automatically exclude the diagnosis of treatment-emergent CSA [159, 160].

Epidemiology:

Depending upon the patient population being tested and the definition being used, the prevalence of treatment-emergent CSA ranges from 3 to 15 %. The persistence of treatment-emergent CSA while on positive airway pressure without a backup rate has been a controversial topic in the field of sleep medicine. Some authors assert that treatment-emergent CSA is a transient phenomenon related to sleep fragmentation and sleep stage shifts that occur while on initial CPAP therapy, results from inadequate titration, or from overtitration of positive airway pressure resulting in the Hering–Breuer reflex effect [161, 162]. Indeed, after 2–3 months of appropriate CPAP treatment in treatment-emergent CSA patients, eliminating obstructive but not central events, Dernaika and colleagues showed that treatment-emergent CSA patients had a 92 % (14 out 21 patients) complete or near-complete resolution of CSA events by polysomnography [163]. However, other authors have found that nearly fifty percent of patients have persistent central events despite compliance with CPAP therapy for a mean of 3 months [164]. Unfortunately, most of these studies are limited by their retrospective design, small sample sizes, and follow-up time. Nonetheless, a prospective study published in 2011 showed that the prevalence of treatment-emergent CSA fell from 12.2 % at time of diagnosis to 6.9 % (95 % CI 4.5–9.3 %) in comparison with those with only OSA while on fixed CPAP treatment for 3 months [165].

Clinical Characteristics of Treatment-Emergent Central Sleep Apnea:

Patients with treatment-emergent CSA tend to be older and have more coronary artery disease, and more fragmented sleep than those patients with OSA [160, 165]. The tendency to develop central apneas during PAP titration may be associated with additional cardiovascular comorbidity as well, including CHF and Cheyne–Stokes breathing pattern, arterial hypertension, and coronary artery disease [165, 166]. However, up to one-third may have no identifiable risk factors.

Pathophysiology:

Treatment-emergent CSA shares physiologic phenotypic features of both obstructive (OSA) and CSA. Like OSA, it is characterized by increased upper airway resistance with elevated critical closing pressure (P_{crit}), accompanied by increased ventilatory effort. Once on CPAP, with stabilization of critical closing pressure, a CSA physiology will predominate or emerge with the absence of ventilatory effort during apneic events likely driven by chemoresponsive ventilatory dysregulation (high "loop gain").

Polysomnography:

During the polysomnographic diagnostic study, treatment-emergent CSA is characterized by predominantly obstructive respiratory events (obstructive or mixed apneas, obstructive hypopneas) with an apnea/hypopnea index (AHI) ≥ 5 events per hour. During positive airway pressure titration, resolution of obstructive events follows the emergence or persistence of central apneas or hypopneas such that the central disordered breathing index is ≥ 5 per hour with >50 % central events. In comparison with those with OSA, and during the diagnostic portion of the polysomnographic study, treatment-emergent CSA patients may possess a mildly elevated central apnea index, particularly during NREM supine sleep, or higher arousal index [160, 167] Regarding other polysomnographic findings, in a finding of uncertain significance, periodic limb movements have been noted to be less frequent on PAP therapy in those with treatment-emergent CSA when compared to those with OSA [168].

Management:

Under the diagnosis of treatment-emergent CSA, different investigators have recruited heterogenous group of subjects with not only obstructive sleep apnea physiology during the diagnostic polysomnographic study but also with concomitant presence of CSAs ("mixed sleep apnea"), Cheyne–Stokes respiration, or ataxic breathing. Therefore, the outcomes used to measure a successful response to treatment with continuous positive airway pressure devices (CPAP) and noninvasive ventilation (NIV) will be tightly linked to the natural history of the disease and its baseline treatment. If we focus in those patients with baseline elevated apnea–hypopnea index but with low central apnea events (CAI < 5/h), in whom implementation of CPAP or BPAP-S shows emergence of CSA, the following conclusions can be drawn about treatment based on current evidence:

Continuous positive airway pressure (CPAP) therapy:

By definition, patients with treatment-emergent CSA have emergent CSAs while on positive airway pressure, associated with increased total arousals, wake time after sleep onset (WASO), and sleep stages shift, making them a susceptible population for fragmented sleep and possible intolerance to CPAP therapy [163]. Treatment-emergent CSA patients have also shown greater difficulties in adapting to CPAP treatment [169]. As mentioned above, although

most treatment-emergent CSA patients tend to improve with long-term CPAP use, there is a substantial group with persistent elevated CSA who may likely benefit from noninvasive ventilation. Unfortunately, no clinical or polysomnographic predictors are yet available to differentiate this subgroup of non-CPAP responders.

Adaptive servo-ventilation (ASV) therapy:

The adaptive servo-ventilation is a feedback control system adding a component of ventilation that is anticyclic to the patient's own respiratory drive periodicity [75, 170].

In comparison with CPAP and BPAP-ST, ASV treatment targeting minute ventilation in treatment-emergent CSA patients has not only been shown to have a significantly greater decrease in the AHI in all positions and stages of sleep, but also a lower residual arousal index, and a higher percentage of REM sleep [76, 171]. This beneficial effect should not be attributable to treatment-emergent CSA patients with occult CHF, as ASV has been proven to be an effective treatment for treatment-emergent CSA in patients with normal BNP, excluding possible confounding of CSA-CSB cases [172].

Two forms of servo-ventilation are currently available in the USA, one targeting a peak respiratory flow and the other targeting minute ventilation. Both devices have comparative acute efficacy in control of AHI, with no significant difference in residual CAI, and improvement in ESS score. The compliance with them is also high at 4–6-week follow-up [173]. Notwithstanding these apparent short-term improvements in sleep associated with ASV, there remains a need for larger, longer-term trials as well as exploration of cost efficacy before ASV can be routinely recommended for treatment-emergent CSA.

Summary

In conclusion, CSA syndromes comprise a wide spectrum of unstable breathing associated with important comorbidities. Identification of treatable conditions, such as CHF and use of opioids, is crucial in the management of these diseases. Even though the mechanism of instability of the respiratory metabolic control system is well established in patients with CHF and high-altitude periodic breathing, the mechanism underlying CSA in other pathologies remains to be investigated. Mounting evidence supports the general use of positive airway pressure devices in these disorders, with different degrees of therapeutic success depending on the underlining etiology and pathophysiology of the CSA.

Sleep-related hypoventilation–hypoxemic diseases are a heterogenous group of sleep-related breathing disorders with diverse pathophysiology, ranging from failure of the central automatic control of breathing to impaired lung function or chest wall mechanics. They are characterized by an elevation of arterial carbon dioxide tension and/or reduction of oxygen saturation during sleep, which may extend into the daytime. The current evidence supports the treatment of these disorders with different modalities of noninvasive ventilation (NIV), titrated to a specific minute ventilation.

While significant progress has been made in understanding CSA syndromes (CSAS) and sleep-related hypoventilation disorders, a paucity of research in these areas still exists. Further clinical trials are needed to expand our knowledge of pathophysiologic mechanisms, associated comorbidities, and the impact of positive airway pressure in the natural history of these diseases.

Positive Airway Pressure in the Treatment of Sleep Apnea–Hypopnea

34

Charles W. Atwood and Patrick J. Strollo

Introduction

The application of nasal continuous positive airway pressure (CPAP) for the treatment of obstructive sleep apnea in adults was first described in 1981 [1]. Since then, it has become the medical therapy of choice for obstructive sleep apnea (OSA). Fundamentally, conventional positive airway pressure (PAP) systems that are employed to treat OSA patients consist of a generator that directs airflow downstream to the patient via tubing and an interface (e.g., nasal mask, oral-nasal mask, nasal cannula or prongs, or oral interface; discussed later in this chapter). Air, under the clinician-prescribed degree of positive pressure, is then introduced into the upper airway. The air pressure pneumatically splints the upper airway, thereby maintaining patency of this conduit and minimizing resistance to airflow. The splinting effect constitutes the primary mechanism of therapeutic action [2, 3]. An additional mechanism of action is the direct relationship between lung volume and upper airway patency mediated through traction on mediastinal and upper airway structures created during lung inflation; [4, 5] it has been postulated that at least part of the effect of CPAP in maintaining upper airway patency is mediated through augmentation of lung volume, although the magnitude of the effect is relatively small [2, 3, 6].

Regardless of the mechanism, nasal CPAP has documented effectiveness in eliminating obstructive and mixed apneas [7]. Some "central" apneas, particularly those observed in patients with predominantly obstructive events, are also eliminated by nasal CPAP [7, 8]. This finding supports the contention that the central portion of mixed apneas and many central apneas may actually represent delayed inspiratory effort due to prolongation of the preceding expiration related to expiratory upper airway instability with augmented upper airway resistance and slowing of expiratory airflow [9, 10]. It is also consistent with stabilization of oscillating ventilatory control during CPAP administration [11–14].

Positive Pressure Modalities Used to Treat Obstructive Sleep Apnea/Hypopnea

Continuous Positive Airway Pressure

The first PAP modality described to treat adults with OSA was CPAP [1]. CPAP may also be conceptualized as *constant* PAP, reflecting the fact that, by conventional definition, this modality delivers the same magnitude of pressure to the patient during inspiration and expiration (i.e., the pressure delivered during the patient's exhalation equals that delivered during inhalation). Fixed-pressure CPAP (i.e., the same pressure is delivered throughout the sleep period) is the standard to which all other modalities are compared.

Bilevel Positive Pressure

Studies of the pathogenesis of OSA have indicated that upper airway resistance increases during expiration despite the absence of negative intrapharyngeal pressure during this phase of the breathing cycle [9, 15, 16]. Sanders and coworkers speculated that instability of the upper airway during expiration is the initial event in the sequence leading

Charles W. Atwood Jr., MD, has received research grants from ResMed, Philips-Respironics and Vapotherm. He is an advisor to Philips-Respironics and Vapotherm.
Patrick J. Strollo Jr., MD, has received research grants from ResMed, Philips-Respironics, Inc., and the National Football League.

to obstructive apnea [10]. Moreover, it was conceptualized that the splinting action of positive pressure in the upper airway, during both inspiration and expiration, was necessary to eliminate obstructive events, *but* less pressure is required to maintain adequate upper airway patency during expiration than during inspiration. This was based on the hypothesis that, during expiration, inherent upper airway instability represents the primary factor that favors airway closure, whereas during inspiration inadequate upper airway patency is related to two factors: the collapsing influence of negative intraluminal pressure and the inherent instability of the airway. The importance of expiratory events was subsequently demonstrated by computed tomography and magnetic resonance imaging to observe expiratory narrowing of the upper airway [17–20]. Application of expiratory positive airway pressure by Mahadevia et al. [21] was associated with a reduction in apnea frequency, although these investigators postulated that the improved upper airway function was related to increased oxyhemoglobin saturation secondary to increased functional residual capacity.

Bilevel positive airway pressure (bilevel PAP) provides the ability to independently adjust the inspiratory and expiratory pressure such that the pressure delivered during exhalation need not be as high as that delivered during inhalation [22–26]. By allowing independent adjustment of the inspiratory positive airway pressure (IPAP) and expiratory positive airway pressure (EPAP), bilevel PAP provides the potential to treat OSA patients with expiratory pressure that is lower than inspiratory pressure [22]. Setting the EPAP at a level that prevents upper airway occlusion during or at end-expiration permits the patient to generate inspiratory airflow or volume at the initiation of inspiratory effort, and this triggers delivery of IPAP, which supports upper airway patency during the inspiratory phase of the breathing cycle. Over and above preventing complete upper airway occlusion, delivery of a sufficient level of IPAP augments upper airway patency and eliminates partial obstructions (hypopneas) as well as upper airway obstruction-related desaturations and arousals from sleep. If the airway were to become occluded during expiration (e.g., EPAP not set sufficiently high), IPAP would not be triggered and the apnea would become apparent.

In an investigation of 13 patients with OSA in which optimal settings of nasal CPAP and bilevel PAP were compared, Sanders and Kern [22] observed that the EPAP delivered during bilevel PAP was significantly lower than the level of CPAP, and the mean value of EPAP for the group was 37 % lower than the required level of CPAP ($p < 0.001$). In contrast, there was no difference between the level of IPAP during bilevel PAP administration and the level of CPAP. There was comparable relief of OSA/H using both modalities. Several subsequent studies have confirmed the effectiveness of bilevel PAP in the treatment of OSA in adults [24–27].

Most bilevel PAP devices can be used in three modes. In the "spontaneous" mode, IPAP is delivered in response to a patient "trigger." In the "spontaneous-timed" mode, the patient may trigger the delivery of IPAP, but in addition, the physician may set the device so that IPAP is delivered at prescribed intervals if a spontaneously triggered delivery does not occur within that interval. This backup feature is infrequently needed in treating patients with OSA, although it has been helpful in providing nocturnal ventilatory assistance to other patient groups such as those with ventilatory muscle dysfunction resulting from neuromuscular disease and those with nocturnal hypoventilation due to chest wall deformities such as kyphoscoliosis. The spontaneous-timed mode may be beneficial in patients with Cheyne–Stokes breathing (CSB) and those who develop problematic central sleep apnea on CPAP in the context of complex central sleep apnea (see later in this chapter). In these patients, the capability for spontaneous triggering facilitates tolerance of the device by the awake patient, whereas during sleep the timed bilevel PAP "breaths" delivered at prescribed intervals prevent the long breathing pauses between lung inflations that are characteristic of central sleep apnea. Additionally, it is now recognized that, at least in some patients, central sleep apnea events may be associated with a closed upper airway [28–30]. Thus, it may be necessary to provide a critical level of EPAP to facilitate delivery of IPAP to the patient. CPAP and bilevel PAP are discussed in the context of complex central sleep apnea, CSB, and cardiovascular disease later in this chapter. There is also a "timed" mode for bilevel PAP devices in which IPAP is delivered with a clinician-set frequency and the patient cannot initiate delivery. In general, we have not found this mode to offer benefit over the "spontaneous-timed" mode.

Autotitrating CPAP and Bilevel PAP

Autotitrating CPAP (APAP) and bilevel PAP devices employ proprietary algorithms to detect impending collapse or instability of the upper airway and adjust the amount of pressure that is delivered in order to maintain patency. Following a period of upper airway stability, the pressure gradually decreases (according to each manufacturer's algorithm) until impending collapse or instability is again detected. The delivered pressure is then increased per the algorithm. Thus, the pressure "floats" throughout the night with the intention of meeting the patient's requirements in real time (Fig. 34.1).

At least in part, the putative advantages of the autotitrating devices (APAP and auto-titrating bilevel PAP) are to reduce the pressure to which patients are exposed and thereby to increase comfort, satisfaction, and adherence to

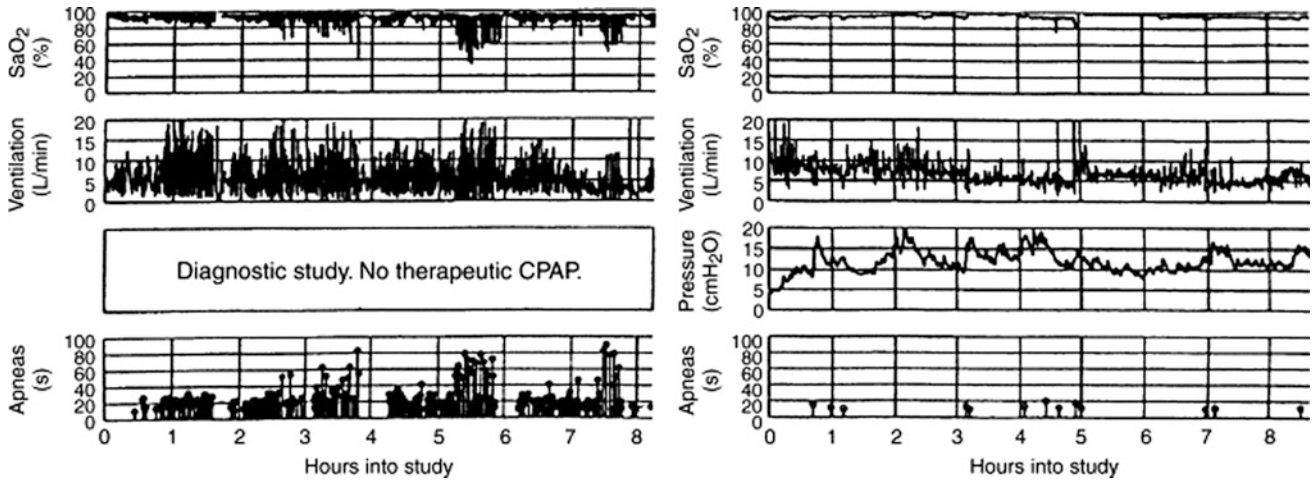

Fig. 34.1 Arterial oxyhemoglobin saturation (SaO_2), minute ventilation, CPAP mask pressure, and apneic events recorded with an oximeter and a prototype of an intelligent CPAP machine in a patient with sleep apnea. *Left* Diagnostic study with repeated episodes of obstructive apnea. *Right* Autotitrating CPAP with pressure levels that vary across the recording (Reproduced with permission from Polo [239])

therapy. Bilevel PAP also is capable of assisting or augmenting ventilation by virtue of the gradient between end-expiratory and inspiratory pressures. The autotitrating devices attempt to respond to concern that the optimal therapeutic PAP prescription may vary across the night (e.g., across various body positions) and across nights. Indeed, investigators recently reported that a notable proportion of patients receiving a prescription of fixed-pressure CPAP were subsequently found to have an apnea–hypopnea index (AHI) >10 on the same prescription [31]. However, the patients with AHI >10 did not differ significantly from those without persistent OSA with regard to quality of life, mood, vitality, or Epworth Sleepiness Scale score.

A review and a meta-analysis of APAP reveals that these devices may provide comparable alleviation of OSA and perceived daytime sleepiness, compared with fixed-pressure CPAP with a mean pressure that is about 2 cm H_2O lower. This does not appear to translate into improved adherence to therapy, however [32, 33]. It is important to note that studies that examined APAP efficacy excluded patients with underlying cardiopulmonary disease as well as other comorbidities. Further studies are needed before recommending routine use of this modality in patients with these comorbidities. Issues related to CPAP, bilevel PAP, and APAP modalities are discussed later in the chapter.

"Pressure-Relief" CPAP and Bilevel PAP

"Pressure-relief" CPAP and bilevel PAP have recently been introduced [34, 35]. These provide expiratory pressure relief that is proportional to expiratory airflow, while pressure increases rising to the prescribed EPAP level at end-expiration. In expiratory pressure relief, the pressure-relief bilevel PAP device provides relief of pressure at end-inspiration [34]. Plausibly, this is facilitated by the high lung volume at end-inspiration that contributes to upper airway patency as well as the fact that, as inspiration reaches its end, airflow diminishes with consequent reduction in collapse-promoting negative intrapharyngeal pressure. Pressure-relief CPAP was as effective in reducing sleep-disordered breathing events and improving sleep continuity as conventional CPAP [35]. Gay and coworkers [34] demonstrated comparability between pressure-relief and convention bilevel PAP in alleviating OSA; however, there are too few studies of these modalities on which to base conclusions.

Adaptive Servo-Ventilation

Although CPAP and bilevel PAP therapy may be associated with improvement in Cheyne–Stokes breathing (CSB) and central sleep apnea, sometimes there is no improvement or worsening [36, 37]. Adaptive servo-ventilation (ASV) has introduced into clinical practice primarily to address CSB in the context of heart failure as well as idiopathic and complex central sleep apnea or treatment-emergent central sleep apnea (central sleep apnea that becomes clinically problematic during application of conventional CPAP or bilevel PAP during treatment of OSA). In general, these devices provide a variable degree of inspiratory pressure support that stabilizes the patient's ventilation over time. Thus, if there is a reduction in the patient's spontaneous ventilation, the degree of inspiratory positive pressure support will increase proportionately to minimize a decrement in ventilation [38]. A backup rate of IPAP delivery may also be set by the clinician.

Teschler et al. [38] evaluated the effects of supplemental oxygen, CPAP, bilevel PAP, and ASV in patients with CSB (with primarily central sleep apnea) due to heart failure and reported that ASV provided the greatest reduction in AHI, slightly but statistically significantly lower than on bilevel PAP. Sleep continuity, sleep efficiency, percent slow-wave sleep, and percent rapid eye movement (REM) sleep were comparable on ASV and bilevel PAP. The ASV settings in this investigation included a backup rate of 15 breaths/min, and the backup rate on the bilevel PAP was set at the patient's awake spontaneous breathing rate, less 2 breaths/min (for the study group, the range of backup rate was 13–18 breaths/min). It is not possible to determine how much improvement in CSB was specifically due to the ASV or bilevel PAP algorithm as opposed to the presence of a backup rate on both modes in this study. A subsequent case series by Banno et al. [36] reported improved CSB on ASV that had failed to improve on CPAP. These authors indicated that they employed the same default settings as Teschler et al. [38], and therefore a backup rate may also have been used.

A small case series of heart failure patients with CSB who failed CPAP and bilevel PAP (with a backup rate) reported a beneficial effect of ASV [39]. The ASV employed in this study included a default backup mode. A randomized 4-week crossover trial of ASV prescribed at therapeutic settings (including a backup rate) versus ASV prescribed at subtherapeutic settings (with a backup rate of 15 breaths/min) was performed on patients with heart failure and CSB [40]. The results demonstrated significantly greater improvement of the AHI during the intervention with ASV at therapeutic settings. Although the active intervention resulted in a substantial reduction in objectively assessed sleepiness compared with subtherapeutic ASV, there were no statistically significant changes in the secondary outcome measures of the study, including subjective sleepiness, questionnaire assessment of health status, and performance using a driving simulator with either therapeutic ASV or subtherapeutic ASV. However, plasma brain natriuretic peptide and urinary metanephrine excretion fell on the active intervention, suggesting a favorable physiologic impact of ASV. These results suggest that ASV results in physiologic improvements, but the absence of subjective improvement in sleepiness is disappointing.

Despite initial enthusiasm for ASV therapy in heart failure patients, the use of this mode has been questioned recently on the basis of a randomized examining the role of ASV in central sleep apnea with systolic heart failure, the SERVE-HF trial. In a study with 1325 subjects with a left ventricular ejection fraction of 45 % or less and clinical heart failure, there was no difference in AHI between the ASV group and the treatment-as-usual control group at 12 months after starting ASV therapy. Furthermore, there was a statistically significant increase in mortality in the ASV therapy group compared to the control group (hazard ratio for ASV was 1.28 (90 % CI 1.06–1.55). This study result has resulted in a questioning of the role of this mode of therapy in systolic heart failure. Further studies being conducted presently may clarify the results of SERVE-HF.

The general features of various PAP modalities are summarized in Table 34.1. It is important to note that algorithms and modes of operation vary across manufacturers and models. This table is not intended to represent definitive features of specific brands and models but rather to describe general features.

Effectiveness of PAP in Treating Patients with OSA

There is abundant evidence that, when applied in sufficient pressure, PAP effectively eliminates OSA events as well as respiratory effort–related arousals. Following initiation of CPAP therapy during sleep, most OSA patients with daytime sleepiness at baseline report increased subjective alertness [41–43]. There is, however, variability across studies. In a meta-analysis of randomized trials, Marshall and coworkers [44] reported that, after controlling for placebo effects, the Epworth Sleepiness Scale score [45] increased significantly, but only by 1.2 points in patients with mild to moderate OSA. The effect of CPAP on objective metrics of sleep propensity during the day (e.g., Multiple Sleep Latency Test [MSLT] or Maintenance of Wakefulness Test) is less clear, with only some studies showing an effect and a less compelling impact in patients with mild OSA [42–47]. The meta-analysis by Marshall et al. examined the ability to remain awake under soporific conditions, assessed by the Maintenance of Wakefulness Test and observed that, over the three randomized trials in which this assessment was performed, sleep latency increased significantly but only by 2.1 min, and there was no significant change in the sleep latency during the MSLT in the four trials in which it was assessed [44]. The investigators called into question the clinical significance of their changes. Another meta-analysis [48] reported a significant reduction in the Epworth Sleepiness Scale score by an average of approximately 3 points, with relatively greater reductions in patients with severe OSA. These investigators also observed only a marginal improvement in the MSLT after introduction of CPAP therapy.

In the context of vigilance and alertness, a critically important functional outcome to examine is the effect of OSA

Table 34.1 General features of positive pressure delivery modalities

Positive pressure modality general features	
Continuous positive airway pressure (CPAP) The clinician may prescribe the CPAP level	
Positive pressure delivered during inspiration equals that delivered during expiration	
"Pressure-relief" CPAP	The clinician may prescribe the CPAP level
• Positive pressure delivered during expiration decreases in proportion to the increasing expiratory airflow early in expiration and increases back to the prescribed CPAP level as the patient's expiratory airflow decreases with the approaching end of exhalation	
The clinician can set the degree of pressure relief	
Bilevel positive pressure	The clinician may prescribe the level of inspiratory positive airway pressure (IPAP) and expiratory positive airway pressure (EPAP)
• EPAP may be set independent of IPAP, but EPAP may not be higher than IPAP	
Some models permit prescribing a timed backup rate	
Pressure-relief bilevel positive pressure	Same as for bilevel positive pressure except the clinician may also prescribe inspiratory and expiratory pressure relief
Autotitrating CPAP	CPAP level fluctuates over the period of use according to a manufacturer-designed algorithm
The clinician may prescribe the minimum-maximum range within which the pressure may fluctuate	
Autotitrating bilevel positive pressure	IPAP and EPAP levels fluctuate over the period of use according to a manufacturer-designed algorithm
• The clinician may prescribe the minimum EPAP and maximum IPAP within which the pressure may fluctuate	
The clinician may prescribe the maximum IPAP-EPAP gradient ("pressure support") up to a manufacturer-designed limit	Adaptive servo-ventilation The clinician prescribes an EPAP level
• Different brands have different algorithms for establishing the minimum and maximum IPAP level and minimum level of pressure support	
In general, the pressure support varies to maintain a target ventilation or a target airflow; there is a default timed backup rate	

Algorithms and modes of operation vary across manufacturers and models. This table is not intended to represent definitive features of specific brands and models but rather to describe general features

and subsequent therapy on motor vehicle crashes [49]. In this regard, a number of studies employing driving simulators have demonstrated improved performance following initiation of CPAP therapy [50–53]. Similarly, a comparison of the number of accidents per driver per year over the 3 years before and following CPAP therapy in OSA patients demonstrated a notable reduction, reaching levels that were comparable to those in individuals without OSA [54] (Fig. 34.2).

Turkington et al. [52] reported that benefits on driving performance, assessed using a simulator, may be evident within 7 days of initiating therapy, while, more recently, Orth et al. observed improvement after only 2 days [53]. This is consistent with earlier data indicating that there may be a reduction in subjective daytime sleepiness after just 1 night of nasal CPAP therapy [55], and that progressive reduction in objective daytime alertness (assessed by the MSLT) may occur over 2 weeks following initiation of therapy [56]. The progressive nature of the improvement in symptoms and the apparent variability in response, as reflected in the previous discussion of the meta-analyses of CPAP effectiveness, highlights the importance of recognizing that patients may not be sufficiently alert to resume full activities (especially those that require vigilance, such as operating vehicles or potentially dangerous tasks) within the first several days of treatment. In addition, although studies have concluded that driving simulators may provide insight into on-the-road driving performance, differences do exist [53, 57]. It is important for clinicians to recognize that in general, studies examining treatment effect on motor vehicle crashes have been uncontrolled. To better assess the improvement in symptoms of daytime sleepiness, it is essential that the healthcare team make follow-up contact with the patient soon after the initiation of therapy. Close follow-up will facilitate evaluation of the patient's ability to perform activities that require alertness as well as to assess therapeutic adherence (see discussion below).

PAP often has a beneficial impact on other symptoms of OSA. Studies have reported relief of tiredness, reduced snoring, decreased nocturnal awakenings with perceived choking or gasping, and a reduction in nocturia [46, 58–64]. It

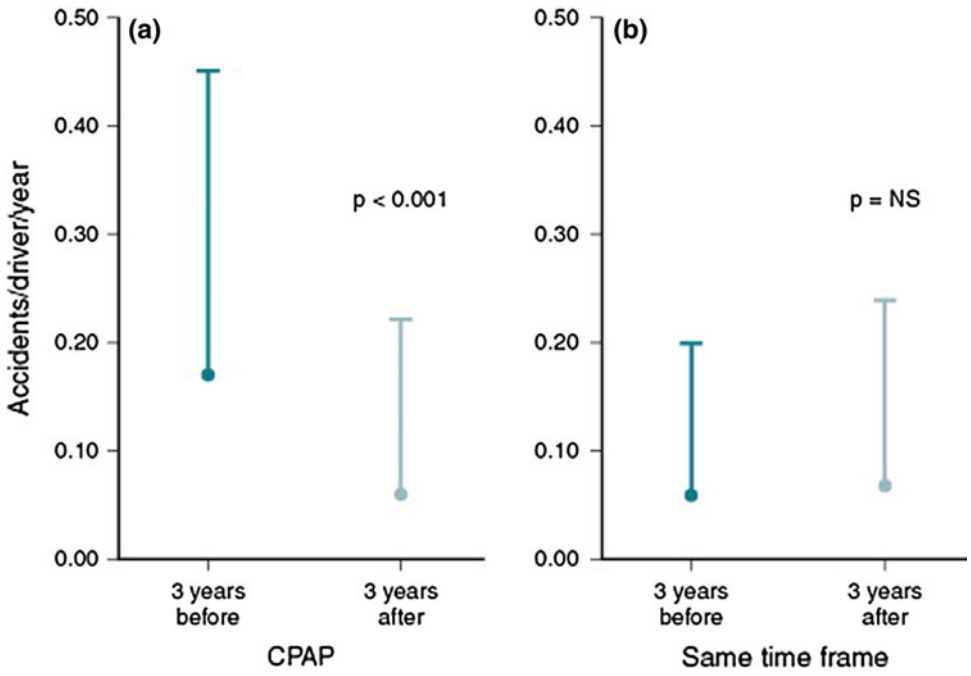

Fig. 34.2 **a** Accident rates (mean ± SD) for patients with OSA over the 3 years before and after initiation of CPAP therapy. **b** Accident rates (mean ± SD) for control subjects over the same time interval (Reproduced with permission from George [54])

is appropriate to note at this point, however, that nocturia—at least in conjunction with benign prostatic hypertrophy—has been reported to negatively influence adherence to PAP therapy [65], probably due to the inconvenience of removing and replacing the interface. It may be possible to extrapolate this finding to OSA patients with nocturia that is unassociated with prostatic hypertrophy. In light of the potentially beneficial effect of PAP use on nocturia, patients should be counseled to stick with the PAP therapy to achieve a favorable outcome, and the etiology of residual nocturia should be investigated and treated.

The impact of PAP on quality-of-life measures and neurocognition has also been assessed. Engleman and co-investigators reported the results of a placebo-controlled trial of CPAP in patients with mild OSA; use of CPAP for >2.5 h/night was associated with improved visual-motor skill, social function, and vitality (using the Medical Outcomes Short Form-36 [SF-36]). In addition, the Hospital Anxiety and Depression Scale Depression Score was reduced. In a non-placebo-controlled study comparing "conservative" management and CPAP for moderate to severe OSA, McFayden et al. [66] examined the results of the disease-specific Functional Outcomes of Sleep Questionnaire (FOSQ) as well as the SF-36 and found that CPAP was associated with improved psychosocial function and the patient's (but not the spouse's) marital satisfaction. Conversely, Barnes et al. found no effect on neurobehavioral function or quality-of-life metrics on the SF-36 or the FOSQ [46]. These investigators speculated that differences in the study population, particularly related to gender, may explain the disparate results. Studies of patients with moderate to severe OSA (e.g., the most symptomatic individuals prior to treatment) indicate the largest effect sizes are in the contexts of sleepiness and vitality. Studies have suggested that patients with moderately impaired pretreatment cognitive performance experience modest improvements [42, 43, 67]. Moreover, data suggest that daily use of PAP for at least 6 h over 3 months is associated with clinically relevant improvement in verbal memory in some, but not all, OSA patients [68]. The most definitive data to date concerning neurocognition in sleep apnea comes from the Apnea Positive Pressure Long-Term Efficacy Study (APPLES) in which 1204 adults with OSA were randomly assigned to effective CPAP vs. sham CPAP and had neurocognitive testing performed. After adjusting for confounders such as baseline education level, gender and ethnicity, the investigators found no significant relationship between OSA (as quantified by AHI) and neurocognitive performance. The small association between OSA and neurocognition that was detected was largely associated with degree of hypoxemia [69].

Side Effects of Pap Therapy

Like most treatment interventions, PAP is often associated with a variety of generally minor, but troublesome side effects (Table 34.2) [16, 19, 25, 45–50, 58, 61, 70–75]. Side effects may be attributable to either the patient-device interface or the sensation of high airflow or pressure. Some patients simply perceive the lifestyle and other challenges associated with nasal PAP to be unacceptable [3, 46, 48, 61, 73, 76–78]. Such individuals are often, but not invariably, younger patients who are unable to envision indefinite nasal PAP therapy. Although some studies have concluded that

Table 34.2 Side effects of nasal CPAP

Side effect	Management measures
Mask related Skin abrasion or rash Conjunctivitis from air leak • Protective skin covering • Customized mask • Reinforce hygienic care of device Eye patch	Optimize mask fit from wide selection of commercially available types of masks, select nonallergenic material
Pressure or airflow related Chest discomfort Aerophagia Sinus discomfort Smothering sensation Difficulty exhaling Difficulty initiating and/or maintaining sleep Pneumothorax or pneumomediastinum Pneumocephalus • Reduce pressure with bilevel positive airway pressure Try to reduce requisite pressure using oral appliance + CPAP (no published data)	Pressure ramp
Problems related to the nasal route Rhinorrhea Nasal congestion, nasal and/or oral dryness Epistaxis (may be massive, especially in anticoagulated patients) • Saline nasal spray • Topical nasal steroid preparation • Consider trial of nasal aerosol of ipratropium bromide solution • Chin strap for oral dryness Oral-nasal mask interface Desensitization over time	Heated humidification
Other Noise Cumbersomeness or inconvenience Spousal intolerance Longer tubing to move device further from bedside (consult device manufacturer for permissible lengths) • Intensify education of patient and spouse Recommend attending a patient support group (A.W.A.K.E Network of the American Sleep Apnea Association)	

side effects do not impact on adherence to therapy [61, 74], others have concluded the converse, citing side effects as a reason for nonadherence [79].

Claustrophobia

Not uncommonly, patients complain of claustrophobia in conjunction with enforced breathing through a nasal mask or nasal prongs system, or with CPAP in general [47, 48, 51, 72, 73, 80, 81]. For those patients who are uncomfortable breathing exclusively via the nasal route, an oral-nasal mask that permits breathing through either the oral or nasal route may be a useful alternative [82, 83] (see later). Clinicians should be aware of one study demonstrating that, when patients were randomly assigned to either nasal or oral-nasal interface, adherence was lower while using the latter [84]. This study did not examine adherence to CPAP when an oral-nasal mask was prescribed as a "salvage" intervention for patients with complaints regarding a nasal interface. A desensitization program to promote acclimatization to nasal CPAP may be useful in some patients [81], and a study found that the sensation of claustrophobia diminishes over time with perseverance of treatment [80]. The investigators suggested that early identification of patients who are likely to be claustrophobic and institution of interventions targeted to address this issue (e.g., desensitization, education, and support) may be of considerable value [80, 85].

Problems Related to Nasal Route of Breathing

Problems with skin abrasion or leakage of air directed into the eyes, with or without consequent conjunctivitis [61, 86], may result from a poor mask fit. Other complaints related to the nasal route of breathing include nasal dryness, congestion, and rhinorrhea. The reported prevalence of such effects varies from 25 to 65 %. One study observed that use of nasal prongs or pillows was associated with better adherence to therapy than a nasal mask [87]. Although the percentage of days during which patients used CPAP was slightly greater when using the nasal pillows (94 % vs. 86 %), the time of CPAP use per night across all nights as well as specifically on those nights during which patients used CPAP was not statistically different between the two interfaces. There was no difference between the interfaces with regard to relief of sleep-disordered breathing and functional outcome assessed by the FOSQ. The authors reported that overall satisfaction was greater with use of the nasal pillows. In our experience, we have found that interface preference varies across patients. Moreover, preferences vary over time in individual patients, with many switching back and forth across interfaces. It may be reasonable to provide patients with several interfaces from which they may choose on any given night. Of course, follow-up is important to ensure ongoing success in alleviation of OSA and symptoms.

Nasal Dryness and Congestion

Nasal dryness and congestion can occasionally be treated simply with either administration of saline nasal spray at bedtime or a room humidifier. For some patients, a topical nasal steroid may be effective. Addition of a low-resistance humidifier to the PAP system may also be extremely helpful in certain patients, and heated humidification systems are now standard on most PAP systems. Richards et al. documented increased nasal resistance in the presence of high nasal flow, such as occurs when there is a mouth leak during nasal CPAP

application [88]. Incorporation of a heated, but not an unheated, humidifier into the CPAP system minimized the increase in nasal resistance, presumably by increasing the relative humidity of the inspired gas and reducing release of inflammatory mediators. The superiority of heated humidifiers to nonheated humidifiers in restoring relative humidity to inhaled air was confirmed in a study by Fleury et al. [89]. The issue of routine prescription of a heated humidifier at the time of the initial PAP prescription has been the focus of several investigations, often yielding conflicting results. In a setting more clinically relevant to OSA patients than that employed by Richards et al., Duong et al. [90] measured nasal airway resistance before and after a night of CPAP in patients randomized to receive heated humidification or placebo. There was no significant difference between the groups with regard to total nasal airway resistance in the evening before CPAP use or in the morning following CPAP use. There was also no difference between the groups with regard to the overnight percent change in nasal airway resistance.

Massie et al. [91] reported that, compared with a cold humidifier, heated humidification of CPAP-delivered air resulted in a statistically significant improvement in adherence, albeit by only an average of 0.6 h. While there were less frequent reports of dry mouth, throat, and nose during application of heated humidification, the global adverse side effect score did not differ by heated versus cold humidification. Three quarters of the patients preferred heated humidification, reflecting that a measurable minority did not. In a more recent study, Mador et al. [92] compared adherence and quality of life in a group of 49 OSA patients prescribed to receive CPAP with heated humidification versus 49 control patients who were not initially prescribed heated humidification but did receive it only if nasal symptoms occurred that were unresponsive to other measures. Six control patients crossed over to heated humidification. There was no difference in adherence or Calgary Sleep Quality of Life Index between the groups over 12 months. There was no improvement in adherence in control patients who crossed over to heated humidification, although nasal symptoms diminished. Similarly, in a randomized crossover trial, Neill et al. [93] observed that, compared with placebo humidification, heated humidification of CPAP was associated with fewer upper airway symptoms and a slightly greater degree of use initially following setup. However, by the end of week 3, there was no difference in adherence or in satisfaction with therapy. The authors concluded that heated humidification may be useful in addressing side effects but is not appropriate for routine prescription to all patients. Nevertheless, it appears that heated humidification may provide benefit to at least some patients. Rakotonanahary et al. [94] observed that chronic nasal mucosal disease, nasal septum deformity, and a history of uvulopalatopharyngoplasty predicted need for heated humidification of PAP.

Thus, there is considerable literature that does not support benefit to the *routine* prescription of heated humidification to all OSA patients at the time of initial setup, although there are selected subsets who benefit from such a prescription. It is reasonable to approach the issue of heated humidification from the perspective expressed by Brown in commenting, "If it's dry, wet it." [95]. In this context, the data indicate that patterns of adherence (or nonadherence) are established early on [96], so there is considerable wisdom in obtaining follow-up very soon after the patient receives the PAP unit in order to detect and address factors that may diminish the enthusiasm to be adherent to treatment.

Although routine use is to be discouraged, occasional administration of a vasoconstrictive nasal spray may be helpful when nasal congestion is related to a self-limited condition such as an upper respiratory tract infection.

Whereas nasal dryness is rarely a serious problem, massive epistaxis has been reported [97]. Mucosal dryness may be a contributory factor to the epistaxis, which did not recur after placement of a humidifier in the CPAP system. In light of this report, it seems prudent to follow patients with a history of bleeding tendencies, epistaxis, or coagulopathy who are on PAP with particular care, and to consider humidifying the delivered air from the outset of therapy.

Rhinorrhea

Rhinorrhea after initiation of PAP therapy, present in approximately 35 % of patients [61], is often a difficult problem to control. The cause of this untoward effect is likely to be related to inflammation, as in nasal congestion. Similarly, one study did not observe a beneficial effect from humidification, although it is uncertain if a heated humidifier was employed [61]. Therefore, it may be worth trying a heated humidifier, as described previously, for the treatment of rhinorrhea. Although we are unaware of published, systematically conducted research studies, we have found the administration of anticholinergic nasal sprays such as ipratropium bromide or Azelastine nasal spray (if used, care must be taken due to sedating potential) may be only variably effective among patients with rhinorrhea. However, as noted previously, nasal steroids have been observed to provide more consistent benefit.

When evaluating a patient with rhinorrhea, it is essential to consider the possibility of a cerebrospinal fluid leak. Kuzniar et al. [98] described two patients who developed rhinorrhea after initiation of CPAP therapy, which subsequently proved to reflect a cerebrospinal fluid leak that in one patient was complicated by meningitis. Clinicians should keep this uncommon but real possibility in mind when assessing rhinorrhea in CPAP users.

Barotrauma and Chest Discomfort

When providing positive pressure therapy, the clinician must always consider the potential for barotrauma. Although clinicians should be vigilant for pneumomediastinum and pneumothorax, these are uncommon in OSA patients receiving CPAP, at least as assessed by review of the literature. Pneumocephalus has been reported in a sleep apnea patient with a cerebrospinal fluid leak who was placed on nasal CPAP [99] and in a patient on nasal CPAP who presented with headache [100]. Pneumocephalus should be considered when any patient using CPAP therapy develops a nasal discharge, or neurologic signs and symptoms including headache, seizures, dizziness, or cranial nerve palsy.

A small number of patients complain of chest discomfort on nasal CPAP therapy [75, 101, 102]. This is probably related to the positive end-expiratory pressure and consequent elevation of resting lung volume [103], which stretches the chest wall muscles and cartilaginous structures, creating a sensation of chest wall pressure that may persist after awakening. Although the complaint of chest discomfort should be completely evaluated in any patient, if a cardiopulmonary workup in an OSA patient on CPAP is nondiagnostic, efforts should be made to reduce the expiratory pressure, if necessary by using bilevel PAP (discussed later). Similarly, a certain proportion of patients perceive discomfort when exhaling against positive expiratory pressure [58, 102]. If the level of CPAP cannot be satisfactorily reduced, a trial of bilevel PAP may be considered [104] (see later).

Effects on Arterial Blood Gases and Oxyhemoglobin Saturation

While it is usually beneficial to patients with OSA, administration of nasal CPAP may be associated with untoward effects on arterial blood gases and oxyhemoglobin saturation. Pépin et al. [61] reported severe oxyhemoglobin desaturation during nasal CPAP therapy in a hypercapnic sleep apnea patient with cor pulmonale. Similarly, Krieger et al. [105] reported persistent and notable desaturation despite CPAP administration *with* supplemental oxygen to hypercapnic OSA patients. Although the cause of this desaturation is not certain, it may be due to one or more of the following: (1) worsening hypoventilation related to the added mechanical impedance to ventilation associated with exhalation against increased pressure; (2) increased dead space ventilation [106]; and (3) that venous return and cardiac output decrease due to increased intrathoracic pressure during CPAP administration in patients with impaired right or left ventricular function and inadequate filling pressure. With regard to the potential contribution of alveolar hypoventilation to nocturnal oxyhemoglobin desaturation during CPAP therapy, Fukui et al. [107] noted that nasal CPAP failed to reduce sleep-related hypercapnia during non-REM sleep in OSA patients, and Piper and Sullivan [108] observed persistent sleep desaturation on CPAP in severe OSA and hypercapnia. Similarly, Resta et al. [18] reported that hypoventilation during sleep on CPAP was more likely to occur in more obese patients and those with higher arterial partial pressure of carbon dioxide ($Paco_2$). This highlights the prudence of conducting CPAP trials under monitored conditions in patients at high risk for nocturnal hypoventilation, including individuals with chronic ventilatory failure (awake hypercapnia) and morbidly obese individuals.

Despite these caveats and troublesome experiences, CPAP administration has also been reported to improve awake arterial blood gases in OSA patients with hypercapnia and cor pulmonale [109–111]. A study has demonstrated that CPAP therapy for OSA reduces pulmonary artery pressure in patients with mild pulmonary artery hypertension [112]. In this study, the pulmonary systolic pressure was related to both the AHI and diastolic dysfunction.

The mechanism responsible for augmented alveolar ventilation during wakefulness in hypercapnic persons has not been clearly defined. The literature is not consistent with regard to the effect of CPAP on the slope of the hypercapnic ventilatory response curve in OSA patients, with some of the differences related to measuring different parameters of ventilatory control and others perhaps related to differences in subject populations. Some investigations observed no change in the slope of the carbon dioxide/ventilation relationship in normocapnic patients [113, 114]. Mateika and Ellythy observed an elevation in the ventilatory recruitment threshold to CO_2 in normocapnic OSA patients compared with normal subjects, with no difference in ventilatory response above this threshold [115]. This may provide insight into the earlier observation by Berthon-Jones et al., who reported a leftward shift in the ventilatory response to carbon dioxide following initiation of CPAP therapy without a change in the slope of the line representing the relationship between carbon dioxide tension and ventilation [114]. These data are consistent with a reduction in the chemoreceptor(s) set point to $Paco_2$ following initiation of therapy.

Although the issue has not been systematically explored specifically in hypercapnic OSA patients, it is possible that alleviation of sleep-related hypercapnia with alleviation of apneas and hypopnea alters the hypercapnic threshold by reducing serum buffering capacity. Alternatively, enhanced chemosensitivity to carbon dioxide during wakefulness may be due to relief of hypoxic depression of central nervous system respiratory centers. While it had been previously believed that sleep deprivation reduces hypercapnic ventilatory responsivity [116], more recent data, collected over 24 h of sleep deprivation with electroencephalographic

documentation of wakefulness, refuted the earlier study [117]. These issues notwithstanding, studies indicate that CPAP often does not reduce $Paco_2$ during sleep and wakefulness in hypercapnic patients [18, 106, 107], and reliance on this modality to reduce awake hypercapnia may be problematic [108]; augmentation of ventilation after maintenance of upper airway patency may facilitate improvement in diurnal hypercapnia [104].

Acceptance of and Adherence to Pap Therapy

The most significant disadvantage to PAP therapy is that patients must actively participate in their own treatment both in terms of the number of nights used as well as the number of hours used per night. Although the optimal duration of nightly PAP use—or for that matter, the minimal amount of use that confers benefit—are unknown, recent studies suggest that use of at least 6 h/night confers greater cardiovascular mortality risk reduction compared with fewer hours of use per night [118] (Fig. 34.3). In addition, PAP use for >6 h/night over 3 months has been associated with a greater likelihood of normalized memory performance [68]. Viewed from the opposite perspective, sleeping for as little as 1 night without CPAP is associated with increased sleepiness [55, 119]. These data highlight the need for clinicians to facilitate maximal PAP use by patients.

Before adherence to a therapeutic PAP prescription can be considered, the patient must accept the opportunity to receive this therapy. The acceptance rate of CPAP varies across a number of studies, ranging from 62 to 92 % [71, 72, 120–125]. Among the reasons for nonacceptance are difficulty falling asleep, frequent nocturnal awakenings, and mask discomfort. In addition, those who accept CPAP therapy are generally more likely to complain of greater tiredness as well as episodes of falling asleep at undesirable times [121].

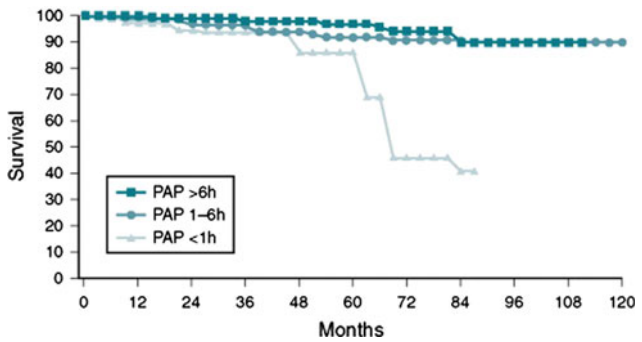

Fig. 34.3 Kaplan–Meier cumulative survival rates according to categories of PAP compliance. Survival rates in the patients using PAP > 6 h/night were significantly higher than in the patients using PAP < 1 h/night. Cumulative survival rates in patients using PAP 1–6 h/night were significantly greater than in patients using PAP < 1 h/night. Cumulative survival rates were not different in the patients using PAP > 6 h/night compared with patients using PAP 1–6 h/night (Reproduced with permission from Campos-Rodriguez et al. [118])

In recent years, there has been increasing interest in "split-night" polysomnography in which the initial portion of the night is spent in performing a diagnostic evaluation for OSA and the remainder of the night is devoted to establishing a PAP prescription [104, 124–131]. If the diagnosis of OSA is established during the initial portion of the night, a therapeutic titration of CPAP is undertaken. The impact of this paradigm has been explored and, in general, split-night studies provide an acceptable strategy for laboratory evaluation and initial PAP prescription without negatively impacting acceptance and adherence in patients with severe OSA [124, 125, 130–132]. Some data suggest, however, that long-term adherence may not be as high in patients with mild to moderate OSA as in patients with more severe OSA, thereby mandating particularly close follow-up in the former group [130]. Current recommendations of the American Academy of Sleep Medicine include that a CPAP titration may be conducted after observing an AHI of 40 (or AHIs of 20–40, based on clinical judgment) over at least 2 h of diagnostic polysomnography, and a CPAP prescription may be established based on a titration over at least 3 h of sleep that documents that CPAP eliminates or nearly eliminates the respiratory events during non-REM and REM sleep (including REM sleep in the supine position) [132]. Although a number of investigations have included bilevel PAP devices in assessing acceptance as well as adherence to therapy following split-night studies, neither these devices nor APAP modalities have been the specific subject of these studies.

Once a patient has "accepted" CPAP therapy, he or she must be adherent to it. In the last several years, investigators and clinicians have been able to objectively monitor daily use and patterns of use over time with meters and software that have been incorporated into the PAP devices. Such objective metrics are particularly important in assisting clinicians with management since subjective patient reports overestimate time of use [61, 71, 73, 123]. Objective adherence monitoring is now the standard of care, with its utility highlighted by the observation that suboptimal patterns of usage are established shortly after initiation of therapy, so that the clinician needs to recognize and address the contributory factors early on [76–78, 80, 96]. Moreover, information regarding the degree to which a patient is adherent to PAP is essential for assessment of a suboptimal clinical response. If a patient's symptoms are inadequately resolved after the initiation of PAP treatment, possible reasons other than poor adherence include delivery of insufficient pressure to maintain upper airway patency during sleep (perhaps due to an incorrect prescription or because of

technical issues such as air leaks through the mouth or skin-mask interface that impair delivery of the prescribed pressure), misdiagnosis of the etiology of the individual's symptoms, the contribution of comorbid elements to the patient's symptoms, or failure to use the device for a sufficient duration on a regular basis. Currently available software within PAP devices provides information regarding delivered pressure and the magnitude of leaks, as well as an estimate of the AHI on PAP therapy. This constellation of information can provide the clinician with important management insights.

Despite the availability of software providing objective adherence information to clinicians, there remain gaps in our knowledge in this regard. For example, although the clinician may know the average duration of daily PAP, the *total sleep time* is not known. This information is highly desirable for optimal interpretation of the machine-use data. For example, 4 h of PAP use may reflect acceptable adherence if the patient is asleep or at least in bed with intention to sleep for 4.5 h (e.g., a late night at work with an early appointment in the morning). On the other hand, 4 h of PAP use may reflect inadequate adherence if the patient is asleep for 8 h. It is evident that it is highly desirable for the clinician to have objective information about a patient's usual bed and sleep time during follow-up subsequent to initiation of PAP therapy.

In general, utilization of PAP ranges from 4 to 6 h/day, with considerable interindividual variability and a measurable proportion of patients with <2 h/night or complete nonadherence. As discussed earlier, >6 h of use per night is associated with reduced cardiovascular mortality and increased likelihood of normalizing memory function [68, 118]. The relative value of <6 h of use per night is unclear, as if there is a threshold of nightly use above which no further benefit is obtained in this regard as well as with respect to cardiovascular and cerebrovascular morbidities. Existing data suggests that optimal relief of daytime sleepiness requires nightly use of PAP. As also noted earlier, sleeping for as little as one night without PAP results in increased sleepiness [55, 119]—but is it necessary to use PAP during *all* sleep time? Hers et al. observed persistent benefit in oxyhemoglobin saturation and sleep continuity for the remainder of the night after CPAP was discontinued following 4 h of use [133]. The investigators postulated that the persistent improvement is related to greater sleep continuity while on CPAP, with increased upper airway stability during the latter portion of the night after CPAP was removed. This hypothesis is based on earlier data demonstrating increased upper airway collapsibility following a period of sleep fragmentation [134]. These investigators as well as others [135] speculated that duration of nightly use of CPAP by at least some OSA patients is determined by their perception of the amount of use required to obtain a satisfactory degree of symptomatic benefit.

It is intuitively evident that greater insight regarding the determinants of adherence would facilitate treatment modifications that would promote more universal and optimal utilization by patients. Unfortunately, our understanding remains incomplete. Some reports suggest that adherence improves as the patient's perception of sleep propensity increases [71, 79, 136, 137]. Notably, the patient's perception of daytime sleepiness, assessed using specific questionnaires such as the "hypersomnia score" [71] or the Epworth Sleepiness Scale [45], predicts adherence with CPAP more reliably than the MSLT, which is an objective measure of sleepiness [58, 73, 138]. Some studies have noted that, after adjusting for confounding factors, lower AHI is an independent risk factor for nonadherence [79, 136]. Conversely, several investigators have observed that adherent patients cannot consistently be differentiated from nonadherent patients by the frequency or variety of side effects of CPAP therapy, initial AHI, gender, weight, or the prescribed level of CPAP [58, 73, 75, 123, 138–140]. More recently, the contribution of "self-efficacy," including the patient's perception of the consequences of untreated OSA and expectations of treatment outcome [76], as well as psychologic factors such as coping strategies and willingness to modify behavior [77, 78], have been examined in the context of adherence. Stepnowski et al. [77] observed that adherence to CPAP was uninfluenced by baseline depression, stress, or anxiety but was significantly related to the patient's score on a Ways of Coping Questionnaire (Fig. 34.4). Additional important contributions to adherence

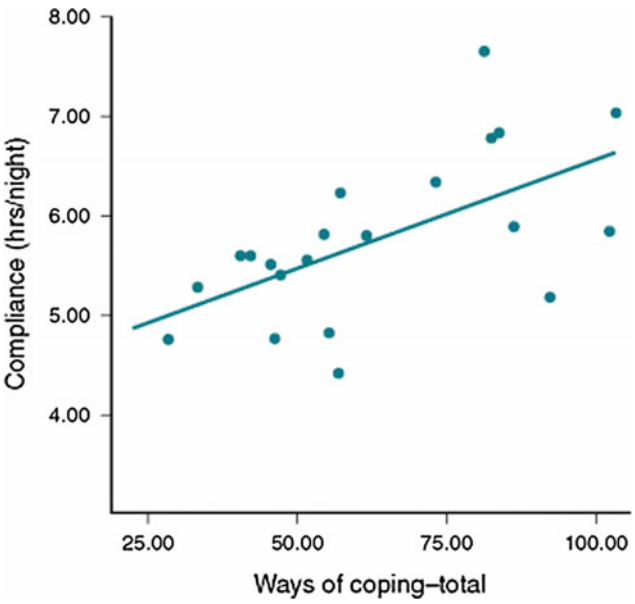

Fig. 34.4 Relation between the total ways of coping questionnaire score and adherence (average number of hours of CPAP use per night). Adherence = 4.38 + 0.02 * ways of coping (Reproduced with permission from Stepnowsky et al. [77])

include the response to therapy with regard to sleepiness, performance and mood, home/family environment/support, encumbrance on lifestyle (e.g., ease of travel, intimacy), and interface comfort.

As discussed earlier, patients commonly experience side effects in conjunction with PAP therapy. Although evidence regarding the impact of side effects on acceptance and adherence varies, it is reasonable and prudent for the clinician to make every effort to minimize if not eliminate them (see Table 34.2). It is likely that the perception of a given side effect varies across individuals and therefore may have a different degree of impact. Thus, a simple comparison of prevalence in compliant and noncompliant patients may be misleading and obscure the impact of a particular side effect on the compliance of individual patients. Several practices may enhance patient acceptance and compliance with CPAP therapy. These are outlined in Table 34.2 as well as later in this chapter. Appropriate patient selection for chronic PAP therapy is an important factor, and educating the patient, utilizing discussion and educational literature addressing the nature of OSA, the consequences of untreated OSA, and a detailed discussion of therapeutic options and implications, is essential [141]. It is intuitively obvious that patients who require "arm-twisting" to take a PAP unit home, even after efforts have been made to explain the need for the device and the manner in which it operates, are unlikely to use it conscientiously on a long-term basis. Therefore, PAP should be provided only to patients who are reasonably receptive to using it or who are sufficiently open minded to give it a reasonable home trial.

Patient–PAP Device Interface Options

Since the initial report in 1981 of CPAP therapy for adults with OSA, which described use of a customized nasal mask [1], there has been an appropriate and ever-growing cornucopia of interfaces from which patients and clinicians may choose in an effort to enhance comfort and convenience. These interfaces include commercially available nasal prongs/pillows or cannula systems, commercial and custom-made nasal masks, commercially available oral-nasal masks [82, 83], and an oral interface [142]. In a 3-week randomized crossover design study comparing nasal pillows and a nasal mask, Massie et al. [87] reported that, when using the nasal pillows, there were less frequent adverse effects and less air leak reported as well as less trouble initiating and maintaining sleep. However, there was no difference between the two types of interfaces with regard to the time of PAP use per night, Epworth Sleepiness Scale score, or FOSQ score.

Clinicians also have the option to prescribe an oral-nasal mask or oral interface for patients who are unwilling or unable to use an exclusively nasal interface or who are unable to keep their mouth sufficiently closed during sleep to permit maintenance of adequate positive intrapharyngeal pressure. In our experience, a chin strap is only variably helpful, and when necessary, the delivery of positive pressure via an oral-nasal mask should be considered. These interfaces also have the advantage of increasing humidity in the inspired air, independent of an external humidifier [93]. Oral-nasal interfaces have successfully reduced the AHI in a substantial majority of the patients in whom they have been applied [82, 83]. However, oral-nasal interfaces may be less acceptable than nasal interfaces to patients who have had an unsuccessful uvulopalatopharyngoplasty [84].

Particular care must be taken when employing an oral-nasal mask, owing to the potential risk of aspiration of gastric contents if the patient vomits. Although to our knowledge this complication has not been encountered in patients with OSA, it remains a concern. Accordingly, patients using an oral-nasal mask for nocturnal PAP should be instructed not to take anything by mouth to allow gastric emptying before applying the positive pressure. Furthermore, before initiating PAP therapy via an oral-nasal mask, patients should be routinely instructed to notify their physician if they are experiencing nausea or vomiting from any cause. They should also be provided with a nasal interface as a temporizing, if not long-term, option and counseled to sleep with the head of the bed elevated.

Coverage of both the nose and mouth by an oral-nasal mask also raises theoretical concerns regarding the potential consequences of machine failure, when airflow that can be entrained by the patient through a nonfunctional or dysfunctional device is limited or nonexistent. Safety valves should be incorporated in the circuit, close to the patient, to facilitate inhalation of fresh air and/or to minimize dead space in the event of machine malfunction. Optimally, an alarm should also be present to signal power failure.

There does not appear to be a significant effect of interface on the requisite positive pressure required to stabilize the upper airway during sleep [83, 87, 142]. Since patients may change their interface preference over time, they should be made aware that a choice remains open to them at all times during their treatment.

Variations and Modalities of PAP Therapy for OSA: Implications for Acceptance and Adherence

Clinical experience indicates that nasal CPAP maintains upper airway patency and acceptable oxygenation during sleep in the overwhelming majority of patients with OSA. Some patients find the administration of CPAP sufficiently bothersome to precipitate complete intolerance of therapy or

at least result in unsatisfactory adherence. Use of variations of CPAP and other PAP modalities have been explored to address patient complaints that appear to be specific to CPAP.

Pressure Ramping

For some patients, the sensation of positive pressure is sufficiently unpleasant to cause difficulty with initiating sleep. Pressure ramping of CPAP allows adjustment of the rate of rise in delivered pressure over time, from a clinician-specified level to the target therapeutic pressure. Thus, a window of time is created during which the delivered pressure is lower than the target pressure and the patient may find it easier to fall asleep. Because the level of positive pressure may be transiently below that required to maintain upper airway patency during sleep, pressure ramping may allow apnea, hypopnea, and oxyhemoglobin desaturation to occur for a variable period of time, until the pressure reaches the prescribed, optimal value. We are unaware of published studies that address the level of risk that the delay in optimal pressure delivery may present to patients, nor are any data available regarding the effectiveness of pressure ramping on patient adherence to CPAP therapy. In fact, Pressman et al. described a case of "ramp abuse" in which a patient repeatedly awoke to reactivate the ramp [143]. Although the published recordings may have been influenced by movement artifact, failure of sleep continuity and probable repetitive episodes of oxyhemoglobin desaturation (because the pressure was subtherapeutic during the time that the patient was asleep) were evident. As Pressman et al. pointed out, such abuse will not be detected if only CPAP machine run time is monitored as a reflection of adherence. Conversely, monitoring run time at the prescribed pressure gives the clinician insight into this activity.

Thus, although pressure ramping is a conceptually attractive feature, its degree of effectiveness and safety remain to be documented, and the specific patient populations for which it might provide maximal benefit have yet to be identified. Whether or not it should be routinely prescribed for all patients has not been systematically evaluated, but since it is available on most commercially available CPAP machines, clinicians may consider pressure ramping should a patient encounter difficulty in initiating sleep due to CPAP. A careful subsequent follow-up is essential.

Bilevel PAP Therapy

This modality has been discussed above. Because in many patients it permits PAP treatment of OSA using expiratory pressures that are not mandated to be as high as inspiratory pressures [22–25] bilevel PAP has been prescribed with the intent to reduce complaints or likelihood of complaints related to some side effects, including a smothering sensation, chest wall discomfort, and bothersome nasal or sinus pressure related to the sensation associated with breathing against a positive pressure. Additionally, some patients may be at increased risk for barotrauma by virtue of emphysema or bullous lung disease (though a review of the literature suggests that this is not a prevalent complication of CPAP therapy for OSA), while in others, elevated expiratory pressure may be associated with a tendency toward alveolar hypoventilation [24, 25, 27, 108].

The existing literature does not support routine prescription of bilevel PAP rather than CPAP with the intent to improve adherence [123]. There may be a subset of OSA patients who prefer the bilevel PAP, including but not limited to the very obese, those with higher $Paco_2$, and those with underlying pulmonary or neuromuscular disease [131]. Bilevel PAP may be a therapeutic alternative for patients who find nasal CPAP uncomfortable [104] or for those in whom the delivery of PAP represents an unacceptable degree of risk (i.e., patients with bullous lung disease). Prospective, controlled studies are required to determine if and to what degree bilevel PAP is successful as salvage therapy for OSA populations who are nonadherent to CPAP.

APAP and Auto-titrating Bilevel PAP

APAP devices have been previously described in this chapter. The capacity to provide a pressure that "floats" across the sleep period and varies in response to the physiologic requirements to maintain upper airway patency led to the assumption that this mode would improve adherence. To our knowledge, there have not been published, systematic trials of autotitrating bilevel PAP in this regard, but there has been a recent meta-analysis examining studies of APAP [33]. Although APAP was comparable to fixed-pressure CPAP in reducing the AHI and did so with a 2-cm H_2O reduction in mean pressure, this modality did not confer a benefit in adherence over fixed-pressure CPAP (Fig. 34.5). At this time, there is a general acceptance that APAP and fixed-pressure CPAP lead to essentially equivalent outcomes for patients with OSA. There may be subgroups which will either prefer or have a better result with one mode or the other but such groups have not been identified yet. Several studies which have compared lab-based CPAP titration vs. home-based APAP trials have found this and a nonsignificant trend toward better adherence in the home APAP group [144, 145]. However, it may be beneficial in improving comfort and tolerance in selected patients. Systematic studies are required to assess the impact of autotitrating bilevel PAP.

Pressure-Relief CPAP and Bilevel PAP

There are few studies addressing the effect of pressure-relief CPAP on adherence. One nonrandomized study demonstrated that adherence to pressure-relief CPAP over 3 months was significantly better than adherence to

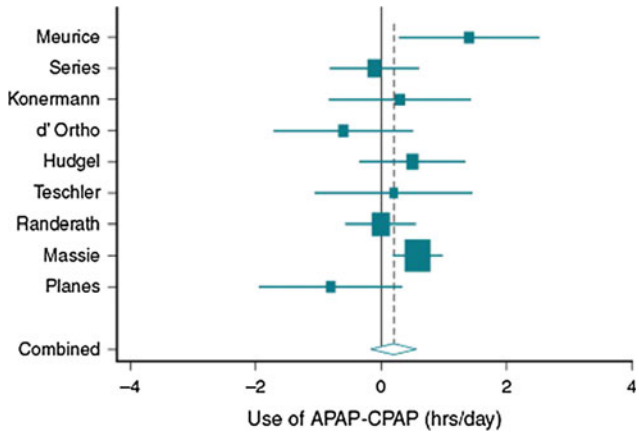

Fig. 34.5 Comparison of nightly adherence to autotitrating CPAP (APAP) versus fixed-pressure CPAP. A positive score indicates a better adherence to APAP than CPAP. *X axis* Nightly adherence with APAP minus adherence on CPAP. *Y axis* Investigations reporting adherence data. The *dashed line with the diamond* at the bottom represents the pooled effect though the mean of the estimate (Reproduced with permission from Ayas et al. [33])

conventional CPAP [141]. There was no difference between pressure-relief and conventional CPAP with regard to the degree of change in subjective sleepiness and FOSQ score. Another study, utilizing a randomized, 7-week crossover design comparing pressure-relief CPAP and conventional CPAP, confirmed the comparability between pressure-relief CPAP and conventional CPAP in alleviating sleep-disordered breathing but found no difference in adherence over 7 weeks [35]. Similarly, there was no significant difference with regard to complaints. To our knowledge there are no published systematic studies examining the impact of routinely prescribed pressure-relief bilevel PAP on adherence. However, a recent study suggested that pressure-relief bilevel PAP may provide some benefit as a salvage therapy for patients who are suboptimally adherent to CPAP despite intensive education and interventions to maximize comfort [146]. Thus, there are too few data on which to make conclusions about the role of pressure-relief CPAP and bilevel PAP. While these modalities may be useful in specific patients, there are no data to indicate benefit from routine prescription to all patients at initial setup.

Follow-up of CPAP Patients and Its Role in Enhancing Adherence

As noted above, it appears that an individual's pattern of CPAP use (or nonuse) is established very shortly after initiating home therapy [72, 73, 122, 147]. It is therefore reasonable to consider that enhanced adherence would result from early and consistent contact between the patient and the care provider in an effort to identify and resolve problems with therapy, provide encouragement, and give support. While this may be a reasonable line of thought, the literature provides conflicting information on this subject. One study indicated that positive reinforcement by periodic telephone contact does not favorably influence therapeutic compliance [74]. In contrast, considerably larger investigations have demonstrated improved adherence in conjunction with intensive educational and support measures after initiation of home treatment [85, 148]. Chervin et al. [141] reported that patients who had received educational literature regarding sleep-disordered breathing and CPAP or bilevel PAP use and patients who received follow-up telephone calls from healthcare personnel were more adherent than patients who had received neither of these interventions. In contrast, intensive follow-up of PAP patients in Hong Kong did not improve adherence when compared to standard care [149].

It is also essential that a physician and staff who are experienced in the care of OSA patients and the difficulties they encounter act as continuing support and educational resources to answer questions and provide reassurance when uncertainties arise. At our center and others, patient support groups serve a very important function in fostering a climate of openness and sharing of information as well as providing a forum for discussion of issues relevant to all types of sleep-disordered breathing (OSA, nocturnal ventilatory failure associated with neuromuscular and chest wall disorders, etc.) and overall health. Group meetings provide patients with the realization that they are not and should not be isolated by their disorder. This is crucial, since many OSA patients have been labeled by society as lazy or malingerers, resulting in social ostracism and low self-esteem. Many of the consequences of OSA are reversible by PAP therapy, with remarkable and gratifying results for all concerned. In our experience, there is no doubt that important benefits are obtained from support groups, judging from the excellent long-term attendance and favorable patient comments.

Summary

When all things are considered, adherence to PAP, which entails the presence of a relatively cumbersome box at or near the bedside and an equally cumbersome (if not unappealing) interface over the nose, is surprisingly good. Adherence to PAP compares favorably to therapies that most would consider substantially less noxious, such as metered-dose inhalers for treating asthma [150]. Without doubt, this relates to the remarkable symptomatic improvement experienced by the majority of users.

Traditional and Evolving Methods of Initiating Pap Therapy

Traditionally, patients have undergone an attended (by a technologist), monitored (by polysomnography) trial of PAP to establish therapeutic levels of pressure prior to initiating long-term therapy. Because the requisite level of PAP may vary according to body position and sleep stage, clinicians should be certain that the delivered pressure is effective in maintaining adequate upper airway patency and oxygenation during sleep in all positions, including and especially the supine position (and when possible during supine REM sleep). It also provides an opportunity for the patient to examine the PAP unit and various interfaces before home use. The most comfortable and leak-free interface with the device (i.e., nasal mask, prongs, or oral-nasal mask) can be selected. Then, while the patient is still awake, he or she may be provided with an opportunity to experience PAP across a wide range of pressures, to permit familiarization with the associated sensations. Another advantage of attended evaluation of the patient on PAP is the immediate availability of knowledgeable and caring healthcare professionals who can respond to questions and allay concerns. When wearing a PAP device for the first time, patients have been anecdotally reported to awaken in the middle of the night disoriented and perhaps frightened by the apparatus. Under these circumstances, albeit rare, reassurance is readily supplied by the laboratory personnel conducting the trial.

Several other benefits have also been attributed to polysomnographically monitored trials of CPAP therapy. Fry et al. [151] observed an increased frequency of periodic leg movements in sleep (PLMS), with and without accompanying arousals during nasal CPAP therapy. These investigators hypothesized that the improved sleep quality and architecture associated with relief of OSA by nasal CPAP "unmasks" PLMS. However, several subsequent studies observed that the Periodic Limb Movement Index was not appreciably different during a diagnostic polysomnogram and during CPAP therapy [152, 153], although arousals may diminish in conjunction with PLMS during CPAP therapy, at least acutely [152]. Nonetheless, periodic limb movement disorder may coexist with OSA and may persist after alleviation of OSA on CPAP, and a patient may not obtain symptomatic abatement of daytime sleepiness or fatigue. Thus, a monitored initial trial of CPAP addresses many issues and concerns that, if not considered, may lead to dismissal of this form of therapy as a viable therapeutic option. Attention to these factors at the outset of therapy will maximize the opportunity for a successful outcome.

Split-Night Diagnostic and CPAP Titrations

This paradigm for initiating PAP therapy has been discussed above in the context of acceptance and adherence. The current healthcare environment has fostered exploration of alternative means of establishing PAP therapy for OSA in order to facilitate access to limited diagnostic and therapeutic resources [154]. As noted earlier in this chapter, some clinicians are requesting that diagnostic and PAP titrations be conducted in single, split-night studies. Although this may lead to a satisfactory CPAP prescription for many patients [120, 124–130] there are a number of patients for whom the duration of time available for CPAP titration is too limited in the context of a split-night study to achieve a satisfactory prescription [129]. In particular, patients with milder degrees of OSA in whom the titration is initiated later in the night (because more prolonged monitoring was needed to establish the diagnosis of OSA) are more likely to have unsuccessful split-night titrations.

An American Academy of Sleep Medicine statement of practice parameters indicates that a split-night paradigm is an alternative to the 2-night diagnostic and therapeutic titration PAP strategy to develop a PAP prescription if the AHI is 40 over a diagnostic study duration of at least 2 h. A split-night study also may be warranted when the AHI is 20–40 in an appropriate clinical context and when PAP titration is conducted over more than 3 h, with elimination or near-elimination of disordered breathing events, including during REM sleep in the supine position [132]. It should be noted that some reimbursement guidelines mandate that the diagnostic study duration be at least 2 h *of sleep*. Clinicians should take care to check on local and current guidelines in this regard. Recent studies have also indicated that the split-night-PSG strategy and the traditional 2-night paradigm provide similar benefits, but the former is associated with lower cost [155, 156]. In addition, split-night studies may reduce the waiting time for initiation of therapy [157].

Home CPAP Titration

Some investigators have advocated in-home initiation of CPAP therapy employing both attended monitoring and unattended/unmonitored titrations [158, 159]. Waldhorn and Wood described titration of CPAP by a technologist in the patient's home using a portable 4-channel monitor recording heart rate, chest wall movement, CPAP pressure in the mask, and oxyhemoglobin saturation to guide CPAP adjustment [159]. The authors reported elimination of apneas, hypopneas, and snoring, but this was assessed by the 4-channel

monitor and not polysomnography. Self-reported adherence to CPAP therapy in this group of 17 patients was an average of 7.23 ± 1 h (mean ± standard deviation [SD]) per night, which is at least comparable to values obtained by conventional in-laboratory titration. Coppola and Lawee [158] reported their experience with unattended home CPAP titration in which 11 patients had increases in CPAP level in response to telephone interviews between the clinician, patient, and bed partner that revealed persistent snoring, apnea observed by the bed partner, and/or symptoms consistent with OSA. Good subjective outcome was reported in these studies, but the absence of objectively assessed adherence (which was unavailable at the time of these studies) is a significant limitation of these data.

Whether or not attended, in-home titration provides a cost-effective and efficient alternative to in-laboratory methodology remains to be determined, but clearly, committing a technician to spend a night monitoring one titration constitutes a measurable utilization of resources. In addition, the applicability of this paradigm across all home environments and social conditions, as well as for patients without bed partners, remains to be determined.

Use of Predictive Formulas to Estimate or Establish the CPAP Pressure Prescription

A CPAP prescription consists of the pressure that maintains satisfactory upper airway patency and oxyhemoglobin saturation during sleep, while providing satisfactory sleep continuity using a interface that is well-tolerated by the patient. Several investigators have suggested that the requisite level of CPAP can be estimated with sufficient clinical accuracy to obviate the need for monitored titration, thus providing a starting point at which titration may begin either in the monitored environment, in order to maximize the time available to "fine-tune" the final pressure prescription, or in the home setting, with further adjustments made on the basis of clinical guidelines or the results of home diagnostic evaluation [160–162]. Miljeteig and Hoffstein [158] reported that the three variables that best predicted the minimal therapeutic CPAP level (defined as that which reduced the AHI to <10) were body mass index (BMI), AHI, and neck circumference. In a subsequent data set from 129 patients, reported in the same paper, the minimal CPAP predicted from this equation was 8 ± 2.1 cm H_2O and the value obtained during laboratory titration was 8.1 ± 3 cm H_2O (mean ± SD). Seventy-one percent of patients had predicted values within 2.5 cm H_2O of the measured values, and 95 % had predicted CPAP levels within 5 cm H_2O of the measured values. The investigators indicated that their predictive equation may not be applicable to all patients due to variability in individual responses to a given level of CPAP.

In a subsequent study of 26 patients, Hoffstein and Mateika prospectively tested the predictive value of the previous equation [161]. For the group as a whole, there was no significant difference between the predicted and the polysomnographically titrated optimal CPAP levels defined as the lowest titrated pressure at which the AHI was less than 10. In 38 % of patients $CPAP_{predicted} = CPAP_{optimal}$; in 38 % of patients, $CPAP_{predicted}$ was within 1 cm H_2O of $CPAP_{optimal}$; in 15 % of patients, $CPAP_{predicted}$ was within 2 cm H_2O of $CPAP_{optimal}$; and in 8 % of patients, $CPAP_{predicted}$ was >2 cm H_2O of $CPAP_{optimal}$. In general, $CPAP_{predicted}$ underestimated $CPAP_{optimal}$, although $CPAP_{predicted}$ was grossly inaccurate in 8 % of the patients, being too high in one and too low in the other. It is important to recognize that the criteria for defining effective CPAP level did not include elimination of respiratory effort–related arousals, as may be seen in the upper airway resistance syndrome [163].

In an open randomized trial, Hukins examined prescription of a CPAP level based on the patient's BMI with that established during a polysomnographic titration [162]. In the formulaic group, CPAP was initially prescribed at 8 cm H_2O if the BMI was <30, 10 cm H_2O if the BMI was between 30 and 35, and 12 cm H_2O was prescribed if the BMI was 35 or more. If the patient could not tolerate the prescribed pressure, it was decreased. The pressure was increased if there was persistent sleepiness or snoring. The formulaic pressure was slightly but significantly higher than that established by polysomnographic titration (13 ± 2 vs. 11.8 ± 2.4 cm H_2O, $p = 0.04$). A sleep study was done after 3 months. Sleep efficiency was greater in the formulaic group, with comparable AHI and Arousal Index as well as percent slow-wave sleep and REM sleep. After 3 months, the polysomnographically prescribed pressure group tended to have a lower Epworth Sleepiness Scale score than the formulaically prescribed group (6.9 ± 3.6 vs. 9.2 ± 5.6, $p = 0.07$), but there was no difference in discontinuation of therapy, adherence, or quality of life as reflected by the SF-36. The average time to initiation of therapy was notably shorter in the formulaically prescribed group. Hukins concluded that the formulaic prescription strategy could be used when there would be an untoward delay in initiating CPAP treatment were the prescription to be developed through in-laboratory polysomnographic titration. Assessment of comparability of the two prescription strategies past the 3-month milestone remains to be done.

Along similar lines, a randomized, single-blind 5-week crossover trial compared a CPAP prescription based on an in-laboratory polysomnographic titration, determining a CPAP level that remained unchanged, and a prescription that was initially based on the formula described by Hoffstein et al. [161], with subsequent patient self-titration according to perception of effectiveness and comfort [164]. Participants

were provided with information regarding the indication for and how to adjust CPAP as well as interfaces. There was no difference between the two prescription strategies with regard to adherence, quality of life using disease-specific instruments, perceived sleepiness, and objective ability to maintain wakefulness under soporific conditions. The CPAP that was identified by patients to be optimal during the self-adjusting study arm was 10.1 ± 2.0 cm H_2O (mean ± SD) compared with the 9.7 ± 2 cm H_2O that was determined during the polysomnographic titration arm. On average, over the 5 weeks in the self-titrating arm of the study, patients made 5.7 changes in the CPAP level from the initial level determined according to formula. The investigators concluded that establishing an initial CPAP prescription using a formula with subsequent patient adjustment is as effective as more conventional methods and may enhance the efficiency with which limited resources are utilized. It should be noted that the duration of this study was only 5 weeks in each arm. Moreover, as the investigators indicated, this strategy may only be applicable in patients with an understanding of the self-titrating instructions and the ability to adjust their own CPAP devices. Clearly, regardless of the method employed to establish the PAP prescription, patient education and follow-up remains an essential element.

Use of APAP Devices

The general principles and use of APAP in the context of adherence have been previously discussed in this chapter. One potential venue for APAP is application in the sleep laboratory with subsequent examination of the data to identify a single "best" level of CPAP to prescribe for chronic therapy with a "fixed" CPAP device (e.g., the value at or below which the pressure is during 90 % of the study, or $CPAP_{90\%ile}$). This would enable titration in an attended environment but without obligating the technologist to manually adjust the level of CPAP. Thus, the technologist's responsibility would de-intensified, perhaps permitting a lower technologist-to-patient ratio (with resultant reduction in cost). Alternatively, in-laboratory titration may be bypassed and the patient sent home on an autotitrating device for a short period to establish the $CPAP_{90\%ile}$ on which a fixed-pressure CPAP device may be prescribed. Finally, the patient may simply be provided with an autotitrating device to use at home in the autotitrating mode.

In a randomized controlled study of 360 OSA patients, Masa et al. [165] compared standard polysomnographic titration with a formula-based prescription [160] and APAP. The evaluative period was 12 weeks. In the formula-based prescription group, the pressure could be increased by 1–2 cm H_2O if the patient's bed partner noted snoring or apnea, after which an "optimal" pressure was deemed to have been identified. There was no difference across the groups with regard to withdrawals. The autotitrating group had a lower response on the SF-36 physical and the EuroQuality of Life Scale than the standard titration group, but there was no difference between the improvement in the formula-based group and the standard titration group. There were no differences among the groups with regard to adherence, side effects, and complaints. The investigators concluded that titration of CPAP can be accomplished with an APAP device or in a paradigm using a predictive formula to establish an initial pressure prescription. It should be noted that this study excluded patients with chronic illnesses or conditions such as cancer, chronic pain, renal failure, moderate or greater chronic obstructive pulmonary disease, substance addiction, and CSB; individuals who had a previous uvulopalatopharyngoplasty; those without a partner; patients with "important" chronic nasal obstruction; and those who lacked sufficient skill in adjusting a nasal mask. Whereas the observations of Masa et al. [165] are of considerable interest, the numerous clinical exclusions reduce generalizability to a measurable proportion of OSA patients seen in sleep disorders centers at this time.

More recently, in a study similar to that of Masa et al., West et al. [166] compared 6 months of APAP; initial application of APAP to identify the $CPAP_{90\%ile}$, which was used to provide a fixed-pressure CPAP prescription; and a CPAP prescription based on neck circumference and the frequency of dips in oxyhemoglobin saturation during baseline sleep. Individuals were not excluded from this study based on comorbidities. At 6 months, data were available in 86 of the 98 randomized patients. The investigators observed that, after 6 months, there was no difference among the groups with regard to the hours used per night, Epworth Sleepiness Scale score, objective ability to maintain wakefulness, 24-h ambulatory blood pressure, health assessed using the SF-36, and the Sleep Apnea Quality of Life Index. The investigators concluded that more complicated treatment initiation and maintenance strategies using APAP offered no benefit to patients over a simpler, formula-based prescription strategy.

In summary, APAP has evolved as a technology, and is now considered an acceptable alternative to fixed-pressure CPAP prescribed on the basis of a sleep laboratory based titration. Treatment of patients with APAP left in the auto mode is commonplace. Some practitioners prefer to use APAP to determine a 90 or 95 % pressure level and use that pressure level in a fixed-pressure mode. Patient and clinician preference should determine which approach will be used for a given patient.

Effect of Positive Airway Pressure Therapy of OSA on Systemic Disorders

Effect of PAP Therapy on Cardiovascular Mortality in OSA Patients

As noted earlier in this chapter, several studies have documented increased cardiovascular mortality in OSA patients, with reduction following initiation of and subsequent adherence to PAP therapy [118, 167, 168]. Although these studies were not randomized controlled trials comparing the effects of PAP therapy with sham PAP, the results are reasonably compelling. In this light, Peker and colleagues [169] assessed incident cardiovascular events in middle-aged men with OSA over 7 years and noted that the incidence of cardiovascular events in patients who were adequately treated (by PAP, uvulopalatopharyngoplasty, or oral appliances) was about 7 % in contrast to about 57 % in patients who were inadequately treated.

Observations regarding the effect of PAP in patients with OSA should not be generalized to patients with central sleep apnea or CSB in conjunction with heart failure. A multicenter, randomized controlled trial of CPAP versus no CPAP in patients with central sleep apnea and heart failure associated with reduced left ventricular (LV) function was stopped early due to relatively higher mortality in the group receiving CPAP compared with the group not receiving CPAP, over the first 18 months of participation in the study [170]. It should be noted that after the initial 18 months, survival was better in the group receiving CPAP. Over the entire duration that the study was being conducted, there was no difference in transplant-free survival between the groups. The authors speculated that the early mortality in the group receiving CPAP may have been attributable to the effects of PAP in the clinical context of relative intravascular volume depletion. They concluded that CPAP is not indicated to improve transplant-free survival in heart failure patients with central sleep apnea.

Effect of PAP Therapy on Cardiac Rhythm Disturbances in OSA Patients

Cardiac rhythm disturbances are common in OSA patients [171–178]. There are several potential mechanisms through which OSA predisposes to rhythm disturbances, including sleep-related changes in sympathovagal balance as well as alteration in sympathetic nervous system activity in conjunction with sleep-disordered breathing events, changes in QT interval, hypoxemia, and the influence of carotid chemosensitivity [179–183]. The favorable response of arrhythmias to CPAP therapy, especially in the absence of structural heart disease, reinforces the linkage between OSA and rhythm disturbances [173, 175, 184–186]. A recent randomized controlled trial reported that, after 1 month, CPAP therapy reduces the frequency of premature ventricular beats by nearly 60 % in OSA patients with heart failure compared to patients who are not receiving CPAP, in whom there was no significant change [186]. The authors acknowledged that, despite randomization, the group receiving CPAP had less severe OSA at baseline. The importance of this study is highlighted by recognition that sleep [179–181] and OSA have been associated with increased QT interval and increased dispersion, which may predispose to serious and potentially fatal arrhythmias especially in the setting of ventricular irritability. In contrast to these studies, one study reported bradyarrhythmias (pauses >3 s and episodes during which heart rate was <40 beats/min) were more responsive to CPAP therapy than supraventricular arrhythmias [175]. The effect on ventricular tachyarrhythmias was not reported.

In summary, it is evident that nocturnal cardiac rhythm abnormalities are prevalent in patients with OSA and treatment with PAP often has an ameliorative effect on them. Clinical judgment is necessary to determine if other immediate interventions (e.g., reduction or elimination of β blockade in the case of bradyarrhythmias, antiarrhythmic medication, pacemaker) are indicated. Moreover, careful follow-up assessment is essential to determine if additional interventions are required.

Effect of PAP Therapy in OSA Patients with Heart Failure

A number of studies support the improvement in LV function after initiation of PAP therapy for patients with OSA and heart failure [167, 187–191]. The mechanisms by which PAP may improve LV function in OSA patients with heart failure include relief of sleep-related hypoxemia, elimination of cyclic increases in LV afterload, reduction in sympathetic nervous system activation [188, 192, 193], and reduced inflammation. Kaneko et al. [190] observed that OSA patients with a notably reduced LV ejection fraction at baseline experienced a significant improvement after one month of CPAP therapy (an average increase of approximately 8 % for the group). These observations were reinforced by Mansfield et al. [191], who conducted a randomized trial comparing a group of OSA patients with heart failure who were treated with CPAP for three months and a group who did not receive CPAP therapy. The group receiving CPAP experienced an improvement in LV ejection fraction by about 5 %, while the group who did not receive CPAP had an increase of approximately 1.5 % (Fig. 34.6). There was no change in systemic blood pressure during CPAP application to explain the beneficial effects, but there was a reduction in overnight urinary norepinephrine excretion, consistent with reduced sympathetic activity in the

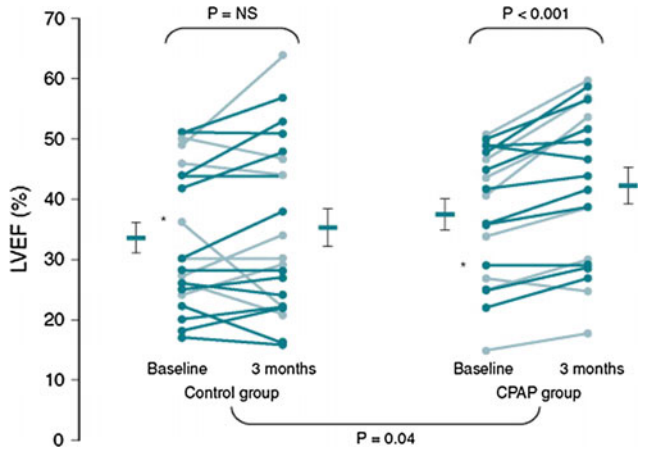

Fig. 34.6 Change in left ventricular ejection fraction over 3 months in OSA patients who were not (*left*) and who were (*right*) treated with CPAP. The *asterisk* indicates patients who were in atrial fibrillation at the indicated point in time (Reproduced with permission from Mansfield et al. [191])

group receiving CPAP. Although this trial did not apply a placebo or sham CPAP control, the consistent results with other studies as well as other aspects of the design support the credibility of the results.

In summary, LV dysfunction in OSA patients may be improved by PAP therapy of sleep-disordered breathing.

Effect of PAP Therapy in OSA Patients with Hypertension

Epidemiologic studies have provided compelling evidence that OSA is associated with increased risk for systemic hypertension (HTN) [194–200]. Sleep apnea has been identified by the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure as a risk factor for HTN [201]. Although it is plausible that PAP therapy would ameliorate diurnal HTN by eliminating intermittent hypoxic exposure and sympathetic nervous system activation, and improve sleep continuity [192, 202–210] the literature provides conflicting data in this regard.

Using a randomized, placebo-controlled design to compare ambulatory blood pressure on CPAP and sham CPAP in subjectively sleepy (Epworth Sleepiness Scale score > 9) OSA patients, Pepperell et al. [211]. observed a small but significantly greater reduction in mean blood pressure during sleep in the active CPAP–treated group (93.7 ± 1.6 and 90.3 ± 1.4 mm Hg before and after one month of active CPAP, respectively; 96.2 ± 1.6 and 95.8 ± 1.5 mm Hg before and after one month of sham CPAP) and during wakefulness in the active treatment group (104.3 ± 1.3 and 101.9 ± 1.3 mm Hg before and after 1 month of active CPAP, respectively; 104.2 ± 1.4 and 106.1 ± 1.4 mm Hg before and after one month of sham CPAP). Although small, the reduction in blood pressure in the active CPAP group would have a notable public health impact on cardiovascular risk. A post hoc analysis however suggested that individuals in whom CPAP use reduced the AHI below 15 may experience improved left ventricular function and heart transplant-free survival time [211].

Similarly, in a randomized sham CPAP controlled trial in individuals with moderate to severe OSA, including notable oxyhemoglobin desaturation, Becker et al. [212] observed a reduction in mean blood pressure by approximately 10 mm Hg after about 9 weeks of active CPAP therapy, while no change was observed in the group receiving sham CPAP (Fig. 34.7). The observation of Becker et al. [213–215] may be the more noteworthy since the sham CPAP was associated with some improvement in OSA. Conversely, there are a number of well-designed studies of groups of OSA patients either with or without subjective sleepiness, and with HTN, that have failed to demonstrate a significant reduction in blood pressure with PAP therapy (Fig. 34.8).

In summary, it is evident that further research is required to define the effect of PAP on HTN in OSA patients. For example, a small case series of OSA patients with medically refractory HTN received benefit from CPAP in this regard [216]. Perhaps the heterogeneity of the data with respect to the effect of PAP on HTN should not be surprising. Hypertension is probably heterogeneous in etiology and duration, with varying degrees of vascular remodeling also potentially influencing therapeutic responsiveness. There may be subsets of hypertensive OSA patients with greater likelihood of deriving blood pressure improvement from PAP therapy, and identifying these patients is a challenge for the future.

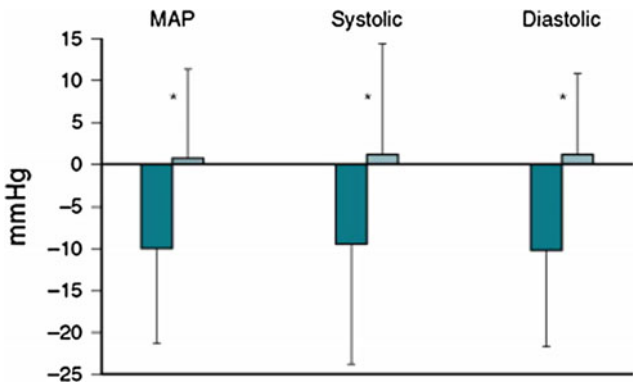

Fig. 34.7 Change in blood pressure in OSA patients receiving active CPAP (*closed bars*) and sham CPAP (*open bars*). Difference in mean arterial pressure (MAP) $p = 0.01$; systolic pressure, $p = 0.04$; diastolic pressure, $p < 0.005$. (Reproduced with permission from Becker et al. [212])

PAP Therapy and Stroke

The association between sleep-disordered breathing, including OSA, and increased risk for stroke is increasingly recognized. Data from the Wisconsin Sleep Cohort indicate that, even after adjusting for age, gender, smoking, HTN, alcohol use, and BMI, sleep-disordered breathing is associated with increased risk for prevalent stroke [217]. There was also a suggestion of an association between sleep-disordered breathing and incident stroke, but this did not reach statistical significance, perhaps due to the study being underpowered to address this issue. Of comparable importance, sleep-disordered breathing following a stroke is a poor prognostic indicator of survival and function [218–223].

In a longitudinal observational cohort study, Yaggi et al. [221] reported the risk of first-time incident stroke or death from any cause over a median follow-up period of 3.4 years in OSA patients (mean AHI = 35) >50 years old compared with non-OSA patients (mean AHI = 2). There were 22 strokes in the OSA group and 2 strokes in the non-OSA group during the study interval. For the composite event of stroke or death, the probability of event-free survival was significantly less in the OSA group. These investigators observed a significant trend for increasing risk of stroke or death from any cause as the AHI increased, with the risk being threefold greater in OSA patients with AHI > 36 compared with the non-OSA group. OSA remained significantly associated with first-time incident stroke and death from any cause, even after adjusting for gender, race, age, smoking status, alcohol ingestion, BMI, and the presence of diabetes mellitus, hyperlipidemia, atrial fibrillation, and HTN. There are several limitations of this study. The study population was substantially male and Caucasian, an analysis of the probability of incident stroke alone in individuals with and without OSA was not performed, and the degree to which OSA was independently associated with first-time incident stroke (not combined with death from any cause) was not assessed. In addition, many of the participants in this study were prescribed treatment for OSA, and this factor, as well as adherence, was not assessed. It is therefore possible that first-time incident stroke and death from any cause were underestimated. The data are consistent with previous cross-sectional studies independently associating OSA with cardiovascular disease and death and therefore add to the concern regarding adverse outcomes from this disorder.

Consequently, the outcome of PAP therapy for sleep-disordered breathing following stroke is of substantial interest. This is a difficult issue to address, and the results of randomized placebo-controlled trials have not, to our knowledge been published. Martinez-Garcia et al. [224] observed that patients noted to have OSA following a first stroke and who were adherent to CPAP therapy had a significantly lower incidence of a second event compared to patients who were intolerant of CPAP. Of course, the possibility that the intolerant group were burdened by an unidentified additional risk for another cerebrovascular event cannot be excluded. Two randomized trials of CPAP versus no-CPAP therapy observed no benefit from CPAP therapy for severe OSA following stroke [225, 226], with the exception of improved depressive symptoms in the CPAP group in one of these studies [226]. Thus, to date studies provide conflicting data regarding the outcome of PAP therapy following stroke. However, a common theme is that there is a greater degree of nonadherence in these patients [149, 225, 226]. Altered cognitive function is probably at least partially responsible for the notable nonadherence in this population [226]. Further studies are required to

determine if PAP therapy of OSA reduces risk for incident stroke and to define patient groups who may benefit from PAP. If there are stroke patients who will benefit from PAP therapy, research is required to define specific measures and programs that will promote adherence.

PAP Therapy of Abnormal Glycemic Control and Type 2 Diabetes Mellitus

There is increasing awareness of the association between OSA, abnormal glycemic control, type 2 diabetes mellitus, and other features of the metabolic syndrome [227–234]. Since insulin resistance, the metabolic syndrome, and diabetes are known risk factors for cardiovascular disease, if causation is established between OSA and these metabolic perturbations, the former would provide an attractive interventional target through which the burden of cardiovascular disorders could be reduced. Interventional studies provide one avenue to determine if OSA contributes to abnormal glycemic control. Only limited data are currently available. Utilizing a hyperinsulinemic euglycemic clamp to assess insulin sensitivity, Brooks et al. [235] demonstrated that four months of CPAP therapy increased insulin sensitivity in very obese OSA patients with noninsulin dependent diabetes. This did not translate into improved fasting glucose, and the authors speculated that the effect of the substantial obesity in the subject population and residual severe insulin resistance masked translation of increased sensitivity to improved glycemic control. Along these lines, Harsch et al. [236] demonstrated that insulin sensitivity increased in nondiabetic OSA patients following three months of CPAP therapy, with the greatest response occurring in individuals with BMI < 30. More recently, Babu et al. [237] reported that diabetic patients with generally moderate or severe OSA who are adherent to CPAP, with use for >4 h/day, have a progressive reduction in hemoglobin A_{1c} (HbA_{1c}) over time after initiation of PAP therapy. No such effect was observed in patients who used CPAP < 4 h/day. Furthermore, the reduction in HbA_{1c} was greatest in those patients with baseline values >7 %. A strength of the study was that no adjustment of medication was permitted during the study interval. However, this was not a randomized trial, and data regarding weight at baseline at the end of the study interval were not described. Thus, the results should be taken in light of these limitations.

In summary, the data are far too limited to permit conclusions regarding the likelihood that PAP therapy of OSA will improve insulin sensitivity and glycemic control, independent of other factors. However, existing information provides cautious encouragement that, at least in less obese patients, treatment of OSA will confer metabolic benefit and perhaps downstream reduced cardiovascular risk. Moreover, a recent randomized controlled trial reported no difference between three months of active versus placebo CPAP with regard to insulin resistance or glycosylated hemoglobin in obese (mean BMI approximately 36) men with type 2 diabetes and OSA [238].

Summary

PAP constitutes a safe and effective treatment for OSA. There have been substantial modifications and developments over the last 25 years in an effort to provide greater patient comfort with regard to interface and modality. In addition, different modalities of PAP have been developed to better address subsets and nuances of sleep-disordered breathing. Notably, randomized controlled trials have demonstrated efficacy of PAP therapy in improving patients' perception of daytime function, and other studies have provided compelling evidence for improved outcomes with respect to systemic disorders, including but not limited to LV function and cardiac rhythm disturbances in OSA patients. Nonetheless, further work is required to identify the best target threshold for patient adherence, identify and address those factors that impede optimal adherence, and identify those subsets of patients who are most likely to obtain benefits from this form of treatment.

Sleep medicine has come a long way since the days when tracheotomy or no therapy was the only treatment options that caregivers could offer their OSA patients.

Preoperative, Perioperative, and Postoperative Evaluation and Management of Sleep-Disordered Breathing

35

Edwin Seet and Frances Chung

Introduction

Sleep-disordered breathing constitutes an important public health issue. The economic cost of sleep-disordered breathing is considerable [1]. Sleep and anesthesia are inextricably linked. An appreciation of sleep physiology is critical to the understanding of the effects of anesthesia induced state of unconsciousness. Furthermore, sleep-disordered breathing has a significant impact on the perioperative surgical patient. The perioperative patient under anesthesia is vulnerable to the effects of arousal suppression and under the watchful protection of the anesthesiologists; it is the therefore also the responsibility of the perioperative physicians to ensure the return of the patients' protective responses in the postanesthesia recovery period. The subsets of sleep-disordered breathing influencing the use of anesthesia would include the following: obstructive sleep apnea (OSA), obesity hypoventilation syndrome, and central sleep apnea [2]—of which OSA is the preeminent and most pertinent.

Obstructive sleep apnea is caused by repetitive partial or complete obstruction of the upper airway, characterized by episodes of breathing cessation lasting more than 10 s during sleep. A consequence of this obstruction and oxyhemoglobin desaturation would be recurring arousals from sleep to restore airway patency, leading to increased sympathetic output, daytime hypersomnolence, memory loss, and executive and psychomotor dysfunction [3].

In this chapter, the authors propose stepwise algorithms based on available evidence from the published literature pertaining to the preoperative, perioperative, and postoperative management of patients suspected or diagnosed of sleep-disordered breathing. In those instances where peer-reviewed evidence is lacking, recommendations are made based on opinion and/or consensus. The algorithms suggested here serve as guides for the perioperative physician. Clinician discretion for the individual patient at the bedside is paramount and should take into account patient-specific and circumstantial factors [4].

OSA Prevalence, Associated Comorbidities, and Perioperative Complications

Obstructive sleep apnea is the most common sleep-disordered breathing disorder affecting 17 % of men and 9 % of women aged between 50 and 70 years [5]. Despite its prevalence, more than half of the patients with OSA were unrecognized and undiagnosed at the time of surgery, putting these patients at increased risks of perioperative and postoperative adverse events [6, 7]. Anesthesiologists and surgeons failed to identify significant number of patients with both preexisting OSA and symptomatic undiagnosed OSA prior to surgery [7]. A similar conundrum is seen even in the context of ambulatory surgery [8].

Obstructive sleep apnea is associated with myocardial ischemia, heart failure, hypertension, arrhythmias, cerebrovascular disease, metabolic syndrome, insulin resistance, gastroesophageal reflux, and obesity (Table 35.1). The prevalence of OSA was 78 % in morbidly obese patients planned for bariatric surgery [9]. Various craniofacial deformities (e.g., macroglossia, retrognathia), endocrine diseases (e.g., hypothyroidism, Cushing disease), demographic (male, age above 50 years), and lifestyle factors (e.g., smoking, alcohol consumption) predispose to OSA [10]. Perioperative physicians should be aware of the possible coexistence of these medical conditions—for the purpose of diagnosis, optimization, and risk stratification prior to the scheduled surgery.

In large population studies, unrecognized and untreated OSA has been associated with higher risks of all-cause

mortality, myocardial infarction, stroke, heart failure, and arrhythmia [11–16]. In the perioperative period, a meta-analysis by Kaw et al. which included 13 studies with 3942 patients showed that the presence of OSA significantly increased the odds of postoperative desaturation (odds ratio 2.3), respiratory failure (odds ratio 2.4), reintubations (odds ratio 2.1), cardiac events including myocardial infarction, cardiac arrest and arrhythmias (odds ratio 2.1), and intensive care unit transfers (odds ratio 2.8) [17]. A more recent large surgical cohort study including 14,962 patients noted that patients who had a diagnosed history of OSA and those who screened at high risk of having OSA on OSA screening tools (e.g., STOP-Bang, STOP questionnaires, Flemons) were associated with critical care admission postoperatively and at an increased cumulative one-year mortality [6].

In the context of a strong association between OSA and adverse perioperative outcomes, prudent risk mitigation strategies and perioperative precautions should be undertaken to reduce adverse events in the vulnerable surgical patients with a suspicion or diagnosis of sleep-disordered breathing.

Classical Diagnostic Criteria of OSA

The gold standard definitive diagnosis of OSA requires an overnight polysomnography reporting the Apnea Hypopnea Index (AHI). The AHI is defined as the average number of abnormal breathing events per hour of sleep. Apnea refers to airflow cessation for at least 10 s and hypopnea occurs when there is reduced airflow with desaturation of ≥ 4 % [18].

The American Academy of Sleep Medicine criteria for OSA diagnosis requires either an AHI ≥ 15, or AHI ≥ 5 with symptoms, such as excessive daytime sleepiness, unintentional sleep during wakefulness, unrefreshing sleep, loud snoring reported by partner, or observed obstruction during sleep [19]. The Canadian Thoracic Society guidelines for the diagnosis of OSA specifies the presence of an AHI ≥ 5 and either of (1) daytime sleepiness not attributable to other factors or (2) at least 2 other symptoms of OSA (e.g., choking or gasping during sleep, recurrent awakenings, unrefreshing sleep, daytime fatigue, or impaired concentration) [20]. The AHI also determines the severity of OSA. OSA is mild for AHI ≥ 5–15, moderate for AHI 15–30, and severe for AHI >30 [19].

Principles of Perioperative Evaluation and Management of OSA Patients

In an attempt to improve the perioperative care for OSA patients, various authors have constructed guidelines or clinical pathways [21–24, 10]. The authors of this chapter would like to propose and update functional algorithms for the preoperative, perioperative, and postoperative

management of sleep-disordered breathing, in particular for suspected and diagnosed patients with OSA [10].

Preoperative Evaluation of the Patient with Diagnosed OSA

During the preoperative clinical consultation, a relevant history of OSA symptomatology should be elicited, followed by a physical examination. Cardiopulmonary examination should be focused at eliciting signs of congestive heart failure (rales, S3, jugular venous congestion) and pulmonary hypertension (right ventricular heave, loud P2). Previous polysomnography results should be reviewed to confirm the diagnosis of OSA and evaluate the severity of the disease (Fig. 35.1).

Patients with long-standing OSA may present with a plethora of clinical signs and symptoms signifying the development of systemic complications, such as hypoxemia, hypercarbia, polycythemia, and cor pulmonale. The presence of significant comorbidities should be determined, especially morbid obesity, uncontrolled hypertension, arrhythmias, cerebrovascular disease, heart failure, and metabolic syndrome.

Obesity hypoventilation syndrome occurs in 0.15–0.3 % of the general population [25]. Pulmonary hypertension may complicate long-term untreated OSA, occurring in 15–20 % of patients [26]. Pulmonary hypertension is important in the perioperative period as certain physiological derangements may raise pulmonary artery pressures further and should be avoided intraoperatively. The American College of Chest Physicians does not recommend routine evaluation for pulmonary arterial hypertension in patients with known OSA [27]. Should there be anticipated perioperative triggers for acute elevations in pulmonary arterial pressures (e.g., high-risk surgical procedures of long duration), a preoperative transthoracic echocardiography may be considered [21]. The indication for additional testing of the cardiovascular system would be contingent on the surgical risk factors, active cardiac conditions, clinical cardiac risk factors, and the patients' functional capacity as per guidelines from the American Heart Association [28].

Bedside oximetry to determine baseline oxygen saturation and serum bicarbonate levels would be useful in risk

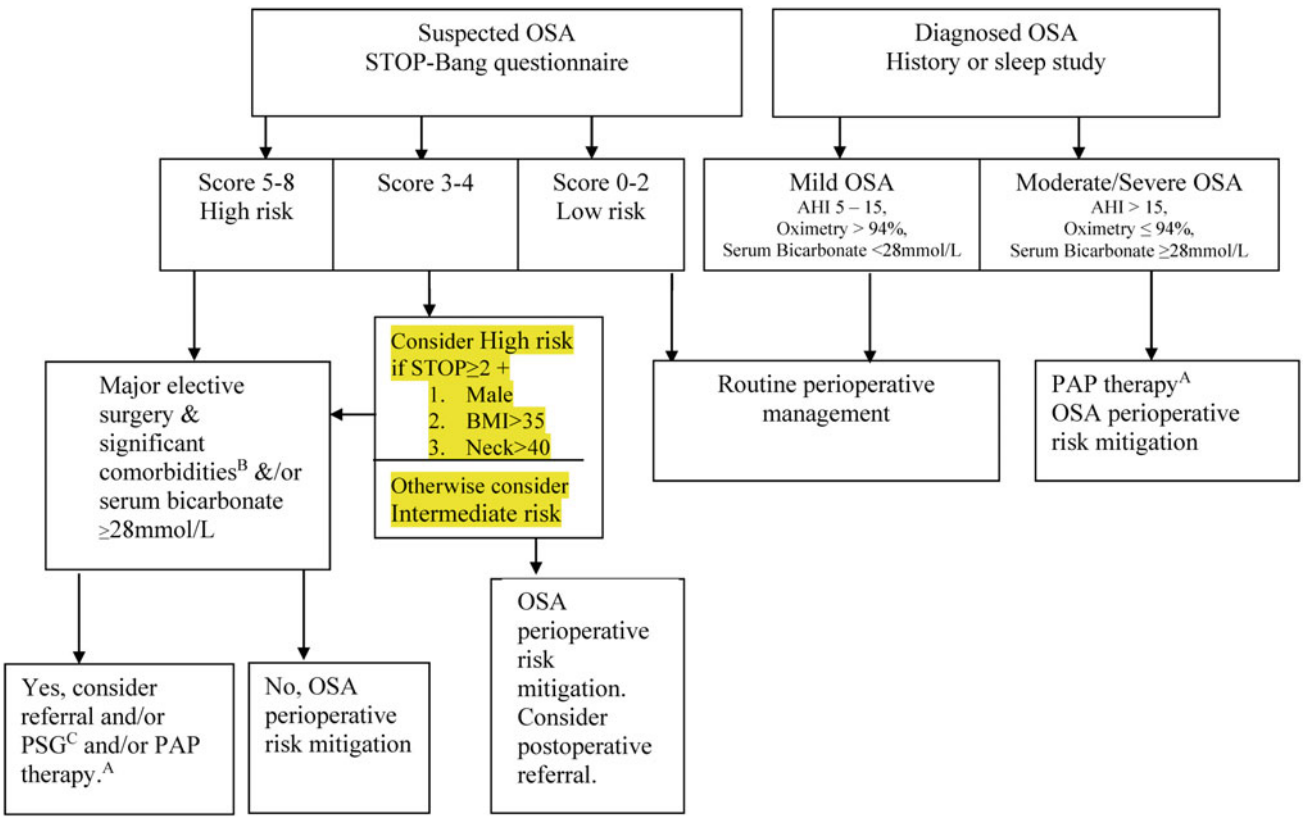

Fig. 35.1 Preoperative Evaluation of Diagnosed or Suspected Obstructive Sleep Apnea Patients. [A]Positive airway pressure (PAP) therapy—includes continuous PAP, bilevel PAP, and automatically adjusting PAP. [B]Significant comorbidities—heart failure, arrhythmias, uncontrolled hypertension, pulmonary hypertension, cerebrovascular disease, metabolic syndrome, obesity BMI >35 kg/m^2. [C]PSG (polysomnography)—includes level 1 to level 4 in-laboratory and portable polysomnography devices. Adapted from Seet and Chung [82]

stratifying the OSA patients (Fig. 35.1). In the absence of coexisting respiratory problems that may contribute to low baseline oxygen saturation, an oximetry reading of ≤ 94 % on room air is a red flag for severe long-standing OSA [29–31]. A raised serum bicarbonate level of 28 mmol/L or more may also be a harbinger for OSA with hypercapnia and may foreshadow perioperative and postoperative adverse events [32–34, 35].

Obstructive sleep apnea patients may be on positive airway pressure (PAP) therapy in the form of continuous PAP or bilevel PAP. These devices may have an automatically adjusting element which provides respiratory assistance based on airflow measurements, fluctuations in pressure, or airway resistance. The updated PAP therapy settings should be obtained. The OSA patients' compliance to the PAP therapy should be assessed. Indications for a reassessment by the sleep medicine physician would include patients who have defaulted follow-up, those non-compliant to PAP treatment, those who have experienced recent exacerbation of OSA symptoms, or those who have since undergone upper airway surgery. PAP therapy defaulters should be encouraged to resume therapy.

To date, there is insufficient evidence to prove conclusively the benefit of PAP therapy in the perioperative setting. The duration of therapy required to effectively reduce perioperative risks has not been delineated. Of note, a retrospective matched cohort study suggested that preoperative PAP therapy may possibly be beneficial based on the observation that OSA patients who did not use home PAP devices prior to surgery but required PAP therapy after surgery had increased complication rate [36]. Furthermore, a short period of 5 days of PAP therapy has been shown to improve gas exchange and sleep-disordered breathing [37]. Patients with moderate or severe OSA who are already on PAP therapy should continue preoperative PAP therapy prior to surgery [23]. Unfortunately, from an observational retrospective study in the surgical population, PAP therapy adherence was found to be extremely low with only a third of the patients using their PAP devices for more than 4 h per night [38].

The anesthesia team in charge of the patients during the perioperative period should be informed about the patient so that adequate preparation of beds with monitoring and risk mitigation measures may be carried out proactively.

Arising from the Busselton Health Cohort study, mild OSA was not an independent mortality risk entity in the general population [12]. It is still uncertain whether the corollary is true and that mild OSA may not be a significant risk factor for the perioperative surgical patient. Based on opinion, preoperative PAP therapy might not be indicated for mild OSA. Figure 35.1 puts forth an algorithm for the preoperative evaluation and management of the patient already diagnosed with OSA.

Preoperative Screening Tools for Evaluation of Suspected OSA

An in-laboratory level 1 polysomnography is the gold standard [19]. Ideally, all suspected patients of OSA should have a diagnosis made by a formal overnight polysomnography, and it may be the preferred modality if patient has significant comorbidities. However, routine testing with an in-laboratory sleep study is prohibitive when considering the cost, resource-intensity, and preoperative time constraints. OSA screening before surgery is therefore recommended as part of a pre-anesthesia and presurgical plan. Several bedside screening tools have been developed to meet the need for an economical and sensitive OSA screening test. These could include the STOP and the STOP-Bang questionnaires [39, 40], the Berlin Questionnaire [41], the American Society of Anesthesiologists (ASA) checklist [23], the Sleep Apnea Clinical Score [22], the Perioperative Sleep Apnea Prediction (P-SAP) score [42], etc.

The authors recommend the STOP-Bang questionnaire—which is a concise, validated and easy-to-use 8-point dichotomized-acronym (Table 35.2) [43]. Each question is scored based on the answer of "Yes" or "No." Patients with STOP-Bang scores of 0–2 may be considered to be at low risk, 3–4 intermediate risk, and 5–8 high risk of having OSA [39, 40, 29–31]. The STOP-Bang questionnaire has high sensitivity and negative predictive value at the expense of lower specificity, especially for patients with moderate-to-severe OSA [39, 40]. A STOP-Bang score of 0–2 is reassuring as the patient is unlikely to have moderate-to-severe OSA. For moderate OSA (AHI > 15) and severe OSA (AHI > 30), the sensitivity of STOP-Bang score is 93 and 100 %, respectively, while the specificity is 43 and 37 %, respectively [39, 40]. At higher cutoff values for STOP-Bang 5 or greater, the specificity of STOP-Bang questionnaire for severe OSA (AHI > 30/h) was increased to 74–95 % [29–31]. Furthermore, the presence of an increased serum bicarbonate level ≥ 28 mmol/L improves the specificity of the STOP-Bang score in predicting moderate-to-severe OSA [32–34].

An up-to-date study validating the performance of the STOP-Bang in obese and morbidly obese patients reported that for identifying severe OSA, a STOP-Bang score of 4 has high sensitivity of 88 %; and for confirming severe OSA, a score of 6 is more specific [32–34]. Another recent retrospective analysis of over 5000 patients demonstrated that the STOP-Bang score may be used to stratify the need for postoperative critical care; and a score of 6 or more was associated with a fivefold increase in critical care admissions versus a score of 2 or less [44]. In summary, the STOP-Bang questionnaire is useful in the preoperative setting for OSA prediction, triaging patients for confirmatory sleep testing, and excluding those without disease [45].

Table 35.2 STOP-bang: obstructive sleep apnea screening questionnaire

S	**S**noring: Do you snore loudly (louder than talking or loud enough to be heard through closed doors)?	Yes	No
T	**T**ired: Do you often feel tired, fatigued, or sleepy during daytime?	Yes	No
O	**O**bserved: Has anyone observed you stop breathing during your sleep?	Yes	No
P	Blood **P**ressure: Do you have or are you being treated for high blood pressure?	Yes	No
B	**B**MI: BMI more than 35 kg/m^2?	Yes	No
A	**A**ge: Age over 50 years old?	Yes	No
N	**N**eck circumference: Neck circumference greater than 40 cm?	Yes	No
G	**G**ender: Male?	Yes	No

Low risk of OSA Yes to less than 3 questions
At risk of OSA Yes to 3 or more questions
High risk of OSA Yes to 5 or more questions

Preoperative Evaluation of the Patient with Suspected OSA

In any preoperative patients presenting for surgery, a high index of suspicion should be present for undiagnosed OSA. A clinical examination should be performed with emphasis on pertinent symptoms and signs of OSA. The bed partner's presence at the interview would be useful in the assessment of snoring and observed airway obstruction or apnea during sleep. The preoperative evaluation and management of the suspected OSA patient is dependent on the urgency of surgery. In the emergency situations, patients should proceed for surgery without extensive OSA workup. Perioperative risk mitigation measures should be undertaken based on the clinical suspicion of OSA.

Emergency surgery is in contrast to the elective operative setting, where referral to a sleep medicine physician, preoperative sleep studies followed by preoperative PAP therapy may be indicated in a subgroup of patients. An algorithm is suggested in Fig. 35.1. Specific considerations for further preoperative evaluation would include a high pretest probability of OSA based on the STOP-Bang score, the risk from major surgery, the presence of other significant comorbidities suggestive of chronic OSA or other forms of sleep-disordered breathing, and the need of postoperative opioids. These comorbidities include uncontrolled hypertension, heart failure, arrhythmias, pulmonary hypertension, cerebrovascular disease, morbid obesity, and metabolic syndrome. Patients with STOP-Bang score 5 or greater with comorbid diseases scheduled for major elective surgery should be considered for a preoperative assessment by a sleep medicine physician. Major elective surgery may have to be delayed to allow adequate time for preoperative PAP therapy. The eventual decision to evaluate a patient preoperatively should be made based on the clinical judgment of the attending physician, taking into account patient-related, surgical-related, and logistical factors.

A recent retrospective study found that patients at risk of OSA on screening had no significant increase in postoperative complications if managed on the OSA risk management protocol. Proceeding with elective surgery without delay for polysomnography was suggested to be clinically safe [46]. In our algorithm (Fig. 35.1), patients with a STOP-Bang score of 3–4 (intermediate risk of OSA) may proceed with surgery without further preoperative testing. The attending anesthesiologist should undertake perioperative risk mitigation measures. These intermediate risk patients may have difficult airway and/or recurrent postoperative postanesthesia care unit (PACU) respiratory events (desaturation, apnea, pain-sedation mismatch) [39, 40, 47]. Such red flags may warrant a subsequent sleep medicine physician referral cum polysomnography on discharge from the hospital. The STOP-Bang has high negative predictive value; therefore, patients who screen 0–2 are unlikely to have OSA. These patients may proceed with surgery with routine perioperative care (Fig. 35.1).

At present, there is inadequate scientific literature regarding the work-up of the suspected OSA and the preparation for surgery. Research is needed in this area to define the safe and cost-effective pathway.

Home Sleep Testing and Nocturnal Oximetry

Portable polysomnography or home sleep testing can be classified into level 2 (full unattended polysomnography with ≥ 7 channels), level 3 (devices limited to 4–7 channels), and level 4 (1–2 channels including nocturnal oximetry) devices. These may be viable alternatives to a level 1, in-laboratory, fully attended polysomnography. Home sleep testing can successfully identify OSA in 82 % of adult surgical patients [48]. Advantages of limited channel home sleep testing include accessibility, ease of use, potential cost-saving, and the ability to study patients in their

home environment. Portable devices may be considered when there is high pretest likelihood for moderate-to-severe OSA without other substantial comorbidities as suggested by the Portable Monitoring Task Force of the American Academy of Sleep Medicine [49]. The Canadian Thoracic Society recommends that portable monitoring devices may be used as confirmatory tests for the diagnosis and treatment of OSA so long as proper standards for conducting the tests and interpretation of results are met [20]. These devices should be used with caution in patients with comorbid diseases and for the diagnosis of other sleep-disordered breathing besides OSA [20].

In the perioperative context, level 2 multichannel home sleep testing has been shown to have a diagnostic accuracy similar to standard polysomnography [50]. In addition, nocturnal oximetry was found to be both sensitive and specific for detecting OSA in STOP-Bang positive surgical patients, and the oxygen desaturation index derived from nocturnal oximetry correlated well with the AHI obtained from polysomnography [29–31]. However, it should be recognized also that there may exist inconsistencies in how physicians interpret nocturnal oximetry tracings and results [51].

These portable devices are useful surrogates for preoperative OSA detection and diagnosis, especially if an in-laboratory polysomnography is not feasible. These home sleep testing helps with expedient risk stratification of suspected OSA patients, allowing preoperative PAP therapy to be instituted in selected cases, with the intention of reducing perioperative adverse events.

Perioperative Management Strategies for OSA Patients

A variety of perioperative risk mitigation strategies may be employed with the aim of ameliorating adverse outcomes for the suspected and diagnosed OSA patient. These are listed in Table 35.3 and elaborated in the section below. In the night immediately preceding the planned surgery, sedative premedication should be avoided [23]. In addition, preoperative multimodal preventive analgesic regimens may have a beneficial opioid-sparing effect.

Intraoperatively, the quintessential concern of the anesthesiologist would be the difficult airway. OSA is a predictor for difficult mask ventilation [52]. Difficult laryngoscopy and tracheal intubation was found to occur 8 times as often in OSA patients compared to those without OSA. Furthermore, patients with severe OSA showed higher prevalence of difficult intubation compared with those patients with lower AHI [53]. In a recent publication, obesity—which commonly coexists with OSA—was found to be a predictor of failed laryngeal mask airway insertion and ventilation [54]. Advanced planning for intraoperative airway management

Table 35.3 Perioperative Precautions and Risk Mitigation for OSA Patients

Anesthetic concern	Principles of management
Premedication	Avoid sedating premedication Consider alpha-2 adrenergic agonists (clonidine, dexmedetomidine)
Potential difficult airway (mask ventilation, tracheal intubation, and supraglottic airway device)	Optimal positioning (head elevated laryngoscopy position) if patient obese Adequate preoxygenation Consider continuous positive airway pressure preoxygenation Two-handed triple airway maneuvers Anticipate difficult airway. Personnel familiar with a specific difficult airway algorithm
Gastroesophageal reflux disease	Consider proton pump inhibitors, antacids, rapid sequence induction with cricoid pressure
Opioid-induced ventilatory impairment	Minimize opioid use Use of short-acting agents (remifentanil) Multimodal approach to analgesia (NSAIDs, acetaminophen, tramadol, ketamine, gabapentin, pregabalin, dexmedetomidine, clonidine, dexamethasone, melatonin) Consider local and regional anesthesia where appropriate
Carryover sedation effects from longer acting intravenous and volatile anesthetic agents	Use of propofol/remifentanil for maintenance of anesthesia Use of insoluble potent anesthetic agents (desflurane) Use of regional blocks as a sole anesthetic technique
Excessive sedation in monitored anesthetic care	Use of intraoperative capnography for monitoring of ventilation
Postextubation airway obstruction	Verify full reversal of neuromuscular blockade Extubate only when fully conscious and cooperative Non-supine posture for extubation and recovery Resume use of positive airway pressure device after surgery

Adapted from Seet and Chung [82]

with alternative intubation strategies in accordance with difficult airway algorithms would be prudent [55].

Preoxygenation using continuous PAP 3–5 min with a head-up tilt has been suggested to achieve higher end-tidal concentration of oxygen. This prolongs the time to desaturation [56]. Two-handed mask ventilation may be needed to attain adequate ventilation. OSA patients with obesity may benefit from being positioned in the head elevated laryngoscopy position to achieve optimal alignment for direct laryngoscopy and tracheal intubation [57]. The use of video laryngoscopes may increase intubation success and reduce intubation times compared to the traditional direct laryngoscope [58].

Gastroesophageal reflux disease secondary to hypotonia of the lower esophageal sphincter is common among patients with OSA [59]. Proton pump inhibitors, antacids, rapid sequence induction, and intubation with cricoids pressure may be considered to decrease aspiration risk. Several of the anesthetic agents result in respiratory depression, such as volatile agents, benzodiazepines, neuromuscular blockers, and most importantly opioids. OSA patients suffer from chronic sleep deprivation and have blunted responses to hypercarbia and hypoxia. These lead to increased sensitivity to the respiratory depressant effects of anesthetic agents. There may be benefits from the use of short-acting anesthetic agents, including propofol, desflurane, and remifentanil.

Opioid-induced ventilatory impairment (OIVI) may be described as central respiratory depression, decreased conscious level, and upper airway obstruction secondary to opioid administration, with the consequence of alveolar hypoventilation. OSA patients are more susceptible to this entity of OIVI. Patients with OSA who received opioids postoperatively were 12–14 times more likely to desaturate compared to those who were given non-opioid analgesic agents [60]. Perioperative opioid-sparing analgesics are therefore recommended. This would include multimodal analgesic agents such as NSAIDs, COX-2 inhibitors, paracetamol, and tramadol. Other novel adjuvants such as pregabalin, gabapentin, dexamethasone, ketamine, dexmedetomidine, clonidine, and melatonin also help with reducing postoperative opioid requirements [61–63].

Loco-regional anesthesia techniques avoid manipulation of the airway and reduce the need for perioperative opioids. Wound infiltrations, peripheral nerve block infusions, and epidural infusions of local anesthetic reduce opioid requirements postoperatively. These techniques may be recommended in OSA patients if the nature of surgery permits. A recent large sample size population-based analysis of database in the USA suggested that regional techniques, in particular neuroaxial techniques, conveyed benefits in reducing major complications, requirement for mechanical ventilation, and intensive care services in OSA patients undergoing joint arthroplasty [64]. The same principles may potentially be extrapolated to other regional techniques (e.g., peripheral nerve blocks, local infiltration anesthesia) in patients undergoing major surgeries; however, the paucity of evidence summons the need for more research in this area. Patients receiving sedation for surgical procedures under monitored anesthetic care should be monitored for adequacy of ventilation by capnography [23].

At the conclusion of the surgery, the extent of residual neuromuscular blockade should be verified and reversal done. Minute amounts of residual neuromuscular blockade can result in aspiration, airway obstruction, hypoventilation, hypoxia, and reintubation [65]. These risks are amplified in the OSA patient. Postextubation, patients should be nursed in a semi-upright or lateral position [23].

Due to the increased coexistence of pulmonary hypertension in OSA patients, many of which remained undetected, intraoperative triggers for elevation in pulmonary artery pressures should be avoided. These risk factors include hypothermia, hypercarbia, hypoxemia, and acidosis.

Postoperative Management Strategies for OSA Patients

The decision regarding the postoperative disposition of the OSA patient is dependent on several factors: OSA severity, postoperative opioid requirement, the nature, and extent of surgery. The main postoperative concern for the OSA patient is OIVI. Improved postoperative monitoring is crucial in mitigating the risk of OIVI; however, critical care and monitored beds are limited. The eventual decision of where the patient is to be monitored and the level of monitoring prescribed is at the discretion of the attending anesthesiologist. Recently, Swart et al. published a PACU order-based approach to facilitate postoperative decision making for patients with OSA. The orders prompt anesthesiologists to consider the baseline preoperative factors and perioperative events associated with higher risk of complications from OSA, diagnostic follow-up and possible sleep medicine consult [66]. We put forth a similar decision-tree aid and functional algorithm detailed in Fig. 35.2 and described below.

Firstly, all patients with previously diagnosed or suspected OSA who had received moderate sedation or general anesthesia should be subjected to an extended period of monitoring in the PACU (Fig. 35.2). An additional 60 min of continuous monitoring in a quiet environment after the modified Aldrete criteria for discharge has been met is suggested [10].

The occurrence of recurrent respiratory events in the PACU is an indication for continuous postoperative monitoring. PACU respiratory events include the following: (1) episodes of apnea for ≥ 10 s, (2) bradypnea <8

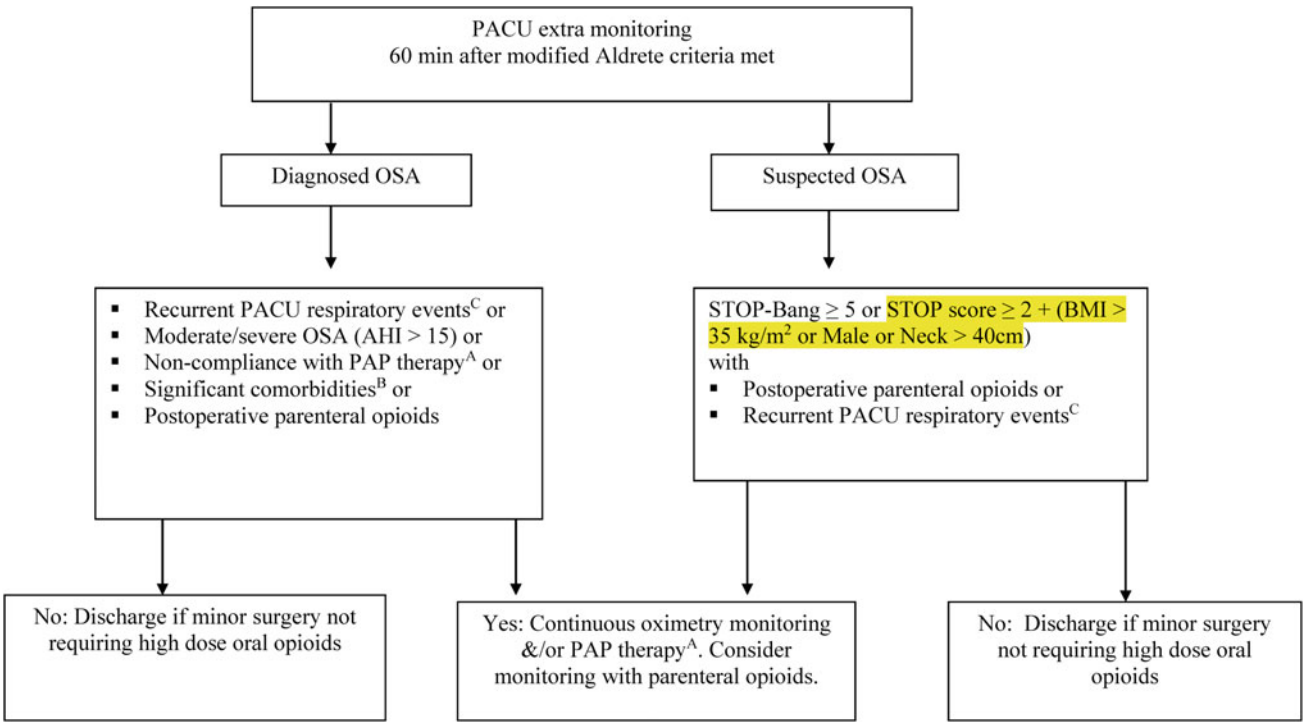

Fig. 35.2 Postoperative management of the diagnosed or suspected. Obstructive sleep apnea patient. [A]Positive airway pressure (PAP) therapy—including continuous PAP, bilevel PAP, or automatically adjusting PAP. [B]Significant comorbidities—heart failure, arrhythmias, uncontrolled hypertension, cerebrovascular disease, metabolic syndrome, obesity BMI >35 kg/m^2.[C] Recurrent postanesthesia care unit (PACU) respiratory event—repeated occurrence of oxygen saturation <90 %, or bradypnea <8 breaths/min, or apnea ≥ 10 s, or pain-sedation mismatch. Adapted from Seet and Chung [82]

breaths per minute, (3) repeated oxygen desaturation to <90 %, or (4) pain-sedation mismatch (high pain and sedation scores concurrently) [47]. Any of the above events occurring repeatedly in separate 30-min intervals may be considered recurrent PACU respiratory events. It was recently found that sedation level may be more reliable a predictor of OIVI than respiratory rate, because OIVI may not consistently be accompanied by bradypnea [67]. Patients with suspected OSA (i.e., scored as high risk on screening questionnaires) and who develop recurrent PACU respiratory events postoperatively are at increased risk of postoperative respiratory complications [47]. Therefore, continuous monitoring of these vulnerable patients with oximetry in an area with personnel trained to respond and intervene is advocated (Fig. 35.2). These areas may include the surgical ward outfitted with remote telemetry and oximetry monitoring. With continuous oximetry monitoring in the ward, care in intensive care units and step-down units are not needed.

For patients who have been previously diagnosed with OSA, red flags which may prompt the need for continuous postoperative oximetry monitoring would include known moderate or severe OSA, significant comorbidities, non-compliance to PAP therapy, and parenteral opioid administration (Fig. 35.2). For patients suspected of OSA with a STOP-Bang score of 5 or greater, and either requiring postoperative parenteral opioids or encountering recurrent PACU respiratory events, continuous oximetry monitoring may likewise be advised (Fig. 35.2).

Additionally, this same cohort of patients who require continuous oximetry monitoring may also benefit from postoperative PAP therapy. Patients with OSA and already on PAP devices should continue their PAP therapy postoperatively [23]. Limited literature suggests possible improved outcomes with postoperative PAP therapy in OSA patients. A retrospective review of 797 patients scheduled for bariatric surgery demonstrated that timely recognition and management of OSA with perioperative continuous PAP may mitigate the risk of postoperative complications [68]. A smaller case series of 14 patients with OSA reported that the use of CPAP continuously for 24–48 h after extubation may reduce the risk of postoperative complications [69]. PAP therapy was also found to decrease postextubation respiratory failure in severely obese patients admitted to the

intensive care unit with an absolute risk reduction of 16 % [70]. In a recent randomized controlled trial of 177 patients, it showed the feasibility of perioperative auto-titrating PAP for OSA patients. Perioperative auto-titrating PAP treatment significantly reduced postoperative AHI and improved oxygen saturation in the patients with moderate and severe OSA [71].

In contradistinction, the utility of postoperative auto-titrating PAP therapy in patients at high-risk for OSA failed to show benefit in reducing hospital length of stay and postoperative complications [72] in a recent study. Future research is necessary to discover the true utility of postoperative PAP therapy.

A multimodal approach to analgesia should be employed to minimize postoperative opioid usage. If postoperative parenteral opioids cannot be avoided, supplemental oxygen is commonly administered to prevent hypoxemia from OIVI. The Anesthesia Patient Safety Foundation further advises that ventilation should also be monitored (e.g., capnography) for the detection of hypoventilation when supplemental oxygen is delivered [73] (Fig. 35.2). Nurse training in detecting respiratory depression and rapid administration of naloxone is critical and can potentially prevent mortality and morbidity.

Recent research by Chung and colleagues uncovered an interesting but troubling phenomenon—the disturbances in sleep architecture were greatest on postoperative night one and breathing disturbances during sleep were greatest on postoperative night three [32–34]. Patients with a higher preoperative AHI were predicted to have a higher postoperative AHI. Preoperative AHI, male gender and 7w2-h opioid dose were positively associated with postoperative AHI [32–34]. Sleep architecture may normalize only after the 5th postoperative night. Therefore, the occurrence of late complications in OSA patients may be attributed to hypoxemia and sympathetic stress from upper airway obstruction in the first few postoperative nights. To date, recommendations on the most expedient duration to monitor OSA patients postoperatively remain controversial.

Ambulatory Surgery and the OSA Patient

There has been an increasing interest in ambulatory surgery for OSA patients. However, there remain concerns for OSA patients and their suitability for same day hospital discharge after surgery because of the risks of postoperative complication—including death from postoperative apnea and hypoxemia. Recent consensus statements from the Society for Ambulatory Anesthesia have been published to guide preoperative patient selection with OSA for ambulatory surgery [74].

On systematic review of relevant studies, the committee found that known OSA patients with well-controlled comorbid diseases and who will comply with postoperative PAP therapy may be considered for ambulatory surgery. Patients unwilling or unable to comply with PAP therapy may not be suitable candidates. Patients should be advised to apply their PAP devices when sleeping even in the day for several days postoperatively. Patients with suspected OSA and optimized comorbid conditions, and who will not require oral opioids postoperatively, may also be safely discharged after ambulatory surgery.

The author's proposed algorithm in Fig. 35.2 in similar fashion recommends that diagnosed or suspected OSA patients without significant comorbidities, recurrent PACU respiratory events or need for high dose oral opioids, be considered for discharge home after surgery at the discretion of the attending physician. Patients and their family should be educated regarding the use of PAP therapy when sleeping, and to avoid opioids due to the adverse effect on breathing.

Patients with severe OSA and uncontrolled comorbidities are not suitable for ambulatory surgery [61, 74]. The threshold for unanticipated hospitalization of the OSA patient should be lowered, for example, with the occurrence of postoperative respiratory events or exacerbation of cardiac comorbidities. Stand-alone ambulatory surgical centers that take care of OSA patients should have prearranged transfer agreements with inpatient institutions that are able to manage postoperative problems associated with OSA.

A judicious criteria for patient selection, detailed preoperative risk stratification and optimization of OSA and related comorbidities, in tandem with well-trained multidisciplinary medical personnel, experienced high volume facilities, and stringent discharge criteria adhering strictly to the protocol to a reliable escort are the essential system processes required for the safe delivery of care for the OSA patient presenting for ambulatory surgery.

Central Sleep Apnea

Central sleep apnea (CSA) is characterized by the lack of drive to breathe, resulting in repetitive periods of inadequate or absent ventilation and compromised gas exchange. CSA is contrasted to OSA, since in the former there is a lack of respiratory effort during airflow cessation. However, significant overlap exists in the pathophysiology of CSA and OSA. In some patients with what seems like apparent OSA, when treated with CPAP to eliminate upper airway obstruction, they emerge with CSA patterns. This unclassified clinical entity has been termed complex sleep apnea syndrome [75]. Typically, CSA can be considered the primary diagnosis when more than 50 % of the apneic episodes

are scored as central in origin (i.e., without respiratory effort).

The various manifestations of CSA include obesity hypoventilation syndrome (OHS), Cheyne–Stokes breathing, high altitude-induced periodic breathing, opioid-induced central apnea, and idiopathic CSA [76]. The former two conditions relevant to the surgical patient and their impact on the perioperative patient will be elaborated in greater detail.

Obesity Hypoventilation Syndrome

Obesity hypoventilation syndrome is characterized by a triad of features—body mass index ≥ 30 kg/m^2, sleep-disordered breathing, and daytime hypoventilation ($PaCO_2 \geq 45$ mm Hg, $PaO_2 < 70$ mm Hg) in the absence of other confounding causes of hypoventilation [77]. The pathogenesis of OHS may include impaired respiratory mechanics secondary to obesity causing increased mechanical load, leptin resistance resulting in central hypoventilation, and impaired compensatory response to acute hypercarbia in OSA [78].

OHS prevalence in the general population is 0.15–0.3 % [78]. It is a disease entity separate from OSA and obesity; however, there is considerable overlap. Distinguishing clinical feature of OHS includes more severe upper airway obstruction, restrictive pulmonary physiology, blunted central respiratory drive, and pulmonary hypertension; 90 % of patients with OHS also have OSA. The estimated prevalence of OHS in patients with known OSA is 11 %, and the prevalence of OHS in bariatric surgical patients is 8 % [25].

Surgical mortality rate was reported to be as high as 8 % in OHS patients undergoing bariatric surgery [79]. Therefore, there should be an increased awareness among perioperative physicians and anesthesiologists of the possibility of undiagnosed OHS in the surgical patient. Useful preoperative clinical predictors of OHS would include serum bicarbonate and room air oximetry. A preoperative raised serum bicarbonate level has a high sensitivity of over 90 % in predicting hypercapnia in OHS patients [35]. If serum bicarbonate is increased in the presence of hypoxemia on room air oximetry during wakefulness, a confirmatory test involving a measurement of arterial blood gases is recommended [25]. A highly sensitive serum bicarbonate threshold of 27 mmol/L is complemented by a highly specific AHI threshold of 100 in the diagnosis of OHS [35]. Preoperative echocardiogram may be considered in patients with OHS in view of the strong association of OHS with pulmonary hypertension of 30–88 % [25].

Perioperative management principles of OHS patients are similar to patients with OSA (Table 35.3). Additionally, the anesthesiologist should be cognizant of an increased mortality risk compared with normocapnic obese patients [80]. Continuous postoperative monitoring is essential to pick up OIVI early for intervention.

Cheyne–Stokes Breathing Syndrome

Cheyne–Stokes breathing syndrome is distinguished by the occurrences of cyclical crescendo and decrescendo breathing amplitude and the presence of a serious medical illness. These would include congestive heart failure, left ventricular systolic dysfunction, stroke, and Shy–Drager syndrome.

For the small subgroup of patients with Cheyne–Stokes breathing syndrome, the main concern to the anesthesiologist would be the associated medical condition—whether of cardiopulmonary or neurological origin. These associated medical conditions should be optimized in the preoperative period. For example, medical heart failure therapy should be the first step in the management of CSA with heart failure [20]. If CSA persists thereafter, there may be a role for PAP therapy in improving cardiovascular function [81]. Intraoperatively, special considerations and precautions for anesthesia relate to their underlying comorbid disease. The incidence of postoperative morbidity and mortality would be high and counseling of patient-specific perioperative risks should be undertaken.

Conclusion

Sleep-disordered breathing is a prevalent yet underdiagnosed condition. A significant number of patients with OSA are unrecognized when they present for surgery. OSA can lead to several systemic complications and is also linked to increased perioperative morbidity. This chapter reviewed the evidence supporting the perioperative management of patients with sleep-disordered breathing and lays out an approach to the screening, evaluation, and management of the known and suspected OSA patients, with the intention of mitigating the perioperative risks in this vulnerable group of patients.

Oral Appliances and Surgical Techniques for Treatment of Obstructive Sleep Apnea Syndrome

36

John A. Fleetham and Fernanda R. Almeida

Introduction

This chapter is based on a recent overview of the treatment of the obstructive sleep apnea syndrome (OSAS) by oral appliances (OAs) and upper airway surgery [4] with additional figures and videos [3]. This treatment approach does not include lifestyle modifications or nasal continuous positive airway pressure (CPAP). Where possible, recommendations are based on data from randomized controlled clinical trials. In the field of OA therapy, there are currently 19 randomized controlled trials with OA compared to placebo (9 studies) or compared to CPAP (10 studies) and 9 randomized controlled trials between appliance designs. However, many of the surgical treatments for OSAS are not supported by such rigorous forms of evidence, and so to a considerable extent, treatment recommendations are based on data from uncontrolled studies, case series, consensus guidelines, and practice parameters. The treatment approach to OSAS should be individualized to each patient based on a careful risk–benefit analysis that takes into account their age, severity of symptoms, presence of associated comorbidities or safety critical occupation, etiology of upper airway obstruction, overnight sleep monitoring findings, the local expertise in terms of specialized treatments, and the ability to provide long-term follow-up. The primary goal of the treatment for OSAS is symptom improvement, so the need to establish effective treatment is more important in patients with marked daytime symptoms. Some treatments, such as CPAP, can be established in a more timely fashion compared to others, such as OA and corrective upper airway surgery. This is an important factor when the patient has a comorbidity/condition or a safety critical occupation. Relevant comorbidities and conditions are ischemic heart disease, cerebrovascular disease, congestive heart failure, refractory systemic hypertension, obstructive/restrictive lung disease, pulmonary hypertension, hypercapnic respiratory failure, and pregnancy. Safety critical occupations include patients working with machinery or employed in hazardous occupations and include truck, taxi, and bus drivers; railway engineers; airline pilots; air traffic controllers; aircraft mechanics; ship captains; and pilots. Car drivers who admit to have fallen asleep while driving within the last two years also require expedited treatment. The indications for the treatment of asymptomatic patients with OSAS are less clear. Treatment may be considered in asymptomatic patients with significant comorbid illness, who work in a safety critical occupation, or who have an apnea–hypopnea index (AHI) > 30 events/h. Certain physical factors limit the use of some treatments. Severe nasal obstruction may preclude nasal CPAP and may need to be addressed before these treatments are considered. Mandibular advancement devices, the most common type of OA used, require adequate dentition for their effective use, while tongue retaining devices can effectively treat edentulous patients. The presence of large tonsils should prompt referral to an otolaryngologist for consideration of tonsillectomy. Corrective upper airway surgery may not be a suitable option for patients who use their voice professionally. Long-term follow-up by either a primary care provider or sleep disorder specialist should be arranged in a similar fashion to other chronic diseases such

as diabetes or hypertension. Patient education about the nature, complications, and treatment of OSAS by a trained healthcare professional (respiratory therapist/nurse/polysomnographic technologist) is an important component of all treatment strategies.

Oral Appliances

Oral appliances (OAs) are now widely used for the treatment of snoring and mild–moderate OSAS, both as primary therapy and as an alternative for patients who are unwilling or unable to tolerate CPAP (Video 1 Overview). OA is an appealing treatment option for patients as they are small and simple to use. There are a variety of synonyms for OA. In addition to dental, they may be called oral, intraoral, or mandibular, and instead of appliance, they may be called a device, splint, or prosthesis. OA therapy for OSAS remains underutilized despite several recent reviews [2] and recommendations from both the Cochrane Collaboration [7] and American Academy of Sleep Medicine [5].

Appliance Type

There are currently a large number of different OA available for the treatment of OSAS (Fig. 36.1) (Video 2–5, Appliance A, B, C, and D). OA increases the size of the upper airway by either advancing the mandible or the tongue. There are other minor design differences in the OA currently available that may also impact on their success and treatment adherence. Mandibular advancement OAs are most widely used and utilize traditional dental techniques to attach the OA to one or both dental arches. Construction usually requires dental impressions, bite registration (Video 6, Bite registration), and fabrication by a dental laboratory. Some OAs are available in a prefabricated form and are sometimes referred to as "boil and bite." These can either be fitted by the patient themselves or molded to the patient's teeth in an office setting. In a recent randomized controlled trial, a prefabricated device has shown to be ineffective and unable to predict efficacy of a titratable custom-fabricated OA. Some OA restricts mouth opening by means of clasps, whereas others allow relatively unhindered movement. More recently, OAs have been developed with an adjustable hinge that allows progressive advancement of the mandible, called titratable appliances, after initial construction until the optimal mandibular position is achieved (Video 7, Titration). The amount of anterior posterior mandibular movement and the speed with which this can be changed varies considerably between patients. Mandibular advancement OA normally requires at least 8 teeth in each of the maxillary and mandibular arches. Furthermore, the patient should be able to advance their mandible by at least 5 mm without discomfort. Severe temporomandibular joint disease and advanced periodontal disease are relative contraindications to mandibular advancement OA treatment.

The other major type of OA available is the tongue retainer that keeps the tongue in an anterior position during sleep by means of negative pressure in a soft plastic bulb. It fits over both the mandibular and maxillary arches and has a flange which fits between the lips and teeth, keeping the appliance anterior in the mouth. This appliance was one of the first to be developed and is available in both a fabricated and prefabricated form. It can be used in edentulous patients and is the OA of choice for patients with no teeth, limited anterior posterior mandibular movement or a extremely large tongue. In a recent study, tongue retaining devices have shown to improve the efficacy of mandibular advancement devices, improving its efficacy [1]. Patients should be assessed prior to OA treatment and not have major active periodontal disease, and dental restorations should ideally be completed prior to treatment (Video 8, Patient Assessment). Patients should be provided with information concerning the efficacy and side effects of OA, and written consent should be obtained (Video 9, Patient information). A combined medical and dental approach to OA treatment is important. OA therapy should be supervised by both medical and dental specialists with a major interest in the management of sleep-disordered breathing.

Mechanism of Action

The majority of OA is designed to maintain the mandible and/or tongue in a protruded posture, thereby preventing upper airway obstruction during sleep. Proposed mechanisms of action of OA include increased upper airway size, decreased upper airway collapsibility, activation of upper airway dilator muscles, and stabilization of mandibular posture. Several different upper airway imaging techniques have been used to assess changes in upper airway size and function with OA in patients with OSAS. These imaging techniques include cephalometry, computed tomography, magnetic resonance imaging, and video endoscopy, but most of these studies show poor reliability in predicting treatment outcomes. Voluntary mandibular and tongue protrusions have been shown to increase upper airway size and alter upper airway shape particularly in the velopharynx in subjects with and without OSAS. Several studies have demonstrated an

increase in the anteroposterior diameter of the upper airway following OA insertion (Fig. 36.2). This increase was predominant in the oropharynx and hypopharynx, but some studies have also suggested an effect on the velopharynx (Figs. 36.3 and 36.4). Almost all of these upper airway imaging studies have been performed during wakefulness, and it is unknown whether the same changes occur during sleep. Mandibular advancement OAs have been shown to increase upper airway muscle tone, which may also contribute to increased upper airway patency.

Efficacy

The effectiveness of OA therapy can be influenced by the patient's body mass index, the severity of OSAS, the presence of positional OSAS, and the degree of mandibular advancement obtained with the OA. Until recently, the majority of the data concerning the efficacy of OA in the treatment of OSAS were from uncontrolled case series studies which were subject to study design issues such as regression to the mean, and selection and reporting bias. With about 18 randomized controlled trials comparing OA to placebo and/or CPAP, there is increasing evidence that OA significantly improve snoring, daytime sleepiness, quality of life, systemic hypertension, and indices of sleep-disordered breathing. A variety of prospective randomized trials have been performed to evaluate the efficacy, side effects, compliance, and preference of OA treatment in patients with OSAS. There are at least 9 randomized controlled trials comparing OA to an inactive control that demonstrate that OA improves daytime sleepiness, systemic hypertension, and indices of sleep-disordered breathing in patients with OSAS. Additional well-designed, large-scale randomized controlled trials comparing active and control OA are required to determine which groups of patients are most likely to benefit from OA treatment, how these patients can be identified, and how much benefit can be achieved and with what cost, side effects, and complications. There are at least 10 randomized controlled trials which have compared the efficacy and side effects of OA and CPAP. Although both CPAP and OA led to similar improvements in daytime sleepiness, health status, and blood pressure, conversely the magnitude of improvement in AHI was significantly more with CPAP. Some studies suggest that the higher efficacy of CPAP is counterbalanced by the higher adherence to OA

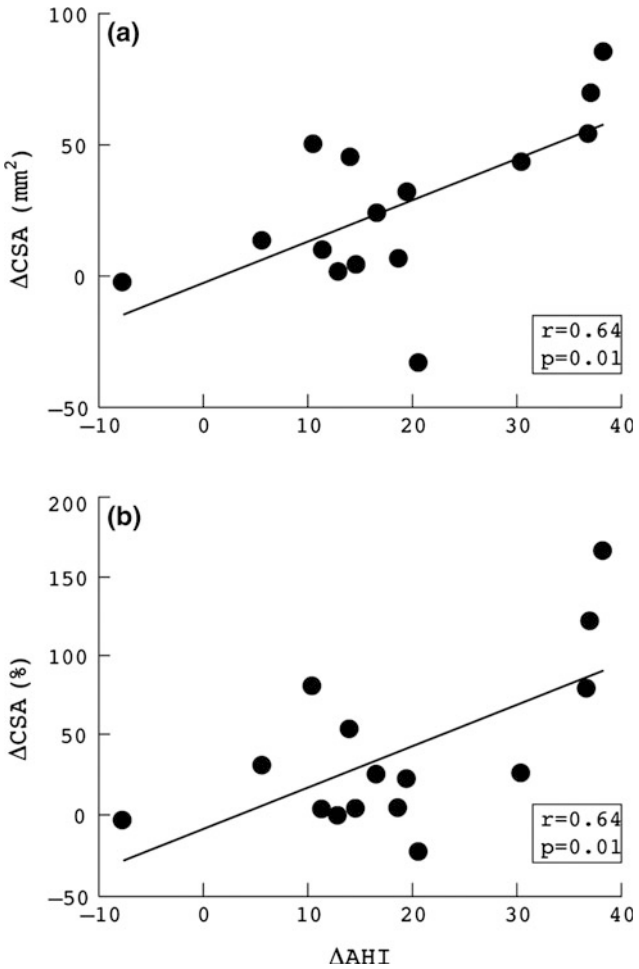

Fig. 36.4 Relationship between change in apnea + hypopnea index (ΔAHI) and **a** the absolute and **b** the proportional changes in cross-sectional area (ΔCSA) of the velopharynx after insertion of a mandibular advancement splint (Reproduced with the permission from BMJ Publishing Group Ltd. Thorax [12])

(hour per night and nights per week), resulting in a similar treatment effectiveness [16]. Furthermore, it takes longer to obtain optimal treatment with an OA than CPAP, which can be a major issue in patients with excessive daytime sleepiness. Patients who responded to both treatments tend to prefer the use of an OA to CPAP. All of the randomized controlled trials have been short-term studies over 3–6 months, but there are now several non-randomized studies establishing long-term efficacy over 4–5 years.

OA design has been proposed as an important determinant of treatment success, and there have been at least 9 prospective comparative studies evaluating different OA designs. Most studies using comparable mandibular protrusion with minimum vertical opening have shown that the differences were minimal. Some studies looking at vertical opening have shown a detrimental effect of the increase in the anterior vertical opening of these devices. There were varying degrees of patients' acceptance, but the incidence of long-term side effects with different OA is independent on the appliance design. Finally, there is one longitudinal parallel group study comparing the effectiveness of OA with uvulopalatopharyngoplasty in patients with mild to moderate OSAS over 4 years, which suggests that an OA was more effective than uvulopalatopharyngoplasty in improving indices of sleep-disordered breathing. However, the significance of this finding is questionable, as there is no definitive evidence of the effectiveness of this type of corrective upper airway surgery. OA therapy may also be indicated as an adjuvant to nasal CPAP when the patient is away from home or electrical power, or used in conjunction with CPAP, allowing patients who were unable to tolerate high CPAP pressures to use CPAP in combination with an OA with an average reduction of 2.5 cm of H_2O pressure. OAs have also been used as combination therapy in patients who have had an unsuccessful response to uvulopalatopharyngoplasty.

Predictors of Success

A variety of predictors of OA treatment success have been proposed. It has been suggested that younger, less obese patients, with smaller neck circumference and with OSAS that occurs predominantly in the supine position, may be more likely to obtain a successful response with an OA. Treatment success may be inversely related to pretreatment severity, but this relationship may just be a function of the definition of treatment success. Several upper airway skeletal and soft tissue measurements made from pretreatment lateral cephalometry have been shown to be associated with treatment success. These include a more micrognathic or retrognathic mandible and small soft palate and tongue. Upper airway fluoroscopy and, more recently, flow-volume curves and nasal resistance measurements have also been proposed as techniques to guide successful OA therapy. A primary oropharyngeal site of obstruction may be associated with a better treatment outcome. However, there is considerable overlap between good and poor treatment responses with all these variables. The utility of any treatment recommendation based on clinical features, OSAS severity, or upper airway anatomy requires prospective validation.

Treatment Adherence

Self-reported treatment adherence data for up to 5 years are available for OA therapy. Self-reported treatment adherence has been reported as high as 96 % patients using OA for >75 % nights and 80 % patients using OA >75 % of each night. Treatment adherence varies between OA type and appears better with mandibular advancement rather than

tongue retaining OA. Adherence rates appear to decrease with duration of use and have been reported as 60 % at one year and 48 % at two years. Previous experience with nasal CPAP suggests that self-reported treatment adherence tends to overestimate actual use. Recently, Vanderveken and colleagues (2012) have described an objective sensor to monitor OA compliance, which has recently been approved for commercialization. Future studies and clinical practice should now include objective OA compliance data.

Side Effects and Complications

Side effects are common, but generally minor. Excessive salivation, mouth dryness, morning-after occlusal changes, and discomfort in the gums, teeth, or jaw are common side effects in the first weeks of OA therapy, but usually resolve with time. More persistent side effects related to temporomandibular joint dysfunction and dental crown damage appear to be uncommon. Long-term common side effects include tooth movement and occlusal alteration (Video 10, Side effects). Small occlusal changes may be found in up to 80 % of patients after continuous five years of OA wear, independent of the appliance used. The clinical significance of these occlusal changes is uncertain. OA adjustment can decrease side effects by reducing pressure on the anterior teeth and excessive mandibular advancement. Side effect types vary between types of OA with tongue pain occurring in tongue retention OA and gagging associated with OAs that have a maxillary component to modify soft palate position.

Cost

The cost of OA therapy varies depending on the type of OA used and the extent and expertise of the dental supervision. Consensus opinion indicates that a prefabricated OA can range from $45 to 100 and custom-made OA ranges from $500 to over $1000. OA usually remains effective for two to three years and after that they can break and require either repair or replacement. OA treatment generally includes about ten dental appointments, and then, dentist service fees vary greatly between $200 per appointment or a fixed fee of $2500, depending on the time spent caring for the patient and geographic economic factors. Costs can equal or exceed those associated with nasal CPAP therapy. There is increasing evidence that OA is a cost-effective treatment for OSAS [10].

Treament Recommendations

A Cochrane systematic review [7] recently concluded that there was increasing evidence that OA improves subjective daytime sleepiness and sleep-disordered breathing compared with control appliances. However, it recommended that until there was more definitive evidence on the effectiveness of OA compared to CPAP, OA therapy should be restricted to patients with mild symptomatic OSAS and those patients who are unwilling or unable to comply with CPAP therapy. The American Academy of Sleep Medicine [5] reviewed similar data to the Cochrane Collaboration and recommended that OAs were indicated for use in patients with mild–moderate OSAS who prefer them to CPAP, or who do not respond to, or are not appropriate candidates for, or who fail treatment with CPAP. They recommended CPAP therapy as first-line therapy for patients with severe OSAS, but OA can also be prescribed for severe OSAS if patients can not tolerate CPAP. OA can have insufficient reduction in OSAS severity and has also shown a placebo effect on sleepiness; therefore, it is important to perform follow-up sleep monitoring to verify the efficacy of OA therapy. Patients treated with OA require long-term dental follow-up to monitor patient adherence, to evaluate OA deterioration or maladjustment, to evaluate the health of the oral structures, and to monitor occlusal changes.

Upper Airway Surgery

Upper airway surgery is the treatment of choice in less than 1 % of patients with OSAS who have a specific anatomic upper airway lesion such as adenotonsillar enlargement, antrochoanal polyp, or tumor. Tracheostomy was the primary treatment for severe OSAS prior to the introduction of CPAP. The long-term morbidity associated with tracheostomy led to the development of a variety of other upper airway surgical procedures for the treatment of OSAS. The goal of these procedures is to remove the site of upper airway obstruction by either increasing upper airway size or decreasing upper airway collapsibility. The procedures achieve this by (1) resection of redundant soft tissue (nasal surgery, uvulopalatopharyngoplasty, laser-assisted uvulopalatoplasty (LAUP), midline glossectomy); (2) induction of scar tissue formation (cautery or radio frequency ablation of soft palate, tongue, or epiglottis); or (3) displacement of bony and ligamentous attachments of upper airway soft tissue structures (maxillary and mandibular osteotomies, tongue, and hyoid suspensions). There are two detailed reviews of the literature on the surgery for OSAS [11, 14]. They identified only a few randomized or quasi-randomized trials comparing upper airway surgery with conservative management or other treatments for OSAS. Consequently, any recommendations regarding the role of upper airway surgery in the treatment of OSAS must take into account the weakness of the existing data. CPAP should be used to treat patients preoperatively and to protect against postoperative

Fig. 36.5 Adenotonsillectomy is first-line therapy for obstructive sleep apnea in children. Copyright © 2014 American Thoracic Society. Cite: Won et al. [19]. Official Journal of the American Thoracic Society

upper airway obstruction. Long-term follow-up is strongly recommended because the long-term efficacy of upper airway surgery has not been well established.

Tonsillectomy

Adenotonsillar hypertrophy is a common cause of OSAS in children. Adenotonsillectomy is first-line therapy for obstructive sleep apnea in children. Both adenoid tissue and tonsillar tissue are removed, and the lateral pharyngeal walls are sutured to prevent collapse (Fig. 36.5). Adenotonsillectomy is curative in 75–100 % of children with OSAS. Adenotonsillar hypertrophy is occasionally the primary cause of OSAS in adults. Eight of 9 patients had a reduction in AHI $\geq$ 50 % or to <20/h postoperatively in a prospective study of tonsillectomy in adult patients [18]. The presence of large tonsils in a patient with OSAS should prompt referral to an otolaryngologist for the consideration of tonsillectomy.

Uvulopalatopharyngoplasty

Uvulopalatopharyngoplasty (UPPP) is a procedure introduced over 25 years ago which has been widely used for the treatment of OSAS. This procedure reduces upper airway obstruction by shortening the uvula, trimming the soft palate, and suturing back the anterior and posterior pharyngeal pillars (Fig. 36.6). Tonsillectomy is performed at the same time if tonsils are found to be enlarged. Uvulopalatal flap is a modification of UPPP. Instead of removing the uvula and soft palate, the uvula is retracted and tucked superiorly under the soft palate (Fig. 36.7). The pharyngeal

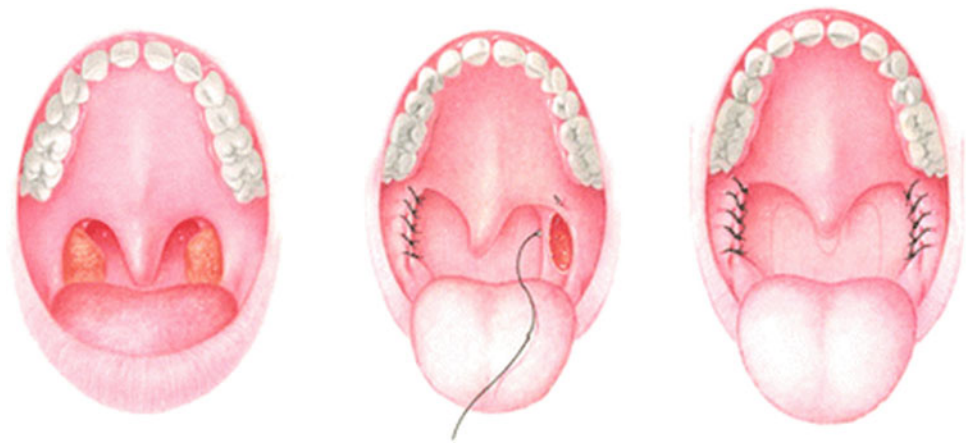

Fig. 36.6 Uvulopalatopharyngoplasty reduces upper airway obstruction by shortening the uvula, trimming the soft palate, and suturing back the anterior and posterior pharyngeal pillars. pillars are sutured back, and tonsils are removed in this procedure as well. Sher and associates [13] performed a meta-analysis of 37 reports on UPPP for the treatment of OSAS published between 1966 and 1995. UPPP resulted in a mean 38 % reduction in AHI. A higher AHI was associated with a lesser improvement post-UPPP. A good response to UPPP, as defined by a 50 % decrease in AHI and a post-operative apnea index <10/h and AHI < 20/h, was obtained in 41 % of patients. There is one randomized controlled trial comparing UPPP with conservative management. Daytime sleepiness was improved in the surgical group, but there was no difference in oxygen desaturation index between the two groups at 12 months. The surgical complication rate was 22 %. Complications included infection, tracheostomy, and dysphagia. One patient had a myocardial infarction and one patient had a transient ischemic attack following surgery.

One randomized trial compared UPPP to lateral pharyngoplasty. Daytime sleepiness was improved in both groups, but AHI was only significantly reduced in the lateral pharyngoplasty group. Nasal regurgitation was noted with equal frequency in both groups. There is another randomized trial of UPPP versus laser-assisted uvulopalatoplasty (LAUP) for the treatment of snoring in patients with palatal flutter [9]. Eighty percent of patients had a subjective improvement in their snoring, and the objective snoring index was also significantly reduced with both procedures. Some of the LAUP patients had a higher snoring index after surgery. No postoperative complications were reported in the LAUP group, but bleeding, velopharyngeal insufficiency, and infection were reported in the UPPP group. Another study evaluated the short-term and long-term responses to UPPP or UPPP plus tonsillectomy [17]. Snoring was improved in the majority of patients at long-term follow-up. The oxygen desaturation index was improved in some patients at short-term follow-up. UPPP in combination with tonsillectomy was more effective than UPPP alone. UPPP can result in an increase in OSAS severity [13], and subjective outcomes do not always match objective outcomes. One study found the majority of patients reported reduced snoring and improved sleep despite lack of improvement in the AHI, and snoring intensity following UPPP surgery. Consequently, it is important to perform follow-up sleep monitoring to verify there has been an objective improvement in OSAS severity.

UPPP may be more effective in patients with retropalatal obstruction than in patients who also have a retrolingual obstruction. Five percent of patients with OSAS and retrolingual obstruction obtained a good response to UPPP compared with 52 % of patients with a retropalatal obstruction. The good responders had a lower mean AHI compared with the poor responders. A study was performed with cephalometry and upper airway CT scans on 20 patients before and after UPPP [6]. Thirty-five percent had a good response to UPPP, and these patients had an increase in the retropalatal oropharynx post-UPPP, whereas poor responders did not. The post-UPPP velopharynx was larger in good responders compared with poor responders. The change in the size of the narrowest segment of the oropharynx correlated with the change in the AHI, suggesting that failure to increase velopharynx size may be one of the causes of a failure to achieve a good response with UPPP. There is limited long-term follow-up on UPPP. In a study of 50 patients following UPPP for OSAS, the good response progressively decreased from 60 % at 6 months to 30 % at 21 months during the long-term follow-up which was associated with significant weight gain. Complication rates

are difficult to determine from the literature. Postoperative pain is common but self-limited. Velopharyngeal insufficiency may occur in up to 40 % of patients. Velopharyngeal stenosis has also been reported and may explain the worsening of OSAS in some patients post-UPPP. Postoperative upper airway obstruction has been reported in 10 % of patients, and some deaths have occurred. UPPP may interfere with the patients' ability to tolerate CPAP therapy. Patients with a prior UPPP develop a mouth leak at a lower CPAP pressures than patients with OSAS without prior UPPP. Furthermore, patients with prior UPPP have a lower adherence with CPAP than patients with OSAS without a UPPP. UPPP may be considered in selected patients with OSAS who have failed CPAP and/or OA treatment. Patients being offered UPPP should be informed about the limited efficacy, potential complications, and the risk of subsequent difficulty with CPAP treatment.

Laser-Assisted Uvulopalatoplasty

LAUP is a modified UPPP procedure with less radical resection of palatal tissue. LAUP is performed with a carbon dioxide laser as either a one-stage or multistage office procedure under local anesthesia. Although it was originally introduced for the treatment of snoring, more recently it has used to treat patients with OSAS. Two meta-analyses by Verse [17] and Littner et al. [8] reviewed over 70 articles published between 1980 and 2000. These meta-analyses revealed a small reduction in AHI post-LAUP. Applying similar criteria to those outlined earlier for UPPP, good response rates between 27 and 41 % were reported with LAUP. Twenty to thirty patients were objectively worse post-LAUP, which may be caused by palatal fibrosis and subsequent upper airway narrowing. Subsequently, in the only randomized controlled trial to date, 45 patients with mild OSAS were assigned to either LAUP or no treatment. AHI was reduced by a mean of 21 % in the LAUP-treated group, compared with no change in the control group. Less than 25 % of the LAUP-treated patients had a good response in terms of a reduction in AHI to less than 10/hr with an associated symptomatic improvement. There was no difference in the change in subjective sleepiness between the two treatment groups. Both snoring severity and frequency, based on visual analogue scales were reduced in the LAUP group. There was no difference between the two treatment groups in change in quality of life scores. Despite this limited efficacy, approximately 50 % of patients were satisfied with LAUP. Reported adverse effects include postoperative pain, nasal regurgitation, dysphagia, infection, change in vocal quality, and a sensation of dry throat. The development of postoperative upper airway edema and narrowing has raised concerns about the advisability of performing LAUP as an outpatient procedure in patients with OSAS. The long-term results of LAUP have not been defined, but there are some data to suggest that short-term improvements are not maintained over time. Practice parameters issued by the American Academy of Sleep Medicine advise that LAUP is not recommended for the treatment of OSAS [8].

Other Palatal Procedures

A variety of other surgical procedures which either stiffen or ablate palatal tissue have been described for the treatment of both snoring and OSAS. These include laser palatoplasty, laser cautery-assisted palatal stiffening, and temperature-controlled radio frequency tissue ablation of the tongue and soft palate (TCRFTA). A randomized controlled trial comparing TCRFTA with sham (placebo) surgery and nasal CPAP therapy has been performed in patients with mild–moderate OSAS [20]. There were no differences in outcomes between TCRFTA and CPAP. TCRFTA increased airway volume, reduced AHI, and improved quality of life. Compared with sham surgery, TCRFTA does not reduce the AHI sufficiently to be recommended as a treatment for OSAS.

Nasal Surgery

There are no randomized controlled trials of nasal surgery as a treatment for OSAS. It is rarely an effective treatment for OSAS. There was an improvement in OSAS following nasal surgery in a subgroup of patients without a narrow upper airway, which suggests that the failure of nasal surgery to improve OSAS may be related to the persistent upper airway narrowing. Relief of nasal obstruction may reduce snoring and may help to facilitate CPAP treatment. Nasal surgery is not indicated as a primary treatment for OSAS, but may play a role in improving CPAP adherence.

Maxillary and Mandibular Surgery

A variety of maxillary and mandibular surgical procedures have been developed to relieve upper airway obstruction distal to the velopharynx, in the retroglossal oropharynx and hypopharynx [19]. Inferior sagittal mandibular osteotomy with genioglossus advancement, hyoid myotomy and hyothyroidopexy, total subapical mandibular osteotomy, bilateral sagittal split mandibular osteotomy, and LeFort 1 maxillary osteotomy are performed in various combinations and are designed to advance the ventral wall of the pharynx. Genioglossus advancement enlarges the hypopharyngeal space by pulling forward the tongue base at the geniotubercle through a mandibular osteotomy (Fig. 36.8).

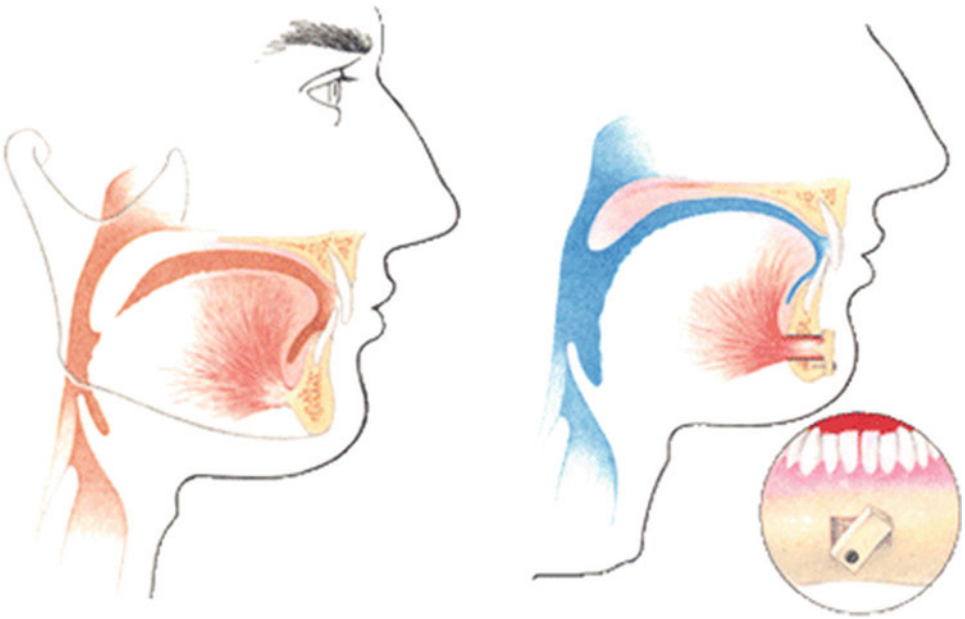

Fig. 36.8 Genioglossus advancement enlarges the hypopharyngeal space by pulling forward the tongue base at the geniotubercle through a mandibular osteotomy (Reprinted with the permission from the American Thoracic Society. Maxillomandibular advancement osteotomy, or phase II surgery, advances the maxilla and mandible to enlarge the retrolingual and retropalatal spaces (Fig. 36.9). There are no randomized controlled studies of this type of surgery for OSAS. The literature is difficult to interpret because of the different surgical procedures, the adjunct procedures used (e.g., hyoid suspension, septoplasty, and UPPP), the selection of patients with different skeletal types, confounding variables such as postoperative weight loss, and varying definitions of a good response. Three hundred and six patients with OSAS were treated in a two-phase surgical approach. Stage I procedures included UPPP for retropalatal narrowing, and inferior sagittal mandibular osteotomy with genioglossus advancement, and hyoid myotomy and suspension for retroglossal obstruction. Patients who failed to respond adequately to the Stage I procedure were offered the Stage II procedure consisting of maxillomandibular advancement. Good response rates to Stage I surgical procedures ranged between 23 and 67 %. Stage II procedures yielded good response rates between 75 and 100 %, whether as primary treatment or following Stage I surgery. More recently, maxillomandibular advancement has been proposed as the primary surgical treatment without a staged approach. Limited long-term follow-up suggests that good response rates of 80 % persist for at least 2 years. A combined surgical and dental approach is important to ensure satisfactory dental occlusion postoperatively. Complications of Stage I surgery include anesthesia of the lower lip in the

majority of patients and postoperative upper airway obstruction. Anesthesia of the cheek, lower lip, and chin is common after Stage II procedures, and a change in facial appearance is to be anticipated. Maxillomandibular surgery may be effective in carefully selected patients with OSAS who have failed CPAP and/or OA treatment.

Tongue-Base Surgery

Glossoplasty, laser midline glossectomy, lingualplasty, and tongue-base suspension have all been developed to remove excess lingual tissue and increase retrolingual oropharyngeal size in patients with snoring or OSAS. There is a randomized trial comparing tongue advancement done by a mandibular osteotomy in conjunction with UPPP, compared to tongue suspension with UPPP. AHI was not reported, but there were significant improvements in subjective daytime sleepiness in both treatment groups. There is insufficient data to recommend tongue-base surgery as a treatment for OSAS. Most forms of upper airway surgery have not been proven to have benefit for the treatment of OSAS in controlled clinical trials. New or unproven procedures should be considered experimental and be rigorously tested in research studies prior to widespread implementation in clinical practice.

Tracheostomy

Tracheostomy was commonly performed for severe OSAS prior to the introduction of CPAP. It is the only surgical procedure that consistently relieves OSAS by bypassing the recurrent upper airway obstruction during sleep. Central apneas and hypopnoea may occur after tracheostomy, but usually resolve within six months. Tracheostomy is associated with long-term morbidity related to granulation tissue and the cosmetic effect with its associated psychosocial morbidity. There are no randomized studies of tracheostomy for the treatment of OSAS. Tracheostomy should only be considered in carefully selected patients with OSAS when all other treatments fail.

Nature, Evaluation, and Treatment of Insomnia

37

Charles M. Morin and Ruth M. Benca

Introduction

Insomnia is a prevalent complaint both in the general population and in clinical practice. Chronic insomnia can present as an independent condition or more often as a coexisting condition with another medical or psychiatric disorder. Insomnia diagnosis and therapeutic approaches have evolved over the last two decades. Whereas it used to be conceptualized predominantly as a symptom of other psychiatric or medical disorders, current diagnostic classifications now recognize insomnia as a disorder on its own [1–4]. In addition, there have been significant advances in the therapeutics of insomnia, from a predominantly symptomatic approach to more focused interventions on perpetuating factors with cognitive behavioral therapy and on more targeted brain receptors with pharmacotherapy [5].

Significance of Insomnia

Population-based estimates indicate that about 30 % of adults report insomnia symptoms, 9–12 % experience additional daytime symptoms, and between 6 and 10 % meet diagnostic criteria for an insomnia syndrome [6–8]. In primary care medicine, approximately 20 % of patients report significant sleep disturbances [9]. Insomnia is more prevalent among women, middle-aged and older adults, shift workers, and patients with medical or psychiatric disorders. Difficulties initiating sleep are more common among young adults, and problems maintaining sleep are more frequent among middle-aged and elderly adults. The incidence of insomnia is higher among first-degree family members (daughter, mother) than in the general population [10], although it is unclear whether this link is inherited through a genetic predisposition, learned by observations of parental models, or simply a by-product of another psychopathology.

Persistent insomnia can produce an important burden for the individual and for society, as evidenced by reduced quality of life, decreased work productivity and increased absenteeism and disability, and higher rates of healthcare utilization [9, 11, 12]. Increasing evidence suggests associations between chronic insomnia and long-term negative health outcomes such as increased risk of hypertension, diabetes, and even mortality [13–16].

Nature of Insomnia

Clinical Presentation and Objective Findings

Insomnia is characterized by a spectrum of complaints reflecting dissatisfaction with the quality or duration of sleep. These complaints may involve problems initiating sleep at bedtime, trouble staying asleep with middle-of-the-night awakenings and difficulty going back to sleep, or waking up too early in the morning with an inability to return to sleep [1–4]. In addition, daytime fatigue, cognitive impairments, and mood disturbances (e.g., irritability and dysphoria) are extremely frequent and often the primary concerns prompting patients with insomnia to seek treatment.

The diagnostic criteria of insomnia have recently been revised with the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders [4] (see Table 37.1) and the third edition of the International Classification of Sleep Disorders [3]. While the main diagnostic criteria for an insomnia disorder remain similar to those of previous DSM and ICSD editions, several important changes were made with the last editions of these classifications. For instance, nonrestorative sleep is no longer part of the insomnia

Table 37.1 Diagnostic criteria for insomnia disorder (DSM5)

• The predominant complaint is a dissatisfaction with sleep quality or duration, associated with one or more of the following symptoms: 1. Difficulty initiating sleep 2. Difficulty maintaining sleep, characterized by frequent awakenings or problems returning to sleep after awakenings 3. Early morning awakening with inability to return to sleep
• The sleep disturbances cause clinical significant distress or impairments in daytime functioning
• The sleep disturbances occur at least 3 nights per week and is present for at least 3 months
• The sleep disturbances occur despite adequate opportunity for sleep • The insomnia is not better explained by and does not occur exclusively during the course of another sleep-wake disorder • The insomnia is not attributable to the physiological effects of a substance • Coexisting mental disorders and medical conditions do not adequately explain the predominant complaint of insomnia

definition, mainly because this complaint is not well defined and not specific to insomnia. Other changes include the addition of a minimum frequency, i.e., 3 nights or more per week with sleep difficulties, and an increase in the duration threshold from 1 to 3 months for defining chronic insomnia. The most important change introduced in both classifications is that there is no longer a distinction made between primary insomnia and insomnia secondary to another medical or psychiatric disorder. When present, such comorbidities only need to be listed, but there is no requirement to make a causal attribution to determine whether insomnia is primary or secondary. This marked departure from previous nosology was based on increasing evidence that (a) symptoms and clinical features often overlap in primary and secondary insomnia, (b) when insomnia is comorbid with another disorder (e.g., major depression), it is often difficult to determine which condition is the cause and which is the consequence, (c) the direction of this relationship may change over time, and (d) treatment outcome is superior when treating both conditions concurrently than treating either alone.

While the DSM nosology has always recognized only one form of primary insomnia, the ICSD used to distinguish among different subtypes, up to the recent edition of ICSD-3. Psychophysiological insomnia, the most common subtype, is presumed to result from conditioned arousal, which is more likely to develop among individuals with an increased psychological and biologic predisposition to insomnia. The sleep of individuals with psychophysiological insomnia is more sensitive to daily stressors and is characterized by extensive night-to-night variability [17]. Paradoxical insomnia involves a genuine complaint of poor sleep that is not corroborated by objective findings. A patient may perceive very little sleep (e.g., 2–3 h per night), whereas PSG recordings show normal or near-normal sleep duration and quality. This condition is not the result of an underlying psychiatric disorder or of malingering, but it is likely to be mediated by psychological and cognitive (information processing) variables influencing the perception of sleep and wakefulness. To some degree, all insomniacs tend to overestimate the time it takes them to fall asleep and to underestimate the time they actually sleep. In paradoxical insomnia, however, the subjective complaint of poor sleep is disproportionate to objective findings. Thus, this condition may represent the far end of a continuum of individual differences in sleep perception. Idiopathic (childhood) insomnia presents an insidious onset during childhood, unrelated to psychological trauma or medical disorders, and is very persistent throughout the adult life. It does not present the variability observed with other forms of primary insomnia. Despite their heuristic value, these insomnia phenotypes have also been abandoned in ICSD-3 nosology, primarily for reasons of simplicity, lack of validity of these phenotypes, and, more important, the desire to harmonize criteria with the DSM-5 classification.

Polysomnographic (PSG) Findings

Polysomnographic (PSG) evaluation of self-defined insomniacs reveals more impairments of sleep continuity parameters (i.e., longer sleep latencies, more time awake after sleep onset, and lower sleep efficiency) and reduced total sleep time compared to self-defined good sleepers [18–20]. Sleep architecture shows increased amount of stage 1, reduced slow-wave sleep, and more frequent stage shifts through the night. A recent meta-analysis has also suggested that rapid eye movement (REM) sleep amount is decreased [20]. Notably, sleep disturbances recorded in primary insomniacs are similar to those observed in patients with generalized anxiety disorder or some affective disorders such as dysthymia [18, 19, 21], perhaps suggesting a common underlying thread to these conditions. In addition, there is a significant overlap in the sleep patterns of subjectively defined insomniacs and good sleepers such that some insomniacs may show better objective sleep than good

sleepers and some good sleepers more sleep impairments than insomniacs; subjective reports of insomnia are often far worse than objective evidence of sleep abnormalities. Investigations of the microstructure of sleep reveal increased beta activity in primary insomniacs relative to healthy controls, both around the sleep-onset period, during non–REM (NREM) sleep and, in some studies, during REM sleep [22–25]. Spindle activity, which is thought to have a sleep-protective role, is not reduced in insomnia, however [24, 26]. These data are consistent with psychological findings of hypervigilance and a ruminative, worry-prone cognitive style among insomniacs.

Daytime Complaints and Neurobehavioral Findings

Most patients with insomnia complaints also report impairments of daytime functioning, involving fatigue, mood disturbances, and difficulties with attention and concentration, with memory, and with completion of tasks [27]. Patients may initially report excessive daytime sleepiness, but a closer investigation usually reveals mental and physical fatigue rather than true physiological sleepiness, which is more likely among patients with insomnia comorbid with another medical (e.g., pain) or sleep disorders (e.g., sleep-related breathing disorders). Insomniacs have trouble sleeping at night, in part because of a chronic state of hyperarousal, which may also interfere with the ability or propensity for sleep during the day.

Despite significant subjective complaints, objective evaluation of daytime performance usually reveals fairly mild and selective deficits (e.g., attention) on various neurobehavioral measures [28, 29]. In general, impairments on these measures are more strongly associated with subjective than with objective sleep disturbances. Individuals with insomnia tend to perceive their performance as more impaired relative to how they should perform and as more impaired than that of normal controls. Discrepancies between subjective and objective performances are similar to those observed between subjective and objective measures of sleep, which may reflect a generalized faulty appraisal of sleep and daytime functioning among individuals with insomnia [30].

Course and Prognosis

The onset of insomnia can occur at any time in life, but the first episode is more common in young adulthood. It is often precipitated by stressful life events, such as marital separation, occupational or family stress, and interpersonal conflicts [31]. In a small subset of cases (e.g., idiopathic insomnia), insomnia begins in childhood, in the absence of psychological or medical problems, and persists throughout adulthood. Insomnia is a common problem among women during menopause and often persists even after other symptoms (e.g., hot flashes) have resolved with hormonal replacement therapy. Insomnia may also have a late-life onset, which needs to be distinguished from normal (age-related) changes in sleep; such late-life onset is often associated with other health-related problems.

Potential risk factors for insomnia include demographic factors (e.g., female gender and advancing age), psychological factors (e.g., a worry-prone cognitive style), hyperarousal, and a personal or familial history of insomnia. For most individuals, insomnia is transient in nature, lasting a few days, and resolving itself once the initial precipitating event has subsided. For others, perhaps those more vulnerable to sleep disturbances, insomnia may persist long after the initial triggering event has disappeared; other factors would then perpetuate sleep disturbances [32]. The course of insomnia may also be intermittent, with repeated brief episodes of sleep difficulties following a close association with the occurrence of stressful events. Longitudinal studies have shown that chronicity rates may range from 45 to 75 % for follow-ups of one to seven years [33–35]. Even in chronic insomnia, there is often extensive night-to-night variability in sleep patterns, with an occasional restful night's sleep intertwined with several nights of poor sleep [17]. The type of sleep difficulties (i.e., sleep-onset or maintenance insomnia) may also change over time. The prognosis for insomnia varies across individuals and is probably mediated by a combination of biologically related predisposing factors and psychological and behavioral perpetuating factors. It may also be complicated by the presence of comorbid psychiatric or medical disorders.

Etiology and Pathophysiology

Insomnia is most likely multifactorial in nature, but its precise etiology is not known. Hyperarousal is a central feature of insomnia, but it is not entirely clear whether this is a state that is conditioned to sleep-related stimuli or a more enduring trait present throughout the 24-h period. It is likely that both biologic and psychological factors contribute to increased arousal and interference with normal initiation and maintenance of sleep.

Biologic basis. Evidence of hyperarousal in insomnia is derived primarily from cross-sectional studies using different physiological, hormonal, and EEG markers (see Bonnet and Arand [36]; and Rieman et al. [37] for reviews). For instance, numerous studies have reported increased body temperature, galvanic skin response, heart rate, and metabolic rate, both near-sleep onset and during sleep, among

individuals with insomnia relative to healthy good sleepers. Investigations using quantitative EEG techniques and event-related potential (ERP) studies have also shown increased high-frequency (beta) activity during sleep (see "Polysomnographic Findings" above), higher amplitude of waking P300 responses [38], and evidence of decreased inhibition and/or increased sensitivity in response to auditory stimuli in insomnia [36, 37, 39]. Neuroendocrine studies have yielded more mixed results, with some findings suggesting increased cortisol and adrenocorticotropic hormone levels during sleep and throughout the 24-h period [40, 41] and other findings failing to reveal significant differences between insomniacs and good sleepers [42].

Neuroimaging studies have suggested possible structural and functional brain abnormalities in insomnia [43]. A positron-emission tomography (PET) study showed increased cerebral glucose metabolic rates during wakefulness and NREM sleep in insomniacs compared to healthy controls [44]. Insomnia patients also exhibited smaller declines in glucose metabolism from wakefulness to sleep in wake-promoting brain areas such as the ascending reticular activating system. Another small magnetic resonance imaging (MRI) study has shown reduced hippocampal volumes in primary insomniacs relative to health controls [45], although this was not replicated in other studies [43]. Others have reported correlations between loss of orbitofrontal gray matter and early morning awakening [46], and loss of prefrontal cortex gray matter and insomnia severity and wakefulness after sleep onset as well as pericentral cortex gray matter loss and sleep latency [47]. On the other hand, another study of insomnia subjects did not find any significant abnormalities in gray or white matter volumes in comparison with normal subjects [48]. Functional MRI studies during waking have suggested hypoactivation of cortical areas in response to tasks, and some spectroscopy studies have demonstrated reduced GABA levels in cortical areas [43]. Further studies will be needed to clarify whether specific structural or functional brain abnormalities are associated with insomnia.

Psychological basis. Psychological and behavioral factors also play an important role in the development and maintenance of insomnia as evidenced by higher levels of presleep cognitive arousal (e.g., intrusive thoughts and worries) and general psychological reactivity among individuals with insomnia relative to good sleepers. Chronic exposure to stress may also contribute to trigger or exacerbate insomnia, although some findings also suggest that sleep disturbance is more the result of reduced ability to cope with daily stressors, combined with increased cognitive arousal at bedtime, rather than from stress alone [49].

Learning and conditioning are also involved in the maintenance or exacerbation of sleep disturbances. The discomfort associated with insomnia can lead to a negative association between temporal (bedtime) and environmental (bed/bedroom) stimuli previously associated with sleep and, over time, the combination of maladaptive sleep habits (e.g., excessive amounts of time spent in bed) and sleep-related cognitive factors (e.g., worry about the consequences of insomnia and excessive self-monitoring) may exacerbate or perpetuate what might otherwise have been a transient sleep problem [50, 51].

Although it remains unclear whether hyperarousal is a direct cause, a by-product, or a consequence of insomnia, it is a central feature in the pathophysiology of insomnia [36, 37]. Along with a reduced homeostatic sleep drive, it is likely to arise from the interaction of biologically based predisposing factors and psychologically based exacerbating factors.

Evaluation of Insomnia

Clinical and Laboratory Evaluations

The diagnosis of insomnia is derived primarily from a detailed clinical evaluation of the patient's subjective complaint (see Table 37.2). The sleep history should cover the type of complaint (initial, middle, late insomnia), its duration (acute vs. chronic), and course (recurrent, persistent); typical sleep schedule; functional analysis of precipitating, perpetuating, and alleviating factors; perceived consequences and functional impairments; and the presence of medical, psychiatric, or environmental contributing factors. A complete history of alcohol and drug use and prescribed and over-the-counter medications is also essential [52–54].

The use of a sleep diary is essential in the evaluation of insomnia (see Table 37.3). A daily sleep diary is very helpful to document the nature and severity of insomnia, identify behavioral and scheduling factors that may perpetuate insomnia, and monitor treatment compliance and progress [55]. The *Insomnia Severity Index* [56] is a brief questionnaire that provides a global measure of the patient's perception of insomnia severity and its impact on daytime functioning (see Table 37.4). Several additional measures of insomnia symptoms, fatigue, anxiety, and depressive symptomatology may also provide useful complementary information in the evaluation of insomnia [53]. A more comprehensive psychological evaluation may be necessary for patients with suspected psychiatric disorders.

Although polysomnography is not indicated for the routine evaluation of insomnia, it is often necessary to rule out other sleep disorders that might contribute to the insomnia complaint (e.g., periodic movements during sleep and sleep apnea) [57]. PSG can also be particularly useful in suspected case of paradoxical insomnia or when a patient is unresponsive to treatment. The role of actigraphy in insomnia

Table 37.2 Evaluation of insomnia

- Nature of the complaint—difficulties falling or staying asleep, early morning awakening
- Daytime symptoms—fatigue, mood disturbances, attention/concentration problems
- Clinical significance—frequency, severity, duration of sleep difficulties
- Onset and course of insomnia
- Typical sleep-wake schedule (weekdays, weekends)
- Sleeping environment (noise, light, temperature)
- Functional analysis—evening activities, prebedtime rituals, triggers of nocturnal and morning awakenings (pain, noise); behavioral responses to insomnia
- Perpetuating/exacerbating (worries about sleep loss, daytime napping, excessive amounts of time in bed)
- Beliefs about sleep requirement expectations and consequences of poor sleep
- Use of sleeping aids/substances (caffeine, alcohol, drugs)
- Other medical problems
- Recent life events contributing to insomnia
- Symptoms of other psychiatric disorders (anxiety, depression)
- Symptoms of other sleep disorders (restless legs syndrome, sleep apnea)
- Previous treatment for insomnia and outcome

Table 37.3 Sleep diary

Name: _____

Week: _____ to _____

	Example	Mon	Tue	Wed	Thu	Fri	Sat	Sun
1. Yesterday, I napped from ___ to ___ (note the times of all naps)	1:50 to 2:30							
2. Yesterday, I took ___ mg of medication and/or ___ oz ___ of alcohol as sleep aid								
3. Last night, I went to bed and turned the lights off at ___ o'clock	11:15							
4. After turning the lights off, I fell asleep in ___ min	40 min							
5. My sleep was interrupted ___ times (specify number of nighttime awakenings)	2							
6. My sleep was interrupted for ___ minutes (specify duration of each awakening)	10 45							
7. This morning, I woke up at ___ o'clock (note time of last awakening)	6:15							
8. This morning, I got out of bed at ___ o'clock (specify the time)	6:40							
9. When I got up this morning I felt ___ (1 = exhausted 2 = fair 3 = refreshed)	2							
10. Overall, my sleep last night was ___ (1 = restless 2 = fair 3 = very sound)	3							

From [185]

evaluation and treatment monitoring is not well established. Although it may represent a useful adjunct, actigraphy is not clinically indicated for routine assessment, diagnosis, or management of insomnia. Nonetheless, it is useful for examining night-to-night variability and for identifying individuals with circadian rhythm disorders. It has also been used to document treatment adherence and outcome in clinical trials of behavioral therapies for insomnia [58]. Although a potentially useful complement to self-report and PSG measures, actigraphy devices and algorithms are not all equivalent and there may be significant variability in the reliability and validity of sleep-wake data derived from different devices.

Table 37.4 Insomnia severity index

Insomnia Severity Index (ISI)

For each question below, please circle the number corresponding most accurately to your sleep patterns in the **LAST MONTH.**

For the first three questions, please rate the **SEVERITY** of your sleep difficulties.

1. Difficulty falling asleep:

None	Mild	Moderate	Severe	Very Severe
0	1	2	3	4

2. Difficulty staying asleep:

None	Mild	Moderate	Severe	Very Severe
0	1	2	3	4

3. Problem waking up too early in the morning:

None	Mild	Moderate	Severe	Very Severe
0	1	2	3	4

4. How **SATISFIED**/dissatisfied are you with your current sleep pattern?

Very Satisfied	Satisfied	Neutral	Dissatisfied	Very Dissatisfied
0	1	2	3	4

5. To what extent do you consider your sleep problem to **INTERFERE** with your daily functioning (e.g., daytime fatigue, ability to function at work/daily chores, concentration, memory, mood).

Not at all Interfering	A Little Interfering	Somewhat Interfering	Much Interfering	Very Much Interfering
0	1	2	3	4

6. How **NOTICEABLE** to others do you think your sleeping problem is in terms of impairing the quality of your life?

Not at all Noticeable	A Little Noticeable	Somewhat Noticeable	Much Noticeable	Very Much Noticeable
0	1	2	3	4

7. How **WORRIED**/distressed are you about your current sleep problem?

Not at all	A Little	Somewhat	Much	Very Much
0	1	2	3	4

Guidelines for scoring/interpretation:

Add scores for all seven items = _____
Total score ranges from 0 to 28
0–7 = No clinically significant insomnia
8–14 = Subthreshold insomnia
15–21 = Clinical insomnia (moderate severity)
22–28 = Clinical insomnia (severe)
© Morin [58, 185]

Treatment

The first step in treating insomnia is to identify and remove the contributing factors. General sleep hygiene recommendations are also useful as preventative strategies. Then, insomnia-specific therapies include psychological and behavioral interventions, medications, and a variety of complementary and alternative therapies (e.g., acupuncture, yoga, and herbal therapies). The rest of this chapter focuses on psychological/behavioral and pharmacological therapies; most of the alternative therapies have not been evaluated adequately with regard to their efficacy and safety in the management of insomnia.

Psychological and Behavioral Therapies

Treatment goals and indications. Psychological and behavioral therapies for insomnia include sleep restriction, stimulus control therapy, relaxation-based interventions, cognitive strategies, sleep hygiene education, and combined cognitive behavioral therapy. A summary of those interventions is provided below and in Table 37.5; more extensive descriptions are available in other sources [52, 59]. The main objectives of psychological and behavioral approaches are to alter factors that perpetuate or exacerbate sleep disturbances. Such features may include hyperarousal, sleep scheduling factors, poor sleep habits, and misconceptions about sleep and the consequences of insomnia. Although numerous factors can precipitate insomnia, when it becomes a persistent problem, psychological and behavioral factors are almost always involved in perpetuating it over time, hence the need to target those factors directly in treatment. The primary indication for behavioral treatment is in the management of persistent insomnia, with evidence available for both primary and comorbid insomnia.

Sleep restriction. Poor sleepers often increase their time in bed in a misguided effort to provide more opportunity for sleep, a strategy that is more likely to result in fragmented and poor quality sleep. Sleep restriction consists of curtailing the amount of time spent in bed to the actual amount of sleep [60]. For example, if a person reports sleeping an average of 6 h per night out of 8 h spent in bed, the initial sleep window (i.e., from initial bedtime to final arising time) would be set at 6 h. Subsequent adjustments to this "sleep window" are based on sleep efficiency (SE) for a given period of time (usually the preceding week); time in bed is increased by about 20 min for a given week when SE exceeds 85 %, decreased by the same amount of time when SE is lower than 80 %, and kept stable when SE falls between 80 and 85 %. Periodic (weekly) adjustments are made until optimal sleep duration is achieved. Changes to the prescribed sleep window can be made at the beginning of the night (i.e., postponing bedtime), at the end of the sleep period (i.e., advancing arising time), or at both ends. To prevent excessive daytime sleepiness, time in bed should not be reduced to less than 5 h per night in bed. This procedure leads to improvements of sleep continuity through a mild sleep deprivation and reduction of sleep anticipatory anxiety. Due to potential residual daytime sedation, sleep restriction should be used with caution with patients operating heavy equipment or required to drive long distances [61]. Sleep restriction is contraindicated in patients with a bipolar disorder, with seizures, or with some parasomnias (sleep walking, night terrors).

Stimulus control therapy. Individuals with insomnia may develop apprehension around bedtime and come to associate the bedroom with frustration and arousal rather than with sleep. Stimulus control therapy [62] consists of a set of instructions designed to strengthen the association between temporal (bedtime) and environmental (bed and bedroom)

Table 37.5 Psychological and behavioral treatments for insomnia disorder

Therapy	Description
Stimulus control therapy	A set of instructions designed to strengthen the association between the bed/bedroom with sleep and to re-establish a consistent sleep-wake schedule: (1) Go to bed only when sleepy; (2) get out of bed when unable to sleep; (3) use the bed/bedroom for sleep only (no reading, watching TV, etc.); (4) arise at the same time every morning; and (5) no napping
Sleep restriction therapy	A method designed to restrict time spent in bed as close as possible to the actual sleep time, thereby producing mild sleep deprivation. Time in bed is then gradually increased over a period of few days/weeks until optimal sleep duration is achieved
Relaxation training	Clinical procedures aimed at reducing somatic tension (e.g., progressive muscle relaxation and autogenic training) or intrusive thoughts (e.g., imagery training and meditation) interfering with sleep. Most relaxation requires some professional guidance initially and daily practice over a period of a few weeks
Cognitive therapy	Psychotherapeutic method aimed at reducing worry and changing faulty beliefs and misconceptions about sleep, insomnia, and daytime consequences. Other cognitive strategies can also be used to control intrusive thoughts at bedtime and reduce excessive monitoring of the daytime consequences of insomnia
Sleep hygiene education	General guidelines about health practices (e.g., diet, exercise, and substance use) and environmental factors (e.g., light, noise, and temperature) that may promote or interfere with sleep. This may also include some basic information about normal sleep and changes in sleep patterns with aging
Cognitive behavioral therapy (CBT)	A combination of any of the above behavioral (e.g., stimulus control, sleep restriction, and relaxation) and cognitive procedures

stimuli and rapid sleep onset and to establish a regular circadian sleep-wake rhythm. These instructions are as follows: (a) going to bed only when sleepy, (b) getting out of bed when unable to sleep (e.g., after 20 min), going to another room, and returning to bed only when sleep is imminent; (c) curtailing all sleep-incompatible activities (i.e., no TV watching and problem solving in bed); (d) arising at a regular time every morning regardless of the amount of sleep the night before; and (e) avoiding daytime napping. Despite the straightforward nature of these recommendations, the main challenge for most patients is to comply with all of them, which is essential to reverse the conditioning processes perpetuating insomnia. Caution is advised in using some of these procedures (e.g., getting out of bed when unable to sleep) with the frail elderly who may be at risk for falls.

Relaxation-based interventions. Relaxation is probably the most commonly used nondrug therapy for insomnia. Some relaxation methods (e.g., progressive muscle relaxation) focus primarily on reducing somatic arousal (e.g., muscle tension), whereas attention-focusing procedures (e.g., imagery training and meditation) target mental arousal in the forms of worries or intrusive thoughts. Mindfulness-based stress reduction [63] is another relaxation variant, and all these methods are fairly equivalent in terms of efficacy for insomnia. The most critical issue is to practice diligently and daily the selected method for at least two to four weeks. Professional guidance is often necessary in the initial phase of training.

Cognitive therapy. This psychotherapeutic method seeks to alter dysfunctional sleep cognitions (e.g., beliefs and expectations) and maladaptive cognitive processes (e.g., excessive self-monitoring) through Socratic questioning and behavioral experiments. The basic premise of this approach is that appraisal of a given situation (sleeplessness) and excessive monitoring of sleep-related cues (e.g., fatigue and time left for sleep) can trigger an emotional response (fear, anxiety) that is incompatible with sleep. For example, when a person is unable to sleep at night and worries about the possible consequences of sleep loss on the next day's performance, this can set off a spiral reaction and feed into the vicious cycle of insomnia, emotional distress, and more sleep disturbances. Cognitive therapy is designed to identify dysfunctional cognitions and reframe them into more adaptive substitutes in order to short-circuit the self-fulfilling nature of this vicious cycle. Treatment targets may include unrealistic expectations ("I must get my 8 h of sleep every night") and amplification of the consequences of insomnia ("Insomnia may have serious consequences on my health") [52]. Cognitive therapy is particularly useful to modify these maladaptive cognitions and to teach patients more adaptive skills to cope with insomnia [64].

Sleep hygiene education. Sleep hygiene education is intended to provide information about lifestyle (diet, exercise, substance use) and environmental factors (light, noise, temperature) that may either interfere with or promote better sleep. Sleep hygiene guidelines include (a) avoiding stimulants (e.g., caffeine), several hours before bedtime; (b) avoiding alcohol around bedtime as it fragments sleep; (c) exercising regularly (especially in late afternoon or early evening) as it may deepen sleep; (d) allowing at least a 1-h period to unwind before bedtime; and (e) keeping the bedroom environment quiet, dark, and comfortable. In addition to these guidelines, it is useful to provide basic information about normal sleep, individual differences in sleep needs, and changes in sleep physiology over the course of the life span. This information is particularly useful to help some patients distinguish clinical insomnia from short sleep or from normal (age-related) sleep disturbances. Although inadequate sleep hygiene is rarely the primary cause of insomnia, it may potentiate sleep difficulties caused by other factors or interfere with treatment progress. Addressing these factors should be an integral part of insomnia management, even though it is rarely sufficient for more severe insomnia, which often requires more directive and potent behavioral interventions.

Multicomponent therapies. Despite some unique features, the interventions described above can be effectively combined together. There is a general preference among investigators and clinicians for combining multiple interventions, with cognitive behavioral therapy (CBT) becoming the standard approach in the field [58]. The most common combination involves a behavioral (stimulus control, sleep restriction, and, sometimes, relaxation), a cognitive, and an educational (sleep hygiene) component, usually referred to as CBT. Such combination is often preferred to address the different components presumed to perpetuate insomnia.

Outcome Evidence

Evidence for efficacy. Several meta-analyses [65–67] and systematic reviews commissioned by the American Academy of Sleep Medicine [58, 68] have summarized the findings from clinical trials evaluating the efficacy of psychological and behavioral therapies for persistent insomnia. Evidence from these sources shows that treatment produces reliable changes in several sleep parameters, including sleep-onset latency (effect sizes ranging from 0.41 to 1.05), number of awakenings (0.25–0.83), duration of awakenings (0.61–1.03), total sleep time (0.15–0.49), and sleep quality ratings (0.94–1.14). Based on Cohen's criteria, the magnitude of those therapeutic effects is large (i.e., $d > 0.8$) for sleep latency and sleep quality and moderate (i.e., $d > 0.5$) for other sleep parameters. When transformed into a

percentile rank, these data indicate that approximately 70–80 % of patients with insomnia achieve a therapeutic response with psychological and behavioral therapies.

In terms of absolute changes, treatment reduces subjective sleep-onset latency and time awake after sleep onset from averages of 60–70 min at baseline to about 35 min at post-treatment, and total sleep time is increased by 30 min, from 6 to 6.5 h after treatment. Thus, for the average insomnia patient, treatment effects may be expected to reduce sleep latency and time awake after sleep onset by about 50 % and to bring the absolute values of those sleep parameters below or near the 30-min cutoff criterion initially used to define insomnia. Treatment effects are similar for sleep-onset and sleep-maintenance problems, although fewer studies have targeted early morning awakening problems. Overall, findings from meta-analyses represent fairly conservative estimates of treatment effects as they are based on averages computed across all nonpharmacological interventions and insomnia diagnoses (i.e., primary and comorbid). On the other hand, although the majority of patients benefit from treatment, only about 40 % achieves clinical remission [58].

Treatment outcome has been documented primarily with prospective daily sleep diaries, although several studies have also complemented those findings with data from polysomnography [69–71] and with wrist actigraphy [72, 73]. In general, the magnitude of improvements is smaller on PSG measures, but those changes tend to parallel sleep improvements reported on daily sleep diaries. PSG findings indicate that treatment does not only alter sleep perception, as measured by patient-reported outcomes, but also produce objective changes on EEG sleep continuity measures. Except for a modest increase in stages 3–4 following sleep restriction, there is little evidence of changes in sleep architecture with psychological and behavioral treatment. In addition to improving sleep continuity parameters, there is also some evidence showing improvements on several secondary endpoints including measures of daytime fatigue, quality of life, and psychological symptoms [58, 73].

Long-term outcomes. A fairly robust finding across behavioral treatment studies is that sleep improvements are well maintained over time, with data available up to 24 and even 36 months after treatment completion. Although interventions that restrict the amount of time spent in bed may yield only modest increases (and even a reduction) of sleep time during the initial treatment period, this parameter is usually improved at follow-ups, with total sleep time often exceeding 6.5 h. Long-term outcome must be interpreted cautiously, however, as few studies report long-term follow-ups and, among those that do, attrition rates increase over time. In addition, a substantial proportion of those patients with chronic insomnia who benefit from short-term therapy may remain vulnerable to recurrent episodes of insomnia in the long term. As such, there is a need to develop and evaluate the effects of long-term maintenance therapies to prevent or minimize the occurrence of those episodes.

Treatment of Comorbid Insomnia. Insomnia is often a pervasive problem among patients suffering from other medical and psychiatric conditions [74]. Although sleep may improve with appropriate treatment of the comorbid condition, sleep disturbances are also likely to persist. Thus, the presence of a comorbid medical or psychiatric disorder should not preclude using a behavioral intervention concomitantly as behavioral factors are often involved in perpetuating or even exacerbating the sleep problem. Evidence from small clinical trials [75, 76] suggests that patients with medical and psychiatric conditions can also benefit from insomnia-specific treatment [77]. Controlled studies have also shown that behavioral treatment is effective for insomnia associated with chronic pain [78], fibromyalgia [79], cancer [80, 81], and various medical conditions in older adults [82, 83]. In general, insomnia symptoms are more severe among patients with comorbid disorders, but the absolute changes on those outcomes during treatment are comparable to those obtained with primary insomnia.

Insomnia in older adults is more likely to be comorbid with another medical or another sleep disorder than to be primary in nature. Recent studies have shown that older adults respond to insomnia treatment, particularly when they are screened for other sleep disorders that increase in incidence in older age (e.g., restless legs syndrome and sleep apnea). A meta-analysis [84] suggested that effect sizes were comparable (moderate to large) for middle-aged and older adults on subjective measures of sleep latency, wake after sleep onset, and sleep quality. Older adults with either comorbid medical or psychological conditions can benefit from sleep-specific treatment [82, 83, 85, 86]. Three clinical trials have shown that a supervised and time-limited withdrawal program, with or without behavioral treatment for insomnia, can facilitate discontinuation of hypnotics among older adults with insomnia who are prolonged users [87–89].

Which insomnia therapies work best? Although there has been no complete dismantling of cognitive behavioral therapies to isolate the relative efficacy of each component, direct comparisons of some of those components indicate that sleep restriction, alone or combined with stimulus control therapy, is more effective than relaxation which, in turn, is more effective than sleep hygiene education alone [58]. Sleep restriction tends to produce better outcome than stimulus control for improving sleep efficiency and sleep continuity, but it also decreases total sleep time during the initial intervention. Although some basic education about sleep hygiene is incorporated to most insomnia treatments, sleep hygiene education produces little impact on sleep when used as the only intervention. A recent study has

shown that cognitive therapy alone can be effective in the management of insomnia [64].

There is no strong evidence that a multicomponent approach is more effective than any of its single component. However, the appeal for this multimodal approach may come from the fact that it addresses different facets presumed to perpetuate sleep disturbances. While little information is available about the active treatment mechanisms of cognitive behavioral therapy, some evidence suggests that stimulus control and sleep restriction are particularly effective for improving sleep continuity, whereas changes in sleep-related cognitions are associated with better maintenance of sleep changes over time [90]. With increasing evidence that hyperarousal is implicated in primary insomnia, there is a need for greater attention to identify the biologic as well as psychological mechanisms responsible for sleep changes.

Combined Behavioral and Pharmacological Approaches

Behavioral and pharmacological therapies can play a complementary role in the management of insomnia. No single treatment is effective with all forms of insomnia or acceptable to all patients. Even among treatment responders, few patients reach complete remission and some residual sleep disturbances often persist even after treatment. Thus, combined approaches should theoretically optimize outcome by capitalizing on the more immediate and potent effects of hypnotics and the more sustained effects of behavioral interventions.

Only a few studies have directly compared the effects of behavioral and pharmacological therapies for insomnia. Three studies compared triazolam to relaxation [91, 92] or sleep hygiene [93], and five investigations compared CBT to temazepam [68], zolpidem [71, 94], or zopiclone [95, 96]. Collectively, findings from these studies indicate that both therapies are effective in the short term, with medication producing faster results in the acute phase (first week) of treatment, whereas both treatments are equally effective in the short-term interval (4–8 weeks). Combined interventions appear to have a slight advantage over single-treatment modality during the initial course of treatment, but it is unclear whether this advantage persists over time. Long-term effects are consistent for the single-treatment modalities; patients treated with CBT maintain their improvements, whereas therapeutic effects are typically lost after discontinuation of medication. Long-term effects of combined interventions are more equivocal. Some studies indicate that a combined intervention (i.e., triazolam plus relaxation) produces more sustained benefits than medication alone [91, 92], whereas others report more variable long-term outcomes [69, 93]. Some patients retain their initial sleep improvements, but others return to their baseline values. As behavioral and attitudinal changes are often essential to sustain sleep improvements, patients' attributions of the initial benefits may be critical in determining long-term outcomes. Attribution of therapeutic benefits to the hypnotic alone, without integration of self-management skills, may place a patient at greater risk for recurrence of insomnia once medication is discontinued. Thus, despite the intuitive appeal of combining behavioral and medication therapies, it is not entirely clear when, how, and for whom it is indicated to combine these treatment modalities for insomnia. Additional research is needed to evaluate the effects of combined treatments and to examine optimal methods for integrating these therapies.

Comparisons of effect sizes from meta-analyses [65, 67, 97] on different sleep variables indicate that behavioral therapy may have a slight advantage on measures of sleep-onset latency and sleep quality and pharmacotherapy (benzodiazepine receptor agonists), a more favorable outcome on total sleep time. One study examined different sequences of CBT and medication therapies [96]. The best results were obtained when CBT was introduced first in the sequence, but medication was found helpful to improve total sleep time, which may be an important advantage given that one component of CBT (i.e., sleep restriction) reduces total sleep time during the initial course of therapy and could lead some patients to premature therapy discontinuation.

Until more evidence-based treatment guidelines become available, several strategies can be considered for selecting the most appropriate treatment in the clinical management of insomnia. The use of hypnotic medication may be particularly indicated in the initial stage of therapy to break the vicious cycle of insomnia and to provide some rapid relief. On the other hand, CBT is essential to alter perpetuating factors and to teach coping skills. As such, it is an essential treatment component to maximize durability of sleep improvements. Ideally, medications should be discontinued, under supervision, after an initial treatment course of a few weeks. However, given that insomnia may be a recurrent problem, even among those who benefit from treatment initially, it may be necessary to use medications intermittently after the initial acute treatment.

Pharmacotherapy (See also Chap. 55 [Monti])

Several different classes of medications are used for insomnia (Table 37.6), including both over-the-counter (OTC) and prescription agents; however, many of these are not approved by the US Food and Drug Administration (FDA) for the treatment of insomnia. Current FDA-approved insomnia medications include a group of benzodiazepine receptor agonists (BZRAs), one melatonin receptor agonist (ramelteon), and one tricyclic antidepressant (doxepin). Although not FDA-approved for the treatment of insomnia,

Table 37.6 Drugs used to promote sleep

Benzodiazepine receptor agonists					
Drug	Dose range	Dose in the elderly	Half-life (h)	Effects on sleep	Side effects
Benzodiazepines					
Estazolam	1–2 mg	0.5 mg	10–24	Total sleep time: ↑ Sleep latency: ↓ WASO: ↓ Stage 1 %: ↓ Stage 2 %: ↑ Slow-wave sleep %: ↓ REM %: ↓ REM latency: ↑	Dizziness, drowsiness, hypokinesia, abnormal coordination, amnesia, GI symptoms
Flurazepam	15–30 mg	15 mg	47–100		Dizziness, drowsiness, light-headedness, staggering, ataxia, amnesia, increased risk of falling, GI symptoms
Quazepam	7.5–15 mg	7.5 mg	For quazepam and 2-oxoquazepam, 25–41; *N*-desakyl-1-oxoquazepam, 70–75		Dizziness, drowsiness, dyskinesia, slurred speech, amnesia, GI symptoms
Temazepam	7.5-30 mg	7.5 mg	6–16 (2)		Drowsiness, dizziness, light-headedness, difficulty with coordination, amnesia, GI symptoms
Triazolam	0.25–0.5 mg	0.125–0.25 mg	1.5–5.5		Drowsiness, dizziness, light-headedness, coordination disorders/ataxia, amnesia
Nonbenzodiazepines					
Eszopiclone	2–3 mg	1–2 mg	5–5.8	Sleep latency: ↓ WASO: ↓	Unpleasant taste, dry mouth, dizziness, drowsiness, amnesia, GI symptoms
Zaleplon	10–20 mg	5–10 mg	1	Sleep latency: ↓	Dizziness, headache, GI symptoms, myalgia, drowsiness, amnesia Drowsiness, dizziness, amnesia, GI symptoms
Zolpidem	5[a]–10 mg	5 mg	1.4–4.5	Sleep latency: ↓ WASO during first 6 h: ↓	
Zolpidem CR	6.25[a]–12.5 mg	6.25 mg	1.6–3.6	Sleep latency: ↓	
Zolpidem SL	1.75[a]–3.5 mg	1.75 mg	1.4–3.6	Sleep latency: ↓	
Indiplon	5–10 mg		1.25	Sleep latency: ↓	
Indiplon NR	15 mg			Sleep latency: ↓ WASO: ↓ Total sleep time: ↑	Drowsiness, dizziness

Melatonin receptor agonist					
Drug	Dose range	Dose in the elderly	Half-life (hours)	Effects on sleep	Side effects
Ramelteon	8 mg	8 mg	2.6	Sleep latency: ↓	Drowsiness, dizziness, fatigue
Antidepressants					
Doxepin	3–6 mg	3 mg	10–30	WASO: ↓ Total sleep time: ↑	Drowsiness At higher doses, drowsiness, dizziness, confusion, blurred vision, dry mouth, constipation, urinary retention, arrhythmias, orthostatic hypotension, and weight gain Exacerbation of restless legs, periodic limb movements, or REM sleep behavior disorder

Other Agents					
Antidepressants					
Drug	Dose range[a]	Dose in the elderly (1)	Half-life (hours)	Effects on sleep	Side effects
Amitriptyline	50–100 mg	20 mg	10–28, including the metabolite nortriptyline	Total sleep time: ↑ Sleep latency: ↓ Stage 2 %: ↑	REM %: ↓ REM latency: ↑ Drowsiness, dizziness, confusion, blurred vision, dry mouth, constipation, urinary

(continued)

Table 37.6 (continued)

Melatonin receptor agonist					
Drug	Dose range	Dose in the elderly	Half-life (hours)	Effects on sleep	Side effects
					retention, arrhythmias, orthostatic hypotension, weight gain. Exacerbation of restless legs, periodic limb movements or REM sleep behavior disorder
Mirtazapine	15–45 mg	7.5–15 mg	20–40	Total sleep time: ↑ Sleep latency: ↓ WASO: ↓	Drowsiness, dizziness, increased appetite, constipation, weight gain
Trazodone	150–400 mg	150 mg	7	Sleep latency: ↓ WASO: ↓ Slow-wave sleep %: ↑	Drowsiness, dizziness, headache, blurred vision, dry mouth, arrhythmias, orthostatic hypotension, priapism
Anticonvulsants					
Gabapentin	300–600 mg	300 mg	5–7	WASO: ↔ to ↓ Slow-wave sleep %: ↑	Drowsiness, dizziness, emotional lability, ataxia, tremor, blurred vision, diplopia, nystagmus, myalgia, peripheral edema
Tiagabine	4–8 mg	4 mg	7–9	WASO: ↓ Slow-wave sleep %: ↑	Drowsiness, dizziness, ataxia, tremor, new-onset seizures in patients without epilepsy, difficulty with concentration or attention, nervousness, asthenia, abdominal pain, diarrhea, nausea
Pregabalin	50–100 mg	25–50 mg	6	Sleep latency: ↓ Slow-wave sleep %: ↑	Drowsiness, dizziness, ataxia, confusion, peripheral edema
Antipsychotics					
Olanzapine	5–10 mg	5 mg	21–54	Sleep latency: ↔ to ↓ WASO: ↓ Slow-wave sleep %: ↑ REM %: ↔ to ↓	Drowsiness, dizziness, tremor, agitation, asthenia, extrapyramidal symptoms, dry mouth, dyspepsia, constipation, orthostatic hypotension, weight gain, new-onset diabetes mellitus
Quetiapine	25–200 mg	25 mg	6	Insufficient data	Drowsiness, dizziness, asthenia, dry mouth, dyspepsia, constipation, orthostatic hypotension, weight gain, new-onset diabetes mellitus
Over-the-counter agents					
Drug	Dose range[a]	Dose in the elderly	Half-life (h)	Effects on sleep	Side effects
Diphenhydramine	50 mg diphenhydramine chloride 76 mg diphenhydramine citrate	25 mg	2.4–9.3	Sleep latency: ↓ WASO: ↔ to ↓ Slow-wave sleep %: ↔ to ↑ REM %: ↓	Drowsiness, dizziness, dyskinesia, dry mouth, epigastric distress, constipation, tachycardia
Melatonin	Dosages not empirically determined	Dosages not empirically determined	0.5	Sleep latency: ↓	Concentration difficulty, dizziness, fatigue, headache, irritability

FDA-approved hypnotics
Listed are recommended maximum amounts for a single dose
[a]Recommended starting dose in women
GABA: gamma aminobutyric acid
WASO: wake after sleep onset
↔: no change
↑: increase
↓: decrease

sedating antidepressants have been prescribed widely; other classes of prescription medications used with increasing frequency for their potential sleep-inducing side effects include anticonvulsants and atypical antipsychotics.

There are a number of reasons for the widespread use of nonapproved medications for insomnia. Until the introduction of eszopiclone in 2005, FDA labeling for all BZRA hypnotics stated that they were indicated for the short-term treatment of insomnia, preferably not for more than a few weeks, and it was recommended that patients be re-evaluated if drugs were to be used longer. Since chronic insomnia typically lasts for years, this meant that those with chronic insomnia could only receive short-term treatment. In addition, concerns about tolerance, dependence, and abuse made physicians as well as patients reluctant to use these agents long term. Until the introduction of ramelteon in 2005, no FDA-approved hypnotics were nonscheduled. Antidepressants, anticonvulsants, and antipsychotics, in contrast, are nonscheduled substances and can be used long term. Furthermore, with the recognition that many insomnia patients have comorbid depression and/or anxiety, the use of an antidepressant might be appealing to treat the mood problem as well as the insomnia; the doses of antidepressants that are prescribed for insomnia, however, are almost always subtherapeutic for the treatment of depression. There is a relative lack of data showing that treatment of insomnia reduces any of its comorbidities, which is another possible barrier to the prescription of hypnotics; physicians may be discouraged from prescribing drugs that are perceived to have potential adverse effects.

More individuals with insomnia self-medicate than take prescription medications, and the fact that many individuals self-medicate for insomnia suggests that the disorder may be undertreated. Population-based studies have found that over 12- to 18-month periods, 10–13 % of people have used only alcohol to help them fall asleep and 10 % have used OTC agents alone, whereas only 5–8 % have used prescription medications [98, 99]. Polls by the National Sleep Foundation have found that 16–28 % of adults have used alcohol and 22–29 % have used OTC agents for sleep at some point during their lives [100, 101]. In general, patients who self-medicate with alcohol or OTC agents tend to do so for shorter periods of time and have less severe insomnia than those who take prescription medications [98].

Benzodiazepine Receptor Agonists

The current FDA-approved BZRAs for insomnia include the older benzodiazepines (estazolam, flurazepam, quazepam, temazepam, triazolam) and the newer nonbenzodiazepines (eszopiclone, zaleplon, zolpidem) (see Table 37.6). These medications all bind to the γ-aminobutyric acid (GABA) type A receptor complex. $GABA_A$ receptors are the predominant inhibitory receptors in the brain, and the binding of a BZRA leads to increased flow of negatively charged chloride ions into a neuron, making it less likely to fire an action potential. Benzodiazepines bind to all subtypes of $GABA_A$ receptors, whereas some of the newer nonbenzodiazepines, particularly zaleplon and zolpidem, bind preferentially to the type I $GABA_A$ receptor. This different pattern of receptor binding affinity may be associated with slight differences in clinical effects. The type I receptor is thought to mediate both the hypnotic and the amnestic effects of BZRAs, but drugs acting selectively on this receptor may be less effective as muscle relaxants or anxiolytics. Clinically, it is important to remember that all BZRAs have the potential to produce amnesia.

Benzodiazepines

Benzodiazepine hypnotics, with the exception of triazolam, have relatively long half-lives. Estazolam, flurazepam, quazepam, and temazepam all reduce latency to sleep onset and tend to improve sleep maintenance, as indicated by decreased waking time after sleep onset, reduced number of awakenings, and/or increased total sleep time [102–108]. Triazolam also promotes sleep onset, but, because of its short half-life, does not appear to be helpful for sleep maintenance [109–111]. Benzodiazepines decrease time spent in stage 1 sleep and increase stage 2 sleep, but they also tend to suppress slow-wave sleep and, possibly, REM sleep. Adverse effects of benzodiazepine hypnotics include daytime sedation, cognitive and psychomotor impairment, and memory impairment [105, 110]; such effects are more common with higher doses and longer-acting agents. Abrupt withdrawal may be associated with rebound insomnia with triazolam as well as the longer-acting agents [109, 112].

As noted earlier, benzodiazepine hypnotics are indicated for the short-term treatment of insomnia. None has been studied in a randomized clinical trial for more than 12 weeks [113], so that long-term efficacy data are not available.

Nonbenzodiazepines

The nonbenzodiazepine BZRAs include those with short half-lives (zaleplon and zolpidem) that are indicated primarily for promoting sleep onset and those with either a longer half-life (eszopiclone) or a controlled-release formulation (zolpidem MR) that reduce sleep latency and improve sleep maintenance. Zaleplon, with the shortest half-life of currently available agents at about 1 h, may be dosed as long as the patient has at least 4 h remaining in bed; 4–6 h after ingestion of 10 or 20 mg of zaleplon, healthy volunteers did not demonstrate next-day impairment in driving ability, memory, or psychomotor function [114]. Although 5 to 10 mg doses of zaleplon primarily promote sleep onset, a dose of 20 mg increases subjective total sleep time [115, 116].

Zolpidem is currently the most commonly prescribed sleep agent. It is effective in promoting sleep onset and also increases total sleep time at doses of 10 mg or greater in both subjective and sleep laboratory studies [117]. The increase in sleep efficiency and/or total sleep is likely due to reduced sleep latency, since consistent effects on waking time after sleep onset have not been observed. A 12-week, placebo-controlled study demonstrated that intermittent use (three to five times per week) of zolpidem was associated with continued benefit on the nights the drug was taken, and no obvious evidence of rebound insomnia on the nights it was not taken [118]. Zolpidem has also been shown to be effective in subjects with depression treated with selective serotonin reuptake inhibitors (SSRIs), resulting in subjective increased total sleep and improved sleep quality and daytime function [119]. Doses of 10 mg of zolpidem administered during the night did not lead to clinically significant effects on driving or psychomotor skills the next day, at least 4–6 h after ingestion, in healthy subjects or insomnia patients [114, 120], but higher doses produced significant impairment [114]. Zolpidem MR consists of a dual-layer tablet: a shell containing 7.5 mg of immediate-release zolpidem and a core containing 5 mg of zolpidem that is released in a delayed fashion for a total of 12.5 mg. There is also a 6.25-mg tablet containing 3.75 mg of immediate-release/2.5 mg of delayed-release zolpidem. The half-life of zolpidem MR remains short, but the duration of action is longer than that with zolpidem, as evidenced by decreased waking time during 3–6 h postingestion, presumably related to the higher blood levels. A double-blind, placebo-controlled multicenter study showed clinical efficacy with zolpidem MR at a dose of 12.5 mg for up to 6 months when taken for 3–7 nights per week, without significant rebound insomnia upon discontinuation [121]. Subjects who took medication reported shorter sleep-onset latencies, improved sleep maintenance, and evidence of better next-day function as indicated by subjective reports of improved concentration and decreased morning sleepiness. More recently, a sublingual formulation of zolpidem has been approved for use in the USA in 1.75 and 3.5 mg doses for the treatment of insomnia due to middle-of-the-night awakening; it may be taken when there is at least 4 h of time in bed remaining. In comparison with 10 mg of immediate-release zolpidem, ingestion of 3.5 mg of the sublingual preparation led to higher zolpidem plasma concentrations at 15 min and greater area under the curve (AUC) from 0 to 15 min [122]. A study comparing sublingual zolpidem with placebo for middle-of-the-night awakening in primary insomnia patients showed significant self-reported reductions in sleep latency, improvements in sleep quality, and improvements in morning alertness [123]. In January 2013, the US Food and Drug Administration issued a requirement that the recommended dosages for all forms of zolpidem be lowered because morning blood levels, particularly in women, could otherwise be high enough to cause impairment in activities that require alertness, such as driving.

Eszopiclone was the first hypnotic to be indicated for the treatment of insomnia without recommendations for restricted duration of use. It has a longer half-life than any of the other nonbenzodiazepines, which accounts for its effects on improving sleep maintenance. In a 6-month placebo-controlled clinical trial, it showed persistent efficacy in reducing latency to sleep onset, decreasing wakefulness during sleep, and increasing total sleep time, as subjectively reported [124]. In another 6-month double-blind study, eszopiclone was shown not only to reduce insomnia, but also to enhance quality-of-life measures and reduce reported work limitations [125]. It is also one of the first agents for which data suggest improved daytime function and/or decreased comorbidity from other disorders. Elderly insomnia patients taking 2 mg of eszopiclone reported reduced daytime napping [126], and depressed patients given a combination of fluoxetine plus eszopiclone had better sleep and higher rates of response and remission 8 weeks later in comparison with depressed patients given fluoxetine plus placebo [127].

Outcome Evidence

Efficacy of BZRAs

Several meta-analyses have assessed the efficacy of BZRA hypnotics in comparison with placebo in the treatment of chronic insomnia. In a review of studies done on adults less than 65 years of age, benzodiazepines and zolpidem were shown to produce significant subjective improvement in sleep latency, total sleep, number of awakenings, and sleep quality, with moderate effect sizes ranging from 0.56 to 0.71 [97]. A meta-analysis of studies performed on adults and elderly adults showed that benzodiazepines produced significant improvements in both subjective and objective sleep parameters; sleep latency was reduced by 4.2 min objectively and 14.3 min subjectively, and total sleep amount was increased by 61.8 min objectively and 48.4 min subjectively [105, 128]. Another analysis of drug effects in elderly insomnia patients showed significant improvement in sleep quality (effect size 0.14), increased total sleep (25.2 min), and decreased awakenings (effect size 0.63) with sedative use as compared with placebo [129]. A comparison of benzodiazepine hypnotics with nonbenzodiazepines concluded that zolpidem may show benefits over temazepam in terms of reducing sleep latency and improving sleep quality and over zaleplon in terms of increasing sleep duration and improving sleep quality [130]. Zaleplon, however, may produce less rebound insomnia than zolpidem. This analysis was limited, however, by the lack of comparative studies and short durations of the studies, which makes it difficult to

assess longer term effects. A more recent meta-analysis of data submitted to the US FDA showed that the BZRA hypnotics led to small but statistically significant reductions in both objective (polysomnographically measured) and subjective sleep latencies [131]. Sleep latency reductions were more likely to be found in studies that were published earlier, in studies with larger drug doses, in studies with younger patients and in female patients, and in studies using zolpidem.

BZRA Side Effects

A number of adverse outcomes have been associated with drugs in this class, whether benzodiazepines or nonbenzodiazepines. Sedation/daytime sleep "hangover" and impaired cognitive and psychomotor performance can be seen at peak blood levels and may occur the following day with longer-acting agents [132]. Anterograde amnesia, or loss of memory for events that occur after taking a hypnotic, is more common with higher doses and with drugs with rapidly increasing plasma levels (e.g., triazolam and the nonbenzodiazepines) or when BZRAs are used in combination with alcohol; confusional arousals or sleepwalking episodes may be a related phenomenon. BZRAs should therefore always be taken immediately prior to bedtime to minimize the risk of amnesia or parasomnias and discontinued in patients who report these side effects.

All medications used for sleep, including BZRAs but also antidepressants and anticonvulsants, can increase the risk of nighttime falls in elderly patients [133–135]. However, insomnia is an independent predictor of falls in the elderly [136], and a study has suggested that insomnia, but not hypnotic use, was associated with a greater risk of falls [137]. A recent Korean study assessing the risk of fractures in elderly insomnia patients found an increased risk of fracture associated with the use of zolpidem (adjusted odds ratio 1.72), but no statistically significant association between the use of benzodiazepine hypnotics and fracture [138]. Other side effects associated with BZRAs include tolerance, rebound insomnia, abuse, and withdrawal. Although concerns about tolerance are likely a factor for physicians and patients in avoiding or limiting the use of these agents, in fact the few longer term studies that have been performed with eszopiclone, zolpidem, and zaleplon have not shown evidence of obvious tolerance [118, 119, 125, 139]. Rebound insomnia, or the worsening of insomnia to a degree greater than baseline, is generally seen for not more than 1–2 days and not in all studies. Abuse of and dependence on BZRAs may occur in patients with histories of substance abuse, but the risk is generally overestimated for those without such histories; insomnia patients tend to show therapy-seeking, not drug-seeking, behavior [140]. Nevertheless, BZRAs should be avoided in those with tendencies to abuse substances.

An attempt to assess risks and benefits for BZRAs in the treatment of insomnia concluded that although these agents improved sleep, they also led to adverse effects in comparison with placebo [105, 128]; daytime drowsiness was increased by a 2.4 odds ratio and dizziness or light-headedness was increased by a 2.6 odds ratio. However, the increase in adverse events did not lead to increased rates of discontinuation of hypnotics. A study regarding the use of BZRAs in elderly insomnia patients, however, raised concerns that there were significant risks with both benzodiazepines and nonbenzodiazepines, including adverse cognitive events (4.78 times more common), adverse psychomotor events (2.61 times more common), and daytime fatigue (3.82 times more common) [129]. The authors concluded that in elderly patients, the risks of BZRAs might outweigh the benefits in some cases.

Indications and Limitations

The benzodiazepines zolpidem and zaleplon are indicated for "the short-term treatment of insomnia," whereas eszopiclone and zolpidem MR are indicated for "the treatment of insomnia," without language limiting duration of use. BzRAs should not be used during pregnancy (all are in FDA Pregnancy Category C) or in patients with histories of substance abuse. They should be used with caution in patients who have pulmonary or liver disease and in the elderly; dosage reductions at least are recommended in these populations. No hypnotics are approved for use in children under 18 years of age.

Melatonin and Melatonin Receptor Agonist

Melatonin, a hormone produced by the pineal gland, is available as an OTC preparation and has been widely used for insomnia and related sleep problems. Currently, ramelteon is the only melatonin receptor agonist approved by the FDA for the treatment of insomnia and is available by prescription. These agents presumably act through their effects on melatonin receptors in the suprachiasmatic nucleus in the brain, although their exact mechanism has not been determined.

Melatonin

Over-the-counter melatonin preparations are rapidly absorbed and have a short half-life (up to 1 h). They are not regulated by the FDA and are thus not approved for the treatment of insomnia. The hypnotic effects of melatonin appear to be relatively smaller in comparison with BZRAs; a meta-analysis concluded that the average decrease in sleep

latency was 4 min, total sleep time was increased by 12.8 min, and sleep efficiency increased by 2.2 % [141]. One study of melatonin for secondary insomnia and circadian rhythm disorders (i.e., jet lag and shift work) failed to find any significant differences in comparison with placebo, except for a slight increase (1.9 %) in sleep efficiency. Several studies, however, have demonstrated that low doses of melatonin (300–500 μg) were effective in producing phase shifts in normal subjects and entraining circadian rhythms in blind individuals [142–144]. A more recent meta-analysis of the efficacy of melatonin in primary sleep disorders, however, concluded that it reduced sleep latency (weighted mean difference (WMD) 7.06 min), increased total sleep time (WMD 8.25 min), and improved sleep quality; although these effects were statistically significant, they were generally smaller in magnitude than effects of prescription hypnotics [145]. Melatonin does not appear to have side effects other than sedation.

Ramelteon

Ramelteon is an agonist of melatonin type 1 (MT_1) and type 2 (MT_2) receptors and is structurally unrelated to melatonin; it does not show affinity for the GABA receptor complex or other receptors thought to be involved in sleep or wakefulness. It has a relatively short half-life (2.6 h), and its metabolite also acts as an MT_1/MT_2 agonist. The most robust effects of ramelteon on sleep are the reduction of latency to sleep onset, but it has also been reported to increase the total sleep time in some studies [146]; it does not appear to decrease wakefulness after sleep onset. Ramelteon is indicated for the treatment of insomnia characterized by difficulty with sleep onset. Its main side effects are somnolence, dizziness, and fatigue. Important distinctions from the BZRA class include no evidence of tolerance, withdrawal, rebound insomnia, cognitive or psychomotor impairment, or daytime sedation, and it is therefore not classified as a controlled substance by the FDA [147]. There are no data at present regarding its efficacy in treating circadian rhythm disorders.

A meta-analysis of ramelteon in chronic insomnia reported that it significantly reduced subjective and PSG-measured sleep latency and increased total sleep as measured by PSG, with no evidence of next-day residual effects [148]. Ramelteon may not be as efficacious for insomnia as some of the BZRAs in terms of the magnitude of sleep improvement, but other factors make it an attractive alternative for many patients: its low toxicity and wide safety margin; lack of many of the adverse effects associated with BZRAs; and its ability to be used in patients with substance abuse histories and a variety of medical disorders, including mild-to-moderate pulmonary disease. It should not be used in combination with fluvoxamine or other potent inhibitors of cytochrome P450 isozyme 1A2, since this leads to dramatically increased levels of ramelteon. It is not recommended for use in pregnant women (FDA Pregnancy Category C).

Warnings for Hypnotics

In 2007, the FDA introduced a change in labeling for hypnotics, including BZRAs and ramelteon, based on the reports of rare but potentially serious adverse events following ingestion of hypnotics (www.fda.gov/bbs/topics/NEWS/2007/NEW01587.html) [149]. These included severe allergic reactions and complex sleep-related behaviors, such as sleep driving, sleep eating, and sleep sex, in which individuals are engaged in these activities without fully awakening. Such reactions are more likely to occur when hypnotics are combined with other sedatives, including alcohol, or taken at higher-than-recommended doses.

Sedating Antidepressants

Despite a relative lack of data and no FDA indication for insomnia with the exception of low-dose doxepin, sedating antidepressants, such as the tricyclic antidepressants (TCAs), trazodone, and mirtazapine, are some of the most commonly used agents for treating chronic insomnia. In general, there are relatively few efficacy data regarding the use of these agents in primary insomnia.

Tricyclic Antidepressants

Amitriptyline and doxepin are some of the more commonly used TCAs in the treatment of insomnia [150]. Their therapeutic effects on depression are related to inhibition of serotonin (5-hydroxytryptamine [5-HT]) and norepinephrine reuptake, whereas their effects on sleep are probably mediated by their antagonistic effects on histamine type 1 (H_1), serotonin type 2 ($5HT_2$), and α-adrenergic type 1 receptors. Doxepin has the most potent antihistamine effects in this class and is approved for the treatment of insomnia in doses of 3 and 6 mg. In studies of adults and elderly subjects with insomnia, doxepin increased total sleep time and sleep efficiency, primarily by improving sleep maintenance later in the night [151, 152]. TCAs tend to have long half-lives, which often leads to daytime sedation and other adverse effects. In general, when used to promote sleep, they are prescribed at doses lower than those recommended for treating depression.

The effects of TCAs on sleep have been studied more frequently in patients with major depressive disorder, in whom they have been shown to reduce latency to sleep onset and increase sleep efficiency [153, 154]. A PSG study in subjects with primary insomnia showed that low doses of

doxepin (1, 3, or 6 mg) led to improvements in objective sleep and subjective sleep maintenance and duration in comparison with placebo, without evidence of side effects such as anticholinergic effects, hangover, or memory impairment [155]. TCAs at higher doses have profound effects on sleep architecture, most notably suppression of REM sleep [156, 157]. REM sleep rebound and sleep disturbance may thus occur following abrupt discontinuation of TCAs, making them less attractive for intermittent dosing.

TCAs can also have adverse effects on sleep, including the exacerbation of restless legs syndrome or periodic limb movement disorder, or precipitation of REM sleep behavior disorder [158]. They can also induce hypomania or mania in patients with underlying bipolar disorder, which is generally associated with severe insomnia.

All tricyclics have significant anticholinergic effects, which lead to many of their side effects, including dry mouth, constipation, urinary retention, and sweating; amitriptyline has such strongest effects. Orthostatic hypotension can result from α_1-adrenergic receptor antagonism, increasing the risk for falls. The TCAs also have quinidine-like effects on cardiac conduction, which can result in the prolongation of the QT interval; cardiotoxicity is a major concern, and these drugs have a high degree of lethality in overdosage.

Trazodone

Trazodone has been one of the most frequently prescribed drugs for insomnia over at least the past decade and is probably used almost exclusively for this purpose at present, usually in doses of up to 100 mg at bedtime. Its popularity is probably due to its low cost, low abuse potential, and lack of restrictions on long-term use. Its effects on sleep are probably due to its antihistaminergic effects at the H_1 receptor, α_1-adrenergic receptor antagonism, and $5HT_2$ receptor antagonism. Given its widespread use, there are surprisingly few studies documenting its effects on sleep. Most of the studies showing positive effects on sleep were performed in depressed subjects, although most of these were limited by problems such as small sample sizes and lack of placebo controls; trazodone resulted in reduced sleep latency, increased sleep efficiency, and total sleep in several studies in depressives [159]. Only one double-blind, placebo-controlled study has been performed in primary insomnia; in this study, trazodone 50 mg and zolpidem 10 mg were compared with placebo over a 2-week period [160]. During the first week, trazodone and zolpidem led to subjective reductions in sleep latency, increases in total sleep and sleep quality, and decreased wakefulness after sleep onset, but zolpidem produced a greater reduction in sleep latency than trazodone. During the second week, trazodone did not differ from placebo, whereas zolpidem still produced a significantly shorter sleep latency and more total sleep. In terms of trazodone's objective effects on sleep architecture, the most consistent finding has been an increase in slow-wave sleep. There are insufficient data to conclude that trazodone does not lead to tolerance or rebound insomnia. Some recent studies have suggested that trazodone may improve both subjective sleep and mood in patients with insomnia and depression [161].

Trazodone is associated with a number of frequent adverse effects, including daytime sedation/drowsiness, dizziness, dry mouth, gastrointestinal upset, blurred vision, and headache; these have led to fairly high discontinuation rates in clinical trials [159]. Although less common, trazodone may also have significant cardiovascular effects, such as orthostatic hypotension, prolonged QT interval, and cardiac arrhythmias. Priapism, although quite rare, is a medical emergency and can occur even with low doses. One of the major metabolites of trazodone, *meta*-chlorophenylpiperazine, has serotonergic effects and may contribute to serotonin syndrome (confusion/delirium, hyperreflexia, autonomic instability) when trazodone is used in combination with other serotonergic agents. These potential side effects raise concerns about using trazodone in elderly or medically ill populations.

Mirtazapine

Mirtazapine tends to be used at low doses (7.5–15 mg) as a sleep-inducing agent and probably affects sleep through antagonism of H_1, $5HT_2$, and α_1-adrenergic receptors. As with trazodone, there are relatively few data regarding its efficacy for insomnia. In normal subjects, mirtazapine increased sleep efficiency and slow-wave sleep on the first night of treatment as determined in a sleep laboratory setting [162]. In an uncontrolled PSG study of depressives treated with 30 mg of mirtazapine, slow-wave sleep increased, REM latency was prolonged, wakefulness after sleep onset decreased, and subjective ratings of sleep improved [163]. In comparison with fluoxetine, depressed subjects who received mirtazapine showed significantly improved sleep by PSG criteria [164]. It is generally believed that lower doses of mirtazapine are more sedating than higher doses, but there are few objective clinical data in support of this. Common side effects of mirtazapine include drowsiness, daytime sedation, dry mouth, increased appetite, and weight gain. Its low toxicity is an advantage in comparison with some of the other sedating antidepressants.

Atypical Antipsychotics

Atypical antipsychotics, particularly quetiapine and olanzapine, are also used with increasing frequency for insomnia. In contrast to the older antipsychotics that act primarily through blockade of dopamine type 2 receptors, the newer agents also act on a variety of receptors in addition, including antagonism of $5HT_{2A}$ and $5HT_{2C}$ receptors, antihistaminergic effects, and antagonism of α_1-adrenergic receptors. Although they may have a role in treating comorbid insomnia in patients with primary indications for their use (e.g., psychotic disorders, bipolar disorder, and treatment-refractory depression), their use in primary insomnia should be avoided if possible. One controlled study on the effects of quetiapine at 25 or 100 mg performed in healthy male volunteers [165] resulted in shorter sleep latency, increased total sleep and sleep efficiency, and improved subjective sleep quality. The 100 mg dose, however, caused a significant increase in periodic leg movements. An open-label study in 18 insomnia patients, using doses of 25–75 mg, reported increases in PSG-recorded total sleep time and sleep efficiency and improvements in self-reported sleep quality [166]. In another study, ziprasidone produced effects similar to quetiapine, but also led to increased slow-wave sleep and REM sleep suppression [167]. One night of administration of olanzapine to healthy male volunteers produced effects similar to quetiapine in comparison with placebo [168]. In an open-label study in depressives, olanzapine added to SSRI treatment led to increased sleep efficiency and slow-wave sleep [169].

In addition to the lack of efficacy data for insomnia, atypical antipsychotics are associated with adverse events. They have lower rates of extrapyramidal effects than the older antipsychotics, but these may still occur. Other concerns are risks for weight gain, glucose intolerance, dyslipidemia, daytime sedation, cognitive impairment, restless legs syndrome, and hepatotoxicity. These agents carry a "black box" warning for increased risk of sudden death in elderly patients with dementia.

Anticonvulsants

Several anticonvulsants acting on the GABA system to increase GABA effects in the brain have been used in the treatment of insomnia. There are few, if any, data regarding their use in insomnia, but they appear to have some sedating and/or sleep-promoting effects. Their advantages include low toxicity and that they are not controlled substances. Gabapentin is thought to increase synaptic levels of GABA, but its mechanism of action is not clearly understood [170]. It has been reported to increase slow-wave sleep in patients with epilepsy [171], improve insomnia ratings in an open-label study of alcoholics with insomnia [172], and increase slow-wave sleep in normal adults [173]. A recent open-label clinical trial in primary insomnia subjects who took a mean dose of 540 mg demonstrated increased slow-wave sleep, increased sleep efficiency and decreased arousals, and subjective improvement in sleep quality [174]. Gabapentin is generally well tolerated and has low toxicity, but can cause daytime sedation, dizziness, and leukopenia.

Tiagabine inhibits GABA reuptake through inhibition of the GABA transporter. It is one of the few anticonvulsants with data from placebo-controlled studies in insomnia. In a study of elderly subjects with insomnia, doses of 4–8 mg significantly increased slow-wave sleep, and doses of 6–8 mg led to decreased awakenings [175]. At the 8 mg dose, subjects reported subjective decreases in total sleep, less refreshing sleep, worse daytime functioning, and more adverse events. Similar effects were seen in a study of tiagabine in healthy elderly subjects [176]. A study in nonelderly adults with primary insomnia using tiagabine doses up to 16 mg also showed that the drug produced increased slow-wave sleep and decreased waking after sleep onset (at the 16 mg dose), but there was no significant effect on latency to persistent sleep [177]. Again, higher doses were associated with more adverse effects, including decreased next-day alertness and cognitive performance, dizziness, and nausea. Thus, although potentially helpful for insomnia, the side effects of tiagabine may limit its utility.

Pregabalin, like gabapentin, was designed as a GABA analogue; like gabapentin, its mechanism is unclear. A comparison of alprazolam with pregabalin in healthy subjects showed that both drugs reduced sleep latency and decreased REM sleep amount [178]; however, pregabalin led to significant increases in slow-wave sleep, whereas alprazolam decreased it; only alprazolam prolonged REM sleep latency. Studies on the effects of pregabalin on sleep have been performed in subjects with fibromyalgia and insomnia and have demonstrated significant subjective improvement in sleep [161]. The most common side effects of pregabalin are dizziness and somnolence.

Antihistamines

Antihistamines are the active ingredients in most OTC medications and act through antagonism of H1 receptors. Diphenhydramine and doxylamine are found in virtually all OTC sleeping medications, but it is important to note that doxepin (described earlier) is a more potent antihistamine than any of the OTCs. Histamine1 antagonists cause sedation in most individuals, but can lead to paradoxical excitation in some individuals, particularly with higher doses and/or in children and the elderly. Despite the widespread use of these agents, there are almost no data regarding their effects on sleep, and there are no rigorous, placebo-controlled studies in insomnia. A study of the subjective effects of diphenhydramine in psychiatric patients

with insomnia showed that it led to global improvement in sleep in about two-thirds of subjects [179], and another outpatient study found that mild-to-moderate insomnia patients in a family practice setting reported more restful sleep and shorter sleep latency with 50 mg diphenhydramine in comparison with those taking placebo [180]. An assessment of motor activity and subjective sleep parameters in normal adults showed minimal or no effects on sleep parameters and a tendency for increased motor activity [181]. Finally, a study in normal men showed that diphenhydramine led to rapid tolerance of its sedative effects [182], suggesting that these agents may not be useful for long-term treatment. A recent meta-analysis summarizing the results of 4 small trials of diphenhydramine failed to find significant effects on sleep, but only subjective sleep reports were collected in these studies [183].

These agents are associated with significant adverse effects, such as daytime sedation, cognitive impairment, increased risk of accidents, dizziness, tinnitus, gastrointestinal symptoms, weight gain, and increased intraocular pressure in narrow-angle glaucoma; as a result, their use has been strongly discouraged for patients with allergic rhinitis in favor of antihistamines without central nervous system effects [184].

Current Status of Pharmacotherapy for Insomnia

The National Institutes of Health held a State-of-the-Science Conference on Manifestations and Management of Chronic Insomnia in Adults in 2005 (http://consensus.nih.gov/2005/2005InsomniaSOS026html.htm). This nonpartisan review of currently available treatments came to several conclusions regarding pharmacotherapy for insomnia.

Benzodiazepine Receptor Agonists

Benzodiazepine receptor agonists, including benzodiazepines and nonbenzodiazepines, are effective in the short-term treatment of insomnia, and most have not been studied long term using randomized clinical trials; eszopiclone has shown sustained efficacy for 6 months in primary insomnia patients. Adverse effects of BZRAs include residual daytime sedation, motor coordination and cognitive impairment, dependence, and rebound insomnia. Side effects are greater in elderly patients. Side effects related to the newer BZRAs are much lower, probably related to their shorter half-lives. Abuse liability of BZRAs does not appear to be a major problem, but data related to long-term use for insomnia require further study.

Sedating Antidepressants

Trazodone is the most commonly prescribed medication for insomnia in the USA. It is sedating and improves several sleep parameters, but there are no studies of long-term use for chronic insomnia. Doxepin has beneficial effects for insomnia for up to 4 weeks; there are insufficient data for other antidepressants such as amitriptyline and mirtazapine for the treatment of insomnia. All antidepressants have significant adverse effects.

Other Agents

There are no data regarding the use of antipsychotics for the treatment of insomnia; these agents have significant risks, and they are not recommended for use in insomnia. Antihistamines are commonly used, but there are no data regarding their efficacy for insomnia. Furthermore, they have significant adverse effects. Melatonin is not regulated by the FDA, and there is significant variability in preparations. It appears to be effective for circadian rhythm disorders, but there is little evidence for efficacy in the treatment of insomnia. There are no data regarding safety in long-term use [5].

The American Academy of Sleep Medicine published a clinical guideline for chronic insomnia in 2008 [54]. In terms of pharmacotherapy, they recommended that choice of an agent should be determined based on clinical parameters such as characteristics of the insomnia, treatment goals, response to previous medications, other medical and psychiatric conditions, potential side effects/interactions with other medications, contraindications, cost, and patient preference. The recommended pharmacotherapy choice sequence is the following:

1. Short-intermediate-acting benzodiazepine, benzodiazepine receptor agonist, or ramelteon.
2. Alternate choice from group 1 if the first choice is not effective or tolerated.
3. Sedating antidepressant.
4. Combination of choice from group 1 and a sedating antidepressant.
5. Consideration of other agents, such as anticonvulsant or atypical antipsychotic, preferably in patients with insomnia related to comorbid conditions for which these agents may be beneficial.

Summary and Conclusions

Insomnia is a prevalent health complaint that may present as an independent disorder or as a condition comorbid to a medical or psychiatric disorder. Persistent insomnia is associated with significant morbidity and healthcare costs. Progress has been made to standardize research diagnostic criteria, but there is still little information about the psychological and biologic bases of insomnia and about its natural history and long-term prognosis. Significant

advances have also been made in developing and validating therapeutic approaches for the management of both acute and chronic insomnia. Despite these advances, insomnia remains under-recognized and undertreated in clinical practice. Additional research is needed to further document the etiology of insomnia and its natural history and to optimize therapeutic outcomes, not only in terms of reducing insomnia symptoms but also in terms of impact on other indicators of morbidity and cost-effectiveness. A significant challenge for the future will be to optimize treatment algorithms and ensure validated therapies are integrated in clinical practice guidelines.

Acknowledgments Preparation of this chapter was facilitated by research grants from the National Institute of Mental Health (MH091053) and by the Canadian Institutes for Health Research (MT-42504).

Introduction

Recent progress for understanding the pathophysiology of excessive daytime sleepiness (EDS) particularly owes itself to the discovery of narcolepsy genes (i.e., hypocretin receptor and peptide genes) in animals in 1999 and the subsequent discovery in 2000 of hypocretin ligand deficiency (i.e., loss of hypocretin neurons in the brain) in idiopathic cases of human narcolepsy–cataplexy. The hypocretin deficiency can be clinically detected by cerebrospinal fluid (CSF) hypocretin-1 measures; low CSF hypocretin-1 levels are seen in over 90 % of narcolepsy–cataplexy patients. Since the specificity of the CSF finding is also high (no hypocretin deficiency was seen in patients with idiopathic hypersomnia), low CSF hypocretin-1 levels have been included in the 2nd revision of the International Classifications of Sleep Disorder (ICSDII) as a positive diagnosis for narcolepsy–cataplexy [1] only 5 years after the discovery of hypocretin deficiency in human narcolepsy.

Narcolepsy–cataplexy is tightly associated with human leukocyte antigen (HLA) DQB1*0602. Hypocretin deficiency in narcolepsy–cataplexy is also tightly associated with HLA positivity, suggesting an involvement of immune-mediated mechanisms in the loss of hypocretin neurons. However, the specificity of HLA positivity for narcolepsy–cataplexy is much lower than that of low CSF hypocretin-1 levels, as up to 30 % of the general population shares this HLA haplotype. The new ICSD-3, published in 2014, reclassifies "Narcolepsy" as "Type I-Cataplexy/Hypocretin deficient" and "Type 2-Hypocretin non-deficient" narcolepsy by attempting to emphasize the pathophysiological basis [2].

The prevalence of primary hypersomnia, such as narcolepsy and idiopathic hypersomnia, is not high at 0.05 and 0.005 %, respectively, but the prevalence of symptomatic hypersomnia (hypersomnia due to a medical condition) may be much higher. For example, several million subjects in the USA suffer from chronic brain injury, and 75 % of those people have sleep problems and about half of them claim sleepiness [3]. Symptomatic narcolepsy has also been reported, but the prevalence of symptomatic narcolepsy is much smaller, and only about 120 cases have been reported in the literature in the past 30 years [4]. A meta-analysis of these symptomatic cases indicates that hypocretin deficiency may also partially explain the neurobiological mechanisms of EDS associated with symptomatic cases of narcolepsy and hypersomnia [4].

Anatomical and functional studies demonstrate that the hypocretin systems integrate and coordinate the multiple wake-promoting systems, such as monoamine and acetylcholine systems to keep subjects fully alert and prevent abnormal REM sleep manifestations [5], suggesting that understanding of the roles of hypocretin peptidergic systems in sleep regulation in normal and pathological conditions is important, as alterations of these systems may also be responsible not only for narcolepsy but also for other less well-defined hypersomnia.

Since a large majority of patients with EDS are currently treated with pharmacological agents, new knowledge about the neurobiology of EDS will likely lead to the development of new diagnostic tests as well as new treatments and managements of patients with hypersomnia with various etiologies.

This review focuses on pathophysiological mechanisms and nosological aspects of narcolepsy and idiopathic hypersomnia. For the treatments of these conditions, the readers should refer to more specific publications available [6–9].

Symptoms of Narcolepsy

Excessive Daytime Sleepiness (EDS)

EDS and cataplexy are considered to be the two primary symptoms of narcolepsy, with EDS often being the most disabling symptom [10]. EDS most typically mimics the feeling that people experience when they are severely sleep deprived but may also manifest itself as a chronic tiredness or fatigue. Narcoleptic subjects generally experience a permanent background of baseline sleepiness that easily leads to actual sleep episodes in monotonous sedentary situations. This feeling is most often relieved by short naps (15–30 min), but in most cases the refreshed sensation only lasts a short time after awaking. The refreshing value of short naps is of considerable diagnostic value. Sleepiness also occurs in irresistible waves in these patients, a phenomenon best described as "sleep attacks." Sleep attacks may occur in very unusual circumstances, such as in the middle of a meal, a conversation, or a bicycle ride. These attacks are often accompanied by microsleep episodes [11] where the patient "blanks out." The patient may then continue his or her activity in a semi-conscious manner (writing incoherent phrases in a letter, speaking incoherently on the phone, etc.), a phenomenon called automatic behavior [11–13]. Learning problems and impaired concentration are frequently associated [11–15], but psychophysiological testing is generally normal.

Sleepiness is usually the first symptom to appear, followed by cataplexy, sleep paralysis and hypnagogic hallucinations [16–20]. Cataplexy onset occurs within five years after the occurrence of daytime somnolence in approximately two-thirds of the cases [17, 19]. Less frequently, cataplexy appears many years after the onset of sleepiness. The mean age of onset of sleep paralysis and hypnagogic hallucinations is also two to seven years later than that of sleepiness [16, 21].

In most cases, EDS and irresistible sleep episodes persist throughout the lifetime although they often improve after retirement (possibly due to better management of activities), daytime napping and adjustment of nighttime sleep.

Cataplexy

Cataplexy is distinct from EDS associated with narcolepsy and pathognomonic of the disease [22]. The importance of cataplexy for the diagnosis of narcolepsy has been recognized since its description [23, 24] and in subsequent reviews on narcolepsy [25, 26]. Most authors now recognize patients with recurring sleepiness and cataplectic attacks as a homogeneous clinical entity, and this is now shown to be tightly associated with hypocretin deficiency (see the section on the pathophysiology of the disease). Cataplexy is defined as a sudden episode of muscle weakness triggered by emotional factors, most often in the context of positive emotions (such as laughter, having good cards at card games, the pull of the fishing rod with a baiting fish, the perfect hit at baseball), and less frequently by negative emotions (most typically anger or frustration). All antigravity muscles can be affected leading to a progressive collapse of the subject, but respiratory and eye muscles are not affected. The patient is typically awake at the onset of the attack but may experience blurred vision or ptosis. The attack is almost always bilateral and usually lasts a few seconds. Neurological examination performed at the time of an attack shows a suppression of the patellar reflex and sometimes that of a Babinski's sign.

Cataplexy is an extremely variable clinical symptom [27]. Most often, it is mild and occurs as a simple buckling of the knees, head dropping, facial muscle flickering, sagging of the jaw or weakness in the arms. Slurred speech or mutism is also frequently associated. It is often imperceptible to the observer and may even be only a subjective feeling difficult to describe, such as a feeling of warmth or that somehow time is suspended [26, 27]. In other cases, it escalates to actual episodes of muscle paralysis that may last up to a few minutes. Falls and injury are rare and most often the patient will have time to find support or will sit down while the attack is occurring. Long episodes occasionally blend into sleep and may be associated with hypnagogic hallucinations. Children with narcolepsy often (about 1/3 of patients) present with a previously unrecognized description of cataplexy that we coined "cataplectic facies," consisting of a state of semipermanent eyelid and jaw weakness [28].

Patients may also experience "status cataplecticus." This rare manifestation of narcolepsy is characterized by subintrant cataplexy that lasts several hours per day and confines the subject to bed. It can occur spontaneously or more often upon withdrawal from anticataplectic drugs [18, 29, 30].

Cataplexy often improves with advancing age. In rare cases, it disappears completely but in most patients it is better controlled (probably after the patient has learned to control their emotions) [16, 31].

Sleep Paralysis

Sleep paralysis is present in 20–50 % of all narcoleptic subjects [19, 32–34]. It is often associated with hypnagogic hallucinations. Sleep paralysis is best described as a brief inability to perform voluntary movements at the onset of sleep, upon awakening during the night, or in the morning. Contrary to simple fatigue or locomotion inhibition, the patient is unable to perform even a small movement, such as lifting a finger. Sleep

paralysis may last a few minutes and is often finally interrupted by noise or other external stimuli. The symptom is occasionally bothersome in narcoleptic subjects, especially when associated with frightening hallucinations [35].

Whereas EDS and cataplexy are the cardinal symptoms of narcolepsy, sleep paralysis occurs frequently as an isolated phenomenon, affecting 5–40 % of the general population [36–38]. Occasional episodes of sleep paralysis are often seen in adolescence and after sleep deprivation, thus prevalence is high for single episodes.

Hypnagogic and Hypnopompic Hallucinations

Abnormal visual (most often) or auditory perceptions that occur while falling asleep (hypnagogic) or upon waking up (hypnopompic) are frequently observed in narcoleptic subjects [39]. These hallucinations are often unpleasant and are typically associated with a feeling of fear or threat [32, 35]. Polygraphic studies indicate that these hallucinations occur most often during REM sleep [32, 40]. These episodes are often difficult to distinguish from nightmares or unpleasant dreams, which also occur frequently in narcolepsy.

Hypnagogic hallucinations are most often associated with sleep attacks, and their content is described by the patient. The hallucinations are most often complex, vivid, dream-like experiences ("half sleep" hallucinations) and may follow episodes of cataplexy or sleep paralysis, a feature that is not uncommon in severely affected patients. These hallucinations are usually easy to distinguish from hallucinations observed in schizophrenia or related psychotic conditions.

Compared to cataplexy, hypnagogic and hypnopompic hallucinations themselves do not have specificity for the diagnosis of narcolepsy, as up to 20–30 % of normal people exhibit these symptoms in various situations [37, 41]. The folklore over the world describes similar phenomenon, including "Kanashibari" in Japan, literally meaning "bound or fastened in metal," "Pinyin" in China, literally meaning "ghost pressing on body."

Other Important Symptoms

One of the most frequently associated symptoms is insomnia, best characterized as a difficulty to maintain nighttime sleep. Typically, narcoleptic patients fall asleep easily, only to wake up after a short nap unable to fall asleep again for an hour or so. Narcoleptic patients do not usually sleep more than normal individuals over the 24-h cycle [42–44] but frequently have a very disrupted nighttime sleep [42–44]. This symptom often develops later in life and can be very disabling.

Other frequently associated problems are periodic leg movements [45, 46], REM behavior disorder, parasomnias [47, 48], and obstructive sleep apnea [46, 49, 50].

Narcolepsy was reported to be associated with changes in energy homeostasis several decades ago. Narcolepsy patients are frequently (1) obese [51, 52], (2) more often have insulin-resistant diabetes mellitus [51], (3) exhibit reduced food intake [53], and (4) have lower blood pressure and temperature [54, 55]. These findings, however, had not received much attention since they were believed to be secondary to sleepiness or inactivity during the daytime. More recently, however, it was shown that these metabolic changes may be found more specifically in hypocretin-deficient patients [56–58], suggesting a direct pathophysiological link.

Narcolepsy is a very incapacitating disease. It interferes with every aspect of life. The negative social impact of narcolepsy has been extensively studied. Patients experience impairments in driving, and there is a high prevalence of either car- or machine-related accidents. Narcolepsy also interferes with professional performance, leading to unemployment, frequent changes of employment, working disability, or early retirement [59–61]. Several subjects also develop symptoms of depression, although these symptoms are often masked by anticataplectic medications [12, 59, 62].

Neurobiology of Wakefulness

In order to understand the neurobiology of hypersomnia, we will first discuss current understandings of the neurobiology of wakefulness. Sleep/wake is a complex physiology regulated by brain activity, and multiple neurotransmitter systems such as monoamines, acetylcholine, excitatory and inhibitory amino acids, peptides, purines, and neuronal and non-neuronal humoral modulators (i.e., cytokines and prostaglandins) [8, 63] are likely to be involved. Monoamines are perhaps the first neurotransmitters recognized to be involved in wakefulness [9, 64] and the monoaminergic systems have been the most common pharmacological targets for wake-promoting compounds in the past years. On the other hand, prototypical hypnotics target the gammaaminobutyric acid (GABA)-ergic system, a main inhibitory neurotransmitter system in the brain [10, 65].

Cholinergic neurons also play critical roles in cortical activation during wakefulness (and during REM sleep) [9, 63]. Brainstem cholinergic neurons originating from the laterodorsal and pedunculopontine tegmental nuclei activate thalamocortical signaling, and cerebral cortical activation is further reinforced by direct cholinergic projections from the basal forebrain. However, currently no cholinergic compounds are used in sleep medicine, perhaps due to the complex nature of the systems and prominent peripheral side effects.

Monoaminergic neurons, such as norepinephrine (NE) containing locus coeruleus neurons, serotonin (5-HT) containing raphe neurons, and histamine containing tuberomammillary neurons (TMN) are wake-active and act directly on cortical and subcortical regions to promote wakefulness [8, 63]. In contrast to the focus on these wake-active monoaminergic systems, researchers have often underestimated the importance of dopamine (DA) in promoting wakefulness. Most likely, this is because the firing rates of midbrain DA-producing neurons (ventral tegmental area [VTA] and substantia nigra) do not have an obvious variation according to behavioral states [11, 66]. In addition, DA is produced by many different cell groups [12, 67], and which of these promote wakefulness remains undetermined. Nevertheless, DA release is greatest during wakefulness [68], and DA neurons increase discharge and tend to fire bursts of action potentials in association with significant sensory stimulation, purposive movement, or behavioral arousal [69]. Lesions that include the dopaminergic neurons of the VTA reduce behavioral arousal [70]. Recent work has also identified a small wake-active population of dopamine-producing neurons in the ventral periaqueductal grey that project to other arousal regions [71]. People with DA deficiency from Parkinson's disease are often sleepy [72], and dopamine antagonists are frequently sedating. These physiologic and clinical evidences clearly demonstrate that DA also plays a role in wakefulness.

Wakefulness (and various physiological systems associated with wakefulness) is essential for the survival of creatures and thus is likely to be regulated by multiple systems, each having a distinct role. Some arousal systems may have essential roles for cortical activation, attention, cognition, or neuroplasticity during wakefulness while others may only be active during specific times to promote particular physiology during wakefulness. Some of the examples may be motivated-behavioral wakefulness or wakefulness in emergency states. Wakefulness may thus likely be maintained by many systems with differential roles to be fully alert. Similarly, the wake-promoting mechanism of some drugs may not be able to be explained by a single neurotransmitter system.

Sleep Physiology and Symptoms of Narcolepsy

Since narcolepsy is a prototypical EDS disorder and since the major pathophysiology of narcolepsy (i.e., deficiency in hypocretin neurotransmission) has recently been revealed, the discussion of neurophysiological aspects of narcolepsy will help understand neurobiology of EDS.

Narcolepsy patients manifest symptoms specifically related to dysregulation of REM sleep [10]. In the structured, cyclic process of normal sleep, two distinct states—REM and 3 stages (S1, S2, S3) of non-REM (NREM) sleep—alternate sequentially every 90 min in a cycle repeating 4 to 5 times per night [73]. As EEG signals in humans indicate, NREM sleep, characterized by slow oscillation in thalamocortical neurons (detected as cortical slow waves) and muscle tonus reduction, precedes REM sleep, when complete muscle atonia occurs. Slow-wave NREM predominates during the early phase of normal sleep, followed by a predominance of REM during the later phase [73].

Notably, sleep and wake are highly fragmented in narcolepsy, and affected subjects could not maintain long bouts of wake and sleep. Normal sleep physiology is currently understood as dependent upon coordination of the interactions of facilitating sleep centers and inhibiting arousal centers in the brain, such that stable sleep and wake states are maintained for specific durations [73]. An ascending arousal pathway, running from the rostal pons and through the midbrain reticular formation, promotes wakefulness [73, 74]. As discussed earlier, this arousal pathway may be composed of neurotransmitters (acetylcholine, NE, DA, excitatory amino acids), produced by brainstem and hypothalamic neurons (hypocretin/orexin, and histamine) and may also be linked to muscle tonus control during sleep [73, 74]. Whereas full alertness and cortical activation require coordination of these arousal networks, effective sleep requires suppression of arousal by the hypothalamus [74]. Narcolepsy patients may experience major neurological malfunction of this control system originated in the hypothalamus.

Narcoleptics exhibit a phenomenon termed short REM sleep latency or sleep onset REM period (SOREMP), in which they enter REM sleep more immediately upon falling asleep than normal [10]. In some cases, NREM sleep is completely bypassed, and the transition to REM sleep occurs instantly [10]. SOREMS are not observed in idiopathic hypersomnia, suggesting a distinct etiology from narcolepsy.

Moreover, intrusion of REM sleep into wakefulness may explain cataplexy, sleep paralysis, and hypnogogic hallucinations, which are symptoms of narcolepsy. Although sleep paralysis and hallucinations manifest in other sleep disorders (sleep apnea syndromes and disturbed sleep patterns in the normal population) [75] (see also "sleep paralysis and hallucinations" section) [75], cataplexy is pathognomic for narcolepsy [10]. As such, identifying cataplexy's unique pathophysiological mechanism emerged to be potentially crucial in understanding overall pathophysiology of narcolepsy.

Discovery of Hypocretin Deficiency in Human Narcolepsy

The significant roles, first, of hypocretin deficiency and, subsequently, of postnatal cell death of hypocretin neurons as the major pathophysiological process underlying narcolepsy with cataplexy, were established from a decade of investigation in employing both animal and human models. In 1998, the simultaneous discovery of a novel hypothalamic peptide neurotransmitter by two independent research groups proved pivotal [76, 77]. One group called the peptides "hypocretin" because of their primary hypothalamic localization and similarities with the hormone "secretin" [77]. The other group called the molecule "orexin" (after the meaning of appetite in Greek) after observing that central administration of these peptides increased appetite in rats [76]. These neurotransmitters are produced exclusively by thousands of neurons, which are localized in the lateral hypothalamus, and project broadly to specific cerebral regions and more densely to others [78].

Within a year, Stanford researchers, using positional cloning of a naturally occurring familial canine narcolepsy model, identified an autosomal recessive mutation of hypocretin receptor 2 (Hcrtr 2) responsible for canine narcolepsy, characterized by cataplexy, reduced sleep latency, and SOREMPs [79]. This finding coincided with the simultaneous observation of the narcolepsy phenotype, characterized by cataplectic behavior and sleep fragmentation, in hypocretin ligand-deficient mice (prepro-orexin gene knockout mice) [80]. Together, these findings confirmed hypocretins as principal sleep/wake-modulating neurotransmitters and prompted investigation of the hypocretin system's involvement in human narcolepsy.

Although screening of high-risk patients with cataplexy (i.e., familial, early onset, and/or HLA negative cases) did not reveal hypocretin-related gene mutation as a major cause of human narcolepsy, narcoleptic patients did exhibit low CSF hypocretin-1 levels [81] (Fig. 38.1). Post-mortem brain tissue of narcoleptic patients, assessed with immunochemistry, radioimmunological peptide assays, and in situ hybridization, revealed hypocretin peptide loss and undetectable levels of hypocretin peptides or prepro-hypocretin RNA (Fig. 38.1). Further, melanin-concentrating hormone neurons, which are normally located in the same brain region [82], were observed intact, thus indicating that damage to hypocretin neurons and its production is selective in narcolepsy, rather than due to generalized neuronal degeneration.

As a result of these findings, a diagnostic test for narcolepsy based on clinical measurement of CSF hypocretin-1 levels for detecting hypocretin ligand deficiency, became available [1]. Whereas CSF hypocretin-1 concentrations above 200 pg/ml almost always occur in controls and patients with other sleep and neurological disorders, concentrations below 110 pg/ml are 94 % predictive of narcolepsy with cataplexy [83] (Fig. 38.2). As this represents a more specific assessment than the multiple sleep latency test (MSLT), CSF hypocretin-1 levels below 110 pg/ml are indicated in the ICSD-2 as diagnostic of narcolepsy with cataplexy [1].

Moreover, separate coding of "narcolepsy with cataplexy" and "narcolepsy without cataplexy" in the ICSD-2 underscores how discovery of specific diagnostic criteria now informs our understanding of narcolepsy's nosology; narcolepsy with cataplexy, as indicated by low CSF hypocretin-1, appears etiologically homogeneous and distinct from most narcolepsy without cataplexy cases, exhibiting normal hypocretin-1 levels [83]. In the 3rd revision, narcolepsy was reclassified as hypocretin-deficient/Type I and hypocretin non-deficient/Type II narcolepsy, and this classification is solely based on the pathophysiological findings. The potential of hypocretin receptor agonists (or cell transplantation) in narcolepsy treatment is currently being explored, and identifying hypocretin deficiency status may be useful in identifying appropriate patients as candidates for a novel therapeutic option, namely hypocretin replacement therapy.

Soon after the discovery of human hypocretin deficiency, researchers identified specific substances and genes, such as dynorphin and neuronal activity-regulated pentraxin (NARP) [84] and most recently, insulin-like growth factor binding protein 3 (IGF BP3) [85], which colocalize in neurons containing hypocretin. These findings underscored selective hypocretin cell death as the cause of hypocretin deficiency (as opposed to transcription/biosynthesis or hypocretin peptide processing problems) because these substances are also deficient in postmortem brain in the lateral hypothalamic area (LHA) of hypocretin-deficient narcoleptic patients [84, 85]. Furthermore, these findings, in view of the generally late onsets of sporadic narcolepsy compared with those of familial cases, suggest that postnatal cell death of hypocretin neurons constitutes the major pathophysiological process in human narcolepsy with cataplexy.

A large kindred of familial narcolepsy (12 affected members) has been reported in Spain [86]. Affected members do not exhibit any symptoms suggesting symptomatic cases of narcolepsy and were diagnosed as familial idiopathic narcolepsy–cataplexy. The family includes a pair of dizygotic twins concordant for narcolepsy–cataplexy in the third generation; the distribution of the disorder indicates an autosomal-dominant transmission of the disease-causing gene. Hor et al. recently performed linkage analysis and sequenced coding regions of the genome (exome sequencing) of three affected members with narcolepsy and cataplexy, and identified a missense mutation in the second exon of the myelin oligodendrocyte glycoprotein (MOG) [86]. A c.398C > G mutation was present in all affected family members but absent in unaffected members and 775 unrelated control subjects [86]. Affected members were hypocretin-deficient, but association with HLA

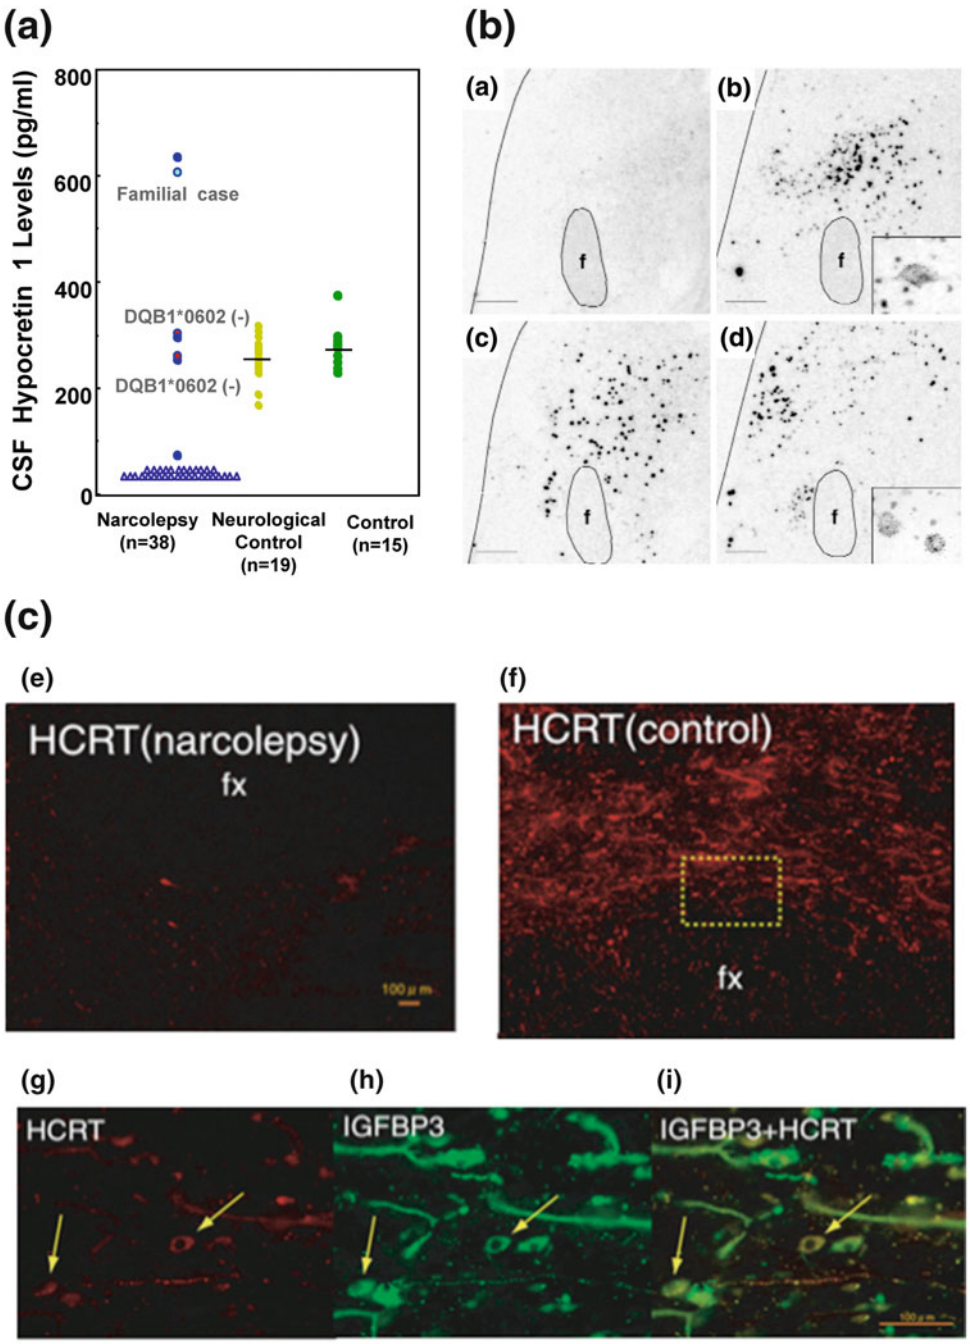

Fig. 38.1 Hypocretin deficiency in narcoleptic subjects. **a** CSF hypocretin-1 levels are undetectably low in most narcoleptic subjects (84.2 %). Note that two HLA DqB1*0602-negative and one familial case have normal or high CSF hypocretin levels. **b** Preprohypocretin transcripts are detected in the hypothalamus of control (*b*) but not in narcoleptic subjects (*a*). Melanin-concentrating hormone (MCH) transcripts are detected in the same region in both control (*d*) and narcoleptic (*c*) sections. **c** Colocalization of IGFBP3 in HCRT cells in control and narcolepsy human brain. *Upper panel* (*e*) Distribution of hypocretin cells and fibers in the perifornical area of human hypothalamus. (*e*, *f*) In control brains, HCRT cells and fibers were densely stained by an anti-HCRT monoclonal antibody (*red fluorescence* VectorRed), while in narcolepsy brains, staining was markedly reduced (*f*). *Lower panel* HCRT immunoreactivity (*g red fluorescence*) and IGFBP3 immunoreactivity (*h green fluorescence*; Q-dot525) and a composite picture (i) arrows indicate HCRT cells colocalized with IGFBP3). Note non-neuronal autofluorescent elements. f and fx, fornix. Scale bar represents 10 mm (*a–d*), 500 mm in *e* and *f*, 100 mm in *g*, *h* and *i* (from [81, 82, 84, 85])

DQB1*0602 was not observed [86]. The mutation may induce secondary hypocretin deficiency with or without immune-mediated mechanisms. MOG has been linked to various neuropsychiatric disorders and is considered a key autoantigen in multiple sclerosis and in its animal model experimental autoimmune encephalitis [87] (Fig. 38.1), and thus autoimmune mechanisms may also be involved in these cases. However, even if autoimmune mechanisms are involved in

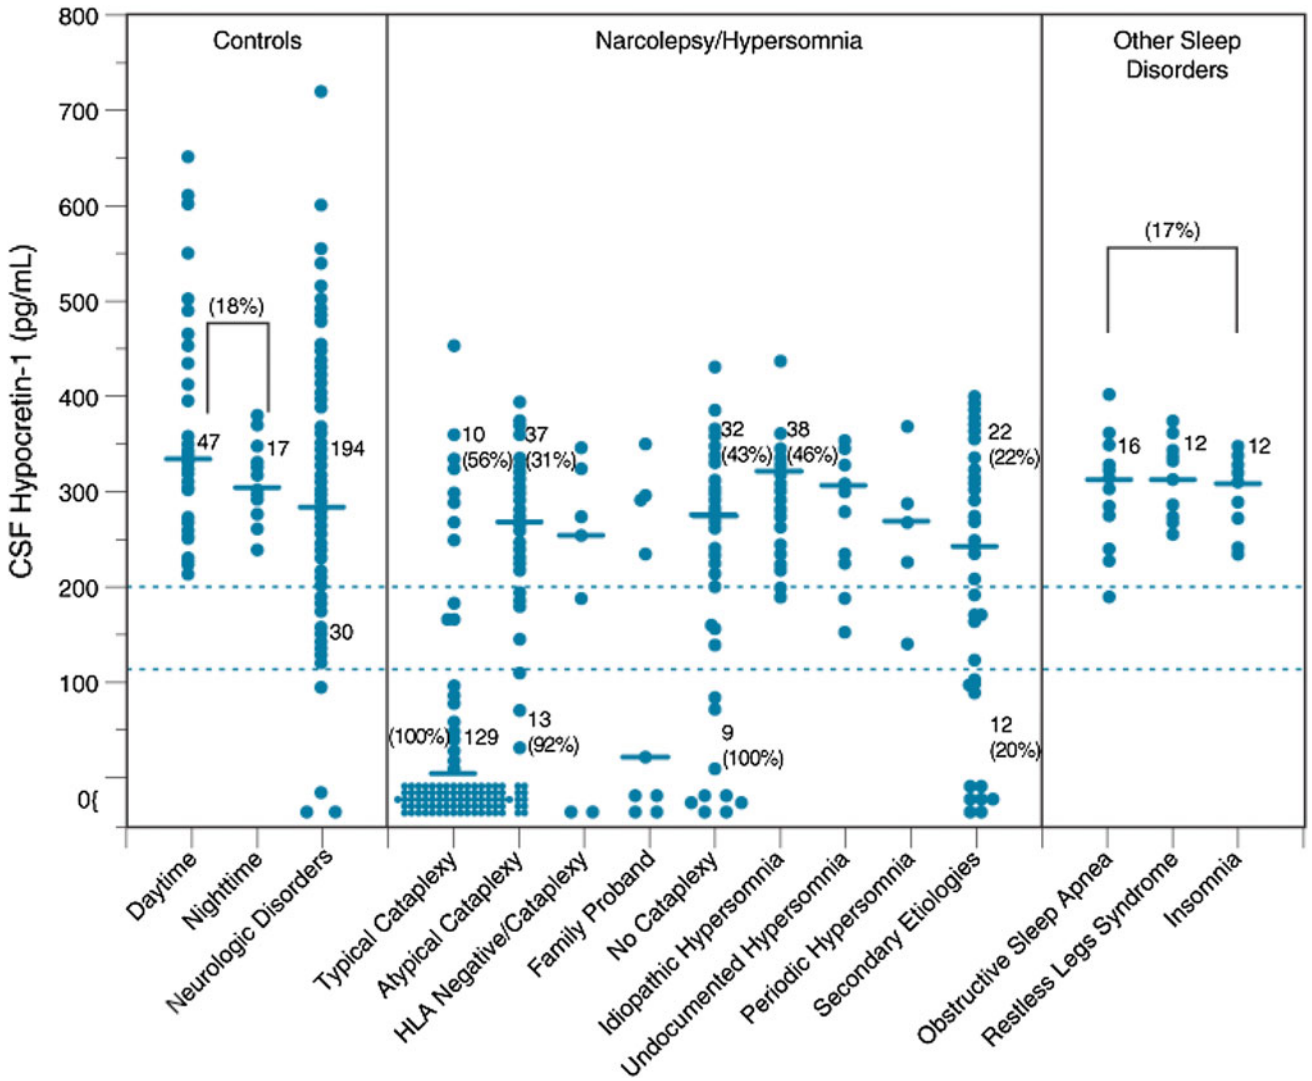

Fig. 38.2 CSF hypocretin-1 levels in individuals across various control and sleep disorders. Each point represents the crude concentration of Hypocretin-1 in a single person. The cutoffs for normal (>200 pg/ml) and low (<110 pg/ml) Hypocretin-1 concentrations are shown. Also noted is the total number of subjects in each range, and the percentage of human leukocyte antigen (HLA)-DQB1*0602 positivity for a given group in a given range is parenthetically noted for certain disorders. Note that control carrier frequencies for DQB1*0602 are 17–22 % in healthy control subjects and secondary narcolepsy, consistent with control values reported in whites. In other patient groups, values are higher, with almost all hypocretin-deficient narcolepsy being HLA DQB1*0602 positive. The median value in each group is shown as a horizontal bar (Updated from previously published data in [82, 83])

these cases, it is possible that the primary target for the immune attack is not the hypocretin system. These results suggest the heterogeneity of the etiology of idiopathic narcolepsy–cataplexy.

What Causes Loss of Hypocretin Neurons?

Because of its strong association with certain HLA alleles (i.e., HLA DQB1*0602 and DQA1*0102) [88], it has long been speculated that narcolepsy results from an autoimmune -mediated mechanism. Increase in antistreptolysin O [ASO] titer in narcolepsy, especially in the period close to the disease onset, was reported [89]. However, attempts to identify specific autoantibodies have been unsuccessful for decades. Recently, Tribbles homolog 2 (Trib2) was reported as a candidate antigen involved in the destruction of hypocretin neurons in narcolepsy [90]. Trib2 was shown to be abundantly expressed in hypocretin neurons, and levels of Trib2-specific antibodies were much higher in patients with narcolepsy, especially shortly after the disease onset. Thus, Trib2 is the first antibody specifically associated with hypocretin-deficient narcolepsy [90]. However, it is still unknown whether Trib2-specific antibodies are directly involved in cell death, or

whether the antibody production is a consequence of cell damage by other unknown mechanisms [91].

Recent large-scale genome-wide association studies (GWAS) showed that susceptibility to narcolepsy is associated with single-nucleotide polymorphisms (SNPs) in the T-cell receptor alpha gene locus [92]. Other SNPs identified are located between *carnitine palmitoyl-transferase 1B* (*CPT 1B*) and *choline kinase beta* (*CHKB*) [93] and those on *purinergic receptor P2Y11* [94], *Cathepsin H* (*CTSH*), and *Tumor necrosis factor (ligand) superfamily member 4 (TNFSF4*, also called *OX40L*) [94]. These genes may be involved either in degeneration of hypocretin neurons or enhancing narcolepsy symptoms. Note that the association with the T-cell receptor alpha locus may be of importance, as the interactions between HLA molecules on antigen-presenting cells and T cell receptors on T cells play critical roles in self/non-self discrimination by the immune system. Many of these genes, including *P2Y11, CTSH,* and *OX40L*, are involved in T cell activation and/or antibody processing [95].

Recently, incidences of narcolepsy–cataplexy after pH1N1 influenza vaccination were reported in Northern Europe [96, 97]. These narcoleptic cases are typically HLA DQB1*0602 positive and hypocretin ligand deficient [96, 97]. In these countries, AS03-adjuvanted vaccination was used. Since the incidence associated with pH1N1 influenza vaccination was less or unchanged in other countries using other adjuvant (or without adjuvant in Japan), it is likely that the enhancement of immunization may induce narcolepsy. However, it is also reported in China that seasonal variation in the narcolepsy onset (most frequent in April and least frequent in November) and increased incidences of narcolepsy (a 3-fold) following the 2009 H1N1 winter influenza pandemic were observed [98]. A large majority of these subjects did not receive influenza vaccinations suggesting influenza infection itself may enhance the incidence of narcolepsy.

These epidemiological data further suggest the involvement of immunological mechanisms responsible for the loss of hypocretin-producing neurons in narcolepsy.

How Does Hypocretin Ligand Deficiency Cause the Narcolepsy Phenotype?

Since hypocretin deficiency is a major pathophysiological mechanism for narcolepsy–cataplexy, it is important to know how the hypocretin ligand deficiency can cause the narcolepsy phenotype.

Hypocretin/Orexin System and Sleep Regulation

Hypocretins/orexins (hypocretin-1 and hypocretin-2/Orexin A and Orexin B) are cleaved from a precursor prepro-hypocretin (prepro-orexin) peptide [76, 77, 99] (Fig. 38.3a). Hypocretin-1 with 33 residues contains four cysteine residues forming two disulfide bonds. Hypocretin-2 consists of 28 amino acids and shares similar sequence homology especially at the C-terminal side but has no disulfide bonds (a linear peptide) [76]. There are two G-protein-coupled hypocretin receptors, Hcrtr 1 and Hcrtr 2, also called orexin receptor 1 and 2 (OX_1R and OX_2R), and distinct distribution of these receptors in the brain is known. Hcrtr 1 is abundant in the locus coeruleus (LC) while Hcrtr 2 is found in the TMN and basal forebrain (Fig. 38.3b). Both receptor types are found in the midbrain raphe nuclei and mesopontine reticular formation [5].

Hypocretin-1 and hypocretin-2 are produced exclusively by a well-defined group of neurons localized in the lateral hypothalamus. The neurons project to the olfactory bulb, cerebral cortex, thalamus, hypothalamus, and brainstem, particularly the LC, raphe nucleus, and the cholinergic nuclei (the laterodorsal tegmental and pedunculopontine tegmental nuclei), and cholinoceptive sites (such as pontine reticular formation) [78, 99]. All of these projection sites are thought to be important for sleep and wake regulation.

A series of recent studies have now shown that the hypocretin system is a major excitatory system that affects the activity of monoaminergic (DA, NE, 5-HT and histamine) and cholinergic systems with major effects on vigilance states [99, 100] (Fig. 38.3b). It is thus likely that a deficiency in hypocretin neurotransmission induces an imbalance among these classical neurotransmitter systems, with primary effects on sleep-state organization and vigilance.

Many measurable activities (brain and body) and compounds manifest rhythmic fluctuations over a 24-h period. Whether or not hypocretin tone changes with zeitgeber time was assessed by measuring extracellular hypocretin-1 levels in the rat brain CSF across 24-h periods, using in vivo dialysis [101]. The results demonstrate the involvement of a diurnal pattern of hypocretin neurotransmission regulation (as in the homeostatic and/or circadian regulation of sleep). Hypocretin levels increase during the active periods and are highest at the end of the active period, and the levels decline with the onset of sleep. Furthermore, sleep deprivation increases hypocretin levels [101].

Recent electrophysiological studies have shown that hypocretin neurons are active during wakefulness and have reduced activity during slow wave sleep [102]. The neuronal

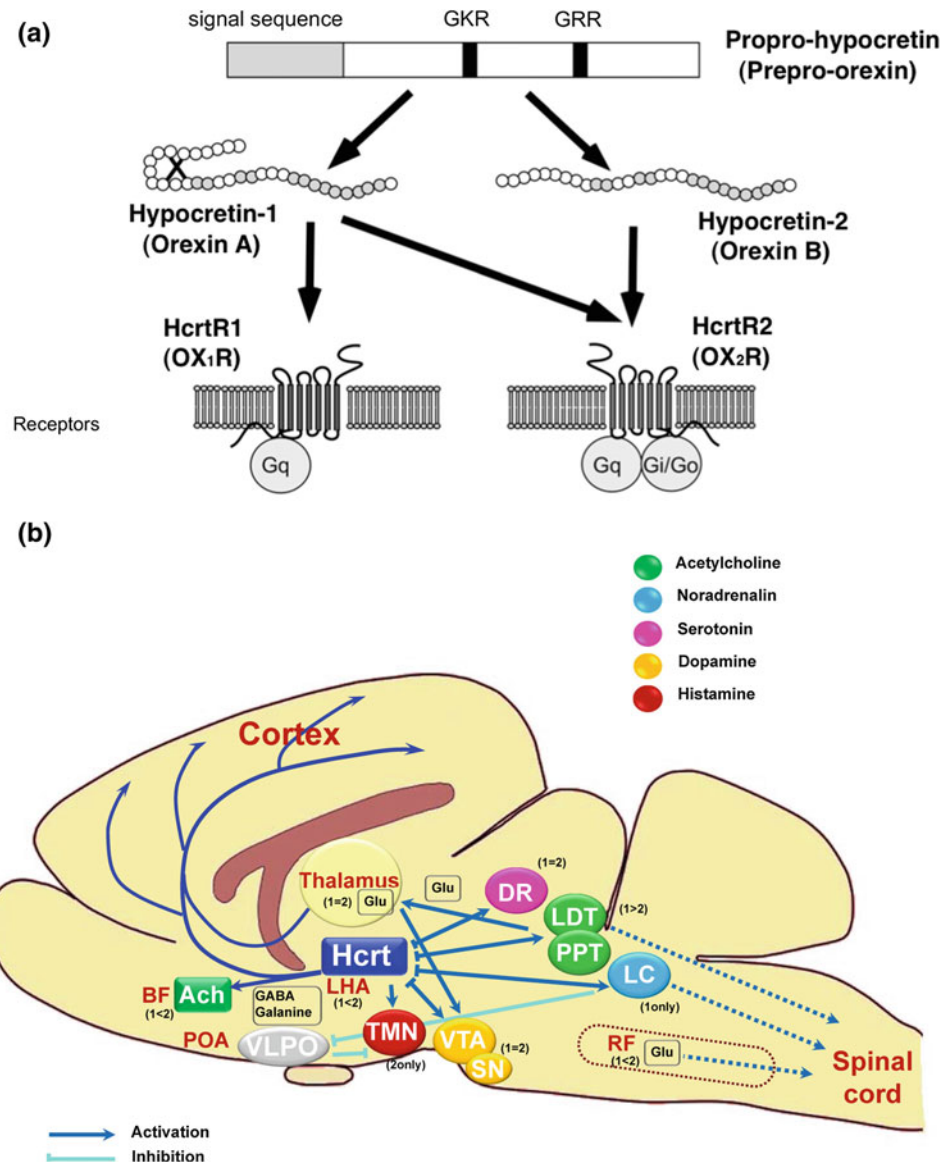

Fig. 38.3 **a** Structures of mature hypocretin-1 (orexin-A) and hypocretin-2 (orexin-B) peptides. **b** Projections of hypocretin neurons in the rat brain and relative abundances of hypocretin receptor 1 and 2. (**a**) The topology of the two intrachain disulfide bonds in orexin-A is indicated in the above sequence. Amino acid identities are indicated by shaded areas. (**b**) The actions of hypocretins are mediated via two G protein-coupled receptors named hypocretin receptor 1 (Hcrtr 1) and hypocretin receptor 2 (Hcrtr 2), also known as orexin-1 (OX_1R) and orexin-2 (OX_2R) receptors, respectively. Hcrtr 1 is selective for hypocretin-1, whereas Hcrtr 2 is nonselective for both hypocretin-1 and hypocretin-2. Hcrtr 1 is coupled exclusively to the G_q subclass of heterotrimeric G proteins, whereas in vitro experiments suggest that Hcrtr 2 couples with $G_{i/o}$, and/or G_q. Adapted from Sakurai [9]. (**c**) Hypocretin-containing neurons project to these previously identified monoaminergic and cholinergic and cholinoceptive regions where hypocretin receptors are enriched. The relative abundance of Hcrtr 1 versus Hcrtr 2 in each brain structure was indicated in parenthesis (data from Marcus et al. [5]). Impairments of hypocretin input may thus result in cholinergic and monoaminergic imbalance and generation of narcoleptic symptoms. Most drugs currently used for the treatment of narcolepsy enhance monoaminergic neurotransmission and adjust these symptoms. *VTA* ventral tegmental area; *SN* substantia nigra; *LC* locus coeruleus; *LDT* laterodorsal tegmental nucleus; *PPT* pedunculopontine tegmental nucleus; *RF* reticular formation; *BF* basal forebrain; *VLPO* ventrolateral preoptic nucleus; *LHA* lateral hypothalamic area; *TMN* tuberomamillary nucleus; *DR* dorsal raphe; *Ach* acetylcholine; *Glu* glutamate; *GABA* gamma-aminobutyric acid; *HI* histamine; *DA* dopamine; *NA* noradrenalin, *5-HT* serotonin

activity during REM sleep is the lowest, but intermittent increases in the activity associated with body movements or phasic REM activity are observed [102]. In addition to this short-term change, the results of microdialysis experiments also suggest that basal levels of hypocretin neurotransmission fluctuate across the 24-hour period and slowly build up toward the end of the active period. Adrenergic LC neurons are typical wake-active neurons involved in vigilance control

and firing rates rapidly change during short sleep/wake cycles, but it has been demonstrated that basic firing activity of wake-active LC neurons also significantly fluctuates across various circadian times [103].

Several acute manipulations such as exercise, low glucose utilization in the brain, and forced wakefulness increase hypocretin levels [100, 101]. It is therefore hypothesized that a build-up/acute increase in hypocretin levels may counteract homeostatic sleep propensity that typically increases during the daytime and during forced wakefulness [104].

Hypocretin/Orexin Deficiency and Narcoleptic Phenotype

Human studies have demonstrated that the occurrence of cataplexy is closely associated with hypocretin deficiency [83]. Furthermore, hypocretin deficiency was already observed at very early stages of the disease (just after the onset of EDS), even before the occurrences of clear cataplexy. Occurrences of cataplexy are rare in acute symptomatic cases of EDS associated with a significant hypocretin deficiency (see [4]); therefore, it appears that a chronic and selective deficit of hypocretin neurotransmission may be required for the occurrence of cataplexy. The possibility of involvement of a secondary neurochemical change for the occurrence of cataplexy still cannot be ruled out. If some of these changes are irreversible, hypocretin supplement therapy may only have limited effects on cataplexy.

Sleepiness in narcolepsy is most likely due to the difficulty in maintaining wakefulness as normal subjects do. The sleep pattern of narcoleptic subjects is also fragmented; they exhibit insomnia (frequent wakening) at night. This fragmentation occurs across 24 h, thus the loss of hypocretin signaling is likely to play a role in this vigilance stage stability (see [105]), but other mechanism may also be involved in EDS in narcoleptic subjects. One of the most important characteristics of EDS in narcolepsy is that sleepiness is reduced and patients feel refreshed after a short nap, but this does not last long as they become sleepy within a short period of time. Hypocretin-1 levels in the extracellular space and in the CSF of rats significantly fluctuate across 24 h and build up toward the end of the active periods [104]. Several manipulations (such as sleep deprivation, exercise, and long-term food deprivation) are also known to increase hypocretin tonus [101, 104]. Thus, the lack of this hypocretin increase caused by circadian time and by various alerting stimulations may also play a role for EDS associated with hypocretin-deficient narcolepsy.

Mechanisms for cataplexy and REM sleep abnormalities associated with impaired hypocretin neurotransmission have been studied. Hypocretin strongly inhibits REM sleep and activate brainstem REM-off LC and raphe neurons and REM-on cholinergic neurons as well as stimulation of local GABAnergic neurons. Therefore, disfacilitation of REM-off monoaminergic neurons together with stimulation of REM-on cholinergic neurons mediated through disfacilitation of inhibitory GABAnergic local interneurons caused by impaired hypocretin neurotransmission are proposed for abnormal manifestations of REM sleep.

Narcolepsy with Normal CSF Hypocretin Levels

There are debates about the pathophysiology of narcolepsy with normal hypocretin levels. Over 90 % patients with narcolepsy without cataplexy show normal CSF hypocretin levels, yet they show apparent REM sleep abnormalities (i.e., SOREMS). Furthermore, even if the strict criteria for narcolepsy–cataplexy are applied, up to 10 % of patients with narcolepsy–cataplexy show normal CSF hypocretin levels. Considering the fact that occurrence of cataplexy is tightly associated with hypocretin deficiency, impaired hypocretin neurotransmission is still likely involved in narcolepsy–cataplexy with normal CSF hypocretin levels. Conceptually, there are two possibilities to explain these mechanisms: (1) specific impairment of hypocretin receptor and their downstream pathway and (2) partial/localized loss of hypocretin ligand (yet exhibit normal CSF levels). A good example for the first hypothesis is Hcrtr 2-mutated narcoleptic dogs; they exhibit normal CSF hypocretin-1 levels [106], while having full blown narcolepsy. Thannickal et al. recently reported one narcolepsy patient without cataplexy (HLA typing was unknown) who had an overall loss of 33 % of hypocretin cells compared to normal, with maximal cell loss in the posterior hypothalamus [107]. This result favors the second hypothesis, but studies with more cases are needed.

Idiopathic Hypersomnia, a Hypocretin Non-deficient Primary Hypersomnia

With the clear definition of narcolepsy (cataplexy and dissociated manifestations of REM sleep), it became apparent that some patients with hypersomnia suffer from a different disorder. Bedrich Roth was the first in the late 1950s and early 1960s to describe a syndrome characterized by EDS, prolonged sleep, and sleep drunkenness, and by the absence of "sleep attacks," cataplexy, sleep paralysis, and hallucinations. The terms "independent sleep drunkenness" and "hypersomnia with sleep drunkenness" were initially suggested. [108], but now this syndrome is categorized as idiopathic hypersomnia with and without long sleep time [1]. Idiopathic hypersomnia should therefore not be considered synonymous with hypersomnia of unknown origin.

In the absence of systematic studies, the prevalence of idiopathic hypersomnia is unknown. Nosologic uncertainty causes difficulty in determining the epidemiology of the disorder. Recent reports from large sleep centers reported the ratio of idiopathic hypersomnia to narcolepsy to be 1:10 [109]. The age of onset of symptoms varies, but it is frequent between 10 and 30 years. The condition usually develops progressively over several weeks or months. Once established, symptoms are generally stable and long lasting, but spontaneous improvement in EDS may be observed in up to one-quarter of patients [109].

The pathogenesis of idiopathic hypersomnia is unknown. Hypersomnia usually starts insidiously. Occasionally, EDS is first experienced after transient insomnia, abrupt changes in sleep–wake habits, overexertion, general anesthesia, viral illness, or mild head trauma [109]. Despite reports of an increase in HLA DQ1,11 DR5 and Cw2, and DQ3, and a decrease in Cw3, no consistent findings have emerged [109].

The most recent attempts to understand the pathophysiology of idiopathic hypersomnia relate to the investigation of potential role of the hypocretins. However, most studies suggest normal CSF levels of hypocretin-1 in idiopathic hypersomnia [83, 110].

Nosological and Diagnostic Considerations of Major Primary Hypersomnias

Narcolepsy–cataplexy, narcolepsy without cataplexy, and idiopathic hypersomnia are diagnosed mostly by sleep phenotypes, especially by occurrences of cataplexy and SOREMPS (Fig. 38.4) (ICSD-2). Discovery of hypocretin deficiency in narcolepsy–cataplexy was a breakthrough, but also brought a new nosological and diagnostic uncertainty of the primary hypersomnias. Up to 10 % of patients with narcolepsy–cataplexy show normal CSF hypocretin-1 levels (Fig. 38.4). As discussed above, altered hypocretin neurotransmissions may still be involved in some of these cases. However, up to 10 % of patients with narcolepsy without cataplexy instead show low CSF hypocretin-1 levels, suggesting a substantial pathophysiological overlap between narcolepsy–cataplexy and narcolepsy without cataplexy, and

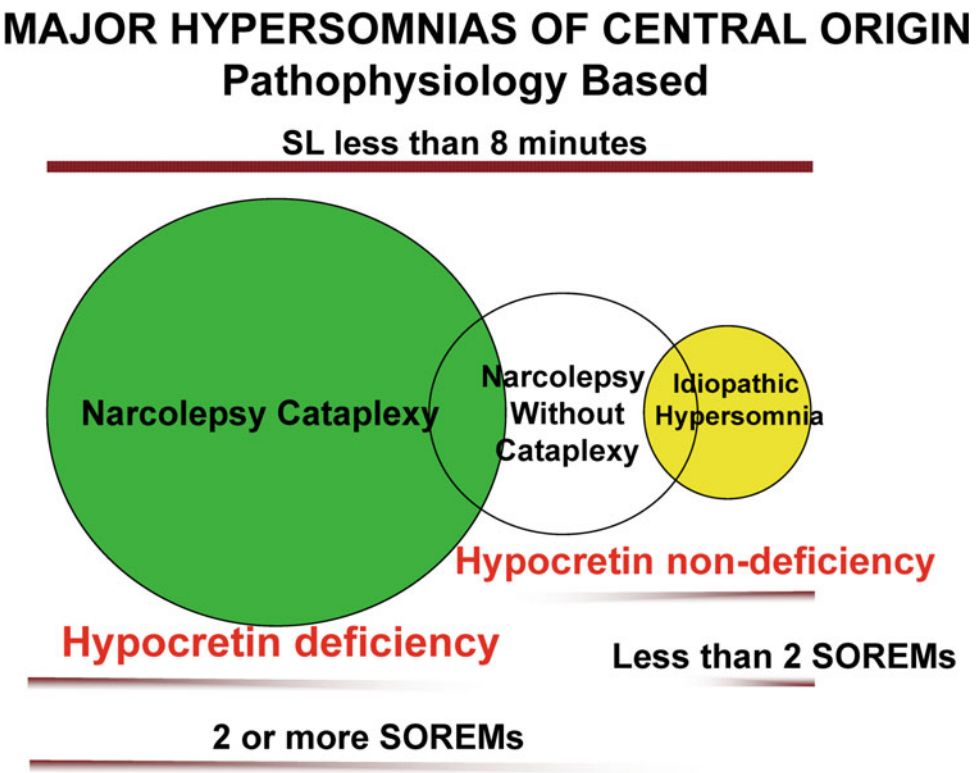

Fig. 38.4 Nosological and diagnostic considerations of major primary hypersomnias. Narcolepsy–cataplexy, narcolepsy without cataplexy and idiopathic hypersomnia are diagnosed by occurrences of cataplexy and SOREMPS. A pathophysiology-based marker, low CSF hypocretin levels are included in the ICSD2 for the positive diagnosis for narcolepsy–cataplexy. However, up to 10 % of patients with narcolepsy–cataplexy show normal CSF hypocretin levels. In contrast, up to 10 % of patients with narcolepsy without cataplexy show low CSF hypocretin-1 levels. These results suggest a substantial pathophysiological overlap between narcolepsy–cataplexy and narcolepsy without cataplexy. Similarly, a substantial overlap likely exists between narcolepsy without cataplexy and idiopathic hypersomnia, as these disorders are diagnosed by the occurrences of SOREMs (2 or more). However, test–retest reliability of detecting number of SOREMs in these conditions has not been systematically evaluated.

the hypocretin-deficient status (measured in CSF) does not completely separate these two disease conditions (Fig. 38.4). The situation is still the same under the ICSD-3 classification.

Similarly, concerns about the nosology of narcolepsy without cataplexy and idiopathic hypersomnia should also be addressed. Since patients with typical cases of idiopathic hypersomnia exhibit unique symptomatology such as long hours of sleep, no feeling of refreshment from naps, and general resistance to stimulant medications, the pathophysiology of idiopathic hypersomnia may be distinct from that of narcolepsy without cataplexy. However, current diagnostic criteria are not specific enough to diagnose these disorders; the test–retest reliability of numbers of SOREMS during MSLT is relatively low (less than 70 %) in narcolepsy and idiopathic hypersomnia [111].

CSF Histamine and GABAA Receptor Modulators in Narcolepsy and Idiopathic Hypersomnia

Although pathophysiology of hypocretin non-deficient hypersomnia is largely unknown, neurochemical changes in these conditions, namely reduced CSF histamine contents and increased activity of GABAA receptor modulators in the CSF, have recently been reported by two groups [112–114].

Histamine is one of these wake-active monoamines [115], and low CSF histamine levels are also found in narcolepsy with hypocretin deficiency [112, 113]. Since hypocretin neurons project and excite histamine neurons in the posterior hypothalamus, it is conceivable that impaired histamine neurotransmission may mediate sleep abnormalities in hypocretin-deficient narcolepsy. However, low CSF histamine levels were also observed in narcolepsy with normal hypocretin levels and in idiopathic hypersomnia, and decreased histamine neurotransmission may be involved in a broader category of EDS than in hypocretin-deficient narcolepsy [113]. Since CSF histamine levels are normalized in EDS patients treated with wake-promoting compounds, low CSF histamine levels may be a new state marker for hypersomnia of central origin [113]. The low CSF histamine levels in EDS were confirmed in a smaller sample of patients [116], but in a much larger sample size, the results were not replicated [117]. The reason for these discrepancies was not known, but an animal study indicated that CSF histamine levels are under the influence of the vigilance state/diurnal changes [118], and histamine in the CSF is very unstable, and thus a highly controlled study design is crucial for drawing definitive conclusion. The methodological differences in histamine measures (HPLC/post-column derivatization vs liquid chromatography-tandem mass spectrometry assay) may also be another factor to be considered for the discrepancy.

Rye et al. [119] recently reported that activities of substance in CSF that augments inhibitory GABA signaling are enhanced in hypersomnia. The authors demonstrated that in the presence of GABA (10 μM), CSF can stimulate GABAA receptor function in vitro (measures of GABAAR-mediated chloride currents in recombinant pentameric human GABAAR-expressed cultured cells). Interestingly, stimulations of GABAA receptor function by CSF of hypersomnolent patients (idiopathic hypersomnia with and without long sleep, long sleepers and narcolepsy without cataplexy) are significantly enhanced compared to those by CSF of control subjects (84.0 % vs. 35.8 %) [119]. This bioactive CSF component had a mass of 500–3000 daltons and was neutralized by trypsin. Flumazenil, a benzodiazepine receptor antagonist, reversed enhancement of GABAA signaling by hypersomnolent CSF in vitro, and flumazenil normalized vigilance in all seven hypersomnolent patients who underwent the drug challenge [119]. The authors conclude that a naturally occurring substances in CSF augment inhibitory GABA signaling, revealing a new pathophysiology associated with EDS. These results are especially interesting, as GABAAR has never been targeted for the treatment of hypersomnia. It is still unknown whether these changes are primary or secondary to the changes in other neurotransmitter systems. In this regard, it is critical to test whether the same change is observed in hypocretin-deficient narcolepsy–cataplexy.

These new findings are interesting as they are some of the first biomarkers for idiopathic hypersomnia, and these finding may lead to the development of new treatments for somewhat treatment-resistant hypersomnia. However, these markers do not discriminate the types of hypersomnia, and similar changes were observed in various types of hypersomnia.

Conclusion

Idiopathic narcolepsy–cataplexy is likely to be a clinical entity and be caused by postnatal selective cell death of hypocretin neurons. This is likely to be mediated by the autoimmune process (i.e., autoantibody presentation by specific human leukocyte antigen subtypes and T cell receptors), but the exact mechanism of the disease is not yet revealed.

Symptomatic narcolepsy has also been reported, but the prevalence of symptomatic narcolepsy is much smaller than the idiopathic type. The meta-analysis of these symptomatic cases indicates that hypocretin deficiency may also partially explain the neurobiological mechanisms of EDS associated with symptomatic cases of narcolepsy.

The pathophysiology of hypocretin non-deficient narcolepsy is debated, and the pathophysiology of idiopathic hypersomnia is largely unknown, but hypocretin deficiency is not likely to be involved in this condition. Decreased histaminergic neurotransmission is observed in narcolepsy and idiopathic hypersomnia, regardless of hypocretin status. Another study reported that activities of substance in CSF that augments inhibitory GABA signaling are enhanced in hypersomnia with various etiologies. Functional significances of these new findings (if these mediate sleepiness or passively reflect sleepiness) need further evaluation.

Although much progress has been made regarding the pathophysiology of EDS, this new knowledge has yet to be incorporated into the development of new treatments, and further research is critical.

Motor Control and Dyscontrol in Sleep

39

Sudhansu Chokroverty, Sushanth Bhat, and Richard P. Allen

Introduction

Motor control in humans is the end result of a complex, intricate interplay between several central and peripheral loci, including the cerebral cortex, basal ganglia, brain stem motor centers, cerebellum, spinal cord, and the peripheral neuromuscular system [1–3]. The delicate balance of excitatory and inhibitory influences, created through the coordination of these systems, determines the occurrence of volitional movements and the suppression of unwanted ones. As an individual progresses from drowsiness to light sleep, slow-wave sleep (SWS), and rapid eye movement (REM) sleep, several additional factors come into play to further modulate motor activity. In recent years, there has been growing interest and a lot of research into normal and abnormal motor control in sleep. Disorders of motor control that occur in sleep may be those that are present during the day (diurnal movement disorders) but that impact sleep, either directly through their motor effects or indirectly through a variety of other mechanisms. Alternately, some motor disturbances are exclusive to sleep or the sleep–wake transition period. Motor disturbances in this latter group are generally classified as *sleep disorders*; the third edition of the International Classification of Sleep Disorders (ICSD-3) includes them in a specific category of sleep disorders called *Sleep-Related Movement Disorders* [4], and the American Academy of Sleep Medicine has elaborated on rules for recognizing them during polysomnography (PSG) [5].

This chapter discusses how motor control in sleep differs from that in wakefulness, classifies and describes disorders of motor control that intrude into sleep, including recommended treatment options, and discusses the investigative techniques employed in the evaluation of motor disorders in sleep. Non-motor symptoms in hypokinetic and hyperkinetic movement disorders that impact sleep are also briefly discussed. The main purpose of this chapter is to provide an overview of the various motor disturbances that impact sleep and to demonstrate a usable approach to the diagnosis and management of these disorders. This chapter should be useful to sleep medicine practitioners who deal with patients presenting with abnormal movements in sleep; however, readers are referred to several excellent volumes that discuss movement disorders in greater depth [6, 7].

Motor Control in Wakefulness and Sleep

The motor system is organized in a functional hierarchy at three levels: the forebrain, brain stem, and spinal cord (Fig. 39.1a, b). These three levels are under the control of two subcortical systems, the cerebellum and basal ganglia, and receive sensory inputs. The spinal cord is the lowest level in the scheme of the motor organization and contains neuronal circuits mediating reflexes and rhythmic movements. The motor neurons and interneurons of these circuits receive inputs both segmentally and supraspinally from higher centers. All motor commands ultimately converge either directly or indirectly (through the descending brain stem pathways) on the motor neurons in the anterior horn cells of the spinal cord, which Sherrington called

Some portions of this chapter are partly modified from Chap. 28, "Motor Functions and Dysfunctions of Sleep," in the third edition of this book (2009), authored by Hening WA, Allen RP, Walters AS and Chokroverty S.

the "final common pathway" for motor actions [1]. In the next higher level at the brain stem, there are two descending systems: the medial descending systems consisting of the reticulospinal, vestibulospinal, and tectospinal tracts controlling posture and the lateral descending system consisting mainly of the rubrospinal system, controlling more distal limb muscles (Fig. 39.2a, b). The highest level, located in the cerebral cortex, controls spinal motor neurons directly through the corticospinal tracts and the brain stem motor neurons through the corticobulbar pathways. The cerebral cortex also controls spinal motor neurons indirectly through its influence on the descending brain stem systems. The major subcortical inputs to the motor cortex originate from the cerebellum and basal ganglia controlling the cerebral cortex through their projections to the thalamic nuclei.

The prefrontal cortex is responsible for the planning and initiation of voluntary movement. The premotor cortex and the supplementary motor cortex are involved in the programming of voluntary movement. Other parts of the cerebral cortex (e.g., somatosensory and association cortices including those responsible for tactile sensations, vision, and hearing) send their projections to the motor cortex for the coordination of skilled movements. Two subcortical circuits, the thalamocorticostriate and dentatorubrothalamocortical circuits, play a significant role in controlling coordination, posture, and muscle tone.

Muscle Tone, Posture, and Reflexes

In addition to voluntary targeted activity, motor control includes the control of muscle tone and posture directed by central generators and spinal stretch reflexes [1]. Phasic muscle contractions producing movements occur on a background of constant muscle tone, which can be defined as a state of mild contraction due to the firing of a few motor units of the muscle (i.e., due to asynchronous sustained firing of motor neurons). Clinically, muscle tone is perceived as the resistance offered by the muscle to stretch as a result of passive movement (flexion or extension) of a joint. The resting muscle tone is produced by viscosity and elastic properties of the muscle. Muscle tone is related to posture, state of alertness, and the degree of muscle stretch. Reticulospinal and vestibulospinal tracts influence the alpha and, to an extent, also the gamma motor neurons to maintain muscle tone.

Movements can be divided into three categories: voluntary, rhythmic, and reflexive. Reflexes are involuntary movements elicited by peripheral stimuli. Voluntary movements are goal-directed. The circuits for rhythmic movements lie in the spinal cord and brain stem. Alterations of muscle tone and movements may be *negative* (atonia and paralysis) or *positive* (hypertonia and abnormal movements). Central pattern generators responsible for locomotion are located in the mesencephalic and spinal locomotor centers. Central pattern generators in the midbrain and pons drive spinal locomotor generators. The mesencephalic locomotor region is under the control of the cerebral and limbic cortex (Fig. 39.3). The nature, however, of pattern generators is uncertain because the exact connection of interneurons is not known.

Motor Control in Wakefulness

In wakefulness, several circuits are involved in the generation and modulation of voluntary movement. These include the cortico-basal ganglionic-thalamo-cortical circuit, cortico-ponto-cerebello-thalamo-cortical circuit, descending brain stem motor pathways, brain stem, and spinal segmental

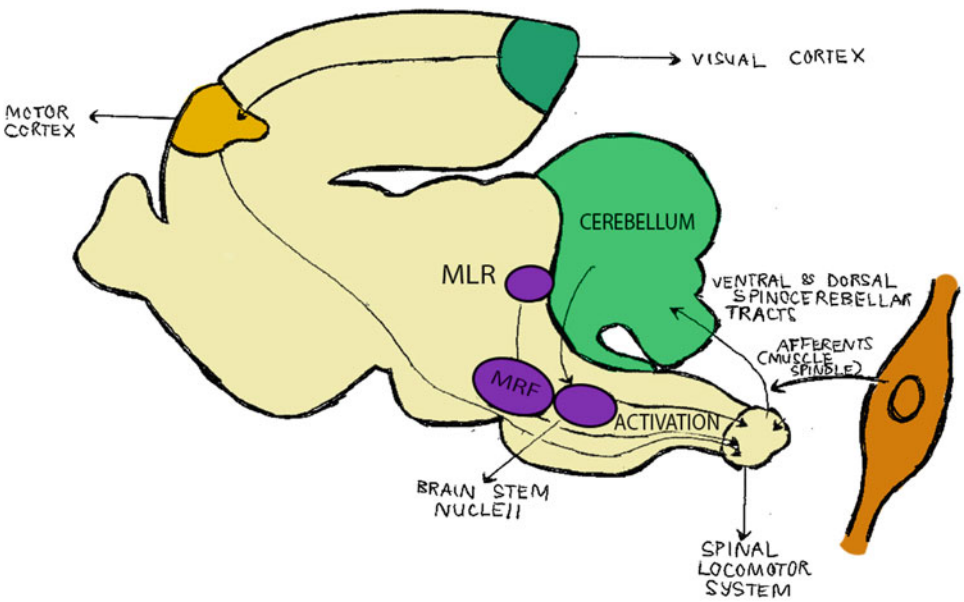

Fig. 39.3 Schematic diagram showing brain stem motor control: Mesencephalc locomotor ergion (MLR) and medial reticular formation (MRF) activating spinal locomotor region after receiving inputs from cerebellum, visual and motor cortices. (Modifed from Fig. 36.10 in "Locomotion." Ref. [8])

circuits. All these circuits are influenced by peripheral afferent inputs. To summarize, the cerebellum participates in the initiation, timing, and coordination of the movements; the basal ganglia help in influencing the direction, force, and amplitude of the movements, as well as the internal generation and assembly of movements; and the cerebral cortex selects, plans, programs, and commands the movement. The corticospinal system then distributes the commands, and the segmental spinal motor apparatus drives the muscles to execute the movements.

Changes in Motor Control in Sleep

In the simplest sense, it can be said that sleep causes a progressive decrease in muscle tone and inhibits gross movements. However, motor control in sleep is far more complex than this simple statement suggests. As in wakefulness, organized movements during sleep are the result of intricate checks and balances at multiple levels of the central nervous system—cerebral cortex, basal ganglia, thalamus, brain stem, cerebellum, and spinal cord. Sleep in general is dominated by central inhibitory drive, but the excitatory mechanism intermittently breaks through the inhibitory phase in normal individuals giving rise to physiologic motor activities during sleep (e.g., gross body shifts and hypnic jerks). It is the breakdown of this delicate mechanism of organized movements during non-rapid eye movement (NREM) sleep and REM sleep, due to a number of inciting factors and diseases, that causes abnormal motor events in sleep. In particular, lower centers (e.g., mesencephalic locomotor region and spinal locomotor generators) are released from controls by forebrain mechanisms as a result of a variety of conditions causing abnormal jerks, shakes, and screams during sleep. It is notable that Pakhomov in 1947 first observed a reduction in muscle tone in finger flexors during sleep [1]. The discovery of REM sleep associated with phasic eye movements and desynchronized EEG in 1953 by Aserinsky and Kleitman [9] paved the way to intense research into motor control during sleep. In 1959 Jouvet and Michel [10] observed muscle atonia in cats during REM sleep. This was followed by Berger's [11] observations of similar atonia in laryngeal muscles during human REM sleep, thus completing the description of REM sleep phenomena. Fundamental contributions to understanding motor control and muscle tone during sleep were subsequently made by Pompeiano [12], Chase and Morales [13], and Morrison [14] and Siegel [15]. To paraphrase Chase and Morales, "motor control landscape" in sleep is characterized by "storms of inhibition" coupled with brief "whirlwinds of excitation" directed toward the "final common pathway" [16, 17].

Modulation of Neuronal Firing

During wakefulness, most central neurons fire irregularly, at different frequencies in different brain regions. In NREM sleep, and especially during SWS, they fire more slowly compared to wakefulness (lower frequency) but tend to fire in bursts. During SWS, for example, thalamic cells fire slowly and are less responsive to afferent activity. These changes are related to the greater synchronization of surface electrical activity as measured by electroencephalography (EEG) during sleep. In REM sleep, by contrast, cellular activity is increased in many motor regions of the brain such as the primary motor cortex [18], thalamus, red nucleus, and cerebellum [19]. This increased firing in the motor centers of the brain is presumably balanced by the increased descending drive that occurs during REM sleep.

Motor Neuronal Modulation

More focused studies have examined motor neurons in the brain stem and spinal cord and traced backward some of the descending influences which modulate them depending on state. Recent studies have begun to establish the brain stem centers whose altered activity is related to the various stages of sleep and wake causing alterations in motor activity [20]. Particular information has been obtained about the control of REM sleep [21]. Neurons located near the border between the pons and midbrain such as the pedunculopontine nucleus (PPN) and laterodorsal tegmental (LDT) nuclei [22] appear to release acetylcholine into the more central reticular formation of the pons and medulla. These neurons can be divided into two classes: REM-on cells are selectively active during REM, while wake/some REM-on cells are also activated during wake. The REM-on cells are selectively inhibited by serotonin [23]. Various, as yet poorly defined, centers or cell groups in the reticular formation are then stimulated [24] to exert descending influences that act upon motor neurons. One current model suggests that cholinoceptive cells in a pontine inhibitory area project to the medulla where they release glutamate to stimulate inhibitory neurons in the medullary reticular formation [25]. Some of this modulation may also occur through suppression of the orexinergic system, which appears to cause arousal and increased motor activity in wake [26].

Reflex Modulation

Since much of motor behavior is generated, at least in part, by reflexes, studying reflexes can be quite relevant to examining changes of the motor system with state. The most commonly studied reflex has been the Achilles tendon reflex or its electrical counterpart, the H reflex. This reflex is diminished in NREM sleep, especially SWS, and then almost completely abolished in REM sleep, especially during rapid eye movements (REMs) [27]. Polysynaptic

spinal reflexes are similarly depressed in NREM and REM sleep [28]. A somewhat related bulbar reflex, the response of the genioglossus muscle to negative pressure in the airway, is decreased in NREM sleep [29] and may be further reduced in REM sleep [30, 31]. This reduced response has significant consequences, because reduced reflex gain may contribute to airway collapse and respiratory difficulties in sleep, especially obstructive sleep apnea (OSA). It has been noted that some brain stem reflexes, such as vestibular reflexes and the blink reflex, show decreased gain in NREM sleep but may then recover partially in REM sleep [32–34]. This recovery of some brain stem reflexes during REM sleep parallels the relatively greater activity of the eye muscles, compared to trunk and limb muscles at that time, and reinforces the mixed picture of excitation and inhibition characteristic of REM. Even drowsiness, short of actual sleep, can attenuate some reflexes, such as the vestibulo-ocular reflex, which has two outputs: quick restorative jerks to head rotation and slower smooth compensatory eye deviations [35]. The more polysynaptic quick jerks are more easily suppressed by even modest drowsiness. While all these various changes in reflex gain indicate altered excitability, they do not indicate where in the reflex arc the changes occur.

The basis for much of the reduced reflex gain during sleep is most likely inhibition of motor output, rather than decrease of sensory response. In one supportive study, Morrison et al. [36] created pontine tegmental lesions in cats that caused REM sleep without atonia. They found that both orienting to tone stimuli and acoustic startle responses were evident in REM sleep in the lesioned cats, but rare or absent throughout sleep in intact cats. Since the same tones elicited brain stem generated ponto-geniculo-occipital (PGO) waves in both normal and lesioned cats, it seems likely that the block to the further responses of orienting and startle reflexes is on the motor side of the reflex arc. PGO waves were also identified in the human pons, recorded during placement of a pedunculopontine nucleus stimulator [37]. On the other hand, sensory transmission may itself be altered by sleep. Studies have indicated that in primary afferent neurons located both in the spinal cord [38] and in the brain stem [39] there is a significant, presynaptically mediated decrease in responsiveness during REM sleep but not NREM sleep.

Reflexes can also change their characteristic motor output in sleep [40] indicating that sleep is not merely a general change in activity levels but a rearranged organization of responsiveness. Sensory stimulation, which would cause motor neuron excitation in waking, can cause additional inhibitory potentials in sleep [41]. In addition, certain reflexes which would be abnormal during waking, such as the Babinski sign, may be elicited in sleep [42, 43].

Effect of NREM Sleep on Motor Control

Progressive muscle hypotonia is a cardinal feature of sleep. In NREM sleep, motor activity is less than in the waking or resting state. At the onset of NREM sleep, intracellular microelectrode recording of motor neurons by Chase et al. [44] clearly showed either no change in membrane potential or a slight hyperpolarization. This, as well as disfacilitation of brain stem motor neurons controlling muscle tone, likely explains the mild muscle hypotonia seen in NREM sleep. Postural shifts, which may signal stage changes (into or out of wake or REM), occur. There are also small flickering movements, called sleep myoclonus, which may cause no apparent movement and are associated with very brief, highly localized electromyography (EMG) potentials seen on PSG [45, 46]. In some cases, these movements may have a greater amplitude and be of increased frequency, at which point they are called excessive fragmentary myoclonus, (EFM, discussed later in this chapter) but the significance of these movements, if any, is unknown [47]. The frequency of all movements decreases with depth of sleep, being least in SWS [48–50]. Postural shifts rarely occur before entrance into SWS. A number of abnormal motor activities such as somnambulism or periodic limb movements of sleep (PLMS) occur predominantly during NREM sleep. In infants, who move more in sleep, most NREM movements are generalized, full body movements or jerks, while REM movements tend to be more focal and uncoordinated [51].

Effect of REM Sleep on Motor Control

REM sleep is dramatically different from NREM. During REM sleep there is tonic reduction in muscle tone, even below that of SWS, in the presence of a highly active forebrain (paralyzed body with activated brain) with inhibition of the mesencephalic locomotor region. This is a protective mechanism to prevent abnormal movements during REM sleep in the presence of highly active cerebral cortex and forebrain regions. However, bursts of small movements ("phasic twitching"), similar to those seen in NREM sleep but more clustered, occur in REM sleep in association with bursts of REMs. During REM there is a close balance between strong upper motor center excitation and inhibition at the level of the motor effecter. When the inhibitory influences break down, significant motor activity may be released. Infants lack this inhibition and have more movement during REM. Inhibition can also be disrupted by lesions in the brain stem of animals which destroy the

inhibitory centers [52, 53] or, it is believed, in human sleep disorders such as REM Sleep Behavior disorder (RBD). The resulting movements may represent an "acting out" of dreams, which characteristically have a motoric component [54, 55].

The mechanism of muscle atonia during REM sleep includes an activation of a polysynaptic descending pathway from the perilocus coeruleus alpha region in the pons to the lateral tegmentoreticular tract, nucleus gigantocellularis, and magnocellularis in the medial medulla (the inhibitory area of Magoun and Rhines), ventral tegmentoreticular, and reticulospinal tracts to the alpha motor neurons, causing hyperpolarization and thus giving rise to muscle atonia (see Fig. 41.5) (see also Chap. 41). Immunocytochemical techniques detected an increased number of C-Fos (a nuclear protein synthesized during neuronal activation) labeled cells in the inhibitory region of Magoun and Rhines [56] during REM sleep. A key element in the REM sleep-generating mechanism in the pons is the activation of GABAergic neurons located in a subgroup of pontine reticular formation, as well as GABAergic neurons in the ventrolateral periaqueductal gray. An activation of GABAergic neurons causes an activation or disinhibition of cholinergic neurons and inhibition of noradrenergic and serotonergic neurons in the pons. The cholinergic neurons, in turn, excite pontine glutamatergic neurons projecting to the glycernergic pre-motor neurons in the medullary reticular neurons, causing hyperpolarization of the motor neurons and motor paralysis during REM sleep. Disfacilitation of motor neurons as a result of a reduction of the release of serotonin and norepinephrine partially contribute to muscle atonia. While many interneuronal regions of the brain stem show increased activity in REM sleep, motor nuclei (masseter, facial, and hypoglossal nuclei) show depressed activity. This is consistent with studies that have shown glycinergic inhibition of hypoglossal neurons in REM [57], perhaps contributing to the difficulties with airway patency in this sleep stage.

Motor neuron control at the cellular level results from synaptic transmission as manifested by the presence of excitatory post-synaptic potentials (EPSPs) or inhibitory post-synaptic potentials (IPSPs). During REM sleep, motor neurons are hyperpolarized by 2–10 mv (Fig. 39.4). There is post-synaptic inhibition causing a decrease in 1a monosynaptic EPSPs resulting in motor neuron hyperpolarization. During wakefulness and NREM sleep, there are a few spontaneously occurring low amplitude IPSPs, but during REM sleep, in addition to an increase of these low amplitude ISPSs, there are additional high amplitude sleep-specific IPSPs noted. These are generated by sleep-specific inhibitory interneurons located mainly in the brain stem (immunocytochemical techniques are used to prove this observation), which send long projecting axons to the spinal and short axons to the brain stem motor neurons. Glycine, the major inhibitory neurotransmitter, is the driving force for these IPSPs. The REM-specific IPSPs are abolished after strychnine (a glycine antagonist) administration [58] by microiontophoretic application into the ventral spinal cord but not after application of bicuculline or picrotoxin (GABA antagonists), thus proving that it is glycine and not GABA which is responsible for these IPSPs. Intermittently during REM sleep

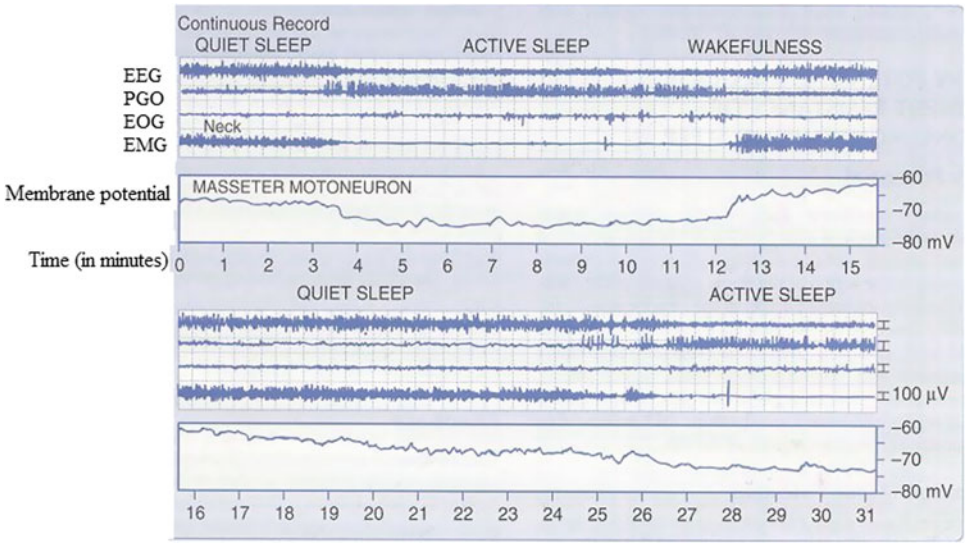

Fig. 39.4 Intracellular recording from a masseter motoneuron of a cat showing membrane potential and state changes during wakefulness, active (REM), and quiet (NREM) sleep. Note abrupt membrain hyperpolarization during active sleep accompanied by neck muscle hypotonia in the eletromyagram (EMG) and depolarization during wakefulness. In quiet sleep, membrane potential resembles that in wakefulness. Electroencephalogram (EEG); EOG, electro-otulogram: PG0, ponto-geniculo.occipital potential. (From Ref. [59])

there are excitatory drives causing motor neuron depolarization shifts as a result of EPSPs [28]. Glutamate is the excitatory amino acid for the REM EPSPs as these EPSPs are abolished by kynurenic acid (a glutamate antagonist) application near the ventral horn cells but not by NMDA antagonists. Muscle movements caused by these excitatory drives during REM sleep are somewhat different from the movements occurring during wakefulness. These are abrupt, jerky, and purposeless. EPSPs during REM sleep reflect increased rates of firing in the motor facilitatory pathways during REM sleep and enhanced IPSPs during REM sleep check these facilitatory discharges thus balancing the motor system during this activated state; otherwise the blind, unconscious subject will jump out of bed, as may happen in RBD (see below) [14]. Facilitatory reticulospinal fibers are responsible for transient EPSPs (phasic discharges) causing muscle twitches in REM sleep. Corticospinal or rubrospinal tracts are not responsible for these twitches because destruction of these fibers in cats [12] does not affect these twitches.

There are several additional factors that dictate the nature of motor control during sleep.

Circadian Activity Cycles

In humans, as in most animal species, the motor system's level of activity is dependent on an underlying circadian rhythm, even in the absence of a day–night light cycle (i.e., under constant conditions). As discussed in Chap. 6, circadian regulation of sleep, like many other important physiologic variables such as temperature, also shows circadian periodicity. While there may be a number of supplementary oscillators which control these rhythms [60–62], the suprachiasmatic nucleus (SCN) is thought to contain the most important oscillator [63] and to be the center which is responsible for the circadian variation of motor activity. The basic mechanism is a transcription–translation feedback loop [64, 65], elements of which are widely distributed in peripheral tissues [66]. Another mediator may be an expression of clock genes, such as the period gene, rPer2, which are widely distributed in different tissues and controlled by the SCN, and a large amount of SCN output is channeled through the subparaventricular zone of the hypothalamus (SPZ), which contains a specific region specialized in modulating motor activity [67, 68]. The SPZ also acts as an integrating center for various environmental influences that can impact on circadian rhythm, such as food availability, ambient temperature, and social interactions. Some of the hypothalamic regulation of motor activity is via the hypocretin system, which stimulates activity at the end of the activity period (the evening for humans) [69, 70]. In humans, activity is concentrated during the daytime hours and sleep at night; decreased movements in sleep may in fact be a marker of better quality sleep [71]. Movements in sleep are associated with autonomic surges, which may have long-term cardiovascular implications [72]. Therefore, this circadian periodicity of movement may be a protective factor. The clear separation of these periods begins to break down in normal aging and in cases of poor sleep or sleep-related disorders as well as in many movement disorders and degenerative conditions.

Development and Aging

The nature and occurrence of movements in sleep are affected by age. Movement frequency during sleep is greatest in infants, then decreases with age, even within the first few months of life [73, 74]. This is most likely due to the immaturity of regulatory mechanisms that maintain motor control in sleep. For instance, in one study, Kohyama [75] found that younger infants appear to lack the profound motor inhibition during phasic REM that is seen in older children and adults. Perhaps as a result of such immaturity, parasomnias such as somnambulism, or soliloquy are present with a greater prevalence during childhood, tending to decrease with age from early childhood on [76, 77]. Rhythmic movement disorder (RMD, see below) is also primarily a disorder of early childhood but may persist into adolescence or even adulthood in patients with significant cerebral injury or with autism [78]. With age, movements in sleep decrease; one study showed that position shifts during sleep decreased from 4.7 per hour in 8–12 year old subjects to 2.1 per hour in those 65–80 years old [79]. With aging, excessive motor activity may emerge again [80], including PLMS, RBD, and increased instability in NREM sleep manifesting as an increase in cyclic alternating pattern (CAP) [81]. In fact, these changes in CAP (see below) at various ages are increasingly being seen as a factor in age-related variation in the frequency and nature of motor dysfunction in sleep.

Drowsiness and the Sleep–Wake Transition Period

Even before sleep onset, the motor system reduces its level of activity. The sleep–wake transition period, a period of relative repose, has been called the *predormitum* by Critchley [82]. The subsequent transition to sleep is signaled by a variety of behavioral and EEG features [83]. The transition to sleep is a frequent inciting factor for a variety of jerks, jumps, and starts that may be a cause of concern to patients and their bedpartners. The most common of this is the "sleep start" or hypnic jerk. Another movement disorder activated in the transition to sleep is a form of propriospinal myoclonus [84]. These conditions are discussed in greater detail below. It is also during the sleep–wake transition period that the symptoms of restless legs syndrome (RLS) become prominent (see Chap. 40). RLS is relatively distinctive in that, unlike almost all other movement disorders, it is activated by rest.

Arousals, brief periods of interrupted, lighter sleep that may or may not lead to full awakening, are often associated

with movements. Arousals may both follow and lead movements such as body shifts. Abnormal movements, such as parkinsonian tremor [85] may recur during arousals. Sleep-related movements, such as PLMS, may provoke frequent arousals or even awakenings and may also continue during periods of arousal from sleep.

Metabolically, physiologically and behaviorally the period just after awakening, or "*postdormitum,*" is distinctly different from the predormitum [86–88]. Sleep offset occurs with abrupt changes in the EEG activity, unblocking of the afferent stimuli and restoration of postural muscle tone accompanied by a reduction of cerebral blood flow with concomitant decrement of cerebral metabolism as compared with that in presleep wakefulness [89]. This is in contrast to sleep onset with gradual changes in the EEG, blockade of the afferent stimuli at the thalamic level (essentially converting an "open" brain into a "close" one) and a reduction of postural muscle tone [90]. Because of these differences between the two states certain motor or other disorders preferentially occur in either predormitum (e.g., propriospinal myoclonus at sleep onset, hypnic jerks, RMD, hypnagogic imagery, and exploding head syndrome) or postdormitum (e.g., sleep inertia, awakening epilepsy of Jang, and sleep benefit in some Parkinson's disease patients). Sleep paralysis and hallucinations may occur in both states (hypnagogic and hypnopompic). Many of these conditions are discussed in greater detail below.

Effects of Sleep Stage on Motor Control

Changes in motor activity are dependent on the sleep state (i.e., wake, NREM sleep, and REM sleep). As discussed above, there is an orderly progression of loss of muscle tone as an individual proceeds through these stages, with muscle hypotonia being most pronounced in REM sleep, where only the diaphragm and extraocular muscles (as well as the middle ear muscles) are spared from almost complete paralysis. This is the underlying principle in measuring chin EMG during PSG. During wake, chin muscle tone is high and a tonically active chin EMG is interrupted by phasic contractions (facial expressions, tension, chewing, etc.). With relaxation and drowsiness, the level of EMG activity decreases. It further decreases as NREM sleep is achieved and deepens to SWS levels. Then, during REM sleep, EMG activity becomes minimal or even inapparent, although it may be occasionally interrupted with brief, irregular bursts of activity in phasic REM sleep, including the tongue [91]. These changes mirror, to a fair degree, the changes undergone by much of the motor system during sleep.

Any discussion on the effects of sleep stages, as determined by PSG, on motor control needs to be tempered by the fact that sleep staging in 30-second epochs, as is standard [5] (see Chap. 24) is based on rules that are arbitrary and are subject to a great degree of interscrorer variation. Physiologic processes are unlikely to adhere to these convenient timescales. For example, Mahowald and Schenck [92] reported on six patients with marked admixture of features from the different sleep–wake states (i.e., wake, NREM sleep, and REM sleep). These patients showed abnormal distribution of motor activity with relation to sleep features. Motor events, although typical of one sleep stage or state, may less commonly occur in other stages. For example, although PLMS are primarily a sleep phenomenon, these movements may also occur during arousals or periods of wakefulness after sleep onset (periodic limb movement in wake, PLMW), often as part of a periodic sequence of movements that span the sleep–wake divide [93]. PLMS occur primarily in NREM sleep but may also occur in REM sleep [94], especially in disorders of disturbed REM sleep such as narcolepsy and RBD [95, 96]. Patients with somnambulism, which typically occurs in NREM sleep, may show REM sleep motor abnormalities suggestive of RBD [97], and confusional arousals have been reported in REM sleep [98]. Even dream-enacting behavior, traditionally thought of as a REM parasomnia seen in RBD, has been reported in NREM sleep [99].

Table 39.1 summarizes the frequency of normal and abnormal motor activities that occur during the various phases of sleep and waking.

Cyclical Alternating Pattern and Movements in Sleep

The evaluation of periodic alternations in EEG activity represents an important additional means of scoring that may be more meaningful than the traditional, AASM mandated epoch-by-epoch scoring of sleep stages from a physiological perspective [5]. In NREM sleep, especially stage N2, this periodicity is common and designated the cyclical alternating pattern (CAP) [100]. First described by Terzano et al. [101], this pattern shows an alternation between bursts of both slow and fast activity (A phase) alternating with a medium frequency, lower amplitude activity (B phase). The burst-like activity (A phase) is associated with autonomic activation (Fig. 39.5). The A phases can include greater or lesser amounts faster frequencies: A1 has the least and A3 the most fast frequencies. A2 and A3 phases are often associated with arousals that can disrupt sleep [102, 103]. A number of different abnormal sleep-related movements are found to be associated with specific phases of the CAP cycle, especially the A phase. These include: PLMS [104] parasomnias or other sleep-related abnormal movements, such as bruxism [105], somnambulism [106, 107], or alternating leg movement activity during sleep (ALMA) [108], and nocturnal paroxysmal dystonia (NPD) [109]. CAP, especially phases A1 and A2, occurs more in early childhood [110], decreases during school age [111], may transiently increase during the adolescent period [112],

Table 39.1 Persistence of various movements in sleep

Motor activity	Awake/active	Drowsiness/sleep onset	Arousal/awakening	Stage 1 NREM	Stage 2 NREM	Stage 3 NREM	REM sleep

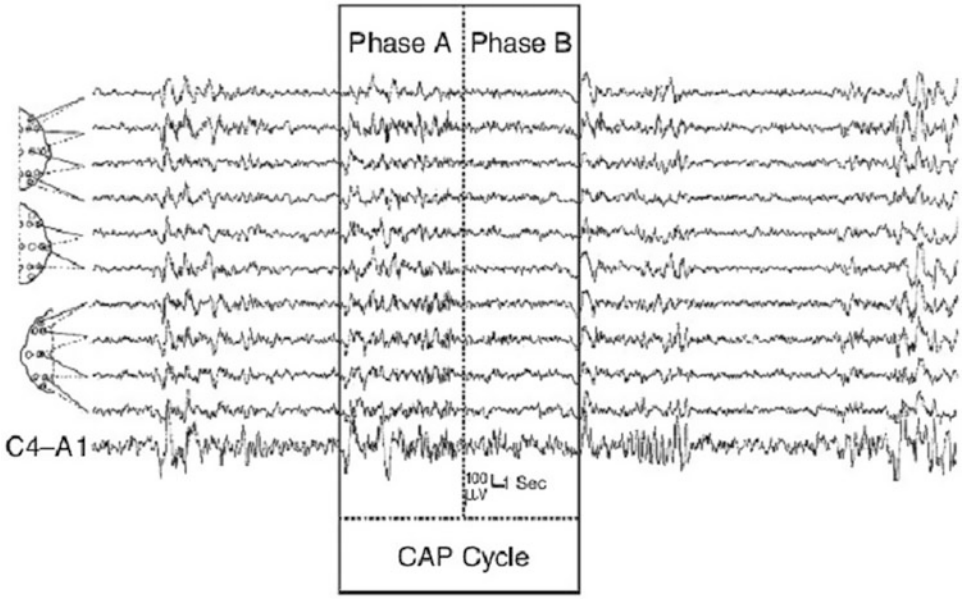

Fig. 39.5 Shows a cyclic alternating pattern (CAP) as part of a CAP sequence in Stage N2 sleep. The CAP cycle (highlighted) is defined by a Phase A (classified into threee subtypes A1, A2, A3 [subtype A2 is shown here] depending on the amount of high amplitude slow waves and low amplitude fast rhythms) followed by a phase B (relatively inactive) [each phase is 2–60 s in duration]. Bipolar EEG derivation (international electrode placement). Channels 1-6 from top: FP2-F4; F4-C4; C4-P4; P4-O2; F8-T4; T4-T6. Channels 7-11 from top: FP1-F3; F3-C3; P3-O1;C4-A1. (Reproduced with permission from Ref. [114])

decreases again in young adulthood, and then finally increases again in older ages [104]. CAP is a normal pattern, but deviations from normal amounts, especially excessive CAP can be abnormal [113].

Classification of Motor Disorders in Sleep

Motor disorders of sleep can broadly be classified into (1) diurnal movement disorders persisting into sleep and (2) primary sleep motor disorders (exclusive to sleep). The latter category can be further subclassified into disorders of motor control as the subject lays in bed trying to get to sleep, immediately before and at sleep onset, during NREM sleep, during REM sleep, during both NREM and REM sleep, and at sleep offset. These are listed in Box 39.1, and the individual motor disorders are discussed in detail in the following sections.

Box 39.1: Disorders due to Failure of Motor Control in Sleep

I. Diurnal Movement Disorders Persisting in Sleep

- Usually persisting in sleep
  - Symptomatic palatal tremor
- Frequently persisting in sleep
  - Spinal and propriospinal Myoclonus
  - Tics in Tourette's syndrome
  - Hemifacial spasm
  - Hyperekplexia
- Sometimes persisting in sleep
  - Tremor
  - Chorea
  - Dystonia
  - Hemiballismus

II. Disorders of Motor Control Unique to Sleep

A. Failure of motor contol while resting in bed trying to get to sleep

- Restless legs syndrome (myoclonic-dystonic movement in quiescence)

B. Failure of motor control at NREM sleep onset (including predormitum, an ill-defined stage between sleeping and waking)

- *Physiological*
  - Physiological body movements and postural shifts
  - Physiological hypnic Myoclonus

  - Hypnic jerks
  - Hypnagogic foot tremor
  - Alternating leg muscle activity
  - Rhythmic limb movements
- *Pathological*
  - Intensified hypnic jerks
  - Rhythmic movement disorder
  - Propriospinal Myoclonus at sleep onset

C. Failure of motor control during NREM sleep

- Partial Arousal Disorders
  - Confusional arousals
  - Sleepwalking
  - Sleep terrors
  - Sleep-related eating disorder (SRED)
- Others
  - Periodic Limb Movements in Sleep

D. Failure of motor control during REM sleep

- *Physiological*
  - Phasic muscle bursts (Myoclonus) including fragmentary hypnic myoclonus
  - Phasic tongue movements
  - Phasic rapid eye movements
  - Periorbital integrated potentials (PIPs)
  - Sleep paralysis
- Pathological
  - REM Behavior Disorder (RBD)
  - Sleep paralysis with narcolepsy
  - Familial sleep paralysis

E. Failure of Motor Control in both NREM and REM sleep

- Rhythmic movement disorder
- Catathrenia
- Excessive fragmentary Myoclonus
- Sleep bruxism
- Upper airway obstructive sleep apnea

F. failure of Motor Control during Sleep offset

- Sleep paralysis
- Hypnopompic hallucinations
- Sleep inertia ("sleep drunkenness")

Description of Individual Motor Disorders of Sleep

A. Diurnal Motor Disorders Persisting into Sleep

As a general rule, most abnormal movements seen during the daytime show a markedly decreased frequency, amplitude, and duration in sleep and tend to be limited to light NREM sleep (stages N1 and N2) [115]. Much less commonly, they will be reactivated during REM sleep as well. Only tardive dyskinesias and primary palatal tremor may show complete cessation of movements during sleep.

The degree of persistence of various abnormal daytime movements into sleep varies greatly (Table 39.1). In one of the most informative studies on the topic, performed using EMG, accelerometry, and split screen video recording. Fish et al. [85] examined the relationship of motor activity not only to conventional sleep staging, but also to epochs with transitions (to lighter or deeper sleep stages or to wakefulness). They also monitored the 2-second periods before onset of dyskinesias in patients with Parkinson's disease, Huntington's disease, Tourette syndrome, and torsion dystonia (both primary generalized and secondary) and scored them for presence of arousals, REMs, sleep spindles, and slow waves. They compared these dyskinesias to normal movements both in patients and in normal subjects. Forty-one of 43 patients had characteristic movements that persisted in sleep. In every disorder, both normal movements and dyskinesias followed the same general plan: most common in wakeful epochs followed by lightening, in stage N1 sleep, REM sleep, then stage N2 sleep, with no movements in SWS. Only Tourette patients had dyskinesias during transition from wake to sleep. The 2-second period before both normal and abnormal movements showed arousals most commonly, followed by REMs, with spindles and slow waves rarely. These results support prior speculation [116] that both dyskinesias and normal movements are likely to be modulated by sleep in a similar fashion. This may be due either to the general suppression of centers for both normal and dyskinetic movements or suppression of some common descending path, such as the pyramidal tract.

It should be noted that all of the abnormal motor activities described in the experiment above, which tended to become attenuated and repressed by sleep, are thought to be generated in higher motor centers, most of them located above the brain stem. On the other hand, movement disorders associated with

abnormalities of the lower motor centers, specifically the brain stem and spinal cord, have a greater tendency to persist during sleep [117]. Perhaps the best example is acquired (rather than primary) palatal myoclonus or palatal tremor (see below), which persists in sleep, although the frequency or persistence of these movements may vary with sleep stages [118]. In addition, spinal myoclonus will often persist during sleep [119]. Similar persistence may be seen in hemifacial spasm [120, 121], which is thought to involve damage either in the brain stem facial nucleus or in the peripheral nerve (cross talk due to ephaptic transmission) or both. Also, fasciculations due to damage to the lower motor neuron, whose generator lies at the spinal cord level, may persist in sleep [122].

In addition to the impact of the movements in sleep themselves, many disorders in which abnormal movements are a prominent feature impact sleep in other ways, including by causing changes in sleep architecture, mood, and level of daytime alertness, and medications treating the primary condition may equally affect the above domains, decreasing the patient's quality of life. These aspects are discussed below.

i. Sleep-Associated Problems of the Hypokinetic Disorders

Parkinson's Disease

Sleep impairment is a cardinal feature of Parkinson's disease. The original quotes from James Parkinson are worthy of note [123].

> But as the Malady proceeds …. (P.6)
>
> In this stage (stooped posture with "unwillingly a running pace"… most likely stage 3), the sleep becomes much disturbed. The tremulus motion of the limbs occur during sleep and augment until they awaken the patient, and frequently with much agitation and alarm. (P.7)
>
> …. and at the last (advanced bedridden stage), constant sleepiness, with slight delirium, and other marks of extreme exhaustion, announce the wished-for release. (P.9)

A spectrum of sleep dysfunction occurs in Parkinson's disease (see Fig. 39.6). Many studies have confirmed the fact that sleep is a major issue for patients with Parkinson's disease and their quality of life [124, 125]. Sleep disturbances also appear to impact cognition in Parkinson's disease, although the mechanisms and exact relationships remain unclear [126]. Many studies have shown sleep architectural disturbances in Parkinson's disease, including shorter total sleep time, lower sleep efficiency, and increased REM latency [127]. There have been conflicting reports on whether dopaminergic therapy improves sleep architectural changes [128, 129]. Early reports do seem to suggest that deep brain stimulation in Parkinson's disease appears to improve NREM sleep, abnormalities of REM sleep, and improve daytime sleepiness [130]. Compared with controls, there appears to be disruption of a number of circadian processes in parkinson's disease; including a sustained elevation of serum cortisol levels, reduced circulating melatonin levels, and altered peripheral clock gene expressions, and sleep disturbances, at least in part, may be related to this mechanism [131]; however, recently published data also suggest that dopaminergic therapy, while increasing melatonin levels (thus theoretically promoting sleep), may also show a delayed sleep onset relative to dim light melatonin onset (DLMO), suggesting that it may uncouple circadian

Fig. 39.6 Schematic diagram showing the spectrum of sleep dysfunction in Parkinson's Disease

and sleep regulation [132]. In recent years, several questionnaires have been developed and validated that can be used to assess sleep-related problems in Parkinson's disease, and liberal use of these instruments helps detect sleep issues [133–137]. Poor sleep in patients with Parkinsons's disease is multifactorial but can broadly be divided into being due to motor and non-motor symptoms.

Motor Symptoms Impacting Sleep

The persistence of the parkinonian tremor into sleep, and its reoccurrence during periods of sleep–wake transition, is a major cause of sleep fragmentation. Parkinsonian tremor decreases in amplitude and duration in early NREM sleep and may lose its alternating aspects and is rarely seen in Stage N3 and often disappears in REM sleep [138]. Bradykinesia often causes trouble turning in bed, which is an additional source of discomfort and may contribute to poor sleep quality.

On the other hand, sleep can also influence these motor symptoms in a positive way; in some patients, sleep can reduce Parkinsonian disability and alleviate symptoms [139–141], perhaps due to the circadian peak of dopamine in the morning [142]. Sleep benefit may last from 30 min to three hours. This may be particularly true of patients suffering from early onset Parkinsonism such as that due to the most common recessive Parkin (PARK2) mutation. Sleep benefit is less consistent in those with the recessive Pink1 (PARK6) mutation [143, 144]. Sleep benefit in this group of early onset patients is often associated with some degree of dystonia.

A major parasomnia that causes motor dysfunction occurring in patients with Parkinson's disease is RBD, which can disrupt sleep and be potentially injurious to the patient and the bedpartner. RBD may precede the diagnosis of Parkinson's disease or other extrapyramidal disorders by several decades. This association may be due to the Parkinsonian degeneration affecting brain areas and systems responsible for sleep–wake regulation [145]. A recent scheme postulates that the synuclein pathology of Parkinson's disease (Lewy Body pathology) ascends from the brain stem to the basal ganglia and finally to the cortex [146, 147], with early involvement of sleep regulatory nuclei before development of motor symptoms [148]. The combination of RBD with olfactory dysfunction may be a strong predictor for later development of Parkinson's disease [149]. In general, RBD patients show subtle motor, cognitive, autonomic, olfactory, and visual changes that are associated with Parkinsons's disease [150, 151], as well as brain perfusion changes determined by single photon emission computerized tomography (SPECT) imaging [152]. A recent finding is that of markedly reduced cardiac I-metaiodobenzylguanidine (MiBG) uptake, consistent with the loss of sympathetic terminals, in idiopathic RBD similar to the deficit seen in Parkinson's disease [153]. One recent study suggests that RBD occurs primarily in Parkinson's disease patients who have the non-tremor form [154]. The authors also suggest that RBD will not precede early onset Parkinson's disease, an observation supported in cases of PARK6 (PINK1) early-onset familial PD [155]. RBD later in the course of Parkinson's disease may be associated with additional complications such as hallucinations [156, 157], which may represent REM intrusions and cognitive decline [158]. A detailed analysis of movements in five patients with Parkinson's disease and RBD found that they had many more movements in sleep than controls, but that most movements were brief and restricted in scope [159]; 3.6 % of all movements were violent while 10.5 % involved vocalizations. It has also been proposed that RBD-related movements may show "normalization" of motor control in Parkinson's disease, with reduction in bradykinesia and vocal hypomimia [160]. Diagnosis and management of RBD is discussed in detail in Chap. 49 and 50.

There has been much research into the association between Parkinsons's disease on the one hand, and RLS and PLMS on the other. Recent studies have suggested that the prevelance of RLS is increased in patients with Parkinson's disease [161–163], including association in one family with a parkin mutation [164]. But this association is only poorly understood [165–167]. Some studies report that most RLS symptoms develop after onset of Parkinson's disease and initiation of dopaminergic treatment. This suggests that RLS may be provoked by such treatment rather than the disease itself; indeed, such treatment has been shown to induce RLS through a process of "augmentation," even in those who do not have RLS [168]. In one communication, subthalamic deep brain stimulation was reported to have induced RLS [169], but this may have been due to decreased medication doses. Similarly, some studies have found increased PLMS in patients with Parkinson's disease [170, 171], but one small study of de novo patients found no such elevation [172]. Thus, while it remains unclear if RLS and PLMS truly occur more frequently in patients with Parkinson's disease outside of dopaminergic treatment, when they do occur, they represent another factor that fragments sleep. Both RLS and PLMS are discussed in greater detail in Chap. 40.

Nonmotor Symptoms Impacting Sleep

Excessive Daytime Sleepiness and Irresistable Sleep Attacks

Excessive daytime sleepiness (EDS) is a common symptoms in Parkinson's disease and has been found to be more frequent in patients than in controls (15.5 % vs. 1 %) [173]. More advanced disease, higher frequency of cognitive decline and co-occurrence of depressive symptoms, more hallucinations,

and longer time on levodopa are predictive factors [174]. This daytime somnolence can exist even without evidence for or complaints of severely disrupted sleep [175, 176]. A related condition is the occurrence of Parkinson's disease-related "irresistable sleep attacks," sudden episodes of sleep that appear without warning on a background of normal alertness [177]. These attacks are much rarer than pervasive daytime sleepiness that the patient is aware of [178, 179]. Genetic variants of the preprohypocretin [180] and dopamine D2-receptor genes [181] have been associated with predisposition to sleep attacks. Some patients with Parkinson's disease have a narcoleptic phenotype, including a finding of sleep onset REM periods (SOREMPs) [182, 183]. This can be seen as 2 or more SOREMPs on multiple sleep latency test (MSLT; 4 or 5 naps scheduled during the day at 2 h intervals). Consistent with narcolepsy, hypocretin neurons are progressively lost with more severe Parkinson's disease [184], most likely due to Lewy Body degeneration. The picture in Parkinson's disease, however, is often more complex, while cataplexy, a key finding in narcolepsy, is generally absent [185]. Additionally, both EDS and irresistable sleep attacks can be caused by dopaminergic medication, especially at higher doses; non-ergot agonists specifically, may be more likely to cause somnolence. Treatment of daytime sleepiness may include the use of stimulants. Some recent studies have supported the use of modafinil as a relatively well tolerated stimulant [186–188], but one double-blind placebo-controlled study failed to support efficacy [189].

Sleep-Disordered Breathing

Respiratory disturbances are common in Parkinson's disease and other related neurodegenerative disorders due to changes in upper airway function or disturbed central regulation of breathing. This may be due to Lewy Body deposition leading to cell loss. Altered upper airway function may be based on weakness of respiratory and upper airway muscles or on altered muscle tone and coordination. The prevelance of SDB in Parkinson's disease has been demonstrated to be indepenedent of the degree of severity of motor and non-motor symptoms [190], but male gender and greater duration of illness are predictors [128]. Patients with Parkinson's disease may have stridor or laryngeal spasm associated with off-states or dystonic episodes [191], although this is more common in multiple system atrophy (MSA, see below). Abnormal vocal cord function with regular rhythmic movements or irregular jerky movements in the glottic area may also produce changes of airflow and contribute to intermittent airway closure [192]. Similar activity persisting during sleep can lead to OSA or upper airway resistance syndrome [193]. Snoring has occurred in the majority of subjects in some series [194]. It has not been definitely established that the prevalance of respiratory dysfunction during sleep in patients with Parkinson's disease as a whole is any higher than in healthy elderly persons [195, 196]. However, in some studies sleep-disordered breathing was more frequent and occurred in up to 50 % of patients with Parkinson's disease [197]. Trouble turning in bed may be a contributory factor in those patients with positional OSA [198]. Patients with parkinsonism and autonomic impairment more often develop sleep apnea and related respiratory abnormalities, including central and obstructive apneas and nocturnal hypoventilation. In the presence of sleep apnea, patients with autonomic impairment are probably more likely than other patients to have nocturnal cardiac arrhythmias. An interesting recent report suggested that treatment with dopaminergic agonists predisposed patients with Parkinson's disease to central sleep apnea [199] but more research on the subject is clearly needed.

Insomnia Insomnia, both sleep initiation and sleep maintenance, is a common complaint among patients with Parkinson's disease and is likely multifactorial [200]. Intrusion of motor symptoms into sleep (see above), depression and anxiety, concomitant sleep-disordered breathing and RLS, and in many cases dopaminergic treatment itself may contribute to insomnia in this population [201]. Other side-effects of medication include nightmares that may worsen underlying anxiety. Nevertheless, where motor symptoms seem to be the biggest impediment to quality sleep, appropriate therapy, including long-acting forms of dopaminergic medications to cover the night [202, 203], and, in some cases, deep brain stimulation [204, 205] may be helpful. Treatment of mood disorders with cognitive behavioral therapy and suitable antidepressants and anxiolytics is also recommended. SDB must be identified and adequately treated with continuous upper airway pressurization (CPAP) therapy.

Other Extrapyramidal Neurodegenerative Conditions

Alpha-synuceinopathies other than Parkinson's disease (the "*Parkinson's plus*" *syndromes*) have sleep disurbances as severe as those seen in Parkinson's disease itself, most likely due to the same pathology of Lewy Body-related neurodegeneration. RBD occurs in most of them and is in fact more common in MSA than in Parkinson's disease. Disturbances of sleep architecture, SDB, EDS, and insomnia are also frequent.

Progressive Supranuclear Palsy (PSP) Patients with this condition have been reported to have severe sleep disruption with reduced total sleep, marked diminution in sleep spindles, reduced REM sleep time with abnormal REMs, disordered sleep architecture, and frequent awakenings [206–212]. RBD is frequent [213, 214], although possibly less common than with Parkinson's disease [215]. As with

Parkinson's disease, sleep disruption increases with severity of the motor abnormalities [208–210]. The greater sleep abnormalities of PSP compared to Parkinson's disease may be due to the greater brain stem pathology, especially that in the pedunculopontine tegmentum, a region linked to control of REM sleep; one report also found that cerebrospinal fluid (CSF) hypocretin levels were lower in patient with PSP than in those with Parkinson's disease [216].

Multiple System Atrophy (see also Chap. 41)

Among the extrapyramidal disorders, sleep disruption appears to be worst in MSA [217–221], and these patients may be especially sensitive to the hypersomnolence induced by dopaminergic therapy [222]. Patients with severe MSA may even lack normal circadian regulation of sleep [223]. As mentioned above, RBD is very common [224], although RBD is unlikely to be seen in pure autonomic failure and provides one means of differentiating the two conditions [225]. PLMS is prevalent as well [221]. A somewhat characteristic feature of MSA is the occurrence of atrophic paralysis of the laryngeal abductor [226], or sleep-related hyperactivity of the adductors, which has been described as dystonic [227], leading to a coarse, snoring-like sound, and laryngeal stridor [228]. In fact, stridor, a potentially life-threatening condition that may cause sudden death from respiratory arrest [229, 230], has been reported as the first or even only apparent sign of MSA [231, 232]. Milder cases may be managed with CPAP [233]; more severe cases require tracheostomy. In some cases, patients with MSA may have predominantly central sleep apnea [234].

ii. Sleep-Associated Problems of the Hyperkinetic Disorders

The hyperkinetic disorders are a diverse group characterized by excessive involuntary movement, often coupled with a deficiency of voluntary movement such as bradykinesia.

Chorea

Chorea consists of movements that occur in a flowing or irregular pattern and appear to migrate from one part of the body to another. They may be increased with action and typically are seen in the face and distal limbs [6].

The best-known cause of chorea is *Huntington's disease*, an autosomal dominant disease with a known mutation of the *IT15* gene located on the short arm of chromosome 4. The mutation in Huntington's disease is the expansion of a CAG repeat in the DNA that leads to increased length of a polyglutamine tract in the protein product, now called *huntingtin*. Currently, research is directed at finding the function of huntingtin in the normal brain and the elucidation of the toxic effect of the mutated protein. Although huntingtin is widely distributed in the brain, the pathology of Huntington's disease is more restricted. Patients also have prominent psychological symptoms, including depression, psychosis, and behavioral disorders. Onset is typically between the ages of 25 and 50, although it may occur even in the first decade or in late adult life. Progression is slow but relentless, with eventual debility, dementia, and inanition occurring in those with onset before old age.

Sleep disturbances in Huntington's disease have been the focus of considerable research. Recently, investigators found that sleep disturbances may be the earliest manifestation of Huntington's disease [235]. There appears to be no correlation between CAG repeat length and sleep disturbances [236]. Investigators have shown a variable persistence of chorea during sleep, with most chorea present in awakening, and in the lighter stages of NREM sleep (stages N1 and N2), similar to other dyskinesias [85]. One study reported an increase in overall sleep movements in Huntington's disease [237]. There has also been some research into sleep architecture in Huntington's disease, but the results have been inconclusive. Some reported deficits include prolonged sleep latency, excessive waking, decreased SWS and REM sleep, and decreased sleep efficiency, possibly correlating to caudate atrophy [238–240]. Reports of alterations in sleep spindles in Huntington's disease have been inconsistent [241, 242]. It has been suggested that nocturnal agitation and sleep disruption in Huntington's disease patients is secondary to anosognostic voluntary movements on arousals, rather than to RBD [236]. A recent study of 30 patients with Huntington's disease showed that they, compared to controls, had shorter sleep duration, reduced sleep efficiency, increased arousals and awakenings, and higher PLMS index in both NREM and REM sleep, but were not at increased risk for RBD or SDB. Greater clinical disease severity predicted decreased REM sleep percentage and greater daytime sleepiness [243]. Other studies have confirmed that unlike patients with parkinsonism, patients with Huntington's disease have not been found to have a significant number of sleep apneas contributing to impaired sleep [244].

Sleep has not been well-studied in other conditions with predominant chorea. Broughton et al. [245] reported that four patients with *Sydenham's chorea*, which follows a streptococcal infection, had reactivation of their movements during REM sleep. Neuroacanthocytosis or chorea-acanthocytosis, is an often inherited movement disorder with chorea, tics, vocalizations, and self-mutilation together with frequent seizures, associated with elevated acanthocytes (spiked red cells) in blood smears [246–248]. Silvestri et al. [249, 250] reported that in this condition, abnormal movements persisted during sleep, but with decreased amplitude, duration, and frequency. Patients frequently vocalized during REM sleep. Sleep was

fragmented and of poor quality. Two siblings with neuroacanthocytosis showed EEG slowing (predominantly delta) both while awake and during REM sleep [251], indicating abnormal cerebral function. RLS has been reported to occur in this condition [252].

Dystonia

Dystonia is a condition characterized by sustained distorted or twisting postures and contorting movements, often mixed with a variety of jerk-like or oscillatory movements [253]. Dystonia can be primary or secondary and can be of variable extent, focal, segmental, or generalized, depending on the area of involvement. Dystonia includes a number of different conditions, some of which, such as early onset torsion dystonia, have a single-gene basis. The protein for early-onset torsion dystonia, torsin A, has been found to bind adenosine triphosphate, but how it causes dystonia itself remains unresolved [254–258]. Not all idiopathic dystonia patients have been shown to have a genetic mutation, however, and there are many cases of secondary dystonia that do not appear to depend on common dystonia genes [259]. One problem in evaluating sleep complaints in dystonia is that the studies so far have often examined a fairly heterogeneous collection of patients with different distributions of dystonia and different etiologies.

Although they usually subside significantly, dystonic movements may persist during sleep at a reduced frequency and amplitude. They are maximally reduced during SWS and may be partially reactivated during REM sleep episodes [260]. In the study by Fish et al. [85] of dyskinetic movements, both primary and secondary dystonic patients followed the general pattern of more frequent dyskinetic movements during wakefulness, fewer movements in stage N1 sleep, only infrequent movements in stage N2, REM, and SWS, and no movements during epochs of deepening sleep. In a study including focal and segmental dystonias, Silvestri et al. [249] found that Meige's syndrome (oromandibular dystonia), blepharospasm, and tonic foot syndrome all showed persistent abnormal activity during sleep, with reduced amplitude, duration, and frequency of EMG bursts. The greatest suppression was in SWS and REM sleep.

Inhibitory mechanisms are postulated to be defective in dystonia. This prompted Fish et al. [261] to study both primary and secondary dystonics to determine whether REM inhibition is intact. They found that all dystonics had normal chin EMG atonia. No patients had complex abnormal activity during REM sleep. In an attempt to analyze motor excitability, the authors successfully stimulated three normals and seven primary dystonics with a magnetic coil over the vertex to evoke a motor response in the fifth finger abductor, the abductor digiti minimi. Whereas response amplitudes were highly variable, dystonics, like controls, showed a decrease in the mean response during REM sleep relative to responses obtained before and after the sleep study in relaxed wakefulness. Latencies were prolonged on average in all groups. The findings of decreased amplitude and prolonged latency were consistent with REM motor inhibition. Occasional high-amplitude responses may have corresponded to periods of phasic excitation. These results indicate that, whatever may be the decreased inhibitory processes in dystonia, they do not involve the descending inhibitory pathways of REM sleep.

Studies of sleep in dystonia have not been systematic; studies have involved small numbers of patients on diverse medications, some of whom had prior thalamic surgery [262]. In these studies, sleep has been found to be inconsistently disrupted, with more severe fragmentation seen in more advanced cases [263]. A number of studies have reported the presence of exaggerated sleep spindles in dystonia [264, 265]. The major therapeutic effort in these patients is the attempt to reduce the dystonic movements. Successful therapy of the movements should also improve sleep.

It is not known that to what degree different forms of dystonia—early- versus late-onset, focal versus generalized—differ in their relationships to sleep, although one striking form of dystonia, variably called *hereditary progressive dystonia with marked diurnal fluctuations* (HPD), *dopa-responsive dystonia* (DRD), and the *Segawa variant*, often shows distinct circadian variability [266–268]. These patients typically present at a young age, often in the middle of the first decade, with postural dystonia, usually affecting one leg and sparing the trunk and neck. Thereafter, the dystonia spreads and parkinsonian signs, which are present at onset in a minority of patients, become more prominent. The condition is usually inherited in an autosomal dominant mode with a mutation in GTP cyclohydrolase I (GCHI) [269, 270]. A number of different mutations in GCHI have been described, but, less commonly, it seems that the condition can be inherited recessively with a mutation in tyrosine hydroxylase [271]. Some studies have found that even patients thought to have more typical idiopathic torsion dystonia may harbor a mutation in the *GCHI* gene [272]. A number of these patients may obtain significant symptomatic relief from sleep, similar to the sleep benefit seen in Parkinson's disease, and therefore are minimally impaired early in the day, and even some dystonic patients unresponsive to L-dopa may have similar benefit from sleep. These patients do show abnormal movements in sleep. Segawa et al. [273] obtained movement counts from PSG with multiple EMG channels (8–12 surface recordings on trunk and limbs) and found that in DRD, there is a decrease in gross body movements in stage I sleep, an increase in stage II sleep, and a decrease in REM sleep. In

contrast, localized twitch movements were depressed in all sleep stages, but followed the normal relative distribution between stages.

Patients with diurnal dystonia or the nocturnal sleep abnormalities of DRD are responsive to low doses of L-dopa, often as little as 50–200 mg per day with decarboxylase inhibitor [274]. Some patients can maintain a stable therapeutic effect with doses every other day. Patients with long-standing disease (24–45 years before treatment) may benefit as well as those with recent onset. DRD patients can use L-dopa without the development of the dyskinetic side effects that are so prominent in juvenile parkinsonism. A few patients may develop "wearing off" phenomena, the re-emergence of symptoms several hours after an oral dose of L-dopa. Older family members may present with a "parkinsonian picture," but still show the same persistent, positive response to L-dopa. This finding is consistent with the idea that a single underlying disease has different manifestations that vary with age, dystonia being prominent in early and late parkinsonism [275–278].

With fluorodopa positron emission technology (PET) scanning, it has been shown in a number of families that patients with DRD have normal to modestly reduced striatal uptake of fluorodopa, including those who present with parkinsonian features later in life [276]. Because of this finding, it can be concluded that these patients have relatively intact dopamine uptake, decarboxylation, and storage systems in the striatum. The genetic abnormalities so far uncovered are involved with the dopamine synthetic system. It has also been speculated that the diurnal fluctuations that characterize DRD may be due to the circadian variation in dopamine production, with greater synthetic activity possible at night. One study found that acute dystonia secondary to neuroleptic medication also shows a circadian pattern [279], with maximal dystonia present between 12:00 noon and 11:00 PM. This could not be accounted for by sleep, fatigue, or time since the last dose of medication (in this case, injections twice daily). Some of this circadian variability may be accounted for by circadian variations in the dopamine system, which seem to show the least activity in the evening hours with maximal activity in the morning [280].

Nocturnal Paroxysmal Dystonia

Nocturnal Paroxysmal Dystonia (NPD) was first described by Lugaresi's group as a condition which might be considered analogous to diurnal paroxysmal movement disorders [281]. Although it is now established that this and related conditions are variants of frontal lobe epilepsy, their atypical presentation often makes the diagnosis quite challenging. The characteristically short lasting attacks of NPD begin with arousal, including an abrupt autonomic activation that can include substantial tachycardia, followed by dystonic choreo-athetoid or ballismic movements and large-scale semi-purposive movements of all limbs. Vocalizations are common. The attacks are quite diverse if considered between patients but appear to be stereotyped in a single patient. Attacks are brief, last about a minute (range 15 s to 2 min for typical attacks) and may be vaguely remembered. Neither tongue biting nor urinary incontinence is common and tend to resolve without a significant period of post-ictal confusion, which is one of the reasons that it was not appreciated early on that at least the brief attacks are a form of epilepsy. In some patients, the attacks are decidedly unilateral The epileptiform nature of these attacks, together with two other conditions, paroxysmal arousals (in which patients awake abruptly from NREM sleep, perhaps with a start or cry, and have fleeting dyskinetic movements, then fall back to sleep) [282] and episodic nocturnal wanderings (attacks of sudden motor activity, including violent ambulation, loud vocalizations, and a variety of forceful gestures commonly occuring in stage 2 NREM sleep [283–285] is now clearly established [286, 287]. Therefore, the diagnosis and treatment of these disorders is discussed in detail in Chap. 44.

However, it is worth mentioning that there have been reports in the literature of attacks similar to NPD that did not respond to antiepileptic treatment. In the original description, two cases had longer duration (2–50 min) attacks, with no epileptic associations [281]. In one case, a patient afflicted with such attacks for 20 years developed Huntington's disease. There are a number of more recently described disorders of at least uncertain etiology. Lugaresi's et al. [288] described a periodic form of NPD which recurs every 30 s to 2 min with usually quite brief attacks (2–13 s in duration) and associated arousals which they called atypical periodic movements in sleep. While showing overlap with the short-lasting NPD, this condition was unresponsive to seizure medications, even though one patient in the original series had a vascular orbital frontal tumor on computerized tomography (CT) scanning and spikes on depth recording. Other such disorders include dystonic attacks provoked both by sleep and exercise [289], apnea-associated paroxysmal dyskinetic movements [290, 291], and post-traumatic nocturnal hemidystonia [292]. Thus, when the diagnosis is in doubt, it is prudent to order a PSG with an extended seizure montage as well as extra EMG channels to distinguish between a motor disorder and an epileptic phenomenon; in our laboratory, we employ a hybrid montage for this purpose (Table 5 from Chap. 18).

Myoclonus

The myoclonias [293] are a diverse group of conditions with abnormal movements generated at various levels of the neuraxis, from cortex (cortical reflex or epileptic myoclonus) to spinal cord (spinal or segmental myoclonus). The basic abnormal movement is a single, repeated, or periodic jerk,

most typically abrupt and "lightning-like." Most of the studies of myoclonus and sleep have focused on the persistence of myoclonic movements during sleep. Whether myoclonus persists in sleep or not appears to be related to the source of the discharge; elegant experiments have shown that myoclonus with a cortical source shows suppressed movements during sleep while (as in epilepsy) cortical discharges persisted, myoclonus of presumed subcortical origin is rapidly suppressed during sleep, and myoclonus of lower-level origins (spinal cord or secondary to peripheral damage) persists during sleep [294]. Thus, cortical and subcortical myoclonus tends to be attenuated by sleep, whereas myoclonus of peripheral origin, such as spinal myoclonus, and propriospinal myoclonus, shows persistence into sleep in varying degrees [295, 296]. Myoclonic jerks associated with startle disease also persist during sleep, although with diminished intensity [297].

Palatal Myoclonus (Palatal Tremor) Palatal myoclonus (more accurately described as palatal tremor) is characterized by rhythmic movements of the soft palate and pharynx at a rate of 1–3 Hz. It is sometime associated with rhythmic ocular, buccal, lingual, laryngeal and diaphragmatic movements, and occasionally also movements of the upper limbs [298]. Two types have been described as follows: a primary or essential type (idiopathic) due to contraction of the tensor veli palatini muscle presenting with a clicking noise in one or both ears, and an acquired or secondary due to contraction of the levator veli palatini muscle [299]. When acquired, it is usually secondary to brain stem damage within Mollaret's triangle (dentatorubroolivary pathways, with damage most common in the central tegmental tract which runs from the region of the red nucleus to the ipsilateral olive). While primary palatal tremor may be completely abolished by sleep, electrophysiologic studies in a small number of patients demonstrated that palatal contractions persist during sleep, albeit with shifts in amplitude and frequency or even altered rhythmicity [300–302]. The range of such cyclic motor dyskinesias may be broader than currently known: a similar tongue movement was reported to persist largely unchanged in sleep [303]. The finding of persistent rhythmicity suggests a relatively autonomous oscillator consistent with the idea that these segmental myoclonias may represent release of a primitive rhythmic center. In contrast to other forms of myoclonus, these dyskinesias appear to arise at a segmental level and to be associated with decreased motor control from higher centers. This dissociation may explain their resistance to modulation by descending inhibitory influences during sleep. The dyskinesias are not completely removed from higher motor centers or the periphery, however, because they may disappear in sleep, change with state, and be influenced by attention [304–306]. In one interesting case, palatal tremor was associated with time-locked respiration, suggesting a coupling of these two rhythms [307].

Palatal tremor is generally refractory to treatment. There are reports of occasional response to anticholinergics, botulinum toxin injections, baclofen, valproic acid, lamotrigine, tetrabenazine, and carbamazepine [308].

Tics

Tics are typically brisk, stereotyped, complex, often repetitive movements [309]. Usually, any given patient has a somewhat limited repertoire of movements that may change over a period of months to years. The prototypical tic disorder is Gilles de la Tourette's syndrome, a condition involving multiple motor tics with vocalizations that usually begins in childhood or adolescence but may subside in later adult life [310]. Tics may be associated with a sensory penumbra and an urge to move. Tourette's patients also have a number of commonly-associated behavioral abnormalities, especially obsessive-compulsive disorder [311, 312]. Of all tic disorders, sleep disorders have been best studied in patients with Tourette's syndrome.

Tics in Tourette's syndrome have been found to persist during sleep in most cases, mostly in stages I and II of NREM sleep, with fewer during SWS or REM sleep [313, 314]. Also observed is increased frequency of disorders of arousal (e.g., somnambulism and pavor nocturnus) and parasomnias in general, as well as poor quality and fragmented sleep [315, 316] in children with Torette's syndrome. Bodily movements in general are increased in Tourette's syndrome; Hashimoto et al. [317] found that both twitch-like and gross body movements were increased over controls during all stages of sleep, with total movements in tic patients markedly increased during REM sleep. Those authors did not attempt to analyze such movements in detail, so it is not clear what fraction of them were actual tics. In one study, patients were monitored after successful treatment of their movements with tetrabenazine, and it was found that sleep also improved [318].

Hemifacial Spasm

Hemifacial spasm consists of intermittent contraction of one side of the face that can be repetitive and jerk-like or sustained. It is believed to arise from irritation of facial nerve or nucleus. Both central and peripheral (ephaptic transmission between adjacent nerve fibers without synapses) factors are responsible for the spasms. EMG recording shows highly synchronous discharges in upper and lower facial muscles. Montagna et al. [319] studied 16 patients, recording from upper and lower facial muscles during sleep studies. In most patients, the dyskinesias decreased during sleep, being approximately 80 % less frequent in SWS and REM

sleep. One patient showed almost no change in the prevalence of spasms. Current therapy for hemifacial spasm includes medications such as carbamazepine, botulinum toxin injection into the affected muscles, or varied surgical treatments, such as vascular decompression of the facial nerve. Combined treatment with pregabalin and botulinum toxin injections has been reported [308].

Other Hyperkinetic Disorders

In *hemiballismus*, there are proximal flinging movements of one side of the body, which may be of a violent nature, associated with damage to the contralateral subthalamic nucleus [320]. In most cases, hemiballismus is a transient phenomenon after local injury to the subthalamus, usually ischemic, although it may be transformed into a chronic choreiform disorder. It was initially thought that the movements totally subsided in sleep. Askenasy [321], however, reported a patient whose movements persisted in sleep, and Silvestri et al. [115] found that the movements were present during stages N1 and N2, as well as during REM sleep, although diminished in intensity and frequency. Puca et al. [322] reported one case in which spindle density and amplitude were greater ipsilateral to the damaged subthalamic nucleus. There was also disrupted sleep, with prolonged latency and an absence of both SWS and REM sleep. Successful treatment with haloperidol improved the sleep and decreased the spindling.

In *athetoid cerebral palsy*, abnormalities of REM sleep have been noted. Hayashi et al. [323] reported on a group of severe adolescent and young adult patients. The significant motor abnormalities were associated with REM sleep: three patients had decreased numbers of REM, two had increased chin muscle tone, and seven had reduced numbers of muscular twitches. The authors suggest this may be related to brain stem pathology in these birth-injured patients. One family with five generations affected by *paroxysmal dystonic choreoathetosis* with dominant transmission was found to show substantial benefit from even brief periods of sleep [324]. In a Serbian family with mutations in the Myofibrillogenesis regulator 1 gene, sleep was reported to be the most effective means of terminating attacks [325].

Sleep-Associated Problems of the Ataxic Disorders

Relatively little research has been done on sleep disturbances in the ataxic disorders. Today, a large number of different genetically based variants of spinocerebellar ataxia have been described and some of these have been examined with respect to sleep. Patients with Machado–Joseph disease (Spinocerebellar atrophy type 3, SCA3) may have both RLS and RBD as common sleep-related problems. Patients with SCA2 can have reduced REM-sleep atonia. One report suggests increased PLMS and RLS in SCA6. SCA6 patients also have impaired subjective sleep quality and tend to have greater daytime sleepiness. It seems likely that the paucity of associations reported to date is more due to the lack of studies than the absence of sleep problems in these disorders [326–331].

B. Motor Disorders Exclusive to Sleep

i. Failure of motor control while resting in bed trying to get to sleep.

This category includes RLS and PLMW, which are discussed in Chap. 40.

ii. Failure of motor control immediately before and at sleep onset

Since normal individuals enter the sleep cycle through NREM sleep, these disorders can also be considered failures of motor control in NREM sleep. Many of these are of unclear clinical significance and require no treatment.

Physiological Hypnic Myoclonus

The term physiological hypnic myoclonus (PHM) was first coined by De Lisi [332] to describe brief asynchronous, asymmetric, and aperiodic muscle twitches during sleep in all body muscles of man and domestic animals resembling fasciculations seen prominently in face and distal body parts (e.g., face, lips, fingers and toes). PHM is also known as physiological fragmentary hypnic myoclonus and is seen prominently in babies and infants. Quantitative study by Dagnino et al. [333] and Montagna et al. [334] in 1988 showed the maximum occurrence of these twitches in stage N1 and REM sleep, decreasing progressively in stages N2 and N3. Presence of PHM also during relaxed wakefulness challenges the term hypnic Myoclonus [335, 336]; however, it should be noted that propriospinal myoclonus at sleep onset and intensified hypnic jerks in many patients [336] are present in relaxed wakefulness before sleep onset. The origin of PHM remains controversial. Facilitatory reticulospinal tract, pontine tegmentum, and corticospinal tract [337, 338] have all been suggested as the generator of PHM. These movements are physiologic without disrupting sleep architecture and require no treatment.

Hypnic jerks including intensified hypnic jerks

Hypnic jerks or "sleep starts" are sudden, brief contractions of the body that occur at sleep onset and are due to excitation of motor centers. They are physiological and occur in up to 70 % of the population at some point in their adult lives. They are often accompanied by a sensation of falling [339]. The movement itself is an abrupt, myoclonic flexion movement, generalized or partial, often asymmetric, which may be accompanied by a sensation or an illusion of falling. Unless very frequent (which does occur rarely) [336, 340] this is a benign movement which has little effect on sleep and carries no negative prognosis. When it occurs, it is

usually a single event, which causes a brief arousal. EMG records show relatively brief EMG complexes (<250 ms in duration) that may be simultaneous or sequential in various muscles. The earliest mention of this phenomenon is credited to Mitchell [341], who described insomnia occurring as a result of hypnic jerks in 1890. Oswald [339] first described the EEG correlates of hypnic jerks. In 1965, Gastaut and Broughton [342, 343] performed the first polygraphic study of hypnic jerks. It was not until 1988 that Broughton [340] coined the term "intensified hypnic jerks" to describe the clinical phenomenon of sleep onset insomnia caused by accentuated and disruptive hypnic jerks occurring at sleep onset. More recently, Chokroverty et al. [336] performed a polysomnographic and polymyographic analysis of ten patients with intensified hypnic jerks and identified four patterns of propagation: synchronous and symmetrical patterned muscle bursts between the two sides and agonist–antagonist muscles similar to those noted in audiogenic startle reflex; reticular reflex myoclonus; dystonic myoclonus; and pyramidal myoclonus with rostrocaudal propagation of muscle bursts.

Hypnagogic Foot Tremor and Alternating Leg Muscle Activation

Hypnagogic foot tremor (HFT) (Fig. 39.7) and ALMA (Fig. 39.8) rarely come to clinical attention, being discovered as incidental findings on PSG. Both occur during lighter sleep and in transitional states into and out of sleep. ALMA has also been documented in wakefulness, all stages of NREM and also, though less frequently, in REM sleep in patients with a variety of sleep disorders [344]. Another feature of ALMA is its occurrence, in addition to the traditional tibialis anterior EMG, in gastrocnemius and sometimes in quadriceps muscles alternating between two sides. Because variant patterns are reported in each, and there is at least some plausible degree of overlap between HFT and

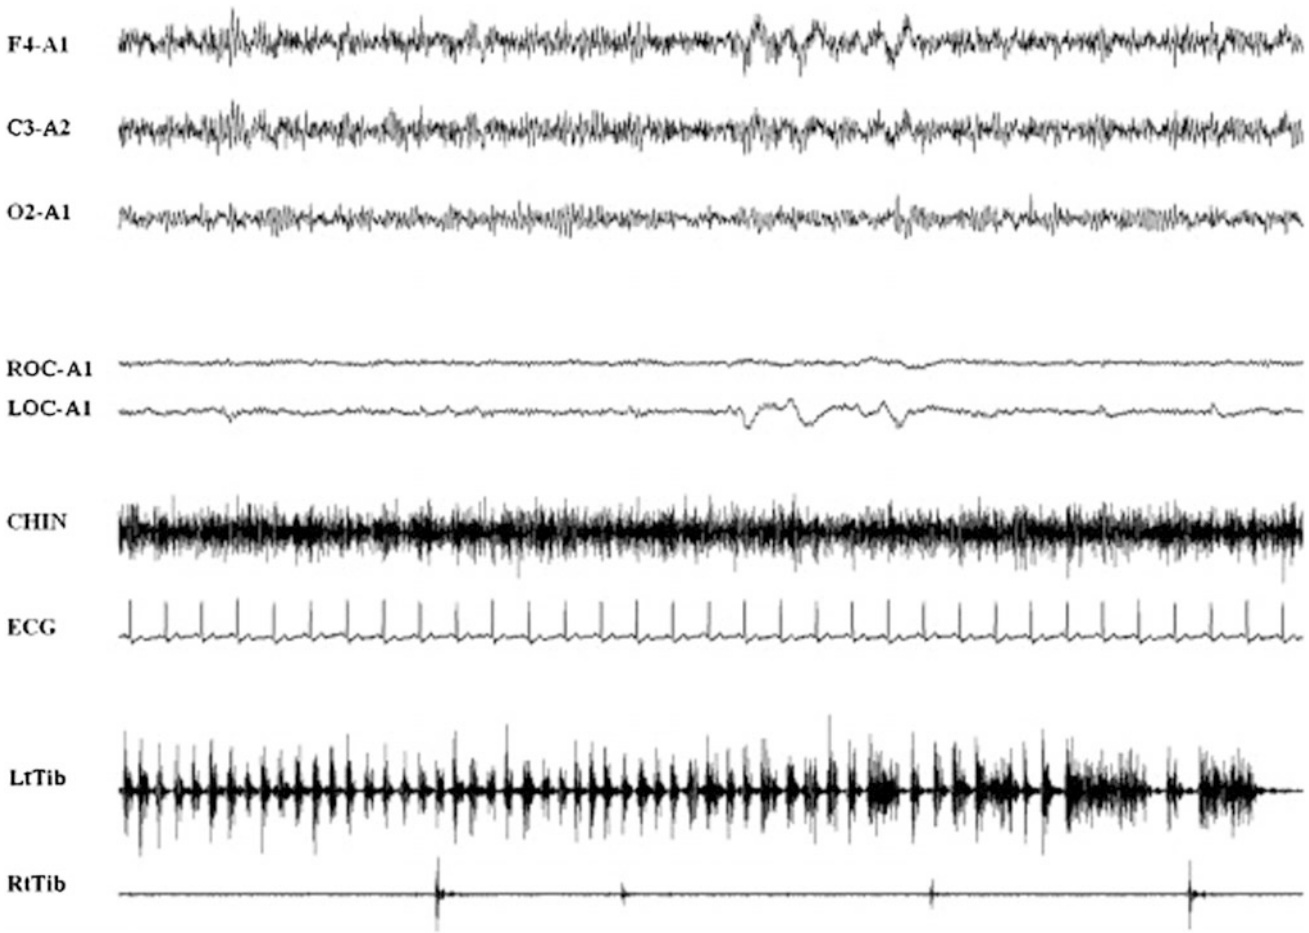

Fig. 39.7 Hypnagogic foot termor. A 30-s epoch of relaxed wakefulness from the polysomnogram of a 69-year-old man affected by snoring and nonrestorative sleep. Note the occurrence of a series of rapid tibialis anterior activations longer than 30 s, with single burst durations of 200–300 ms. Top three channels, electroencephalography. ROC and LOC: electrooculogram channels. ECG, electrocardiogram. LtTib and RtTib, tibialis anterior electromyography channels. (Reproduced with permission from Ref. [114])

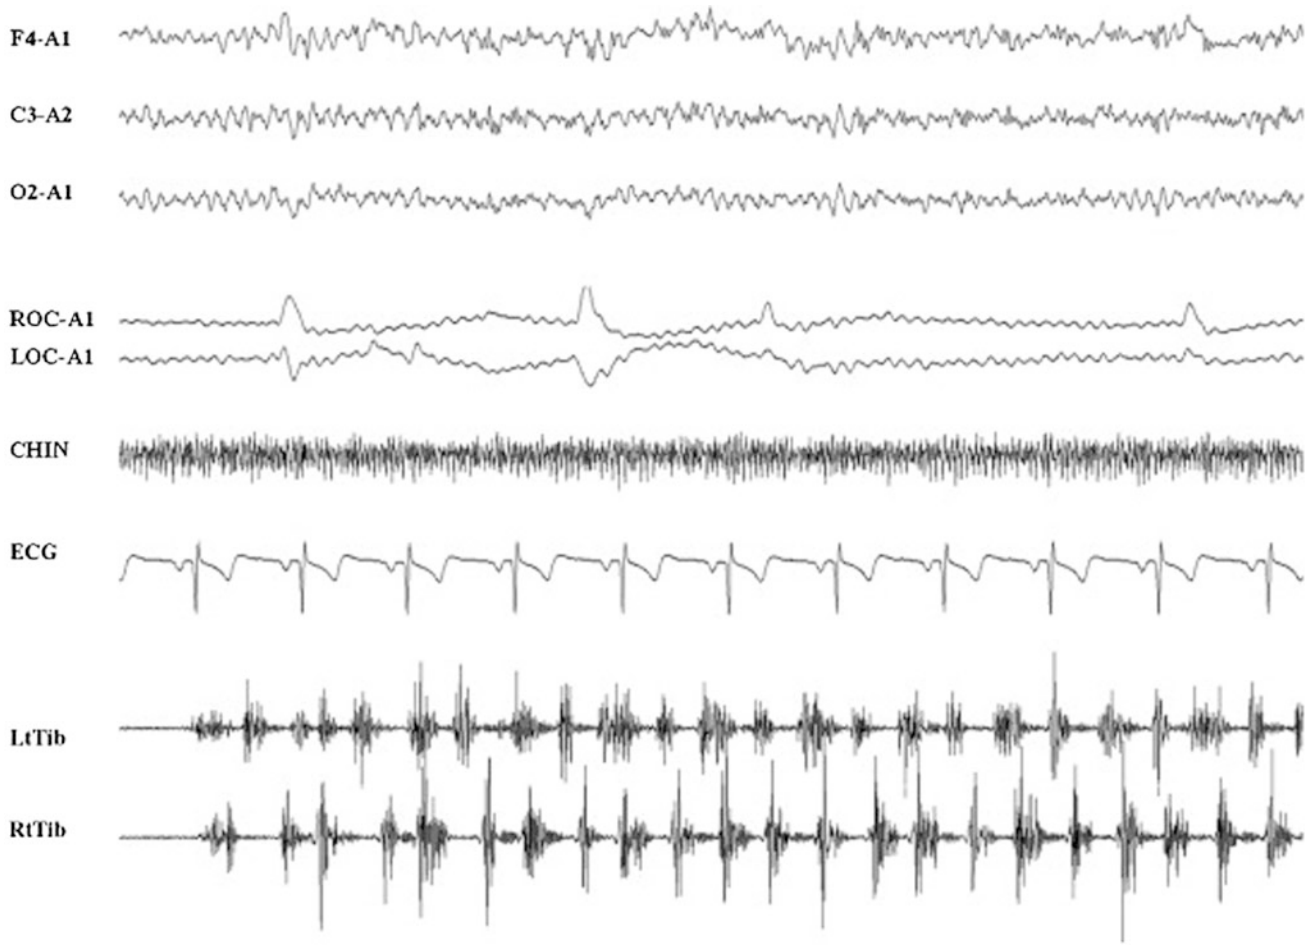

Fig. 39.8 Alternating leg muscle activation. A 10-s epoch of relaxed wakefulness transitioning to N1 sleep from the polysomnogram of a 32-year-old man with chronic insomnia and no comorbid history of restless legs syndrome, affected by snoring and nonrestorative sleep. Note the occurrence of a series of alternating tibialis anterior activations longer than 10 s, with single burst durations of 200–300 ms. Top three channels, electroencephalography. ROC and LOC: electrooculogram channels. ECG, electrocardiogram. LtTib and RtTib, tibialis anterior electromyography channels. (Reproduced with permission from Ref. [114])

ALMA (and also PLMS) further investigation may be required to ascertain whether they are distinct or merely variant conditions. It has also been suggested that both may be variants of RMD (see below). HFT is defined by the AASM Manual for the Scoring of Sleep and Associated Events as rhythmic contractions of foot and leg occurring during sleep onset generally bilaterally but asynchronously at a frequency of 0.5–4 Hz [5] and was first described by Broughton [340]. Wichniak et al. [345] later performed polysomnography on 375 consecutive subjects and found HFT (which they called "rhythmic feet movements while falling asleep" and described as rhythmic, oscillating movements of the whole foot or toes) in 7.5 %. Per the AASM Manual for the Scoring of Sleep and Associated Events, ALMA consists of EMG bursts that occur alternately in each leg in a rhythmic pattern of 0.5–3 Hz and was first described by Chervin's et al. [346], who found it in just over 1 % of reviewed PSGs; most of those showing the phenomena were taking anti-depressants. The duration of an individual movement varies between 100 and 1000 ms. For both HFA and ALMA, at least 4 movements must be present in a row to make the diagnosis [5]. ALMA requires the presence of alternating activity and has been suggested to be an equivalent of a locomotor rhythm [347]. Diagnosis of either requires a PSG recording. Convincing evidence of any definite clinical consequence of these movements is yet to be presented. In one patient, pramipexole-reduced ALMA and improved sleep [347], together with a reduction of associated CAP. The clinical significance of both HFT and ALMA remains undetermined requiring no treatment.

Rhythmic Movement Disorder

RMD (Fig. 39.9) is characterized by repetitive, stereotyped, rhythmic movements involving large muscle groups,

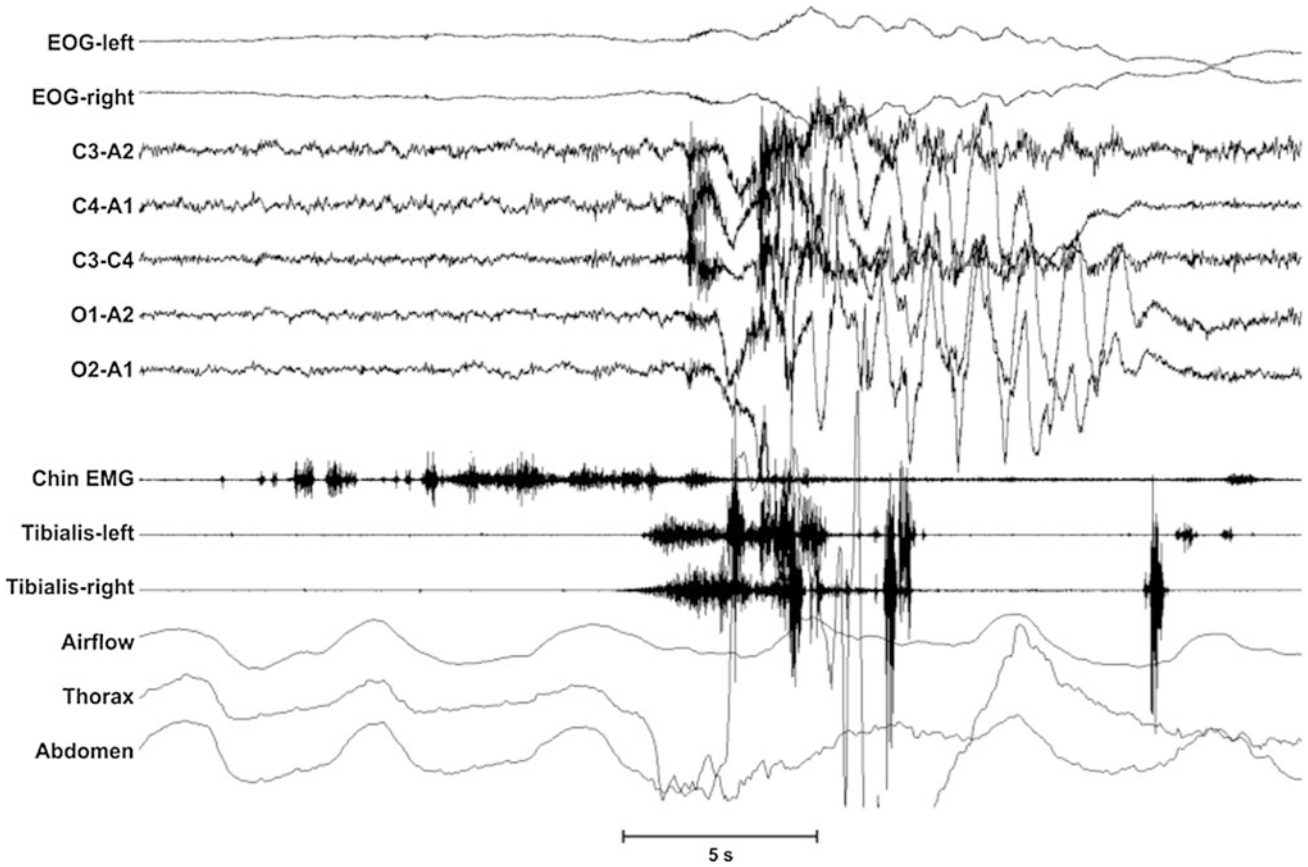

Fig. 39.9 Rhythmic movement disorder. Polysomnographic recording of a rhythmic movement disorder (RMD) episode. RMD typically consists of repetitive stereotyped and rhythmic motor behaviors, such as head banging, body rolling, and body rocking. These movements generally occur at sleep–wake transitions and after arousals from sleep but may also occur in wakefulness, and rarely during REM sleep. These episodes may also occur at the termination of a respiratory event in obstructive sleep apnea syndrome. (Reproduced with permission from Ref. [114])

occurring predominantly during sleep onset or during sleep–wake transitions, at a frequency of 0.5–2 Hz. It can take many forms, including head banging ("jactatio capitis nocturna"), body rocking, body rolling, and leg rolling. Reports of events matching the current description of RMD have been abundant in the literature [348, 349] and even reported as early as in 1880 [350] although the term *jactatio capitis nocturna* was first used by Zapert [351]. According to the AASM Manual for the Scoring of Sleep and Associated Events, in addition to the above frequency criterion, the minimum number of individual movements to make a cluster of rhythmic movements is 4 movements and the minimum amplitude of an individual rhythmic burst must be at least 2 times the background EMG activity [5].

RMD generally presents before 18 months of age and tends to occur immediately before sleep during relaxed wakefulness continuing into stage N1 and sometimes into stage N2. Rare case may show a REM predominance [352, 353]. Bouts of movements may be related to CAP [354]. While RMD is most common in pre-pubertal children, there are older children [355] and also adults [356–361] who will show persistent or emergent rhythmic movement. Most older children with persistent disorder are usually suffering from organic brain dysfunction (cerebral palsy, autism or attention deficit disorder). In developmentally normal children, however, RMD is generally benign and the child usually outgrows the movements by the second or third year of life.

Because RMD is a benign phenomenon in itself, treatment is not always necessary. However, it may cause significant injury. In addition, RMD may be secondary to frequent arousals from another condition, commonly OSA [362]. RMD may present in a rather dramatic fashion, and so may need to be distinguished from tremor or segmental myoclonias, as well as RBD or nocturnal seizures. Given this, evaluation of a patient with suspected RMD requires careful clinical history and physical examination, viewing of a video recording of the events if possible, and occasionally PSG. PSG is always recommended for most cases of RMD in patients in whom a primary sleep disorder is being

considered and should be performed with an extended seizure montage if nocturnal epilepsy is suspected. In case of primary RMD, behavioral therapy and in severe cases with potential for inflicting injury clonazepam (0.5–1 mg nightly), imipramine (10 mg at night) or melatonin [363] maybe helpful [308]. Protective measures should be used in cases with violent movements.

Propriospinal Myoclonus at Sleep Onset

Propriospinal myoclonus is a form of spinal myoclonus in which the excitatory impulses are believed to travel through relatively slow-conducting intersegmental propriospinal pathways [364–366]. However, *propriospinal myoclonus at sleep onset* was described fairly recently by Montagna et al. [367, 368] who performed polygraphic studies that showed that the myoclonic activity began in spinally innervated muscles, propagating at low speed to rostral and caudal muscular segments, and hypothesized that a spinal generator may be facilitated by changes in supraspinal control related to vigilance levels. They identified it as a potential cause of severe anxiety and insomnia. The myoclonic movements typically involve the trunk with possible extension into the limbs. In a recently described form of this myoclonus, the myoclonic jerks are only evident during relaxation or recumbency [369], especially when the patient is drowsy. Unlike PLMS, the movements are relatively easily abolished by even light sleep. They may, however, produce a substantial difficulty with sleep induction and can therefore be a cause of significant insomnia. Cases have been described that are associated with RLS [370] and an important consideration in the differential diagnosis of propriospinal myoclonus at sleep onset is the myoclonic form of PLMW seen while sitting or lying in patients with RLS [371]. One case of propriospinal myoclonus that occurred during sleep was reported after a thoracic spine fracture that progressed to "myoclonic status" and respiratory failure [372]. The treatment of this condition is challenging and some cases respond to clonazepam, zonisamide and other antiepileptic drugs used in the classic propriospinal myoclonus [308].

iii. Failure of Motor Control During NREM Sleep

This includes PLMS (discussed in Chap. 40) and the disorders of partial arousal, such as sleep terrors, confusional arousals and sleepwalking/Parasomnias (discussed in Chap. 50).

iv. Failure of Motor Control During REM Sleep

This includes RBD (discussed in Chaps. 49 and 50). The scoring criteria for REM without atonia, an essential neurophysiological component in the diagnosis of RBD, is provided in Table 39.3.

v. Failure of Motor Control in both NREM and REM Sleep

Benign Sleep Myoclonus of Infancy

This is a transient, sometimes familial condition that begins soon after birth and resolves within months [373–377]. It may, however, persist for up to a year after birth, hence the recent change in nomenclature from "benign neonatal sleep myoclonus" to "benign sleep myoclonus of infancy." The myoclonic jerks are brief, asynchronous, and repetitive, involving primarily the distal limbs, especially the arms, but also the trunk; the jerks are often generalized. The jerks occur during all stages of sleep, with most occurring in NREM sleep, and typically do not arouse or wake the infant [378]; waking the child will cause them to cease promptly. The movements do not occur continually in sleep and, when not present in sleep, they may be precipitated by rocking the infant or by gentle restraint during sleep [379]. The exact pathophysiology is unknown, but these movements most likely represent an exaggeration of the normally greater sleep-related movements in infants [380]. Although completely benign, self-limiting and with no long-term sequelae, the clinician is often called upon to reassure frantic parents that their baby is not having seizures, which it may superficially resemble [381–383]. When in doubt, EEG or PSG may help alleviate some of the concern.

Sleep Bruxism

While bruxism or teeth grinding can occur during the day, *nocturnal bruxism* (Fig. 39.10) is to be clearly differentiated from daytime bruxism. Nocturnal, or sleep bruxism, when frequent and intense enough, can interrupt sleep and cause significant dental wear [384]. It is associated with arousals and autonomic activation during sleep [385, 386]. SPECT studies show an asymmetry in D2 dopamine receptor binding in bruxism patients at the level of the basal ganglia compared to controls suggesting that dopaminergic cell dysfunction may play a role in the pathogenesis of bruxism [387]. Bruxism tends to decrease with age, although bruxers may also have increased movements during sleep in general, and may be more common in the supine position [388]. Bruxism may also be a sign of recurrent OSA-related arousals, and thus any patient with bruxism should be screened for possible sleep-disordered breathing.

Bruxism may need to be distinguished from other dyskinetic movements which involve the jaws, including oromandibular dystonia and idiopathic myoclonus in the oromandibular region during sleep. Idiopathic myoclonus in the oromandibular region (e.g., faciomandibular myoclonus) during sleep is an apparently isolated, non-epileptic condition that occurs predominantly in stages 1 and 2 NREM sleep [389–391]. It consists of isolated or short runs of shock-like jaw movements with brief EMG bursts.

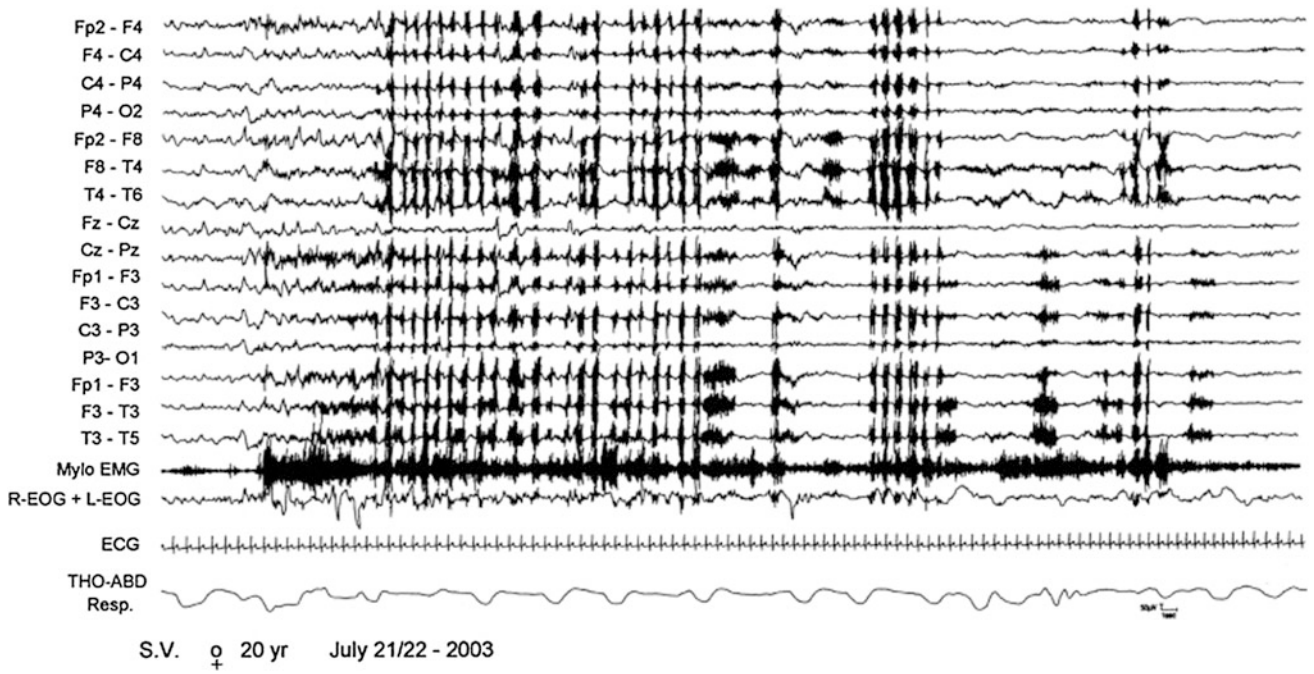

Fig. 39.10 Sleep bruxism. A 20-year-old woman referred for nocturnal awakeings with vocalization and sleepwalking. Polysomnogram shows arousal from slow-wave sleep with subsequent rhythmic masticatory muscle activation and teeth grinding (note electromyographic [EMG] artifacts on electroencephalogram [EEG] channels) typical of sleep bruxism. Top 15 channels, EEG. Mylo EMG, mylohyoid EMG activity. R-EOG + L-EOG, right and left electrooculogram; ECG, electrocardiogram; THO-ABD, thoracoabdominal respiration. (Reproduced with permission from Ref. [114])

Sleep-related bruxism has been described in every stage of sleep. While highest level of activity occurs during stage N3 and wakefulness, no difference has been described with regard to percentages of the sleep stages [392]. A close association between sleep bruxism and REM sleep has also been described [393, 394]. In 2008, Manconi et al. [395] published an interesting case report of a patient with sleep bruxism and catathrenia (see below) occurring in a synchronized fashion. They hypothesized about the presence of a common trigger mechanism for both phenomena.

According to guidelines put forth by the new AASM Manual for the Scoring of Sleep and Associated Events [5], bruxism can be identified by either brief (phasic) EMG elevations of 0.25–2 s and sustained (tonic) EMG elevations of >2 s. These EMG elevations must be at least twice the amplitude of the background EMG. Phasic bruxism events must occur in a sequence of 3 or more and this sequence can be said to comprise a bruxism episode. At least 3 s of stable EMG must be present before a new episode of bruxism can be scored. Bruxism can be reliably scored by audio in combination with polysomnography by a minimum of 2 audible tooth grinding episodes/night of polysomnography in the absence of epilepsy. In addition to chin EMG, additional masseter electrodes may be placed at the discretion of the investigator or clinician for optimal detection of bruxism. An alternate term for the phasic type of bruxism is *Rhythmic Masticatory Muscle Activity*.

The treatment for bruxism has yet to be standardized; various modalities have been employed, including dopaminergic agents [396], anticonvulsants [397], or with botulinum toxin injections [398]; dental devices may also help [399, 400] but some studies suggest caution in their use [401].

Catathrenia (see also Chap. 41)

Catathrenia, or nocturnal groaning, is a relatively newly described entity characterized by loud expiratory vocalization, whose exact pitch and timber may vary from individual to individual but is fairly stereotyped in a given patient (see Fig. 41.12). Not strictly a disorder of motor control, it may rather represent a disorder of breathing in sleep and is classifies as such according to the ICSD-3, although this is disputed by some [402]. While far more frequent in REM sleep, it may also occur in NREM sleep and alternates with normal breathing. It was actually first described by Pevernagie et al. [403] but was first named by Vetrugno et al. [404]. The same group subsequently reported in 2007 [405] that the groaning was accompanied by disproportionately prolonged expiration causing reduced tidal volume and bradypnea without oxygen desaturation, and that patients experienced no additional symptoms after a mean follow up

of 4.9 years. They speculated that catathrenia was due to persistence of a vestigial type of breathing pattern. In 2011, Ott et al. [406] performed laryngoscopy under deep sedation in a patient with catathrenia and found that while the glottis was open at inspiration, there was subtotal closure of the glottis at expiration, resulting in the characteristic groaning. The following year, Koo et al. [407] performed acoustic analysis of catathrenia and found that it had morphologic regularity, with two types of sound pitches (either a monotonous sinusoidal pattern or a sawtooth-shaped signal with higher fundamental frequency), as opposed to snoring which was distinct from catarthrenia and had an irregular signal. Several authors have reported the efficacy of CPAP in treating this benign but socially awkward condition [408–410]. The anatomical factors that predispose to catathrenia, namely broad upper airway, yet protrusive upper incisors and flat mandibular angles, have recently been described [411].

Excessive Fragmentary Myoclonus

Excessive Fragmentary Myoclonus (EFM) is essentially a variant PSG finding (Fig. 39.11), often found incidentally, that has yet to be demonstrated to be of clinical relevance. This condition may be another in which inadequate inhibitory drive fails to block descending activation from higher centers or it may represent a condition of excessive activation of higher centers during sleep. A neurophysiologic analysis by Vetrugno et al. [412] failed to disclose any cortical prepotential on EEG–EMG backaveraging suggesting a subcortical origin. The condition has been found in degenerative developmental disease (Niemann-Pick) [413] and as a consequence of brain stem lesions [414] but usually occurs in isolation [415]. Generally, EFM is not accompanied by gross visible movements; if movements are present at all they are small movements involving the corner of the mouth or small movements of the fingers or toes. In most cases no movement across a joint space occurs and the movements may resemble fasciculations, mere dimplings seen over the muscle associated with very brief EMG potentials (<50 ms). According to the AASM Manual for the Scoring of Sleep and Associated Events [5], EFM is present when at least 20 min of NREM sleep is recorded on PSG with the characteristic EMG pattern present (bursts typically <150 ms and of variable ampltude) and at least 5 EMG potentials per minute. Although classically described in the lighter stages of NREM sleep, they may occur in REM sleep, where the pattern resembles the normal phasic twitches seen in REM sleep, except they are more evenly spread throughout an individual epoch and not clustered as are phasic REM twitches. Some, [416] but not all [417] reports suggest that they are least common in slow-wave sleep. Given the lack of known clinical consequences, treatment is not required.

vi. Failure of motor control at sleep offset

Sleep paralysis

Transitions out of sleep may also be associated with *sleep paralysis,* a condition in which an individual is paralyzed while awakening from sleep. Weir Mitchell [341] is given credit for an early description of the condition in 1876 and he termed it "night palsy". Adie [418], in the 1920s observed occurrence of sleep paralysis in narcolepsy patients and Wilson in 1928 [419] introduced the actual term. There are earlier descriptions in the Chinese, Indian, Persian and Greek cultures and mythologies, as well as in famous novels such as Herman Melville's *Moby-Dick* (1851).

During episodes of sleep paralysis, breathing and eye movements are usually preserved. This condition is thought to represent a variety of REM sleep tonic motor inhibition [420]; recordings of the state can show REMs together with an electrophysiological pattern consistent with REM sleep [421]. Sleep paralysis is generally associated with arousal from a REM period (hypnopompic) or, less commonly progress into REM sleep from wake (hypnagogic) [422]. The latter would be very unusual in the normal course of events and more likely to occur with narcolepsy, though it may occur in many non-narcoleptic individuals, sometimes with a familial pattern. There are three forms of sleep paralysis, isolated or recurrent isolated sleep paralysis (physiological occurring mostly in adults up to 30–50 % of the population), familial sleep paralysis and sleep paralysis as part of narcolepsy. Several studies suggest that, at least in some populations, sleep paralysis may be quite common [423–425]. When it does occur in normal individuals, it is generally infrequent, but may cause significant anxiety, especially the first time that it occurs. A similar condition, *nocturnal alternating hemiplegia of childhood*, involves paralysis limited to one side while awakening from sleep [426]. This may be a variant of hemiplegic migraine, a complicated headache disorder with paralysis due to suppressed activity in certain brain regions.

Physiological sleep paralysis is generally brief, lasting for seconds to a few minutes, but sometimes may last longer, particularly *recurrent isolated sleep paralysis*. On occasions the episodes are accompanied by hypnagogic or hypnopompic hallucinations. The episodes may be triggered by sleep deprivation, stress, physical exertion or supine position. Isolated or recurrent sleep paralysis does not require any specific treatment other than reassurance, life-style changes, regularizing sleep–wake schedule but in severe cases causing anxiety and panic short-term treatment with

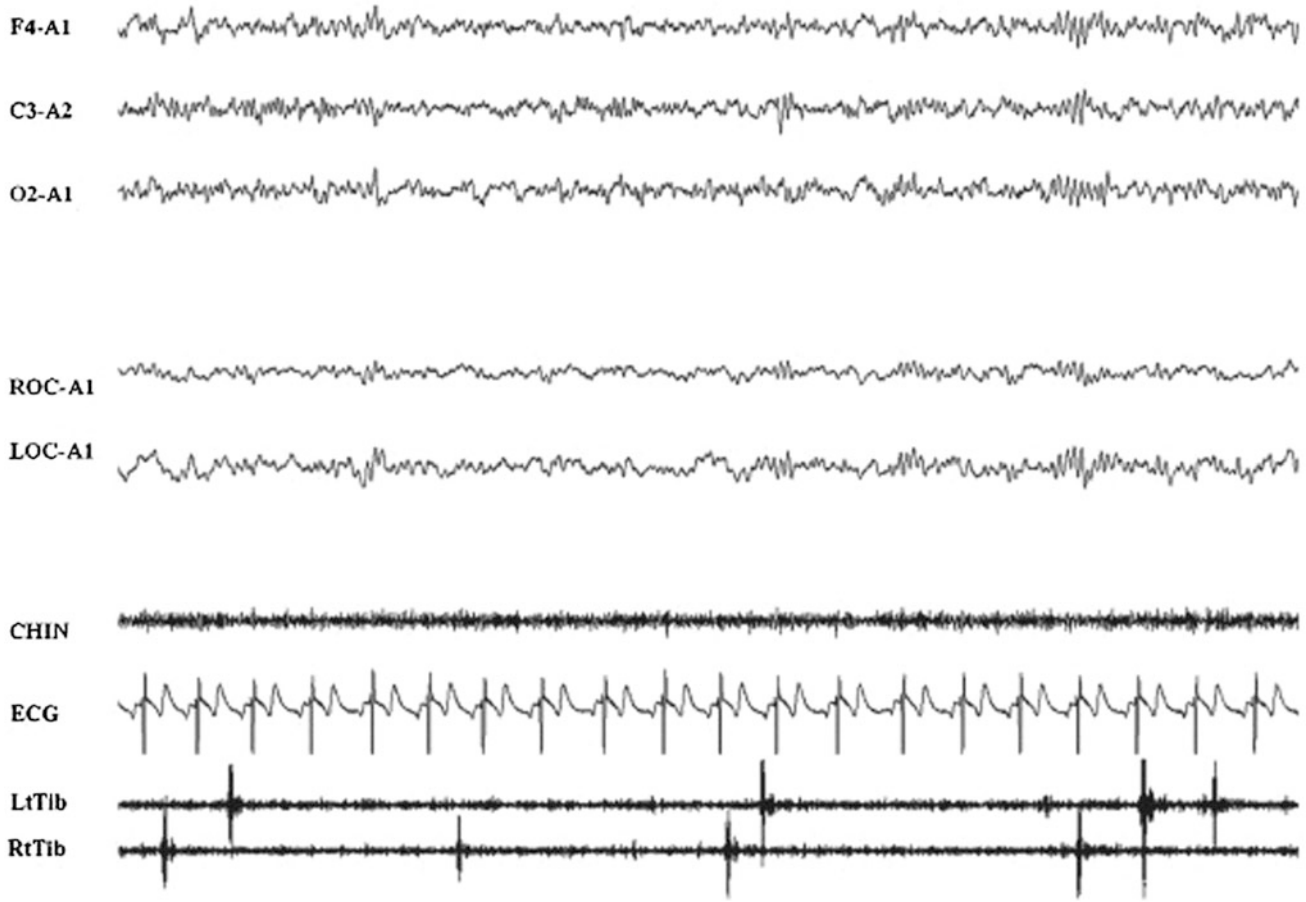

Fig. 39.11 Excessive fragmentary myoclonus. Poysomnogram epoch from the study of a 71-year-old man who presented a 2-year-history of continuous twitch-like movements of the arms and legs throughout the night, which did not wake him from sleep. Note the brief, asynchronous, asymmetric potentials in the limb electromyography (EMG) channels (RtTib and LtTib). Visually, they presented as brief twitch-like movements not causing movement of major joints. Excessive fragmenrtary myoclonus is considered a benign phenomenon with no clinical consequence. Top three channels, EEG. ROC-A1, LOC-A2, electrooculography channels. CHIN, chin EMG. ECG, electrocardiography. (Reproduced with permission from Ref. [114])

selective serotonin reuptake inhibitors (SSRIs) or tricylic antidepressants may be beneficial.

Sleep Inertia

This is most likely not a disorder of motor control in sleep in the strictest sense, but is discussed here for conveneience. Sleep inertia, also known as *sleep drunkenness* is a transient physiologic state of hypovigilance, confusion, impaired cognitive and behavioral performance, and grogginess that immediately follows awakening from sleep [427]. Put simply, the subject is physiologically awake (body awake) but cognitively asleep (brain asleep). EEG of sleep inertia is characterized by a generalized decrease of high frequency beta-1 and beta-2 EEG power but an increase of delta power in the posterior scalp region concomitant with decreased frontal delta power [428]. This state can last from minutes up to four hours, most commonly about five minutes and rarely may exceed 30 min. Prior sleep deprivation, awakening from SWS and short naps may aggravate sleep inertia. It is also more intense when awakening from near the trough rather than the peak of the circadian core body temperature rhythm. Sleep disorders, particularly idiopathic hypersomnia, as well as narcolepsy-cataplexy syndrome and obstructive sleep apnea syndrome may be associated with prolonged sleep inertia. Bedrich Roth and collaborators were probably the first to describe idiopathic hypersomnia with sleep drunkenness in the 1950s [429]. One suggestion for the pathogenesis of sleep inertia is build-up of adenosine and this state can be reversed by caffeine acting through adenosine A2a receptors, thus explaining the well-known reinvigorating effects of an early morning cup of coffee.

Table 39.2 American Academy of Sleep Medicine (AASM) polysomnography scoring criteria for sleep-related movements [5]

Movement	Criteria
Hypnagogic foot tremor	• Frequency of EMG bursts 0.5–4 Hz • Duration of each burst: 250–1000 ms • Minimum number of bursts needed to score: 4 • Occurs at sleep–wake transition, stage N1 and stage N2 sleep • Burst series duration: 10–15 s
Alternating leg muscle activation	• Frequency of EMG bursts 0.5–3 Hz • Duration of each burst: 100–500 ms • Minimum number needed to score: four • Occurs at sleep–wake transition, arousals, NREM and REM sleep • Burst series duration: 20–30 s
Rhythmic movement disorder	• Frequency of EMG bursts: 0.5–2 Hz • Episode duration variable: seconds or minutes • Series of RMD: at least 4 rhythmic movements • Occurrence mainly during drowsiness or sleep, or after sleep onset (mostly during stage N1 or N2) • Amplitude of EMG burst at least twice the EMG background
Excessive fragmentary myoclonus	• At least 5 bursts per minute during NREM sleep • Burst duration: 75–150 ms • Myoclonus index: number of 3-s mini-epochs containing at least one fragmentary myoclonus potential, included within each 30 s epoch
Periodic limb movements	• PLM sequences are identified by at least four LM • Interval between two consecutive PLM (onset-to-onset) is 5–90 s • PLMS index: number of PLMS divided by the number of hours of sleep • PLMS with arousal index: number of PLMS associated with arousal divided by the number of hours of sleep • Periodicity index: ratio of consecutive intermovement intervals, all separated by 10–90 s (at least 3 intervals) divided by the total number of movements
Sleep bruxism	Phasic or tonic increase of chin EMG signal, at least twice the amplitude of the background EMG activity (A) Tonic increase of the chin EMG signal lasting more than 2 s (B) Phasic increase of the chin EMG signal, rhythmic masticatory muscle activity (RMMA); at least 3 consecutive contractions, with a frequency of 1 Hz • Burst duration: 0.25–2 s • Interval between each episode of sleep bruxism: 3 s of stable background chin EMG signal • At least 4 episodes of sleep bruxism/hour of sleep, or at least 25 individual masticatory muscle bursts per hour of sleep associated with at least two audible episodes of tooth-grinding

Scoring Criteria for Sleep-Related Movements

These are summarized in Tables 39.2 and 39.3.

Methods for Studying Sleep-Related Movements

As with any branch of clinical medicine, there is no substitute to a well-taken history and thoroughly-conducted physical examination. Not only is this good clinical practice that ensures that the appropriate test is ordered, but in many cases where the underlying disorder is clearly benign, and reassurance and observation is desirable (such as hypnic jerks), may obviate the need for testing at all.

A. Accelerometry Based Testing

i. Actigraphy

Actigraphy is a validated, relatively cost-effective and convenient alternative to expensive, cumbersome in-laboratory procedures in the assessment of sleep–wake cycles and movements in sleep, in both clinical practice and research. Depending on the equipment and technique used, recordings can be made for many days or even months. In assessing sleep disorders, this extended recording can allow for the capture of rare events, overcoming the problem of variability which can limit the accuracy of more abbreviated studies, and repeated measurement of sleep in different conditions (evaluation of sleep patterns, disease progression or remission, therapeutic responses). In addition to the cost consideration, the small size, light weight and ease of use of most of these devices allows for its application in multiple settings; the activity monitors can be taken out of the laboratory, self-applied, and even transmitted by mail. They may be particularly useful in uncooperative patient groups with degenerative disease who would not tolerate a laboratory sleep study.

The limitations on activity monitoring result from the relatively non-specific results and the limited information monitored. All movement, even transmitted movement, is recorded. There is generally no information about cerebral

Table 39.3 Scoring criteria for REM without atonia

Criteria	Lapierre and montplaisir [95]	SINBAR	REM sleep atonia index
Muscle	Submental	Mental, FDS	Chin
EMG activity	Tonic: 50 % tonic >2 × background amplitude (or >10 μV) Phasic: >4 × background amplitude 0.1–10 s	Tonic: 50 % tonic >2 × background amplitude (or >10 μV) Phasic: >2 × background amplitude 0.1–5 s Any: >2 × background amplitude 0.1 s	Tonic: ≥1 μV
Epoch duration	20/2 s mini-epochs	30/3 s mini-epochs	1 s
Cut-off and combination	Tonic: >30 % Phasic: >15 %	Phasic chin: 16.3 % Any chin EMG (3 s): 18 % Any chin EMG + phasic FDS EMG (3 s): 32 % Any chin EMG + phasic FDS EMG (30 s): 27 %	AI <0.8

state (EEG), eye movements (too small to be reflected in a limb monitor), or breathing. Therefore, they do not provide much useful information about physiological state and crucial information about exact sleep stages.

Typically, activity monitoring devices use accelerometry to quantify movement. Several small self-contained devices currently available on the market provide a direct assessment of the amount of activity or body movement at the point of the body where they are attached. These are all derived from the work of Colburn and Smith who produced the first of these meters and documented the methods for others to use [431]. Virtually all of these use a piezoelectric sensor (usually a ceramic bender unit). The ceramic bender generates its own electric current that is directly proportional to the amount of acceleration. The activity devices usually include a volatile memory chip and a small computer or micro-controller chip. They are programmed to determine the amount of activity in a unit time and record that amount at a determined storage rate. The activity accepted by these devices is usually filtered so that they cover the dominant frequency ranges for human movement of about 0.5 to 10–15 Hz [432]. Later the data are downloaded to a computer, typically a desktop or laptop PC, usually through a special interface device. Various manipulations can then be performed on the downloaded data for further quantification or illustration. The activity data are maintained with a time-date code so that the activity can be analyzed by the time of each day recorded. The self-contained units are battery powered; current models provide batteries capable of actively recording for from 14 days to 4 years. Although shorter battery life does limit the maximum duration of the recording, battery life may increase as this technology develops. Another limitation on the duration of monitoring is the amount of computer memory available to retain the stored values. Currently, the memory size available for these monitors is 4 MB–1 GB. Duration of monitoring is inversely proportional to the rate at which values are stored. For low storage frequencies (e.g., once every minute), these capacities translate into a total monitoring period of 3–720 days. However, at high storage rates useful for examining individual movements (e.g., 10 per second), total monitoring would only be from about 7 min up to 29 h. These devices all use internal circuitry to sample the output voltage at a certain frequency (sample frequency or rate). The amount of activity can be determined by checking the number of times the voltage reaches or exceeds a minimum criteria (threshold crossing) or by some integration or summation of the total voltage from the individual samples. Integration provides the more sensitive approach, especially for examining individual movements as opposed to total activity. After a certain number of samples, the result either in total threshold crosses or integrated voltage is stored. The storage frequency or rate limits the time resolution of this technique. For assessing total activity occurring in spans of a few seconds to minutes, the digital sampling can be at relatively low rates (e.g., 4–8 Hz) and still provide an adequate measurement. But for higher storage frequencies designed to examine individual movements, a sampling frequency of 10–40 Hz is probably necessary. Storage rates of 10 Hz or more would be ideal although slower movements can be analysed with storage rates perhaps as low as 1 Hz.

In sleep–wake detection for the evaluation of various circadian rhythm disorders and in insomnia, the patient wears the device on the non-diominant wrist, and simultaneously keeps a sleep log for comparison. There have been several validation studies published, in both children and adults as well as in special populations, under a variety of conditions, evaluating a large number of wrist actigraphs from various manufacturers. Most devices show good sensitivity and specificity (of the order of 86–96 %), but low specificity (30–40 %); detection of wake is usually unsatisfactory [433–437]. These caveats should be borne in mind when interpreting data from actigraphy.

For movement disorders, the activity monitor is placed at the site of the abnormal movement. In general, the goal of such recording is to count and quantify such movements, not merely to indicate when movement occurs. Various earlier studies showed that abnormal movements associated with hyperkinetic disorders could be quantified using actigraphy [438, 439], if appropriate filtering was used to select for frequencies associated with the movements. Early studies attempted such a quantitation in PLMS. The total movement activity during sleep for patients was determined from activity monitors worn on the ankle of the affected leg, but the correlations between overall activity and the number of PLM were not high (values of about 0.6) [440]. More recently, sophisticated systems for counting movements have been developed and validated [441–443], making these systems useful for therapeutic monitoring or assistance in diagnosis of PLMD and RLS [444–446]. A much better correlation between total activity and specific abnormal movements may be obtained with a finer-grain analyses [447]. Recognizing the distinctive profile of individual movements requires matching the descriptive powers of an EMG record. To detect the onset and end of a specific movement requires sensitivity to higher-frequency components of the movement, necessitating sampling rates in the range of 10–40 Hz. Moreover, there are major data-storage problems for this condition. PLM are, by definition, greater than 0.5 s in duration (see Chap. 40). Activity measurements to detect PLM should have storage frequencies of at least 4 Hz and preferably 8–10 Hz to enhance measurement accuracy. A fine-grain analysis with 40 Hz sampling and storage at 10 Hz available from one of these monitors (PAM-RL, Respironics, Pittsburg, PA) provides a description closely matching the EMG recordings for these movements (Fig. 39.12). The recording at 10 Hz can then be saved for up to 7 days depending on the memory size in the units. In the more advanced activity meters such as the PAM-RL detections are based on sampling at 40 Hz with data stored for the activity summed over 4 samples (10 Hz data storage). The descriptive information about the movement along with total activity per 0.1 s permits a review of

Fig. 39.12 Example of a high-precision activity monitor worn on the ankle to detect leg movements

machine scoring to determine if criteria are met for periodic movements of sleep. The data provides an excellent agreement with the nocturnal PSG for number of leg movements (Fig. 39.13) with a correlation of 0.997 and an average error for rates per hour of less than 1.0. when done in the laboratory setting with calibrated meters [448]. The monitors when used off the shelf in a standard clinical setting also have very good agreement with results from the PSG and are considered validated for this use [443]. The PAM-RL has an advantage for home recordings since it records separately the PLM rates when the legs are stretched out from when they are upright (subject sitting or standing). Thus they give the PLM rates for the sleep position (although not sleep, per se) (Fig. 39.14).

The use of the new ambulatory monitors that provide this fine-grain analyses of movements might be further extended to assess other movement disorders in sleep, such as RBD or rhythmic movement disorder. But even such a development would fail to provide relevant information about the patient's sleep–wake state. This can be approached by adding illumination or position information. To detect body position, a system has been developed [449] which requires wearing small monitors on the trunk and also on the leg just above the knee. Each monitor records position in three-dimensional space for each epoch (30 s to 1 min), and the combination of the two provides a description of the overall body position as standing, sitting, reclining, supine, prone, or lying on the right or left side. These monitors, when compared to direct observation of a subject's body position, show an excellent overall agreement (contingency coefficients C = 0.85–0.91, maximum value of C for these data = 0.913). Activity data collected at the same time as position data permits differentiating abnormal movements that occur while the patient is lying down from those while standing or sitting. It also permits the detection of events during the sleep time when the patient sits or stands up, such as occurs for sleepwalking.

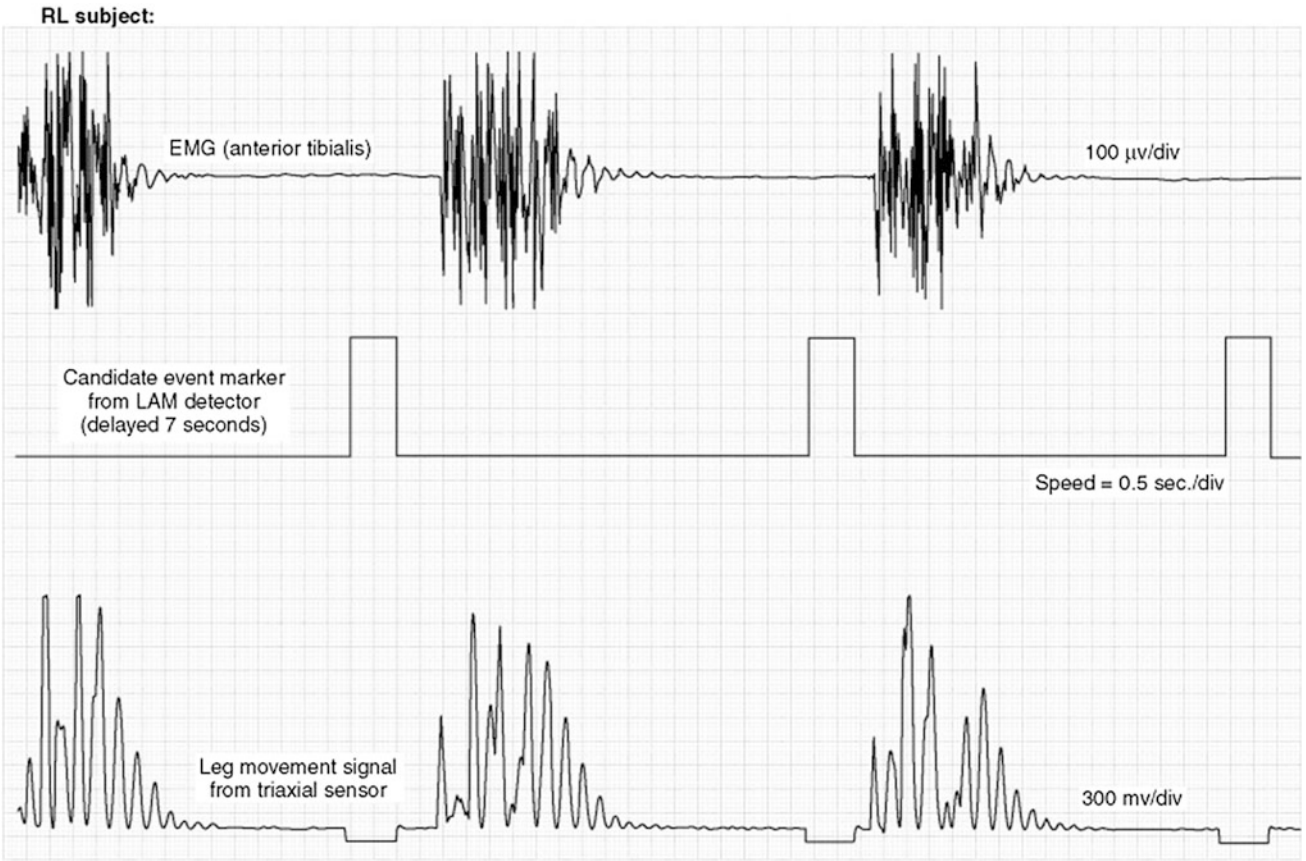

Fig. 39.13 Example of the real-time output of a high-precision activity monitor worn on the ankle (*bottom line*) compared to anterior tibilais EMG activity (*top line*). The *middle line* shows the real-time automatic detection of a significant leg movement made by the activity meter. The decision rules for the real-time leg movement detector create a 7-s delay in the detection

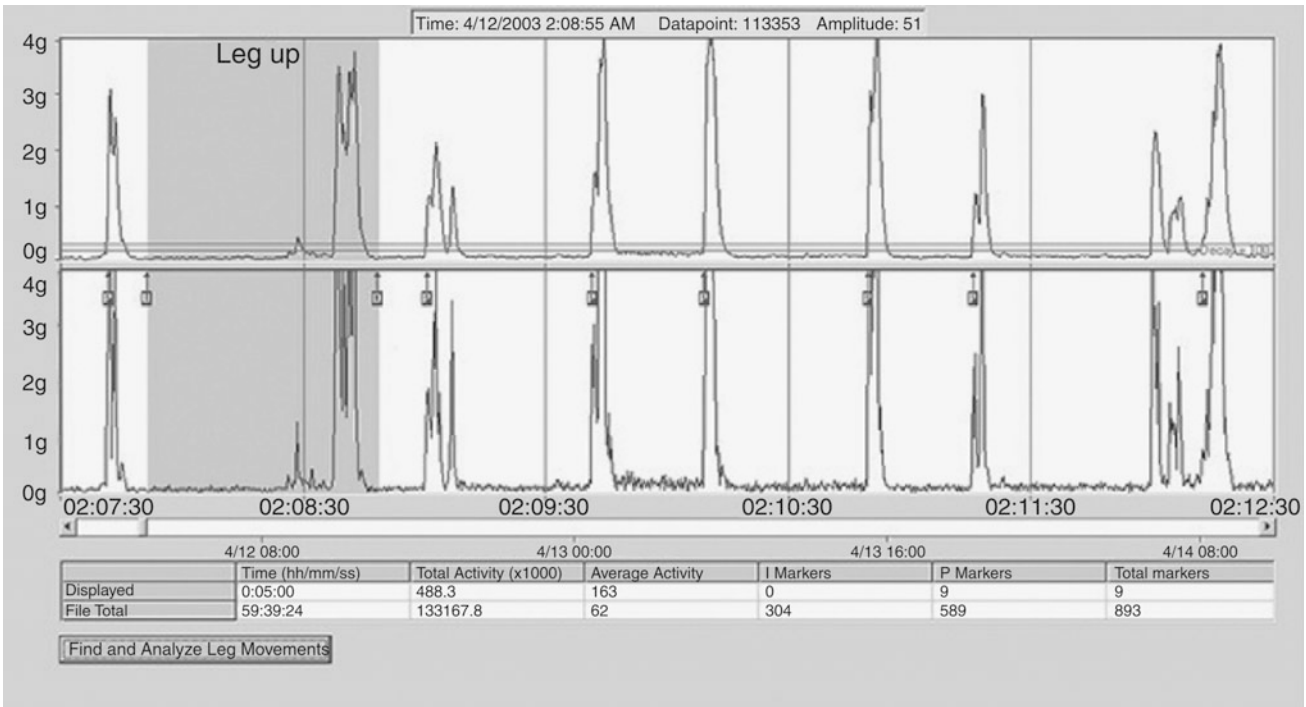

Fig. 39.14 Example of a computer display of stored leg activity and leg position data from a high-precision activity monitor worn on the ankle. The lighter areas on the graph (*white background*) indicate the leg is in a mostly horizontal position

ii. Consumer-oriented sleep technology

In recent years, there has been an explosion of inexpensive, consumer-oriented, readily available technology that is meant to monitor, among other parameters, sleep quality and duration. Entries into this category include standalone wearable devices (e.g., FitBit, Jawbone) as well as smartphone-based software programs ("apps") [450, 451]. While they all essentially use accelerometry-based techniques, as does actigraphy, to score sleep or wake (and in some cases distinguish between "light" and "deep" sleep) based on body movement, in most cases, the exact technology is proprietary, which limits detailed evaluation. "No-contact" bedside devices that detect sleep through radiowaves have also recently become available [452]. While such consumer-oriented sleep technology is very popular, mainly due to its convenience and easy accessibility, there is very little data validating it against established means of evaluating sleep [453]. Therefore, the sleep community remains uncertain as to how to approach this technology and how to interpret the information obtained from such devices and apps that patients bring with them to their clinic evaluations [454]. Recently published studies do suggest that this technology, while showing variable correlation with PSG-based scoring, has a sensitivity and specificity for sleep–wake detection that may be comparable to actigraphy [452, 455–458]. However the data are preliminary as of now. Thus, although the use of consumer-oriented sleep technology is likely to increase in the coming years, until larger studies that evaluate this technology are available, its exact role in clinical sleep medicine and research, if any, remains unclear.

B. Neurophysiological Studies

Polysomnography

Video PSG is the gold standard in diagnosing a variety of sleep disorders, specifically sleep-disordered breathing, abnormal movements in sleep, and nocturnal seizures. PSG techniques are discussed in detail in Chap. 17, and the scoring of sleep stages and respiratory events in sleep is discussed in Chaps. 24 and 25 respectively. Many abnormal movements in sleep as well as parasomnias are induced by arousals, which can be due to factors not obviously associated with the movements themselves, most commonly OSA. Treating OSA will decrease arousals, in turn decreasing the abnormal movements and parasomnias. Thus, even patients with what appear to be typical abnormal movements in sleep (HFT, ALMA, RMD, etc.) should be screened for possible OSA and undergo a PSG if they present with risk factors for sleep-disordered breathing.

When dealing with patients with abnormal movements in sleep, certain modifications to the PSG montage are helpful (see Chap. 18). While the standard PSG with a single EMG lead for the legs does provides a certain degree of information about certain motor disturbances, specifically PLMS, they may not be helpful when dealing with abnormal movements involving the upper extremities, the cranially innervated muscles, or even more proximal or more distal lower extremity muscles. For this reason, a multiple muscle montage that includes extra EMG channels recording from additional cranially innervated muscles (such as the sternocleidomastoideus, masseter and other muscles), upper limb (e.g., biceps, triceps, extensor digitorum communis, flexor digitorum subliminis), and lower limb muscles (e.g., quadriceps, hamstrings, gastrocnemius, and extensor digitorum brevis) and axial muscles (e.g., cervical, thoracic and lumbar paraspinals, rectus abdominis, intercostal muscles) (see Table 18.4) is recommended in those patients who have more complex movements by history. Similarly, an extended seizure montage with extra EEG channels (see Table 18.2), or a hybrid montage using select additional EEG and EMG channels (see Table 18.5) may be of benefit in patients in whom abnormal movements in sleep are suspected to be secondary to nocturnal seizures. Technician observations are invaluable in the documentation and description of events, and where the question is one of RBD, in eliciting dream recall. The sleep specialist can ask for no stronger ally than a vigilant technician who is aware of the clinical question being asked and is able to focus the camera on the area and movement of interest when abnormal movements occur.

Where patients complain of daytime sleepiness or abnormal movements during daytime naps, multiple sleep latency testing (MSLT), with multiple muscle montage if indicated, may be considered (see Chap. 22).

While ambulatory sleep studies (or home sleep tests [HST]) are gaining increasing acceptability and use in the evaluation of OSA, they suffer from significant limitations in the evaluation of abnormal movements in sleep, including a limited number or most often no EEG or EMG channels, no corresponding video recording, and no observer to document unusual behavior. Therefore, at the present time, HST is not recommended in the evaluation of patients with abnormal movements in sleep, such patients need to be evaluated by in-laboratory PSG.

Motor Evoked Responses

To more directly examine the impact of sleep on the motor system itself, motor evoked potentials (MEPs) can be studied. In one study of MEPs evoked by stimulating the motor cortex with a strong magnetic stimulus during sleep, it was noted that the MEPs decreased during NREM sleep [459]. Results during REM sleep have shown a much greater degree of variability in amplitude of evoked responses. Hess et al. [459] found that responses were of normal or increased amplitude, suggesting enhanced cortical excitability during REM sleep. In contrast, Fish et al. [261] found that average amplitude was decreased in 3 normal subjects with prolonged latencies in REM sleep compared to wakefulness

despite variability of response amplitudes indicating maintenance of motor inhibition during REM sleep. In a group of narcoleptic patients, stimulation during cataplexy resulted in apparently normal MEPs [460]. While these results remain to be harmonized, the variability is consistent with the fluctuating balance between inhibitory and excitatory processes in REM. A finding of decreased mean amplitude, however, is more consistent with the general inhibitory balance of REM sleep in normals. When sleep apneas are superimposed on sleep, MEP amplitude may decrease further [461]. The use of MEPs in the evaluation of abnormal movements in sleep is mainly in the realm of research at this point and not of much value in everyday clinical practice.

Other methods used in Special Circumstances

In selected cases, a number of specialized techniques to evaluate for abnormal movements occurring in sleep can be performed. These include EEG–EMG studies with back averaging, reciprocal inhibition, long loop reflex (the "C" reflex), startle reflex, and somatosensory evoked potentials (SEP, e.g., giant SEP in cortical myoclonus). A detailed description of these techniques is beyond the scope of this chapter, but the reader is referred to other sources for further information [462].

C. Neuroimaging Studies

The development of new imaging techniques that permit assessment of activity in the waking brain provides an additional method of studying regional contributions to state-dependent motor activity. Studies of cerebral blood flow and metabolism have largely paralleled those of cellular activity. Techniques, including functional magnetic resonance imaging (fMRI), SPECT, and PET scans including ligand studies, MR spectroscopy, functional or resting connectivity, diffusion tensor imaging (DTI) and tractography (for white matter imaging), voxel-based morphometry (for gray matter imaging), and transcranial sonography have all been employed in research and are discussed in greater detail in Chap. 21.

Blood flow and metabolism may be greater during REM sleep than in waking but are widely depressed during NREM sleep, especially SWS [463, 464]. Examining differential regional activities in relation to sleep states or features can provide insights into sleep mechanisms. In one study, Hofle et al. [465] correlated activity in different brain regions with power in different EEG frequency domains (e.g., delta, here 1.5–4.0 Hz). The greatest decrement associated with increased delta power (characteristic of SWS) was in the thalamus, consistent with the depressed thalamic activity of sleep. The presence of sleep spindles, most common in stage N2 sleep, is associated with activation of the thalamus, paralimbic areas, and the superior temporal gyrus [466]. Slow (11–13 Hz) and fast (13–15 Hz) spindles show this common activation, plus distinctive activations of the superior frontal gyrus (slow spindles) compared to sensorimotor cortical areas (fast spindles), medial frontal areas, and hippocampus. During REM sleep, in contrast to NREM sleep, there is activation of the brain stem core and thalamus as well as limbic areas of the brain and primary and secondary sensory areas [467–469], including visual cortices [470]. Hong et al. [471] examined the association between REMs and blood flow and found associations both with the midline attentional system active in REM sleep and areas involved in generating waking saccadic eye movements and subserving visual attention. Higher cortical areas, including prefrontal cortex and multimodal sensory and associative cortex, remain suppressed during all sleep stages [472]. REM sleep can be divided into those baseline periods without REMs and the periods with REMs, during which sensory receptivity is decreased [473]. During actual rapid eye movements, fMRI studies have shown additional activation in posterior thalamus and occipital visual cortex [474] or within a thalamocortical network including limbic and parahippocampal areas. Additional studies have shown that the basal ganglia are suppressed in SWS, but very strongly activated in REM sleep [463]. The significance of these basal ganglia changes for the motor system and for movement disorders in sleep remains unclear but is of great potential interest. These results in imaging studies suggest an evolving of sleep states in terms of the involved brain structures, including the motor system.

Imaging studies can also begin to assess potential deficits due to altered sleep conditions, such as sleep deprivation [475], which can cause depression of frontal lobe activity that is only partially restored after a compensatory sleep.

Principles of Treatment of Sleep Disorders Related to Abnormal Movements

The first and foremost step is to determine if sleep dysfunction is related to these abnormal movements at night, or if these are due to an associated common primary sleep disorder (e.g., OSA which has a prevalence in the population of about 14 % in men and 6 % in women between 30 and 70 years old; or a persistent insomnia disorder which may affect the quality of life in about 10 % of the population), or a comorbid psychiatric illness (e.g., anxiety, depression).

The basic treatment can be divided into two categories:

1. Treatment of the abnormal movements at night possibly responsible for sleep dysfunction using standard treatment for these movements. If these movement disorders are causing sleep dysfunction, optimal treatment of these involuntary movements should improve patient's sleep dysfunction. Pharmacologic treatment of these jerks and shakes has been addressed briefly in the text (see above).

Most of these abnormal movements do not require a specific treatment as these are mostly benign and will disappear in time but sometimes may persist into adulthood. However, treatment may be required if the movements are violent, injurious, or potentially violent. Pharmacotherapy usually includes benzodiazepines, selective serotonin reuptake inhibitors (SSRIs), or other antidepressants or anxiolytics for short-term relief. Non-pharmacological treatment may consist of psychotherapy, reassurance, and education of the patient and the family, progressive relaxation, and good sleep hygiene (sleep health) practice (e.g., regularize sleep–wake schedule, avoid alcohol, coffee consumption, and smoking near bed-time.). Also, attention should be paid to environmental safety measures, such as removing harmful sharp objects from bedroom, placing a mattress or other soft surface next to the bed, locking doors, and windows to prevent the patient from injuring himself/herself.

2. If sleep dysfunction is due to a primary sleep disorder, this should be treated using the standard method (e.g., CPAP for OSA and cognitive behavioral therapy (CBT) for insomnia with or without hypnotics used intermittently). Any comorbid psychiatric illness should be treated using generally accepted measures (e.g., SSRIs or other antidepressants and anxiolytics for depression and anxiety). Patients should always follow some common sense sleep hygiene measures. In a subset of patients with sleep onset or maintenance insomnia and circadian disruption associated with abnormal movements, especially when caused by neurodegenerative disease (e.g., Alzheimer's disease and Parkinson's disease) appropriately timed bright light therapy has been found to be useful. A word of caution is in order. Pharmacotherapy should be initiated at low doses, particularly in the elderly and those with neurodegenerative diseases, to minimize side effects. Finally, patients should be advised to avoid prolonged use of sedative-hypnotics and reduce or eliminate medications that may contribute to sleep dysfunction or OSA.

Box 39.2 lists these general principles of treatment.

Box 39.2: Principles of Treatment of Sleep Dysfunction Related to Abnormal Nocturnal Movements

- First determine if sleep dysfunction is related to abnormal nocturnal movements or a primary sleep disorder or a comorbid psychiatric-illness
- Treat primary movement disorder if it is causing sleep dysfunction
- Treat associated primary sleep disorder
- Treat comorbid psychiatric illness
- Initiate good sleep hygiene measures including regular sleep–wake dysfunction
- For pharmacotherapy try a non-benzodiazepine receptor agonist or a melatonin receptor agonist for short-term hypnotic use
- Start with a small dose and gradually increase the dose to minimize side effects in the elderly or those with neurodegerative disease
- Reduce or eliminate medications that may contribute to sleep disturbance or sleep apnea
- Attend to environmental safety precautions to avoid injury to patients
- Use appropriately timed bright light exposure in a subset of patients with insomnia and circadian rhythm disruption.

Summary and Conclusion

This chapter discussed an important aspect of human motor control (and dyscontrol) that has been largely neglected for a long time because it sits in the borderland of two important disciplines in medicine—those specializing in movement disorders and those specializing in sleep medicine. An understanding of motor control mechanisms is important for both fields. A breakdown in the delicate balance of motor control due to an affection of the afferent, central, or efferent structures can cause a dysfunction of voluntary movements or appearance of abnormal movements causing both positive and negative symptoms. Sleep modulates motor phenomena with progressive decline of motor activity due to increasing dominance of central inhibitory drive; concomitantly, the excitatory mechanism breaks through the inhibitory phase causing the appearance of motor events (some are physiological, but others are clearly pathological) Movement disorder specialists deal with diurnal involuntary movements, whereas sleep specialists encounter abnormal motor activities during sleep that may disturb sleep and result in impaired daytime functioning. The question often arises as to whether these are diurnal movements persisting during sleep, or abnormal movements triggered by sleep or intruding into sleep. This dilemma is highlighted by the fact that there are considerable similarities and overlaps between nocturnal and diurnal movements, and sleep may be disturbed by both diurnal and nocturnal motor events. There is a growing realization that both diurnal and nocturnal motor events may result from a common neurobiological alteration in the molecular mechanisms of motor control and sleep wakefulness. In this chapter, we briefly outlined motor control of human voluntary movements in wakefulness and sleep as well as suggested some pathophysiological mechanisms for abnormal jerks and shakes at night. We also provided a brief description of these conditions based on a method of

classification for easy comprehension. Finally, we summarized principles of treatment of sleep dysfunction associated with these abnormal nocturnal motor events.

Richard P. Allen

Periodic Leg Movements of Sleep (PLMS)

Periodic Leg Movements of Sleep have been well defined as stereotyped involuntary movements occurring during sleep periods in a series of movements that for a given individual have a remarkably stable period, typically about 15–30 s. The naming and very loose criteria defining these have unfortunately created considerable confusion. The periodicity requirement became extended to include movements occurring with intermovement intervals (IMI) of 5–90 s ignoring movements with an IMI <5 s [1]. This has led to the identification of movements as periodic that are actually somewhat random without a well-defined mode describing their period. For example, some reports describe these as occurring for arms [2], leading to the unfortunate use of the term periodic limb movements. More careful analyses revealed that arm movements rarely show the well-defined modal period required for periodic phenomena [3]. They reflect somewhat randomly occurring frequent arm activity that is considered periodic because of an overly inclusive period requirements that have been used to define PLM.

Leg movements meeting the broad criteria for PLMS have also been found to occur in resting waking either during the night sleep period or for RLS patients when lying down attempting to rest without movement during the day in what has been called the suggested immobilization test [4]. These periodic leg movements in waking have been termed PLMW, but it should be again noted that the periodicity is not well established for these events during waking [5] except possibly when they occur in transitions into or out of sleep during the night's sleep period [6].

There is an extensive literature on PLMS that is exclusively based on EMG recordings of the anterior tibialis muscle. Thus, the considerable knowledge we have about PLM applies to activation of the anterior tibialis muscle that produces only a dorsiflexion and small inversion of the foot. This may occur with leg movements, but the PLM we measure is not a leg movement, nor does it involve any other part of the body. The foot dorsiflexion of PLM often occurs with activation of other muscles producing leg movements, but in one study about 39 % of the PLM occurred without any significant leg movement [7]. The appropriate terminology therefore is periodic foot dorsiflexions, but given the terminology history, the term periodic leg movements is acceptable with the caveat that the legs are often not moving.

The dorsiflexion of PLMS has been described as part of a larger envelope of episodic muscle activation, but the few studies attempting to document a more extended muscle pattern of periodic leg muscle activations during sleep have not provided a coherent picture except for the consistently primary role of the anterior tibialis muscle. Thus, when other leg muscles are recorded for observed periodic EMG events, the anterior tibialis is essentially always involved and usually is the first muscle to contract [8]. In about 13–39 % of the cases, it is the only muscle or movement involved [7, 9, 10]. Sometimes the anterior tibialis muscle activation of PLMS also occurs with activation of the extensor hallucis longus producing an extension of the big toe with some ankle dorsiflexion partially mimicking the Babinski's reflex [11]. PLMS occasionally occur with a triple flexion reflex at the ankle, knee and hip [10]. PLMS are too slow to be called myoclonus. PLMS typically last a few seconds (see Fig. 40.1). However, the movements may begin with one or more brief, myoclonic jerks that then blend into a more tonic phase; alternatively, a more sustained movement may terminate in a jerk [12, 13]. Movements are often bilateral, involving both feet, but may be predominant in one foot or alternate between feet. This may depend on sleeping position as well as biological factors. The most striking characteristic feature of PLMS is their repetitive, very periodic nature

This chapter is a revision of a portion of a chapter from the third edition written by our dear departed and esteemed colleague Wayne Hening, MD, PhD, as the lead author.

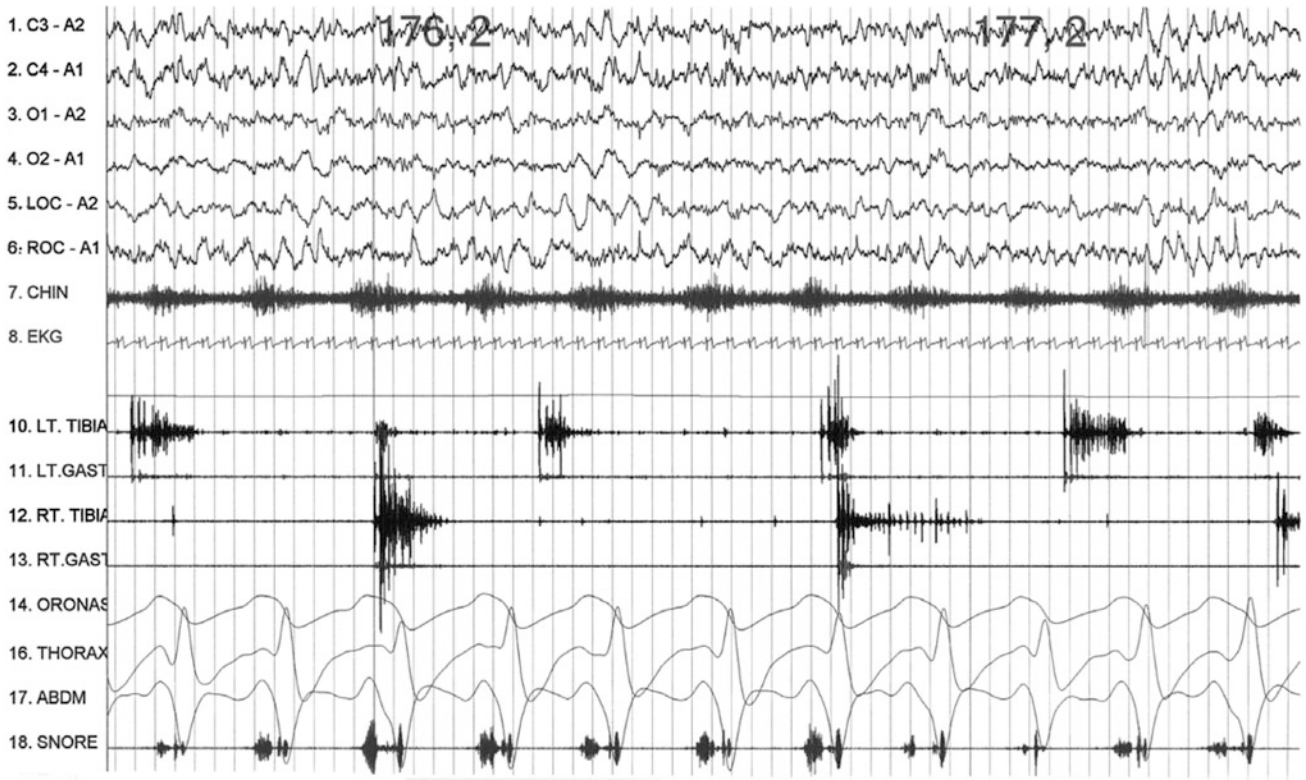

Fig. 40.1 Polysomnographic (PSG) recording showing periodic limb movements in sleep (PLMS) characterized by dystonic and dystonic–myoclonic electromyographic (EMG) bursts in left (LT) and right (RT) tibialis (TIBIA) and gastrocnemius (GAST) muscles during stage 2 (N2) non-rapid eye movement (NREM) sleep in an adult patient with restless legs syndrome (RLS). Top 4 channels show electroencephalograms (EEG) using international nomenclature (*A1* left ear; *A2* right ear; *ABDM* abdominal respiratory effort; *CHIN* submental EMG; *EKG* electrocardiogram; *LOC* left electro-oculogram; *ORONAS* oronasal airflow; *ROC* right electro-oculogram; *THORAX* chest respiratory effort)

providing a well-defined mode for the period or inter-movement interval (IMI). The variation in the inter-movement interval (IMI) between onsets of PLM approximates a lognormal distribution for the classically defined IMI ranging from 5 to 90 s. The average and standard deviation of the log IMI provides a measure of the periodicity and its spread which are both more stable over nights than is the measure of actual number of PLMS [14]. These measures with number of PLMS describe the periodic nature of the movements and the density with which they occur. There are also leg movements in sleep with IMI <5 that appear to be somewhat random in log space. An IMI of 10 s provides the best discrimination between these different distributions for short and long IMI. Thus, PLMS events are better described as occurring with IMI >10 s [15]. PLMS in moderate-to-severe RLS patients often occur in bouts of dozens to a hundred or more movements that last for many minutes. While most PLMS occur in stage 2 sleep, they also occur in all of the other stages of sleep including some in REM sleep and in waking during the sleep period [6].

Periodic Leg Movements of Sleep are defined by PSG recording. The current American Academy of Sleep Medicine (AASM) manual [16] and the World Association of Sleep Medicine (WASM) [1] criteria count movements if they occur in sleep as part of a series of four or more movements during any sleep stage including wake with IMI intervals of 5–90 s (in some older publications, intervals as short as 4 s or as long as 120 s have been accepted). Recent data have indicated the IMI interval for PLMS should be adjusted to be 10–90 s [15]. EMG activation must last 0.5–10 s. The number of movements associated with arousals may also be counted [1]. Box 40.1 lists the WASM criteria defining PLMS. Although patients may also have foot movement meeting the PLM criteria during wakefulness, only movements that occur during sleep are typically counted. A new measure, the periodicity index, is a ratio of all PLMS (with IMI range of 10–90 s) to all leg movements in sleep [17].

Box 40.1: Definition of Periodic Leg Movements in Sleep or Resting Wake (PLM)

Candidate leg movement (CLM) is defined by the following characteristics of a surface EMG recording of the anterior tibialis muscle

CLM onset occurs with EMG ≥ 8 μV above resting EMG.
CLM ends at the onset of the first 0.5 s with EMG always <2μV above resting EMG
CLM must be ≥ 0.5 and ≤ 10 s duration

Periodic leg movement (PLM) is a CLM that

has an intermovement interval (IMI) defined by onset from preceding CLM to onset of this CLM that is ≥ 5 and ≤ 90 s.

Is one of the 4 consecutive CLM that meet the IMI criterion above (giving 3 consecutive IMIs of 5–90 s).

Combining movements from two legs into one PLM event.

The movements from either leg should be counted.

Movement in one leg separated by less than 0.5 s from a movement in the other leg should be counted as a single leg movement.

From Zucconi et al. [1].

The biological basis for PLMS is particularly complicated by interaction with sleep state and the expression of these with spinal cord transactions. It is unclear how much the periodicity of PLMS stems from spinal versus brain activity, but certainly brain activity at least modulates PLMS expression and periodicity if not driving these. For example, neurotoxic lesions at the ventral mesopontine junction in cats produce increased leg movements in sleep that to some degree imitate PLMS [18]. The genetics of PLMS appear to match at least in part that for RLS with shared association for allelic variations in BTBD9, MEIS1, MAP2k4/SKOR1, TOX3, and PTPRD [19–21]. The possible genetic relation of RLS to PLMS is further supported by family history data indicating that increased PLMS occur with older adults without RLS who have an RLS relative but do not occur for those with a family member who has neither RLS nor significant number of PLMS [22]. PLMS also like RLS occur more with low serum ferritin, indicating a shared relation to impaired iron status [23]. Thus, occurrence of PLMS not attributed to medical conditions or medications may represent significant increased risk of RLS and accordingly may carry some of the health risks associated with RLS.

Individuals with elevated frequency of PLMS are often asymptomatic, but may have unrecognized sleep problems, particularly for those with higher rates of PLMS and/or more pronounced general leg movements occurring with the PLMS. Unfortunately studies do not provide information of the extent of general leg movement with the PLMS, so the potential for PLMS impact on sleep is not adequately described. Some small studies have indicated that the number of PLMS, disregarding any amplitude considerations, have little impact on sleep [24–26]. A larger population study, however, documented that PLMS with rates >15/h relate to poor sleep [27]. Amount of PLMS may relate to sleep disturbance more when the PLMS involve a greater spread of muscle activation not limited to the foot movement of the anterior tibialis, as is often clinically reported in RLS patients, but aside from limited data reported in one abstract [28], this has not been adequately documented. Bed partners sometimes complain more about the movements than the patients and are often an excellent source of information about the condition and its severity.

Periodic Leg Movements of Sleep may begin at any age, but prevalence increases markedly in healthy elderly people, with as many as 58 % having a PLMS index greater than 5 [29, 30]. Some studies have found no association between number of PLMS and either objective measures of sleep or symptomatic reports in the elderly, or only very weak associations [31]. Because of these findings, elderly patients with PLMS should only be treated when the PLMS can be linked to their sleep complaints, which usually means excluding other sources of sleep dysfunction.

Periodic Leg Movements of Sleep may occur as an isolated condition or may be associated with a large number of sleep, neurologic, or other medical disorders, and with medications such as neuroleptics and antidepressants. Among sleep disorders, the more striking associations are with narcolepsy [32–36] and RLS [37], because PLMS are common in these patients even at a relatively young age. PLMS are also common in patients with OSA [38] and RBD [39]. Patients with OSA may have a significant degree of PLMS, sometimes associated with significant sleep fragmentation even after successful treatment of their apnea [38]. The presence of PLMS in disorders involving the basal ganglia including Parkinson's Disease (PD) [40, 41], Lewy-Body Dementia [42], and MSA [43–45] is also noteworthy and may contribute to sleep problems in these disorders. Among medical conditions, the association of PLMS with uremia and end-stage renal disease is likely to be an important one related to mortality [46, 47] and to risks of stroke, cardiovascular disease, and cardiac structural abnormalities [48, 49]. PLMS have also been associated with increased risk of mortality for patients with systolic heart failure [50]. It has been reported that intrinsic and extrinsic lesions of the spinal cord may be associated with PLMS. This has been noted for multiple sclerosis [51, 52], radiculopathy [53], and transection [54]. It should be noted that the degree that these conditions produce leg movements with well-defined periodicity has not been well evaluated.

A number of studies have examined the relationship between PLM and other measures of central nervous system (CNS)/autonomic activity such as EEG, heart rate, and blood pressure. A general summary is that PLM are linked to periodic changes in activity level in different neural and neuro-responsive systems; furthermore, these modulations

do not appear to be caused by the PLM themselves, but are likely to be parallel phenomena produced by some common or associated biology [55–57]. Reducing the PLMS for RLS patients using dopamine agonists, however, appears to involve a biology that also reduces the associated cardiovascular changes. One suggestion is that the sympathetic nervous system may actually have a role in generating PLMS [58].

A specific feature of NREM sleep, the cyclic alternating pattern (CAP) is a recurrent alternation between "baseline" and more activated EEG patterns [59, 60]. PLM almost always occur during the activated ('A') phase of CAP [61]. The 'A phase' can be further subcategorized depending on the EEG frequencies most common: A1 activations consist primarily of slow waves while A3 activations are dominated by faster rhythms. The A3 phases are very strongly related to AASM-defined arousals. It has been proposed that a hierarchy of activations may be correlated with PLMS, with milder activations consisting solely of autonomic changes, slow waves, or K complexes while more intense ones are associated with EEG desynchronization and arousals [56, 57].

Periodic Limb Movement Disorder (PLMD)

Periodic Limb Movement Disorder is a condition diagnosed by excessive PLMS (>15/h for adults and >5/h for children) related to either significantly disturbed sleep at night or significant problems with functioning during the day that cannot be better explained by another disorder [62]. The prevalence and overall significance of PLMD is somewhat controversial. Individuals with elevated frequency of PLMS are often asymptomatic, but may have unrecognized sleep problems, particularly for those with higher rates of PLMS and/or more pronounced general leg movements occurring with the foot dorsiflexion of the PLMS. Unfortunately prior studies do not provide information of the extent of any general leg movement with the PLMS foot dorsiflexion, so the potential for PLMS impact on sleep is not adequately described. Small foot dorsiflexion no matter how many may not produce significant sleep or wake problems. Some small studies have found that the number of PLMS, disregarding any amplitude considerations, have little impact on sleep [24–26]. A large population study, however, documented that PLMS with rates >15/h relate to poor sleep [27]. Bed partners sometimes complain more about the movements than the patients and are often an excellent source of information about possible PLMD and its severity.

Restless Legs Syndrome

RLS is a neurological disorder of sensorimotor functioning predominantly characterized by an urge to move or restlessness focused on the legs that is provoked by rest, relieved by movement or CNS arousal, and increased with a circadian pattern during the evening and night [37]. RLS is a common disorder in the North American and European populations [63]. Associations with 16 specific allelic variants have been found by genome-wide association studies [21, 64–66]. However, while the degree of heritability determined by twin studies is relatively high (69 %) [67], the degree of familiarity is modest [68], and the 16 known RLS allelic variations account for a very small part (<15 %) of the familial pattern. The relative risk (Risch's lambda [69]) in first-degree relatives is in the range of 3–5 [68]. This suggests that RLS like other common diseases has a complex genetic diathesis that interacts with strong environmental factors. RLS, however, unlike other common diseases has one major well-defined commonly occurring environmental factor of iron deficiency [70]. Thus, all conditions compromising iron status produce increased risk of RLS. Conversely effectively all of the conditions that are associated with increased risk of RLS also have decreased iron status, e.g., pregnancy [71, 72], rheumatoid arthritis [73], and uremia [74, 75]. A unifying theme may be deficiency of iron in critical brain regions, particularly well documented for the substantia nigra and thalamus [76–83]. Box 40.2 lists major risk factors for RLS.

Box 40.2: Restless Legs Syndrome Risk Factors

Demographic and Lifestyle Factors

Increasing age
Female sex
Family history (early onset)
Living at high altitude
Smoking
Sedentary lifestyle
Caffeine
Alcohol consumption.

Medical, Surgical, and Neurological Conditions

Renal failure
Diabetes mellitus
Iron deficiency and anemia
Rheumatoid arthritis
Magnesium or vitamin B_{12} deficiency

Hypothyroidism
Heart failure
Surgical Gastric resection
Lung transplantation
Neurologic Polyneuropathies and radiculopathies
Parkinson's disease
Multiple sclerosis
Spinocerebellar ataxia (SCA3 or Machado–Joseph disease).

Other Factors
Pregnancy
Blood donations.

Medications (These may increase PLMS and also RLS)
Anti-histamines (only CNS-active)
Dopamine antagonists, e.g., antiemetics, antipsychotics (only CNS-active)
Serotonin and Norepinephrine reuptake inhibitors (SSRI, SNRI)
(Serotonin- and norepinephrine-releasing agents are also expected to increase PLMS and possibly RLS, but this has not been evaluated).

RLS significantly impacts patient's health and quality of life. Cross-sectional surveys have found RLS occurrence to be associated with general poor health, both physical and mental [63, 84–86], as well as specific disorders such as diabetes [87] and heart disease [88–90]. RLS may occur secondary to these disease states, particularly for cardiac diseases, rather than causing them [91]. RLS, in turn, relates to a diminished quality of life [63, 85, 92] and may be responsible for varied forms of psychological distress, particularly anxiety and depression [93, 94], impaired daily functioning [95], and loss of work productivity [96]. In vulnerable populations, such as dialysis patients, RLS occurs with increased mortality [96, 97]. Thus, there is evidence that RLS is provoked by a number of different disorders and also contributes to both morbidity and mortality. Much of this effect may occur through the impairment of sleep (Fig. 40.2) caused by RLS [98, 99]. Almost all studies have found RLS to be a chronic disease with both increasing prevalence (Fig. 40.3) and generally increasing severity with age [63]. Thus, RLS presents a cumulative burden substantially contributing to loss of quality of life and decreased health status in old age. Subjects with RLS report the same very poor health-related quality of life on the Medical Outcomes Short Form-36 as do those with other chronic diseases such as hypertension, congestive heart failure, and angina [85].

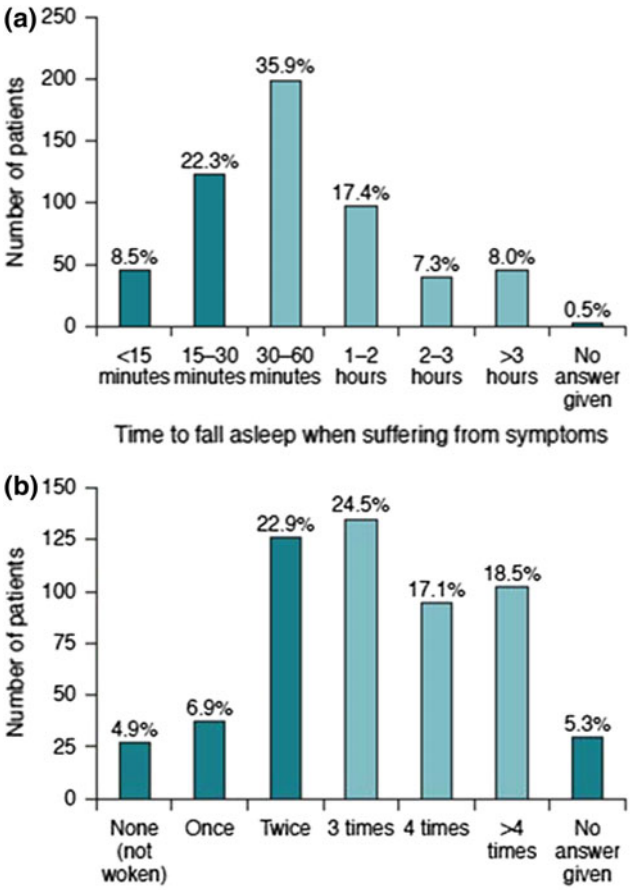

Fig. 40.2 Sleep impairment with RLS Fig. 40.1. Time to fall asleep (**a**) and number of reported awakenings (**b**) for RLS patients on nights when bothered by symptoms. *Unshaded bars* indicate those in the range considered abnormal and consistent with insomnia. Data are derived from RLS, Epidemiology, Symptoms, and Treatment (REST) general population study in the USA, France, Germany, Italy, Spain, and the United Kingdom. Clinical Features and Diagnosis of RLS

restless legs syndrome was first extensively described by Karl Ekbom, a Swedish neurologist who named the condition and elucidated its clinical features [100–102]. Over the last decade, the key clinical features required for diagnosis have been determined through a consensus process [37, 103, 104] and include the 5 essential diagnostic features presented in Box 40.3. In addition, there are two significant specifiers that should be considered with the diagnosis: Clinical Course and Clinical Significance (see Box 40.3).

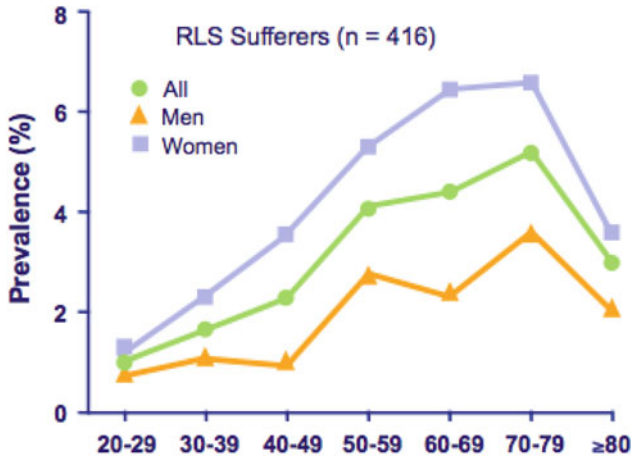

Fig. 40.3 RLS prevalence by age and gender. Population based sample of 15,391 adults ≥age 18 in Western Europe and the USA. RLS sufferer defined as those with RLS symptoms ≥2/week with moderate or severe distress when present. Note that there is little gender difference in the youngest group. Graph slightly modified from Allen et al. [63]

Box 40.3: Restless Legs Syndrome (Willis Ekbom Disease): Clinical Diagnostic Criteria

Adapted from Allen et al. [37].

Essential Diagnostic Criteria for RLS/WED

1. An urge to move the legs usually but not always accompanied by uncomfortable and unpleasant sensations in the legs.
2. The urge to move and any accompanying unpleasant sensations begin or worsen during periods of rest or inactivity such as lying or sitting.
3. The urge to move and any accompanying unpleasant sensations are partially or totally relieved by movement, such as walking or stretching, at least as long as the activity continues.
4. The urge to move and any accompanying unpleasant sensations during rest or inactivity are worse in the evening or night than during the day or only occur in the evening or night (when symptoms are very severe, the worsening at night may not be noticeable but must have been previously present).
5. The occurrence of the above features is not solely accounted for by symptoms primary to another disorder or behavioral condition (e.g., myalgia, venous stasis, leg edema, arthritis, leg cramps, positional discomfort, habitual foot tapping).

Specifiers for Clinical Course of RLS/WED

(a) Chronic-Persistent RLS/WED: untreated symptoms on average occurred ≥2/week for past year
(b) Intermittent RLS/WED: untreated symptoms occur on average <2/week for past year but with more than 5 lifetime events.

Specifiers for Clinical Significance

RLS/WED symptoms significantly impair social, occupational, educational, or other important areas of functioning

Special notes

1. Sometimes the urge to move occurs with discomfort involving arms as well as legs.
2. For very severe symptoms or in an advanced stage or in intractable cases relief with activity and/or the worsening in the evening may not be present, but then must have been previously present earlier in the course of the disease.
3. The specifiers for clinical course may not apply to children nor to special cases of provoked RLS/WED where frequency may be high but duration short, e.g., pregnancy.

Other body parts, especially the arms can be involved in RLS [105], especially during sever exacerbation of symptoms as occurs with RLS dopaminergic augmentation [106]. The legs, however, are almost always involved first and more prominently. RLS without leg symptoms at onset is at least rare [107], and the diagnosis requires involvement of the legs.

Clinical features supporting but not required for diagnosis [37] include familial aggregation [68, 108], significant numbers of PLM [4, 109] with established periodicity [110], prominent response to dopaminergic treatment [111], and daytime alertness despite significant sleep loss (Table 40.4). These supportive clinical features can be used to support diagnosis in uncertain cases, but the diagnosis must be based on evaluation of clinical history. The current diagnostic criteria apply to all conditions. Special problems with eliciting the sensory symptoms from children [112] and cognitively impaired elderly may require diagnosis guided by evaluating other conditions supporting the diagnosis (see Box 40.4).

Because frequent PLM are associated with RLS, the measurement of PLM has been proposed as a diagnostic test. The Montreal group has taken the lead in validating such a

test. They reported finding that the best discrimination for RLS from matched healthy controls was the PLMW per hour wake during sleep time but not dramatically better than the accuracy for PLMS per hour of sleep (92 % vs. 84 %). In contrast, somewhat unexpectedly the number of PLMW with arousal per hour of sleep had much lower accuracy (74 %) [109]. That study also included evaluation of the diagnostic accuracy of the Suggested Immobilization Test (SIT), a test designed to provoke RLS symptoms by having the subject remain sitting reclined in a bed without activity for a sustained period (usually an hour). The subject's rating of sensory discomfort provided about the same accuracy as the PLMS and PLMW, but there is an obvious problem of expectation for this sensory report from healthy versus diagnosed RLS patients. The PLMW from the SIT had poor accuracy (75 %). Work on evaluating the periodic nature of the PLM may provide better diagnosis, but this is only recently being considered [17].

To study responsiveness to dopaminergics, a test dose of levodopa was used. A greater than 50 % improvement of symptoms was strongly associated with a true RLS diagnosis, and a positive response to this test was a reliable indicator that a patient would subsequently benefit from dopaminergic treatment [113]. This has to be balanced against two larger clinical trials, where about 40 % of patients did not respond to the dopamine agonist ropinirole despite using a dose escalation to maximize treatment benefit [114, 115]. Thus, a failure to respond to dopamine treatment cannot be considered 100 % accurate for a negative diagnosis of RLS, and clearly there are always placebo responders in any clinical treatment.

Because there is, as of yet, no accepted laboratory marker for RLS, the standard for diagnosis remains a clinical one and is derived from the patient's history [116]. Laboratory evaluation is useful mainly to support the diagnosis of RLS and to identify any possible underlying medical condition (e.g., uremia) [116]. To determine RLS, in the clinic or the community, it is necessary to first establish the presence of the five diagnostic features noted previously. While earlier epidemiologic studies used ad hoc questions to ascertain the presence of RLS [117, 118], more recent ones have generated probes based on the first four diagnostic features [63, 119] [88, 95, 120–123]. A study at Johns Hopkins University, however, has demonstrated that up to 16 % of individuals without RLS may meet the original four diagnostic criteria [124]. Definitive diagnosis, therefore, requires discriminating RLS from its mimics as required by the 5th diagnostic criterion in the current diagnostic standard for RLS [37].

Several multi-question diagnostic instruments have been developed for epidemiologic studies. Two have been validated. One three-question instrument developed by Klaus Berger and endorsed at the National Institutes of Health (NIH) diagnostic consensus conference [104] had an inter-rater kappa of 0.67 between two experts who, however, had access to the questionnaire results [125]. This questionnaire, however, does not exclude mimics as required by the current diagnostic criteria. Another questionnaire developed at Johns Hopkins University was validated by independent clinician interview. It dealt somewhat with excluding mimics [126] and had a sensitivity of 89 % and specificity of 80 % in an American primary care practice. A much revised version of the questionnaire that specifically included items to exclude common mimics (Cambridge Hopkins RLS diagnostic questionnaire—CHRLSQ) was validated by the previously validated telephone diagnostic interview [127], had a sensitivity of 87 % and a specificity of 94 % in a population of blood donors [128]. The 13 items that are the validated diagnostic part of this questionnaire, the CHRLSQ-13, is available from the authors and has been used in clinical studies [70].

Two different approaches have been taken to make more definitive interview-based diagnoses for clinical or research purposes. First is a telephone interview, the Hopkins Telephone Diagnostic Interview for RLS (HTDI) [127]. This includes questions that address the diagnostic features, but also questions to assist with differential diagnosis and uncover mimics. Finally, there are questions concerning the key aspects of the disorder. Agreement with expert interviews was found to be 92 %, approaching the inter-rater reliability of two-expert face-to-face interviews of 96 % [127]. A second approach is a protocol that begins with questions about diagnostic features but then includes tests related to features supporting the diagnosis (see Box 40.4). This diagnostic interview includes questions on family history, a sleep study to look for PLM, a physical examination to exclude other causes for symptoms, and a dopaminergic challenge test [129]. It gives higher scores to patients with more frequent symptoms and therefore may not correctly identify those with sporadic symptoms. Its diagnosis is basically one of clinically significant RLS and is mainly useful in a sleep clinic or sleep laboratory setting.

Box 40.4: Conditions Supporting the RLS Diagnosis

- **Family History**: The prevalence of RLS among first-degree relatives of people with RLS is 3–5 times greater than in people without RLS.
- **Response to Dopaminergic Therapy**: Nearly all people with RLS show at least an initial positive therapeutic response to either L-dopa or a dopamine receptor agonist at doses considered to be very low in relation to the traditional doses of these medications used for the treatment of Parkinson's disease. This initial response is not, however, universally maintained.
- **Periodic Limb Movements** (during wakefulness or sleep): Periodic limb movements in sleep (PLMS) occur in at least 85 % of people with RLS; however, PLMS

also commonly occur in other disorders and in the elderly, but are uncommon in children.

- **Sleep Disturbance**: Disturbed sleep is a common major morbidity for RLS and deserves special consideration in planning treatment. This morbidity is often the primary reason the patient seeks medical attention.
- **Lack of profound daytime sleepiness**: The significant sleep disruption with moderate-to-severe RLS often fails to produce the expected profound daytime sleepiness (this may also occur for other hyperarousal conditions including some insomnias).

Overall either the CHRLSQ-13 or the HTDI (also appropriate for a clinical interview) provide the best general methods for diagnosis of RLS in studies.

Epidemiology, Biology, and Genetics of RLS

Prevalence of RLS in Different Ethnic Groups

It is not clear whether substantial and true differences exist between different ethnic groups in the prevalence of RLS. RLS must be defined clinically from history. Different groups with different languages unfortunately may respond differently when asked apparently equivalent questions about their medical history. Population-based studies, even when using several questions to diagnose RLS, vary in how many individuals detected have true RLS and how many of those with RLS are missed [125, 130]. A rough guide from one study with validation using trained physician diagnosis [131] is that the positive predictive value—how many of those identified with RLS actually have the disorder—is on the order of 40–60 % in studies using well-established diagnostic criteria based on the first 4 consensus diagnostic criteria without some screening required by the 5th diagnostic criterion. This means that less than half may actually have RLS. It is generally considered that false positives in such studies are more likely than false negatives, but this has not been tested.

Despite these methodological limitations, repeated studies have shown that there is a high prevalence of RLS in Western (European and European-derived) populations [63, 88, 95, 119–123]. It seems reasonable that the true rate in Western adults is on the order of 4–10 % for RLS at any frequency. One large-scale study, the REST population study conducted in the USA and Europe, found an overall prevalence of 7.2 % in adults [63]. That study used a questionnaire later found to have a positive predictive value of 59 % [131]. The study also looked at a measure of clinically significant RLS, a frequency of twice a week or more and moderate or greater distress when symptoms occurred and found a frequency of 2.7 %. A later study based on trained physician diagnosis found an overall frequency of approximately 4.4 % and confirmed the prior study showing clinically significant RLS frequency was 2.7 %; the prevalence of RLS with high impact of symptoms on patients life was 0.8 % [131]. These trained physician diagnosed rates are considered the most reliable estimates of RLS prevalence in the European and presumably white North American populations.

While several studies have suggested a lower prevalence in some non-Western countries [132–135]. other studies have found approximately the same prevalence as in the European/USA populations [136, 137]. In two methodologically rigorous studies, which used personal interviews to verify diagnosis, the frequency in Japanese elderly was around 1 % [134] and among Korean adults, 7.5 % [138]. The information on African Americans is scant. Very few African Americans seek treatment for RLS in clinics, and the previous published epidemiologic studies have not addressed the prevalence of RLS among African Americans. One preliminary study in Baltimore did not find a lower frequency in African Americans [139]. Given these uncertainties, it is not completely established that RLS is much more common in whites than in other ethnic populations.

Besides ethnicity, age and gender are strongly associated with RLS. Almost all studies [63, 88, 95, 119–123] have reported positive correlations of RLS with age (but see Sevim et al. [132]) that is more pronounced for women. Adults younger than 35 years appear to have no gender differences in prevalence [63], but after that prevalence increases significantly more for women than men. This critical age likely relates to pregnancy occurring since nulliparous women have the same risk of RLS as men [123, 140]. A systematic study of RLS frequency in children [141] found that 1.9 % of those 8–11 years of age and 2.0 % of those 12–17 years of age reported symptoms of RLS; 0.5 % of the younger group and 1 % of the older group had clinically significant RLS (twice a week and bothersome when occurring). There was no gender difference for children.

Incidence and Natural History of RLS

As noted above, RLS onset can occur at any age from childhood to old age for both genders. Incidence has been reported for one sample of American adults $\geq$ 40 years old to be 1.7 % per year [142]. RLS incidence per year in two different German population samples was 1.3 and 4.1 %. Persistence of RLS was low over 2–5 years at about 40–50 %, suggesting marked variability in RLS symptoms [143]. Unfortunately, these studies on incidence and persistence of RLS have been based on diagnostic methods that as noted above have low positive predictive values of about

50 %. The percentage falsely identified as having RLS (40–50 %) approximates the percentage not reporting persistence of RLS symptoms at the 2–5 year follow-up interview. Thus, it is unclear how many reporting on follow-up interview new onset or remission of symptoms were not those previously misclassified as RLS by the survey methods.

It has been assumed that the natural course of RLS is that of slowly progressive worsening, but while this is reported for some it is not always the case. Many cases report spontaneous remissions sometimes lasting years [144]. Although gradual worsening and spontaneous remissions are reported, the degree and rates of occurrence of these are not known. Three placebo studies of augmentation have reported evidence for definite spontaneous worsening of RLS during placebo treatment for 6 months at median 6 month rate of 1.0 % (<0.5, 1.0, and 6.0 %) [145–147]. The blinded comparison of pregabalin and pramipexole treatment [148] found approximately the same rate of RLS worsening on pregabalin (2.1 % for 12 months) consistent with the natural worsening on placebo. These studies would suggest that the natural progressive worsening beyond current moderately severe RLS occurs at a low rate of about 2 % of the patients over one year. But this remains to be better studied. Overall, it appears that the natural course of RLS is highly variable, including natural gradual worsening with changes in medical factors (e.g., iron status), periods of exacerbation, and also spontaneous remissions.

Secondary (Causally Related) and Comorbid Conditions for RLS

Elevated prevalence (>20 %) of RLS has been reported in studies based on clinical samples of persons with a number of medical conditions such as iron deficiency [70, 149], pregnancy [150–152], and uremia [153–155]. Their causative relation to RLS is supported by the reversibility of symptoms of RLS after treatment or resolution of iron deficiency anemia [156], pregnancy [151], and uremia [157]. Considerably higher prevalence of RLS has also been reported among these putatively causal comorbid conditions (iron deficiency [70], pregnancy [158], and uremia [159, 160]) even in Asian countries with low prevalence of RLS in the general population. One constant factor noted in these causally related conditions is that they typically predispose to low iron stores [161]. Decreased iron stores may also explain the finding that RLS may be more common among those who have been regular users of nonsteroidal anti-inflammatory medications that can cause gastrointestinal bleeding [162] and may be aggravated by blood donation [163] and may be more common among frequent blood donors [164] but not among those donating 3 times a year or less [165]. Such conditions may not only provoke RLS, but increase risk of RLS later in life. It has been also hypothesized that pregnancy similarly causes significant iron deficiency and may also cause lasting metabolic changes that predispose to increased RLS in later life [123, 166].

In some co-morbid neurologic conditions, the association with RLS is not so clearly related to iron metabolism, nor do any of these, unlike the iron-related ones noted above, show clear temporal patterns suggesting a causal relation, i.e., RLS resolved with treatment of the associated condition. These appear to be more comorbid rather than causal. It has long been suggested that neuropathy might predispose to RLS. Neuropathic findings have been reported in RLS patients [167, 168]. However, one study did not find an unusual prevalence in a neuropathy clinic [169], while another study reported that 30 % of neuropathy patients had RLS [170]. Radiculopathies [171, 172] and myelopathies may also cause or exacerbate RLS. There has also been an association between RLS and certain neurodegenerative conditions, including Machado–Joseph disease (SCA3) [173, 174], and demyelinating diseases such as multiple sclerosis [175–177]. Treatments of these conditions have not been reported to reduce RLS. In PD, RLS actually generally starts after beginning dopaminergic therapy [178], suggesting some analogs of the augmentation seen with dopaminergic therapy of RLS (see later).

RLS Biology

The cause of RLS remains unknown, though the functional abnormality is almost certainly neural in origin [179, 180]. A striking finding has been the almost universal response of RLS patients to medications that enhance dopamine system function [181]. Measures of dopamine dysfunction, however, have been equivocal or mixed [179, 182], but the larger imaging studies [183, 184], CSF studies [185], and autopsy studies [186] document increased not decreased dopamine in RLS. The reason that levodopa and dopamine agonists relieve the condition remains unclear but may reflect overcorrection of postsynaptic downregulation of response to dopamine [187, 188]. Drugs that antagonize the dopamine system may also unmask RLS symptoms, especially in treated patients [189, 190].

Studies have almost universally supported regional deficiency of brain iron in RLS despite normal peripheral iron (See Fig. 40.4). This most clearly involves the substantia nigra [76, 77, 81, 83, 191, 192] and the thalamus [79, 83]. Nigral iron deficiency has been shown in animals to produce increased striatal dopamine [193] as seen in RLS [184, 188]. Autopsy studies have suggested that the iron deficiency in RLS is associated with abnormal levels of cellular iron regulatory proteins [194, 195]. Brain iron deficiency is expected to cause RLS [188, 196] by producing a

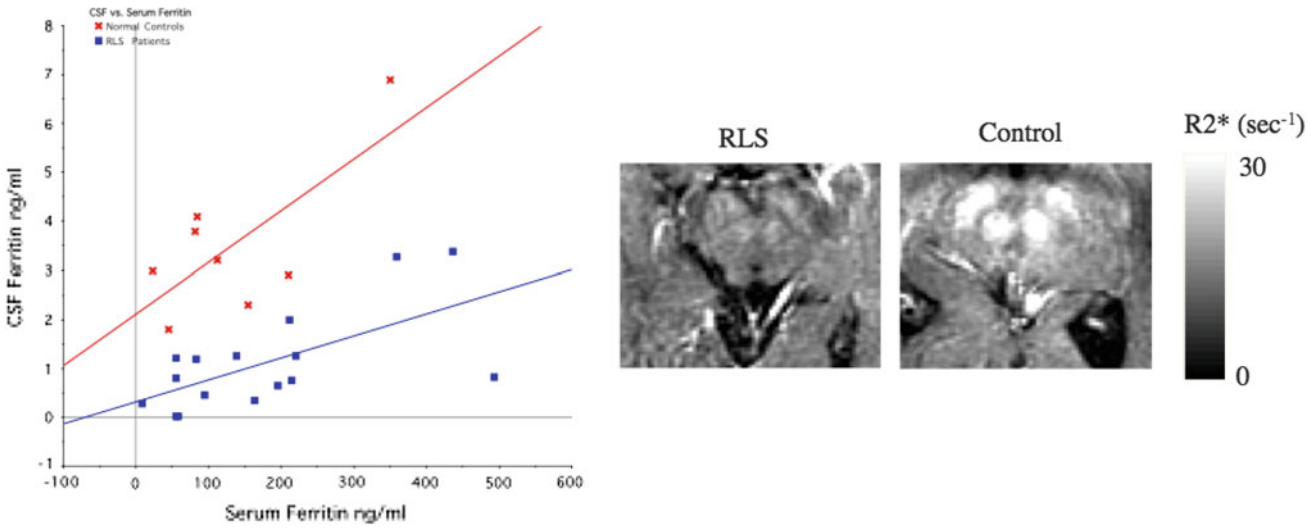

Fig. 40.4 Brain iron deficiency in RLS with normal levels of peripheral iron (serum ferritin *left graph*) but low levels of CSF ferritin (*left panel*) and also low levels of iron on MRI R2* (*right panel*)

dysregulation of brain dopamine function, perhaps related to altered amplitude of circadian dopamine variation. Recent identification of activation of hypoxic pathways in RLS [197, 198] indicates possible synergistic interaction between iron deficiency and hypoxia factors contributing to the dopaminergic dysfunction in RLS. Thus, COPD patients [199, 200] and those traveling or living at high altitudes [201] activating hypoxic pathways show higher rates or exacerbation of RLS.

It has been suggested on theoretical grounds that the A11 dopamine system, which descends to the spinal cord, could be involved in RLS, acting through D_3 dopamine receptors [202]. D_3 knockout mice show increased activity, as do mice with A11 lesions [203, 204]; however, these do not show the appropriate circadian pattern except when combined with iron deficiency [205]. Moreover, as noted above, RLS does not occur with neuronal loss and has increased not decreased dopamine; thus lesion studies reducing dopamine cells have somewhat limited usefulness. An autopsy study also failed to find any abnormalities in the A11 system of RLS patients [206].

The opioid system has also been suggested to be abnormal in RLS based largely on the therapeutic benefits of opioids for RLS [207–209]. A recent autopsy study documented decreased thalamic beta-endorphin cells [210], but an opioid imaging study failed to find significant difference from controls [211].

There is no evidence of neurodegeneration in RLS [212, 213]. Thus, RLS appear to have a pervasive functional abnormality in which brain systems are intact but have multiple abnormal functioning and interactions. Some limited evaluations of the resting state have documented abnormal interactions for RLS involving particularly the thalamus [214, 215]. Transcranial magnetic stimulation has also revealed increased excitability of the motor cortex in RLS [216–220] that is reduced by dopamine agonists [221, 222]. Further documenting the pervasive nature of the RLS brain abnormalities decreased myelination has been found in autopsy studies [223] and correspondingly decreased white matter in specialized MRI studies [223–225].

Overall, a mild brain iron deficiency possibly appears to be the most consistent abnormality reported for RLS and based on animal and clinical studies appears to largely explain the known biological abnormalities in RLS particularly those related to changes in dopamine [188]. Animal models of iron deficiency demonstrate increased activity that can occur in the hours before the primary sleep period, similar to RLS [226]. In this iron model of RLS causation, iron deficiency is expected to act principally through a dysregulation of brain dopamine function, perhaps related to altered amplitude of circadian dopamine variation [188]. The iron deficiency could also cause decreased myelination, white matter, resting state, and cortical excitability changes in RLS. The iron deficiency synergism with hypoxic pathways deserves special attention.

Familial Aggregation and Genetics in RLS

A striking finding in series of RLS cases is that some families have a high proportion of members with RLS [144, 153, 227, 228]. One obvious explanation would be that the disorder is under a large degree of genetic control. Three twin studies have suggested an elevated risk to monozygotic co-twins of affected individuals [67, 229, 230]. The first two studies suffered from major methodological limitations [229,

230]. The first study restricted to monozygotic twins had biased sampling from a clinical setting [231]. The second used general unvalidated questions for identification of RLS that cannot be considered accurate [230]. The third study used a preexisting twin sample with accurate diagnoses and found significantly greater concordance in monozygotic twins providing the heritability factor of 69 % [67].

The search for genetic determinants of RLS has been limited by two factors. First, the risk to first-degree relatives of patients has only been modest, on the order of three- to sevenfold [68]. Second, the frequency of RLS (4–10 % of adults) is quite high for a simple genetic disorder and suggests complex genetics likely involving environmental interaction. An initial approach to finding genetic determinants, searching for candidate genes active in the dopamine and iron pathways presumed to be involved in RLS did not reveal specific mutations contributing to RLS [232, 233]. One exception was the association of a fast metabolizer allele of monoamine oxidase A with RLS in women [234]. Another exception was the finding that variants in the neuronal nitric oxide synthase 1 gene (*NOS1*) are associated with RLS [235]. This gene is active in the nitric oxide/arginine pathway that is involved in sensory processing and affects both dopamine and endogenous opioid transmission. Multiple linkage analyses using large families with high rates of RLS occurrence failed to find any gene significantly related to RLS.

Genome-wide association studies in case-control populations, however, have found multiple specific allelic variations associated with an increased risk of RLS. Two groups initially reported significant associations in three genes [21, 66] *BTBD9* (6p), *MEIS1* (2p), and *MAP2K5/LBXCOR1* (15q). These genes do not have clearly known functions in adults, but are active during development, especially in the formation of the limbs. They are expressed within the nervous system [236]. One group found that *BTBD9* was better linked to the presence of increased PLM than to the purely subjective symptoms of RLS [21], underscoring the important connection between RLS and PLM. The group also found that serum ferritin, the best marker of body iron stores, was decreased in a dose-response fashion in patients with the RLS-PLM predisposing variant. Further association studies have identified RLS risk alleles in 5 other genetic regions. There are now a total of 16 allelic variations identified with increased risk of RLS. These occur on MEIS1, BTBD9, PTPDR, MAP2K5/LBXCOR1, TOX3, and the 2p14 region. The alleles are on intron (noncoding) portions of the genes. The functional relation of these genes to known biology of RLS is being explored. One important study documents the MEIS1 RLS alleles relating to a loss of function [237]. Knockout animal and fly studies have shown that BDBT9 and MEIS1 are both involved in the development of the dopamine system and also have effects on iron metabolism [238, 239]. Overall, these genetic data further support the strong relation between iron metabolism, dopamine, and RLS.

Evaluating the Severity and Impact of RLS

Standard Clinical tools have been developed and validated to evaluate the severity of RLS. The first of these was the Johns Hopkins Restless Legs Severity Scale (JHRLSS) that categorized the patients by time of onset of symptoms: mild for bedtime and evening only, moderate for afternoon before 6PM, and severe formorning before 12 noon [240]. This scale was designed to evaluate severity only for patients who had nearly daily symptoms, and the scale is rarely used today.

The second scale developed by the International Restless Legs Syndrome Study Group to evaluate RLS severity (IRLS) has become accepted as the primary scale for use in evaluating RLS severity (see Box 40.5). It has been well validated [241] and found to be responsive to changes in clinical estimates of RLS severity [242, 243]. This 10-item scale scores each item as 0–4 with 4 indicating greatest severity. Total scores of 0–10 indicate mild, 11–20 moderate, 21–30 severe, and 31–40 very severe RLS [241]. The IRLS has been found to have two factors, one for symptoms of RLS and the other for effects of RLS on life [244]. The IRLS scale has been translated into at least 15 different languages and is available from MAPI Research Trust at http://www.proqolid.org/.

The current diagnostic criteria for RLS also include added specifiers describing the RLS severity based on the clinical course as chronic-persistent (symptoms at least twice weekly for most of the past year) vs. intermittent (symptoms < twice weekly over the past year) [37].

Box 40.5: International Restless Legs Syndrome Study Group Rating Scale (IRLS)

(For permission to use contact: MAPI Research Trust at http://www.proqolid.org/).

The subject is given a copy of the questions. The clinician asks before each question:

"*In the past week…*"

The clinician not the patient records the subject's answers on the data sheet.

Each item is scored for 0—none, 1—mild, 2—moderate, 3—severe, 4—very severe (exceptions to this scoring are noted below)

1. Overall, how would you rate the RLS discomfort in your legs and arms?
2. Overall, how would you rate the need to move around because of your RLS symptoms?
3. Overall, how much relief of your RLS arm or leg discomfort did you get from moving around?
   4—No relief
   3—Mild relief
   2—Moderate relief
   1—Either complete or almost complete relief
   0—No RLS symptoms to be relieved
4. How severe was your sleep disturbance due to your RLS symptoms?
5. How severe was your tiredness or sleepiness during the day due to your RLS symptoms?
6. How severe was your RLS as a whole?
7. How often did you experience RLS symptoms?
   4—Very often (6–7 days in 1 week)
   3—Often (4–5 days in 1 week)
   2—Sometimes (2–3 days in 1 week)
   1—Occasionally (1 day in 1 week)
   0—Never
8. When you had RLS symptoms, how severe were they on average?
   4—Very severe (8 h or more per 24 h)
   3—Severe (3–8 h per 24 h)
   2—Moderate (1–3 h per 24 h)
   1—Mild (less than 1 hour per 24 h)
   0—None
9. Overall, how severe was the impact of your RLS symptoms on your ability to carry out your daily affairs—for example, carrying out a satisfactory family, home, social, school, or work life?
10. How severe was your mood disturbance due to your RLS symptoms—for example, angry, depressed, sad, anxious, or irritable?

The total score ranges from 0 to 40.

As a rough guide, the overall score divides into different levels of severity: 0 No, 1–10 Mild, 11–20 Moderate, 21–30 Severe, 31–40 Very Severe RLS.

(Note, IRLS is copyright protected and not to be used without permission. Fees may apply)

There are two well-validated disease-specific quality of life scales for RLS that have been used in the major clinical trials, i.e., the RLSQoL developed at Johns Hopkins [242, 245, 246] and the RLS-QoL developed in Germany [247]. The Hopkins scale is available from MAPI Research Trust at http://www.proqolid.org/, and it has been translated into several different languages.

Treatment of RLS and PLMD

A spectrum of treatment options, both non-pharmacologic (Box 40.7) and pharmacologic (Box 40.8), is available to address the wide range in severity and frequency of RLS symptoms. Before embarking on a decision to treat RLS or PLMD, some general comments about treatment guidelines are warranted (Box 40.6). For the purpose of treatment guidelines, patients can be classified (Table 40.1) into intermittent (usually mild), chronic, and persistent (usually moderate-to-severe with the added category of refractory or intractable [248] and into degree of clinical significance. These classifications depend on the intensity and frequency of symptoms, impairment of quality of life, and response to treatments. The IRLS, a validated clinical scale assessing RLS severity (Box 40.5), has been used as a primary end point in almost all clinical trials.

Box 40.6: General Treatment Guidelines for Restless Legs Syndrome (RLS)

Does the patient have RLS? (this must be established first).

- Does the patient have primary RLS or comorbid (secondary) RLS?
  (This distinction is important as the comorbid conditions must be identified and treated where possible).
- Always evaluate iron status and also determine if non-pharmacological treatment will suffice.
  (It is important to determine if mild or intermittent symptoms without significant disability can be managed by non-pharmacologic measures).
- Define RLS severity to guide treatment evaluation.
  Use the IRLSSG [see Box 40.5 and Table 40.1] or provide an overall clinical impression.
- Define end points in therapy and evaluate these on follow-up.
  For example, elimination of RLS symptoms or IRLS score <11, reduction or elimination of leg jerks during sleep as obtained by history from bed partner or polysomnography study, a significant reduction in IRLS scale score, quality-of-life improvement.

Box 40.7: Non-pharmacologic Treatment of Restless Legs Syndrome (RLS)

- Follow sleep hygiene measures (see Table 26.17 in Chap. 26).
- Consider discontinuing or reducing medications that can worsen RLS (see Box 40.2).

Table 40.1 Classification of RLS for treatment purpose

Categories	Key features
Mild (Intermittent) RLS	• Intermittent mild symptoms (< 2/week, mild-to-moderate distress when present) • Sometimes bothersome • Maybe predictable and situational
Minimal RLS	• IRLS score of 1–10 (see Box 40.5)
Moderate RLS	• Symptoms (significantly bothersome) occurring at least twice a week interfering with quality of life • IRLS score of 11–20
Moderately severe RLS	• Same as moderate RLS symptoms • IRLS score of 21–30
Severe RLS	• Significant and intense symptoms occurring daily interfering with daytime function and quality of life • IRLS score of 31–40
Refractory or intractable RLS	• Severe daily symptoms despite adequate doses of dopaminergic medication • IRLS score of 40 • Severe sleep disturbance • Impairment of quality of life and severely impaired daytime function

IRLSSG International Restless Legs Syndrome Study Group; RLS, restless legs syndrome
Modified and adapted from Hening et al. [327] and Silber et al. [328]

- Avoid substances that may trigger RLS (e.g., alcohol, smoking, caffeine-containing drinks).
- Exercise regularly at moderate intensity (avoid vigorous exercise, which may exacerbate RLS symptoms).
- Participate in mentally alerting activities (activities promoting alertness benefit RLS symptoms).
- Use counter stimulation measures (e.g., hot or cold showers, massage, getting up, and walking).
- Adjust sleep schedule to be somewhat delayed.
- Participate in patient support groups.

Important pharmacologic treatment options for RLS (see Box 40.8) include the α2δ ligands (particularly gabapentin enacarbil), the dopaminergic agents, the opioids, the sedative-hypnotics, and both oral and intravenous (IV) iron. Box 40.9 lists some general principles of pharmacotherapy for RLS. The first review and standards for RLS treatment were published in 1999 by the AASM [86, 249]. They established that clinicians managing RLS should be able to make an accurate diagnosis, understand primary and secondary RLS and the comorbidities of RLS, and follow patients at appropriate intervals to adjust treatment as needed. The most recent evidentiary reviews include one from the American Academy of Neurology [250]. A management paradigm has been published by the Medical Advisory Board of the RLS Foundation [248]. Two important treatment guidelines have been published by the International Restless Legs Syndrome Study group (ILRSSG): one for long-term treatment [251] and another important one in collaboration with the European RLSSG and the USA RLS foundation on initial treatment and managing augmentation [252].

Box 40.8: Pharmacologic Agents commonly used in Restless Legs Syndrome

Alpha-2-delta ligands:

Gabapentin enacarbil (approved), pregabalin, gabapentin

Dopaminergic medications:

Dopamine agonists: pramipexole (approved), ropinirole (approved), rotigotine patch (approved), cabergoline (not recommended*)
Levodopa combined with a decarboxylase inhibitor

Opioids (mild, moderate, strong):

Oxycodone/naloxone (approved in Europe)
Oxycodone, hydrocodone, methadone, buprenorphine

Benzodiazepines:

Clonazepam

Iron treatments:

Oral iron (in those with low serum iron or ferritin below 75 ng/ml)
IV iron (iron deficiency and non-responders to oral iron)
Ferric Carboxymaltose (FCM)

Low molecular weight dextran
Iron Sucrose (uncertain benefit for adults with RLS)

*concerns about fibrosis require added regular cardiac monitoring.

Box 40.9: Principles of Pharmacotherapy for Restless Legs Syndrome
Individualize the therapy.

- Start with monotherapy rather than polytherapy.
- Begin with a very small dose and gradually increase every 3–5 days to an optimal or maximal tolerable dose.
- Try monotherapy even in an apparently severe case using small-to-medium dose (a surprising number of such patients will respond satisfactorily).
- Try to convert patients on polytherapy (placed on treatment before referral to you) to monotherapy if possible (it is possible to do so in many such patients).
- Try to reduce the dose or eliminate some medications if patients complain of undesirable side effects from multidrug treatment.

Perform regular follow-up to monitor for side effects, progression of the disease, augmentation, tolerance, and rebound.

The treatment guidelines include as-needed medication for infrequent RLS, α2δ agents as preferred, and dopamine agonists as a second choice initial treatment for moderate-to-severe RLS, second-line treatment involves low-dose, very long acting dopamine agonists, moderate strength opioids, and combinations of α2δ agents, low-dose dopamine agonist and moderate strength opioids. An array of strategies (switching agents, combination treatment, strong opioid agents, IV iron) is used for refractory patients who fail other treatments. These reviews, particularly the ones from the IRLSSG, provide an easy route into the RLS therapeutic literature.

Pharmacologic Treatment of RLS (see Boxes 40.8, 40.9, 40.12, and Table 40.1)

Historic Note and RLS Augmentation

Opioids as the first treatment used for RLS [253, 254] were rapidly replaced by levodopa and then dopamine agonists when they became available. The dopaminergic medications showed more consistent and immediately effective treatment than opioids [255, 256] without the dependence and abuse problems. Gabapentin was also used to treat RLS, but the early results were somewhat mixed [257] complicated by its uneven uptake into blood and apparently less effect on PLMS. The dramatic efficacy of the dopaminergic treatment left little room for this alternate treatment except in non-responders. This changed with the awareness that treatment with the dopaminergics over 3–10 years produced a major problem of augmenting the RLS symptoms. RLS augmentation produced symptoms becoming more severe, more extensive, and occurring for more of the day especially in the afternoon and morning where they had not previously occurred [106]. Augmentation on the dopamine agonists did not usually appear until after 6 months to 10 years of treatment [258, 259]. Initially, there was some uncertainty if augmentation was iatrogenic or a natural progression of symptoms. It also was unclear if effective treatment by non-dopaminergic drugs might also produce significant augmentation. This issue was directly addressed in a major large clinical study comparing at therapeutically effective doses the dopamine agonist pramipexole with the α2δ ligand pregabalin over one year of treatment. The results of this study showed that pregabalin compared to pramipexole was equally or more effective and had significantly less augmentation. The one-year augmentation rate for pregabalin (1.7 %) was the same as that seen in other studies on placebo, indicating this reflected possible natural progression in this study without any dose increase and/or noise in the clinical measure of augmentation. In contrast, the 9 % augmentation on 0.5 mg pramipexole for one year demonstrated that augmentation was iatrogenic, not natural progression, and based on other studies probably occurred for all dopaminergic treatment of RLS. The study also demonstrated augmentation occurred mostly after the initial 6 months of treatment and was increased with higher dose (see Fig. 40.5). After this study, the treatment of RLS shifted from using dopamine agonists as the primary first-line treatment to instead using the α2δ agents as first line and dopaminergics only when there was a reason not to use the α2δ agents. Moreover, with increased experience, very severe and intractable cases of RLS have been identified and often require returning to using dopamine agonists, but those with very long half-lives, e.g., rotigotine, and also the initial drug used for RLS, i.e., opioids. Now with the most extreme RLS moderate and high potency opioids are used. The one relatively new treatment for RLS that at this point in 2016 is still being evaluated is intravenous (IV) iron. Given the RLS biology of brain iron deficiency, it is hoped that some treatment, possibly IV iron, could actually reduce this biological abnormality and thereby provide effective treatment. The range of current treatments is presented in brief here as they are currently (2016) recommended by the IRLSSG.

α2δ Ligands

The α2δ ligands have analgesic and anticonvulsant activity. They bind to the α2δ voltage gated calcium channel

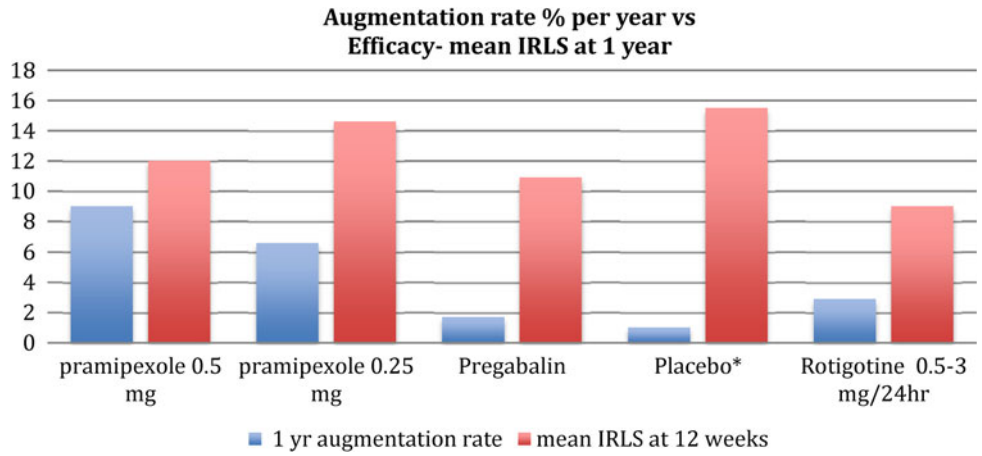

Fig. 40.5 Long-term treatment efficacy versus augmentation. *Red bars* indicate mean clinical severity of RLS on the IRLS scale after 12 weeks of treatment. *Higher values* indicate more severe RLS, with <10 considered minimal RLS, 10–15 mild RLS, >15 moderate RLS symptom severity. *Blue bars* indicate rates of RLS augmentation after 1 year of treatment. Higher values are more augmentation. The 1 % on placebo indicates natural progression without treatment, the values significantly higher than that indicate the percentage with drug induced worsening of RLS (augmentation). Note Pregabalin 300 mg in this study is as effective as pramipexole 0.5 mg with augmentation not significantly greater than for placebo. In contrast, pramipexole shows significant dose-related augmentation. Data sources for pramipexole: Allen et al. [37]; rotigotine: Benes et al. [147]; Placebo: Garcia-Borreguero et al. [145] and Benes et al. [147] pro-rated from 6 months data

reducing neurotransmitter release in pathways involving several neurotransmitters [260], including glutamate [261]. There are three α2δ ligands used for RLS: gabapentin enacarbil, pregabilin, and gabapentin. Gabapentin was initially used for RLS with generally good but mixed results in uncontrolled, open label trials for mild-to-moderate RLS. The studies were small, and results were considered inconclusive for a first-line treatment recommendation [257, 262]. Trials comparing gabapentin to other RLS treatments generally found gabapentin to be almost as effective, although somewhat less effective in reducing the PLMS [263, 264]. In a double-blind, cross-over study, gabapentin in doses of 600–2400 mg was more effective than placebo in treatment of RLS, but 13 % of the RLS patients continued to have abnormally high rates of PLMS [265]. Gabapentin is poorly taken up into the blood with wide variations between individuals and even across days in a given individual. This problem limits reliably delivering effective treatment and leads to needing larger doses. The other two α2δ ligands resolve that problem. One, gabapentin enacarbil is a pro-drug overcoming the gabapentin uptake problem. It reliably delivers gabapentin to the blood and maintains a reasonable blood level for 12–18 h with almost complete clearance in 24 h [266]. Large controlled clinical studies have documented efficacy with mostly mild side effects for gabapentin enacarbil treatment of RLS at single daily doses of 600–1200 mg [267–271]. This drug is now approved by US Food and Drug Administration (FDA) for treatment of moderate-to-severe RLS at a dose of 600 mg per day, although in the clinical studies effective doses range from 300 to 1200 mg. Pregabalin has a different chemical structure, and has none of the uptake problems of gabapentin. In controlled clinical trials compared to placebo, one dose of 100–300 mg pregabalin provided effective treatment for 12–16 h [148, 272–275] with higher doses up to 600 mg used for RLS with neuropathic pain [276].

The α2δ ligands currently recommend (Box 40.8) for initial first-line treatment of RLS based on adequate clinical studies are gabapentin enacarbil (300–600 mg once daily) and pregabalin (100–300 mg usually only once daily). Gabapentin is likely to be effective except for the problem of its variable uptake into blood. It also has not been evaluated in large clinical trials, so there may be other unknown limitations. Gabapentin use is thus complicated by a wide range of doses ranging from 300 to 2400 mg a day and a need to give it 1–3 times a day. Failure with gabapentin given its uptake problems does not mean the other α2δ agents will not be effective.

Cost is a significant issue. Gabapentin but not the other α2δ ligands are available as a generic at a lower price than the other α2δ agents.

Levodopa

Akpinar [277] and Montplaisir et al. [189] first reported a profound response of RLS symptoms to small doses of levodopa. Subsequent studies have consistently found that levodopa reliably ameliorates RLS symptoms, decreases PLM [255, 256], and improves sleep [181, 278], but in the

vast majority of cases daily chronic longer term use produces RLS *augmentation* [106, 146]. It is not recommended for daily use.

Dopamine Agonists

Dosing of dopaminergic agents for RLS differs from the typical dosing schedule in PD. Many RLS patients can be successfully managed with low doses given 2 h before symptom onset. Generally, a single dose taken at night can benefit those with late evening and bedtime symptoms, while more severe patients with significant evening symptoms can take one dose in the early evening and a second before bedtime. For the patient who develops a rapid escalation in RLS severity, with increasing medication requirements in the first 2 years of therapy, augmentation should be carefully considered.

Because of reports of fibrosis and valvulopathy with ergot-derived agonists (pergolide, bromocriptine, cabergoline) [279] non-ergot-derived agonists are preferred treatment. Ropinirole, pramipexole, and rotigotine have been approved for the treatment of RLS after several large multicenter studies [114, 115, 280–284]; they have also been shown to markedly decrease PLMS in RLS [285–287]. Rotigotine is provided as a transdermal patch that, unlike oral agents, provides continuous delivery over 24 h and sustains a near-constant blood level.

RLS Augmentation on Dopaminergic Treatment: Rates and Management

As noted above in the history of RLS treatment, augmentation is an iatrogenic increase in the severity of RLS with long-term dopaminergic treatment (see Fig. 40.5). It also occurs for tramadol [288]. Its primary manifestation is worsening of RLS and the progression of symptoms earlier in the day. This has been defined for clinical studies at the NIH RLS consensus conference [104] (Box 40.10). Based on a study of levodopa patients in which 60 % developed augmentation, a validated severity questionnaire has been developed [289]. A series of questions for early identification of augmentation have been proposed by the IRLSSG as part of their official guidelines for managing augmentation [252] (Box 40.11).

Box 40.10: NIH Workshop Diagnostic Criteria for RLS Augmentation

Adapted from Allen et al. [104].

RLS augmentation can be diagnosed if A and B are met

(a) Either of the following two criteria are met:
   1. Criterion 1: RLS symptoms occur at least 2 hours earlier than was typical during the initial course of beneficial stable treatment.
   2. Criterion 2: Two or more of the following key features of RLS augmentation are present:
      - An increased overall intensity of the urge to move or sensations is temporally related to an increase in the daily medication dosage, or a decreased overall intensity of the urge to move or sensations is temporally related to a decrease in the daily medication dosage.
      - The latency to RLS symptoms at rest is shorter than the latency either during initial therapeutic response or before treatment was instituted.
      - The urge to move or sensations are extended to previously unaffected limbs or body parts.
      - The duration of treatment effect is shorter than the duration during initial therapeutic response.
      - Periodic limb movements while awake occur for the first time or are worse than either during initial therapeutic response or before treatment was instituted. In addition to meeting one of these two criteria, the diagnosis requires both of the following:
      - Augmented symptoms meeting these criteria are present for at least 1 week for a minimum of 5 days.

(b) No other medical, psychiatric, behavioral, or pharmacologic factors explain the exacerbation of the patient's RLS and any symptoms meeting these criteria for augmentation.

Box 40.11: Indications for early identification of RLS augmentation

Adapted from Garcia-Borreguero et al. [252].

1. RLS/WED symptoms appearing earlier than before the drug was started?
2. Higher doses or dosing earlier in the day than after the first 2 months on treatment
3. Intensity of symptoms when present is worse than before starting treatment?
4. Symptoms occur for the first time in new parts of the body (e.g., arms) not affected before starting treatment.

Levodopa augmentation rates have been reported to occur in as many as 80 % of RLS patients, with 50 % of them requiring a change in medication [106, 290]. Dopamine agonists have slower development of augmentation with rates of 20–30 % over 3 years (20–30 %) [291–293] but persisting development at the rate of about 7–8 % new cases each year for over 9 years and presumably indefinitely [259, 294]. Any increasing dose requirement for relief of

increasingly intense symptoms may suggest tolerance. Tolerance does not itself cause augmentation with an earlier onset of symptoms or spread to other parts of the body. Tolerance, however, is often an early observable sign of augmentation [291] and should always be considered a warning sign of augmentation. Iron deficiency may be a predisposing factor for augmentation [295].

The treatment of augmentation involves primarily reducing or discontinuing the use of dopaminergic and switching to or adding a non-dopamine medication. The options are well described in the treatment guidelines provided by the IRLSSG [252]. The critical issue involves appreciating the importance of minimizing the use of dopaminergic medication for patients who develop augmentation. The continuously acting dopaminergic medication, rotigotine, appears to have fewer problems with augmentation and may provide a treatment for augmented RLS although often at higher than regulatory approved doses [296], but in general avoiding any dopaminergic medication is the safest way to minimize augmentation problems.

Anticonvulsants (Other than α2δ Agents)

Carbamezapine had in earlier studies demonstrated successful use in RLS [297–300]. However, clinical experience has not demonstrated as good a response as that seen with dopamine agonists or gabapentin. There are only limited case reports or small series with other anticonvulsants, such as lamotrigine [301, 302] and topiramate [303]; thus, these are usually tried only in patients who are unable to tolerate other agents.

Opioids

Moderate potency opioids (e.g., oxycodone, hydrocodone) are used mostly for second-line treatment, and the moderate-to-high potency opioids (methadone, buprenorphine) are used only for treatment of refractory RLS. Opioids have been documented to be effective in RLS [208, 209, 259, 304]. Because of individual variation in response to the different classes of opioids, it is often worthwhile trying more than one agent. Longer acting medications such as methadone often provide relief for some of the most severely affected patients, including those who have failed dopaminergic therapy [209, 304]. One opioid agent, tramadol, which also has serotoninergic properties, has been reported to cause augmentation [288, 305].

Sedative Hypnotics

Despite the early use of benzodiazepines for treating RLS and PLMD, the sedative-hypnotic agents do not have reliable effectiveness in eliminating RLS sensations or eliminating PLMS [306, 307]. They are best reserved for mild cases with primary sleep disruptions where they may enable the patient to sleep through the symptoms or as adjunctive therapy for persisting insomnia. When used alone, they may increase the risk of falls if during the night the patient awakens and gets out of bed to relieve the RLS symptoms.

Iron Treatment

The biological basis of RLS includes brain iron deficiency. Thus, iron unlike other treatments may correct the biology causing the disease and modify the course of the disease. Barriers to changing brain iron status include limited absorption of iron from the gut, regulation of iron transport across the blood brain barrier, and the biological problems with iron management that may have contributed to the development of the brain iron deficiency in the first place.

Oral iron treatment despite limitation of absorption from the gut is considered a primary treatment for all RLS patients based on the biology of RLS, general clinical experience, and one small placebo-controlled, double-blind clinical trial [308]. Iron transport from the gut to blood is generally extremely limited when serum ferritin values are high. Oral iron is unlikely to be effective for patients with higher values of serum ferritin as shown by failed benefit when given to RLS patients with a mean serum ferritin of 135 mcg/l [309]. In contrast, oral iron was shown to be effective treatment for RLS patients with serum ferritin ≤ 75 mcg/l [308]. Oral iron (usually iron sulfate 325 mg with vitamin C 100 mg taken once or twice a day) is recommended for all RLS patients with fasting morning serum ferritin ≤ 75 mcg/l and transferrin saturation <45 %. These serum values indicate iron levels are likely too low for RLS, and there is no indication for iron overload such as that associated with hemochromatosis. Oral iron treatment is usually continued if tolerated until serum ferritin increases to >100 mcg/l or transferrin saturation increases to >45 %. It can be reinstated as needed to keep serum iron levels high. Recent data on effects of oral iron on hepcidin levels indicate that taking oral iron more than once a day provides little extra benefit, and it may even suffice or be preferable to take it once every other day [310].

IV iron treatment bypasses the gut rapidly increasing iron in the blood available for transport to the brain. IV iron has been found to provide effective treatment in both open-label studies at doses of 500 mg of ferric carboxymaltose (FCM) [311] and 1000 mg iron dextran [312–314], and also two well-controlled clinical trials of 1000 mg of FCM [315, 316]. About half of the cases in these studies reported significant benefit from the iron treatment lasting for at least 2–4 months, and about 20 % of all patients reported essentially complete relief from RLS lasting for more than 6 months. Two controlled studies with 1000 mg IV iron sucrose failed to show significant benefit compared to placebo [317, 318], but the iron sucrose unlike iron dextran and FCM releases its iron rapidly and is thus less likely to provide the longer duration of iron availability needed for transport to the brain. Iron dextran at high molecular weight can produce

anaphylaxis and is therefore not recommended. This problem is much less for iron dextran at low molecular weight and may not be a significant problem at all for the other IV iron formulations. Curiously, IV iron appears to benefit about 40–60 % of RLS patients with long lasting benefit for 20–30 %, but some show no benefit at all even from a second added dose treatment [315]. The role of IV iron in treatment of RLS remains to be better developed, but it holds promise for at least some RLS patients.

Treatment of Refractory and Intractable RLS

Box 40.12 provides reasonable guidelines for treatment of intermittent and chronic persistent RLS. The situation is much more complicated for the severe RLS refractory to most of the treatments for RLS. The general guidelines for these patients is to first ensure adequate iron stores and if serum ferritin is < 100 mcg/l consider a trial on 1000 mg IV iron using one of the formulations that provides relatively slow release of the iron, e.g., ferric carboxymaltose. These infusions can usually be arranged through hematology clinics. The main pharmacological approach in these patients is the use of low doses of long half-life, potent opioids, e.g., methadone [259, 304], buprenorphine, or prolonged release oxycodone–naloxone [209]. The prolonged release oxycodone–naloxone has been approved for treatment of refractory RLS in Europe, but opioids are not approved for any use in RLS. All of these drugs need to be used carefully given the risk of dependence. The dose for these drugs will be below or at the low end of the doses used for treating pain. If higher doses are needed, care should be taken to ensure the drug is not treating some other condition, e.g., pain, or that dependence has not developed.

Box 40.12: Treatment Strategies for Mild, Moderate, Severe, and Refractory or Intractable Restless Legs Syndrome (RLS)

All RLS

Oral iron treatment if serum ferritin $\leq$75 mcg/l and transferrin saturation <45 %.

Mild or Intermittent RLS

Non-pharmacologic measures (NP)

Levodopa PRN (no more than once a week), low-dose α2δ ligand

Sedative-hypnotic PRN for sleep if needed and helpful.

Moderate-to-Moderately Severe RLS

α2δ agent nightly

Very low-dose dopamine agonist (with caution regarding augmentation)

Combination of α2δ agents and very low-dose dopamine agonist

Mild-to-moderate potency opioids.

Severe, Refractory RLS

Combination opioid and α2δ agents and low-dose dopamine agonists

Oxycodone–naloxone (approved for RLS in Europe)

High-potency opioids in very severe cases at very low doses (e.g., Methadone at 5–10 mg/day not to exceed 20 mg/day). Evaluate for possible IV iron treatment.

Pharmacologic Treatment of PLMD and PLMS

The periodic limb movement disorder (PLMD) occurs with high rates of PLMS (>15/h for adults and $\geq$5/h for children) associated with disrupted sleep or waking unrelated to other sleep disorders or to medications. The PLMS of PLMD may mark inflammatory processes and/or iron deficiency. The iron status should be carefully evaluated and oral or IV iron treatment considered even for low normal iron stores, provided transferrin saturation is <45 %. Iron treatment options are the same as that for RLS above, except treatment success can be evaluated by documenting decrease in the PLMS. Possible causes for the inflammation or low iron should also be evaluated and appropriate treatment considered.

Treatment of PLMD other than with iron starts with α2δ agents to reduce the PLMS and also generally improve sleep. Low-dose L-dopa and dopamine agonists are also very effective for reducing PLMS, but the dopamine treatment of PLMS without RLS can lead to the development of RLS [106] and therefore should be used very cautiously and only at very low doses. Opioids are of uncertain benefit. Clonazepam was demonstrated to improve sleep but not the PLMS [306]. In most cases, it is important to look for other causes of the sleep and daytime functioning complaints and determine that the treatment of the PLMS produced significant changes in these to justify continuing the treatment.

Treatment of PLMS without RLS or PLMD is not clearly indicated. Very high rates of PLMS themselves have been related to significant health, particularly cardiovascular health problems. High rates of PLMS may thus deserve some attention. PLMS are associated with the increase in heart rate [319] and rises in blood pressure [320–322]; it has been suggested that, untreated, they may lead to persistent diurnal hypertension, but this connection appears to be very limited [323]. It nonetheless provides a potential rationale for treating PLMS that occur without a related sleep complaint in vulnerable patients [320]. Treating sleep disruption with PLMS in RLS patients might be less effective than in those without RLS, because some arousals may persist in RLS patients even when PLMS are effectively suppressed [324]. In RLS patients, there may be a different relationship between movements and arousals than in those without RLS [325]: in RLS, the PLMS may be more closely connected to an underlying abnormality. Nonetheless, dopaminergic treatment reducing the PLMS for RLS patients has been

shown to significantly reduce the transitory heart rate and blood pressure increases during sleep [326]. Consideration regarding treatments to reduce PLMS needs to be carefully balanced by the adverse effects of treatments and the limited data indicating clear benefit for the treatments especially in otherwise healthy individuals.

Summary

RLS is the 2nd or 3rd most common neurological disorder after essential tremor and headache. It is often misdiagnosed, under-diagnosed, under-recognized, and mistreated or under-treated. RLS should be strongly considered in any subject complaining of leg discomfort or excessive restlessness of the legs while lying in bed in the evening and of having difficulty falling asleep or maintaining sleep or of non-restorative sleep. Most patients get relief from treatment with α2δ ligands or low-dose dopaminergic drugs. Long-term 5- to 10-year treatment benefits from dopaminergics appear to be severely limited by the augmentation problem. It is hoped, but unclear if the long term treatment with α2δ ligands will be better than dopaminergic treatment.

PLMD treatment benefits are somewhat unclear, but iron status should be evaluated and appropriate treatment considered if serum ferritin is low. PLMS without RLS or PLMD has uncertain clinical significance, except to indicate possible iron deficiency. They may, however, occur with significant unrecognized sleep disruption and treatment as PLMD can be considered. PLMS at very high rates may be associated with health and cardiovascular problems, but there are no data at this point to indicate treating the PLMS themselves provides clinical benefits.

Sleep, Breathing, and Neurologic Disorders

41

Sudhansu Chokroverty and Federica Provini

Introduction

To understand the effects of neurologic lesions on sleep-wake cycles and sleep states, and to understand the normal interactions of sleep and breathing, it is important to have a clear understanding of the functional anatomy of sleep and breathing. In the first section of the chapter, therefore, a brief overview of the anatomy and physiology of sleep is presented. The section on the functional anatomy of sleep is followed by a short discussion of the control of breathing during sleep. For details, readers are referred to some excellent reviews and monographs [1–10] and to Chaps. 5 and 8 in this volume.

Most of the anatomic structures that control sleep and breathing are located in the central nervous systems (CNS). These regions are influenced not only by other CNS structures but also by inputs from the peripheral neuromuscular system and other body systems. It is important to understand not only that the neurologic illnesses may affect sleep and breathing but also that alterations of sleep and breathing may adversely affect the natural history of a neurologic disorder. A number of excellent sources provide systematic descriptions of the effects of neurologic lesions on the pattern and control of breathing [11–21]. The effect of acute and chronic neurologic disorders on the state of sleep and the resulting interaction on breathing has not received wider attention, and understanding of such an interaction is essential for treatment and prognosis in various neurologic disorders. In neurologic illnesses, breathing disorders may manifest as hypopnea, apnea, irregular or periodic breathing, or alveolar hypoventilation. Similarly, sleep disturbances may manifest as hypersomnia, hyposomnia (insomnia), parasomnia, or circadian rhythm sleep disorders. The discussion is grouped into two major sections: (1) sleep and breathing disorders secondary to somatic neurologic illness and (2) sleep and breathing disorders secondary to autonomic failure. The somatic neurologic disorders are subdivided into CNS disorders and peripheral neuromuscular disorders.

Functional Anatomy of Sleep and Wakefulness

The neuroanatomic substrate of wakefulness, rapid eye movement (REM) sleep, and nonrapid eye movement (NREM) sleep are located in separate parts of the CNS [1, 22, 23]. There are no discreet sleep/wake-promoting centers; rather, these states are produced by changes in the interconnecting neuronal systems modulated by neurotransmitters and neuromodulators.

Neuroanatomic Substrates of Wakefulness

The ascending reticular activating system (ARAS), consisting of neuroanatomic and neurochemical components of the arousal system containing glutamatergic and other neurotransmitters and neuromodulators (Fig. 41.1), determines the state of wakefulness [1]. Cerebral cortical activation during wakefulness is maintained by projections from the ARAS terminating in the thalamus and by thalamocortical projections to widespread areas of the cerebral cortex. In addition, there are extrathalamic projections from the brain stem reticular neurons ending in the posterior hypothalamus and the basal forebrain regions; the latter in turn project to the cerebral cortex to help maintain wakefulness. All these pathways regulating wakefulness utilize hypocretinergic (orexinergic), cholinergic, noradrenergic, dopaminergic, and

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_41

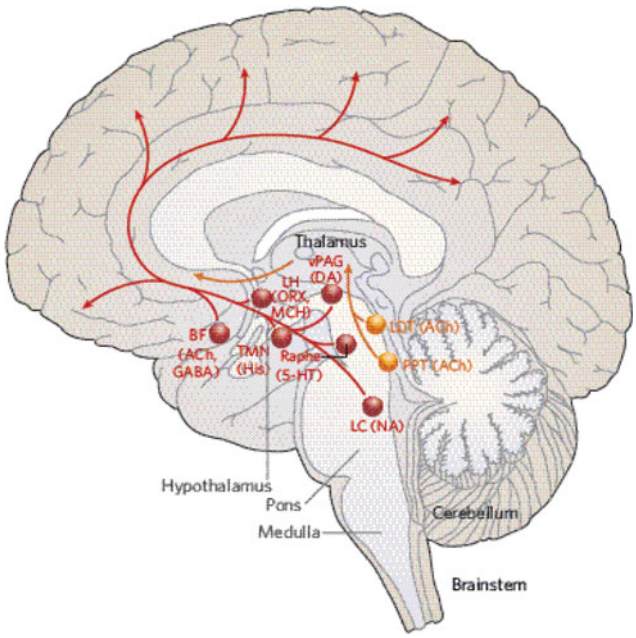

Fig. 41.1 Ascending Reticular Activity system (ARAS): The ascending arousal system. Two major pathways are shown. One (shown in yellow) providing upper brain stem input to the thalamic-relay nuclei and to the reticular nucleus of the thalamus coming from the pedunculopontine and laterodorsal tegmental (PPT/LDT) nuclei, which are acetylcholine (ACh)-producing neuronal groups. The second major group of neurons (shown in *red*) come from the noradrenergic (NA) locus coeruleus (LC), serotoninergic (5-HT) dorsal and median raphe nuclei, dopaminergic (DA) periaquiductal gray matter (vPAG), and histaminergic (His) tuberomamillary neurons (TMN). Additional cortical input merges from the basal forebrain (BF) neurons containing GABA or ACh, and by lateral hypothalamic (LH) peptidergic neurons that contain melanin-concentrating hormone (MCH) or orexin (hypocretin) (ORX). Reproduced from Saper et al. [29], with permission.

histaminergic neurons. The cholinergic neurons fire at the highest rate during wakefulness and REM sleep but decrease their rates of firing at the onset of NREM sleep. The wake-promoting aminergic neurons include noradrenergic neurons in the locus coeruleus (LC), serotoninergic neurons in the dorsal raphe of the brain stem, histaminergic neurons in the tuberomammillary nucleus of the hypothalamus, and also dopaminergic neurons (probably through D1 receptors), particularly in the ventral periaqueductal area. Noradrenergic neurons in the LC show the highest firing rates during wakefulness, the lowest rate during REM sleep, and an intermediate rate during NREM sleep. The excitatory amino acids glutamic and aspartic acids, intermingled within the ARAS and present in many neurons projecting into the cerebral cortex, forebrain, and brain stem, are released maximally during wakefulness. The discovery of hypothalamic hypocretin neurons with their widespread CNS projections (Fig. 41.2) directs our attention to the role of the hypocretinergic system in controlling sleep-wake regulation. De Lecea and coauthors [24] described two neuropeptides in the lateral hypothalamus and perifornical region that were termed hypocretin-1 and hypocretin-2. In the same year, independently, Sakuri et al. [25] described two neuropeptides in the same region that they named orexin A (corresponding to hypocretin-1) and orexin B (corresponding to hypocretin-2). It was shown thereafter that these hypocretin systems have widespread ascending and descending projections to the LC, dorsal raphe nucleus (DRN), ventral tegmental area, tuberomammillary nuclei of the posterior hypothalamus, laterodorsal tegmental (LDT) and pedunculopontine tegmental (PPT) nuclei, ventrolateral preoptic (VLPO) nucleus in the hypothalamus, basal forebrain, limbic system (hippocampus and amygdala), cerebral cortex, thalamus (intralaminar and midline nuclei), and autonomic neurons (nucleus tractus solitarius, dorsal vagal nuclei, and intermediolateral neurons of the spinal cord) (Fig. 41.2) [26–28]. Hypocretin systems promote wakefulness mainly through excitation of tuberomammillary histaminergic, LC noradrenergic, and midline raphe serotoninergic and dopaminergic neurons. Sleepiness may partly be induced by a reduction of activity of the hypocretin systems. These systems also participate in REM sleep regulation indirectly through activation of the aminergic neurons (REM-off), which in turn inhibit REM-generating neurons in the LDT/PPT (REM-on) [22].

Neuroanatomic Substrates of REM Sleep

Transection experiments in cats through different regions of the midbrain, pons, and medulla [22, 30, 31] established the existence of REM sleep-generating neurons in the pons (Fig. 41.3). A transection at the junction of the pons and midbrain (level A) produced all the physiologic findings compatible with REM sleep caudal to this transection, whereas rostral to the section, in the forebrain region, the recording showed no signs of REM sleep. The structures rostral to a section between the pons and medulla (level B) showed signs of REM sleep but structures caudal to the section showed no signs of REM sleep. Following transection at the junction of the spinal cord and medulla (level C), REM sleep signs were noted in the rostral brain areas. Finally, transections at the pontomesencephalic (A) and pontomedullary (B) junctions produced an isolated pons that showed all the signs of REM sleep. The pons is, therefore, sufficient and necessary to generate all the signs of REM sleep.

To explain the mechanism of REM sleep, three animal models are available. The earliest is the McCarley–Hobson reciprocal interaction model (Fig. 41.4) based on reciprocal interaction of REM-on and REM-off neurons [1, 22] (see also Chap. 5). The cholinergic neurons in the PPT and LDT

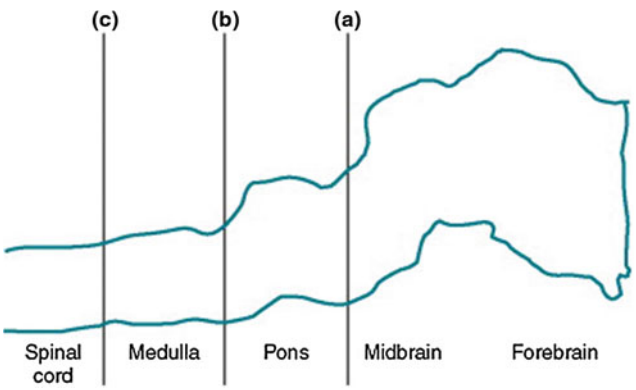

Fig. 41.3 Schematic sagittal section of the brain stem of the cat. **a** Junction of midbrain and pons. **b** Junction of pons and medulla. **c** Junction of medulla and spinal cord. Modified from Jouvet [30] and Siegel [31]

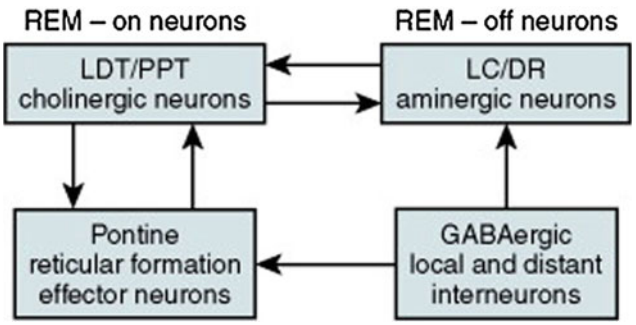

Fig. 41.4 Schematic diagram of McCarley–Hobson model of REM sleep mechanism. *GABA* γ-aminobutyric acid; *LC/DR* locus coeruleus/dorsal raphe; *LDT/PPT* laterodorsal tegmental/pedunculopontine tegmental nuclei. Modified from McCarley [22]

nuclei in the pontomesencephalic region are REM-on cells responsible for REM sleep, showing the highest firing rates at this stage. The aminergic neurons located in the LC and DRN are REM-off cells and are inactive during REM sleep. Histaminergic neurons in the tuberomammillary region of the posterior hypothalamus can also be considered as REM-off cells. Thus, the cholinergic REM-on and aminergic REM-off cells are all located within the transections of the pons as described previously. LDT-PPT cholinergic neurons promote REM sleep through pontine reticular formation (PRF) effector neurons, which in turn send feedback loops to the LDT-PPT. Cholinergic neurons of the PPT and LDT project into the thalamus and basal forebrain regions as well as to the PRF and are responsible for activation and generation of REM sleep. Aminergic cells play a permissive role in maintenance of the REM sleep state. In the latest modification of the reciprocal interaction model, McCarley [22] suggested that γ-aminobutyric acid (GABA) also plays a role in the REM sleep generation. At the onset of REM sleep, there is activation of GABA neurons in the pons that causes inhibition of the LC/DRN (REM-off neurons) as well as activation of (or disinhibition of) cholinergic neurons in the pons [32]. The reason for GABA activation is not known, and the source of GABAergic neurons is probably both local (e.g., a subgroup of PRF GABA neurons) and distant (e.g., GABAergic neurons in the ventrolateral periaqueductal gray). The theory for muscle hypotonia or atonia during REM sleep postulates that inhibitory postsynaptic potentials are generated by dorsal pontine interneurons in the region of the peri-LC alpha ventral to the LC that project to the lateral tegmentoreticular tract and then to the medial medullary region (the inhibitory zone of Magoun and Rhines in and around the nucleus magnocellularis and gigantocellularis in the paramedianus); the reticulospinal tract from this region projects to the anterior horn cells of the spinal cord, causing hyperpolarization and muscle atonia (Fig. 41.5) [1, 2, 33–37]. An experimental lesion in the peri-LC alpha region [38] as well as the medial medullary region [39] produced REM sleep without muscle atonia. In human REM sleep behavior disorder, causing dream-enacting behavior associated with REM sleep without muscle atonia, a structural or functional alteration of the pathway maintaining muscle atonia during REM sleep is most likely responsible [40].

In the model, proposed by Lu et al. [41] (Fig. 41.6), there is a "flip-flop" switch interaction between GABAergic REM-off neurons in the deep mesencephalon, vlPAG, and lateral pontine tegmentum (LPT), and GABAergic REM-on neurons in the sublaterodorsal (SLD) nucleus, with a dorsal extension of the SLD named the precoeruleus. These mutually inhibitory neuronal populations (SLD GABAergic REM-on and GABAergic REM-off neurons in the deep mesencephalon–lateral pontine tegmentum) serve as a flip-flop switch. Ascending glutamatergic projections from precoeruleus neurons to the medial septum are responsible for the hippocampal electroencephalographic (EEG) theta rhythm during REM sleep. Descending glutamatergic projections from the ventral SLD directly to the spinal interneurons, apparently without a relay in the medial medulla, inhibit spinal ventral horn cells by both glycinergic and GABAergic mechanisms. Cholinergic and aminergic neurons play a modulatory role and are not part of the flip-flop switch. McCarley [22] suggested that this model is based on c-fos labeling only without electrophysiologic recordings. Furthermore, this model does not address how REM periodicity occurs in this flip-flop switch utilizing two mutually inhibitory neuronal populations. Finally, this model also does not explain the gradually increasing duration of REM sleep throughout the night and generally absent REM sleep during daytime naps.

In the model proposed by Luppi's group [42–46] (Figs. 41.7 and 41.8), neurons active during REM sleep are identified in a small area in the dorsolateral pontine tegmentum called the sublaterodorsal (SLD) nucleus in rats (corresponding to the dorsal subcoeruleus nucleus in humans or peri-LC alpha region in cats). At the onset of REM sleep,

there is an activation of REM-on glutamatergic neurons from the SLD. During NREM sleep and wakefulness, these neurons in the SLD would be inhibited (hyperpolarized) by tonic GABAergic input from GABAergic REM-off neurons located in the SLD, deep mesencephalic and pontine reticular nuclei, and ventrolateral periaqueductal gray (vlPAG) as well as monoaminergic REM-off neurons. Ascending dorsal SLD REM-on glutamatergic neurons can cause cortical activation through projections to thalamocortical neurons along with REM-on cholinergic and glutamatergic neurons from the LDT/PPT mesencephalic and pontine reticular nuclei and basal forebrain regions. Descending ventral REM-on glutamatergic SLD neurons would cause muscle atonia through excitatory direct and indirect projections to glycinergic and GABAergic premotor neurons in the magnocellularis and parvocellularis reticular nuclei in the medulla, causing hyperpolarization of the motor neurons. In the Luppi model, therefore, the glutamatergic neurons play a crucial role in REM generation. GABAergic neurons are responsible for inactivation of monoaminergic neurons during REM sleep, and cholinergic neurons do not play a crucial role in activating REM executive neurons in this model. In experimental REM deprivation studies in rats, Luppi's group [42] showed that during REM recovery sleep, C-fos-activated SLD neurons were not cholinergic (i.e., there was no increase of choline acetyltransferase and the enzyme synthesizing acetylcholine) nor were they GABAergic (i.e., glutamate decarboxylase, the enzyme synthesizing GABA, did not increase in the majority of the SLD neurons). Most of the C-fos-labeled neurons localized in the SLD after REM recovery expressed vesicular glutamate transporter 2 (vGLUT 2), a specific marker of glutamatergic neurons. Therefore, SLD neurons triggering REM sleep are glutamatergic. The melanin-concentrating hormone (MCH) neurons in the lateral hypothalamus also participate in promoting REM sleep (see further on).

There are thus certain similarities and differences between these two contemporary models (Lu-Saper and Luppi) which can be summarized as follows: In both these models the pontine SLD neurons play a critical role. In the Luppi model the SLD REM-on neurons are glutamatergic, whereas in the Lu-Saper model GABAergic neurons in both REM-off and REM-on (SLD) regions play a crucial role in REM sleep by activating dorsal (for EEG) and ventral (for muscle atonia) glutamatergic pathways in the SLD. Both these models recognize the importance of glutamatergic system for generating EEG desynchronization and REM muscle atonia. In their initial report Luppi's group suggested both a direct and

an indirect projection from SLD to spinal cord via a relay in the VMM. The latest report [44, 45] from this group, however, suggested that REM muscle atonia is mediated mainly by a relay in the VMM and to a minor extent by a direct projection to spinal cord. Saper's group, on the other hand, initially [41] suggested a direct projection from SLD to spinal cord without a relay in the VMM. In their latest [46] report this group modified their initial suggestion, now saying that REM atonia is mainly due to a direct spinal projection, but VMM may also play a minor role. The two models (Lu-Saper and Luppi) thus seem to be merging in finding a common ground to explain REM muscle atonia.

Luppi's group [44] recently recognized the important role played by the lateral hypothalamus in REM sleep generation (see further on). They hypothesized that the melanin concentrating hormone (MCH)/GABAergic (REM-on) neurons in the lateral hypothalamus constitute a master generator of REM sleep by a direct inhibitory input to vlPAG region and deep mesencephalic (DPMES) reticular nucleus (REM-off GABAergic neurons) controlling onset and maintenance of REM sleep. Earlir Saper's group [47] highlighted also the role played by the diffuse (extended) VLPO neurons of the hypothalamus in REM sleep generation by inhibiting vlPAG regions during REM sleep.

Brooks and Peever [48] initially challenged the glycinergic and GABAergic neurochemical mechanism of REM motor atonia based on microdialysis experimental evidence in rats that REM atonia persists even when glycine and GABA receptors are blocked and after simultaneous application of glutamatergic agonists to the trigeminal motor pool. These authors [49], however, reversed their conclusion and showed that addition of baclofen (a GABA b antagonist) to bicuculline (a GABA a antagonist) and strychnine (a glycine antagonist) during microdialysis restored muscle tone supporting the role of glycinergic and GABAergic neurons in REM motor atonia.

Neuroanatomic Substrates of NREM Sleep

Neurophysiologic studies of sleep really began after astute clinicopathologic observations by von Economo, who examined patients with encephalitis lethargica at the beginning of the twentieth century [50]. It was noted that lesions of encephalitis lethargica, which severely affected the posterior hypothalamic area, were associated with the clinical manifestation of extreme somnolence, whereas morphologic alterations in the anterior hypothalamic region were associated with sleeplessness. These observations led scientists to believe in the existence of the so-called sleep-wake centers [50–53].

Before the middle of the last century, the emphasis of sleep physiologists was on the passive [53–55] theories of sleep. Beginning in the late 1950s, thought shifted toward active sleep theories [3, 5, 56–65]. The passive theory postulates that sleep results from withdrawal of both specific and nonspecific afferent stimuli to the brain stem and the cerebral hemisphere. Proponents of active sleep theories suggest that activity of sleep-promoting neurons or the fibers of these so-called centers determine the onset of sleep. Most likely, proponents of both active and passive theories are partially correct, as far as the physiology and anatomy of sleep are concerned. These conclusions are based on stimulation, ablation, or lesion experiments. Later, these studies were extended to include extracellular and intracellular recordings and pharmacologic injections of chemicals into discrete areas to induce different states of sleep or to inhibit sleep [66].

The passive theory originated with two classic preparations in cats by Bremer [54, 67]: cerveau isolé and encephale isolé. Bremer found that midcollicular transection (cerveau isolé) produced somnolence in the acute stage and that transection at the C1 vertebral level, to disconnect the entire brain from the spinal cord (encephale isolé), caused EEG recordings to fluctuate between wakefulness and sleep. From these experiments, Bremer concluded that in cerveau isolé preparations, all the specific sensory afferent stimuli were withdrawn, and thus, sleep was facilitated, whereas such stimuli maintained the activation of the brain in encephale isolé preparations. These conclusions, however, have been modified since the discovery by Moruzzi and Magoun [55] in 1949 of the existence of nonspecific groups of neurons and fibers in the center of the brain stem called the reticular formation. Moruzzi and Magoun [55] stated that the brain stem ARAS energized the forebrain and that withdrawal of this influence in cerveau isolé preparation resulted in somnolence or coma. The observations of Moruzzi and Magoun [55] that EEG desynchronization results from activation of the midbrain reticular neurons, which directly excite the thalamocortical projections, have been confirmed by more recent intracellular studies [68, 69]. It was thought that wakefulness resulted from activation of the ARAS and diffuses thalamocortical projections [1]. After stimulation of these structures, the EEG shows diffuse desynchronization, whereas lesions in these structures produce EEG synchronization or the EEG NREM sleep pattern. This also supports the suggestion of Steriade et al. [70] that, at the onset of NREM sleep, there is deafferentation of the brain due to blockage of afferent information first at the thalamic level, causing the waking open brain to be converted into a closed brain resulting from thalamocortical inhibition. The reticular nucleus of the thalamus is responsible for the origin of the sleep spindles [1]. Stimulation of this nucleus produces spindle-like activity, whereas destruction of it abolishes the spindles unilaterally and bilateral destruction abolishes the spindles on both sides.

The passive sleep theories were challenged by findings that came in the wake of midpontine pretrigeminal brain stem transection in cats performed by Batini et al. [57, 58]. This preparation is only a few millimeters below the section that produces the cerveau isolé preparation. In contrast to the somnolence produced by the cerveau isolé preparation, the midpontine pretrigeminal section produced persistent EEG and behavioral signs of alertness. These observations imply that structures located in the brain stem regions between these two preparations (cerveau isolé and midpontine pretrigeminal) are responsible for wakefulness. Data demonstrate cholinergic neurons in the PPT nucleus and in the LDT nucleus in the region of the midbrain-pontine junction [1]. These groups of cholinergic neurons have been shown to have thalamic and basal forebrain projections as well as projections toward the medial PRF. These neurons are responsible for activation and for generation of REM sleep in the McCarley–Hobson model [1] (see Chap. 5). The forebrain cholinergic neurons from the basal nucleus of Meynert project to the cerebral hemisphere, particularly to the sensorimotor cortex, and lesions in these neurons disrupt the EEG waves and elicit diffuse slow waves [1]. The finding of cholinergic neurons at the mesopontine junction confirms the conclusions drawn by Batini et al. [57, 58] after midpontine pretrigeminal transections.

The active hypnogenic neurons for NREM sleep are thought to be located in two regions [1]: (1) the region of the nucleus tractus solitarius (NTS) in the medulla and (2) the preoptic area of the hypothalamus and the basal forebrain area (see Chaps. 5 and 8). Recently, another region in the medulla is thought to be promoting slow-wave sleep (SWS) active GABAergic neurons in the medullary parafacial zone (PZ) by releasing synaptic GABA onto parabrachial neurons which then excite basal forebrain by releasing glutamate and modulate cortical EEG [71]. The evidence is based on stimulation, lesion, ablation studies, extracellular and intercellular recordings [1], and expression of c-Fos protein immunoreactivity. The active inhibitory role of the lower brain stem hypnogenic neurons on the upper brain stem ARAS has been clearly demonstrated by Batini et al.'s [57, 58] experiment of midpontine pretrigeminal sectioning. Similarly, electrical [62] stimulation of the preoptic area, which produced EEG synchronization and a behavioral state of sleep, supported the idea of the existence of active hypnogenic neurons in the preoptic area [1]. Nauta's [53] experiments in 1946 that showed insomnia after lesions of the preoptic region also supported the hypothesis of active hypnogenic neurons in the forebrain preoptic area. Experiments by McGinty and Sterman [64] in 1968 confirmed Nauta's observations. More recently, ibotenic lesions in the preoptic region have been found to produce insomnia, and these results support the active hypnogenic role of the preoptic area [1, 72]. In the same experiments, however, injections of muscimol (a GABA agonist) in the posterior hypothalamus transiently recovered sleep, suggesting that the sleep-promoting role of the anterior hypothalamus is dependent on inhibition of posterior hypothalamic histaminergic awakening neurons. It is also notable that in 1934, Dikshit [73] induced sleep by intrahypothalamic injection of acetylcholine, suggesting the presence of a sleep center in the hypothalamus. Contemporary theory suggests that NREM sleep-promoting neurons are found in the VLPO area and the median preoptic nucleus (MnPn) [74] of the anterior hypothalamus as well as in the region of the NTS and the parafacial zone (PZ) in the medulla. VLPO neurons consist of two subgroups—"clustered" and "diffuse" or extended—depending on the distribution pattern [47, 75].

It has recently been shown that MCH neurons (GABAergic) also play an important role in promoting and stabilizing sleep along with VLPO and MnPn of the anterior hypothalamus [47, 74–78]. MCH neurons are intermixed and interconnected with hypocretin (orexin) neurons in lateral hypothalamus and receive inhibitory inputs from arousal neurotransmitter system (e.g., noradrenergic, serotonergic, histaminergic, and cholinergic) [78]. MCH neurons also project widely to other hypothalamic neurons as well as to the limbic system including the amygdala [79]. The hypothalamic preoptic (e.g., VLPO and MnPn) and MCH neurons are sleep-promoting neurons as evidenced by increasing firing of the units on intracellular recordings and increased expression of C-fos immunoreactivity in VLPO and MnPn as well as after optogenetic stimulation of MCH neurons [76, 78]. VLPO neurons are responsible for sleep consolidation and maintenance, whereas MnPn is responsible for sleep onset. Activation of VLPO and MnPn (using GABA and galanine inhibitory neurotransmitters) results in inhibition of the arousal systems in the brain stem (aminergic, serotonergic, and dopaminergic), forebrain (cholinergic), and posterolateral hypothalamus (hypocretinergic and histaminergic). Thus, there is a reciprocal interaction between sleep-promoting and wake-promoting neurons [74, 47]. The beginning and ending of the state may be determined partly by self-inhibition of the respective neurons and dissipation of sleep-promoting factors (e.g., adenosine, the cytokine interleukin-1β or IL-1β and prostaglandin D2 or PGD2). The strong anatomic connection between suprachiasmatic nucleus (SCN) controlling circadian regulation and VLPO-MnPn-MCH neurons responsible for homeostatic regulation suggests an important role for SCN in sleep-wake regulation, but their functional interaction is not clearly determined.

The tightly clustered VLPO neurons project to the tuberomammillary nuclei, inhibiting them and promoting NREM sleep, whereas diffusely distributed (extended) VLPO neurons along with MCH neurons project to and inhibit the aminergic nuclei in the LC and the dorsal raphe

region of the brain stem as well as inhibiting the pontine GABAergic neurons in the ventrolateral periaqueductal gray (VLPaG)/SLD, participating in REM sleep [76, 77, 80]. It is notable that MCH neurons fire maximally during REM sleep and to a lesser extent during NREM sleep [76, 77]. In narcolepsy, loss of hypocretinergic neurons facilitates (disinhibits) MCH neurons, thereby promoting sleepiness and cataplexy.

The contemporary theory for the mechanism of NREM sleep thus suggests a reciprocal interaction between two antagonistic neuron types in the VLPO and MnPn of the anterior hypothalamus and MCH neurons in the lateral hypothalamus and wake-promoting neurons in the tuberomammillary nuclei of the posterior hypothalamus, as well as the LC, dorsal raphe, basal forebrain, and mesopontine tegmentum [1, 22, 47, 74, 75]. Reciprocal interaction between sleep-promoting neurons in the region of the NTS and wake-promoting neurons within the ARAS of the brain stem independent of the reciprocal interaction of the neurons of the forebrain also plays a role in the generation of NREM sleep, as stated earlier. In summary, the active and passive theories of sleep may be viewed as complementary rather than mutually exclusive mechanisms [1]. The role of postulated humoral sleep factors (e.g., prostaglandin D_2, the cytokine interleukin-1β (IL-1β), growth hormone-releasing factor, and muramyl peptides) remains undetermined in the absence of experiments to test their role at the cellular level in critical brain areas. It has been suggested that adenosine, a neuromodulator, may act as a physiologic sleep factor modulating the somnogenic effects of prolonged wakefulness [81]. This has been postulated after experiments in cats have shown that adenosine extracellular concentration in the basal forebrain cholinergic region increased progressively during prolonged spontaneous wakefulness.

Many important unanswered questions remain regarding the mechanism of sleep. Why do VLPO and MnPn neurons fire at sleep onset? What initiates the cascade of disfacilitation in the brain stem wake-promoting neurons? What initiates activation of LDT-PPT neurons during REM? What causes activation of GABAergic pontine SLD neurons at the onset of REM sleep? What activates pontine glutamatergic neurons at REM onset? What causes activation of wake-promoting neurons at sleep offset? And, finally, what maintains NREM-REM cycling? We here provide a speculative summary to answer some of these questions. VLPO, MnPn, and MCH excitation at NREM sleep onset is initiated by progressive accumulation of adenosine (a sleep-promoting factor in the forebrain region accumulated during prolonged wakefulness) and probably also by an excitatory drive from the suprachiasmatic nucleus (SCN) as well as reciprocal inhibition of aminergic and orexin wake-promoting neurons; progressive inhibition of aminergic REM-off and hypocretinergic neurons causes disinhibition of REM-on neurons and initiates REM sleep; a simultaneous cascade of disfacilitation of the brain stem arousal system with decreased environmental afferent stimuli culminates in blockade at thalamic levels. Physiologically, facilitation (or disinhibition) after a certain period (perhaps determined in the case of sleep-wake regulation by the SCN regulatory neurons connected anatomically to sleep-wake neurons) will be followed by inhibition (or disfacilitation), i.e., these sleep-promoting neurons are self-inhibiting, and thus, the cycle will begin again. For additional discussion on the functional anatomy of sleep, the reader is referred to Chaps. 5 and 8.

Marked impairment of the arousal and cognition systems may result in coma or severe sleepiness. The reversibility of this state of awareness differentiates sleep from coma. There are also physiologic and metabolic differences between sleep and coma. Coma is a passive process (loss of function), whereas sleep is an active state resulting from physiologic interactions of various systems in the brain stem and cerebral cortex. Metabolic depression of the cerebral cortex and brain stem characterizes coma and stupor, whereas in sleep oxygen use and metabolic rhythm remain intact. By disrupting the arousal system and stimulating the sleep-promoting neurons, focal neurologic lesions may also cause excessive sleepiness. For example, lesions of the brain stem, thalamus, hypothalamus, and PAG regions may produce excessive sleepiness, stupor, and coma. These lesions may also affect lateral hypothalamic hypocretinergic neurons as well as REM-generating neurons in the pons and cause various REM sleep alterations including symptomatic narcolepsy.

Functional Anatomy of Respiration in Sleep and Wakefulness

The neuroanatomy of respiration, its control, and physiologic changes during sleep in healthy individuals are described in detail in Chap. 11. Briefly, respiration is controlled by the automatic or metabolic and behavioral systems [11–14, 82–86]. The two systems are complemented by a third system known as the *arousal system,* which may also be called the *system for wakefulness stimulus* [86, 87]. These respiratory systems work in concert with the various peripheral and central inputs to maintain acid-base regulation and respiratory homeostasis [9]. The location of the respiratory neurons makes them easily vulnerable to a variety of central and peripheral neurologic disorders, particularly central neurologic disorders involving the brain stem. Many acute and chronic neurologic illnesses may affect central or peripheral respiratory pathways, giving rise to acute respiratory failure in wakefulness and sleep. Some conditions may affect control of breathing only during sleep. Such a condition may cause undesirable, often catastrophic, results, including cardiorespiratory failure and even sudden death.

Sleep-Related Respiratory Dysrhythmia in Neurologic Disorders

Many types of sleep-related respiratory dysrhythmia have been noted in association with neurologic illnesses [87–89] (Fig. 41.9). The most common types are sleep apnea and sleep hypopnea.

Sleep Apnea

Three types of sleep apnea have been noted [87–90]: central, upper airway obstructive, and mixed. Normal individuals may experience a few episodes of sleep apnea, particularly central apnea, at the onset of NREM sleep and during REM sleep. To be of pathologic significance, the sleep apnea

Note unusual type of mixed apnea (initial obstructive apnea for a period of 14 s followed by central apnea for a period of 8 s) during REM sleep

should last at least 10 s and the apnea index (number of apneas per hour of sleep) should be at least 5. In the American Academy of Sleep Medicine (AASM) scoring criteria [89], in addition to duration of 10 s, apnea is scored when the peak amplitude drops by 90 % or more of the baseline, and this amplitude reduction must last for at least 90 % of the event's duration.

Cessation of airflow with no respiratory effort constitutes central apnea. During this period, there is no diaphragmatic and intercostal muscle activity or air exchange through the nose or mouth. Upper airway obstructive sleep apnea (OSA) is manifested by the absence of air exchange through the nose or mouth but persistence of diaphragmatic and intercostal muscle activity.

During mixed apnea, initially airflow ceases, as does respiratory effort (central apnea); this is followed by a period of upper airway OSA. On rare occasions, this pattern may be reversed, resulting in an initial period of OSA followed by central apnea (Fig. 41.10).

Sleep-Related Hypopnea

Sleep-related hypopnea is manifested by decreasing airflow at the mouth and nose and decreased thoracoabdominal movement causing a reduction in tidal volume. Until recently, there was no standard definition of hypopnea; however, in the 2007 AASM scoring criteria [89], the recommended definition for hypopnea is a reduction of nasal pressure signal excursion (or that of the alternative airflow sensor) by 30 % or more of the baseline amplitude lasting for a period of at least 10 s and accompanied by a 3 % or more desaturation from the pre-event baseline or the event is associated with an arousal. Furthermore, at least 90 % of the event's duration must meet the amplitude reduction criteria for hypopnea. An alternative suggestion in the subsequent slight modification (the version 2.1 update) of the same manual is a reduction of the amplitude excursion in the nasal pressure signal (or that of the alternative airflow sensor) by 30 % or more of the baseline lasting for at least 10 s and accompanied by oxygen desaturation of 4 % or more from the pre-event baseline. This amplitude reduction must be present for at least 90 % of the event's duration. An apnea-hypopnea index (AHI; defined as the number of apneas plus hypopneas per hour of sleep) of 5 or less is considered normal. The respiratory disturbance index (RDI), a term often incorrectly used interchangeably with AHI, includes respiratory effort-related arousals in addition to apneas and hypopneas per hour of sleep. Most investigators consider an AHI or RDI of 10 or more to be clinically significant.

Sleep-related apneas and hypopneas in neurologic diseases are secondary sleep apnea syndromes, in contrast to primary OSA syndrome, in which no cause except for some minor deviations of the upper airway anatomic configuration is found to account for the appearance of apnea. The neurologic illness may be aggravated by the secondary sleep apnea because of the adverse effects of sleep-induced hypoxemia and hypercapnia and repeated arousals with sleep fragmentation. In long-standing cases, there may be pulmonary hypertension, congestive cardiac failure, and other manifestations of chronic sleep deprivation.

Paradoxical Breathing

The thorax and abdomen move in opposite directions during paradoxical breathing, indicating increased upper airway resistance. In upper airway resistance syndrome, this may be noted without any change in oronasal airflow; in OSA, however, paradoxical breathing is accompanied by the reduction or absence of oronasal airflow.

Cheyne–Stokes and Cheyne–Stokes Variant Patterns of Breathing

Cheyne–Stokes breathing (CSB) is a special type of central apnea manifested as cyclic changes in breathing with a crescendo-decrescendo sequence separated by central apneas (see Fig. 41.11) [91–94]. The Cheyne–Stokes *variant pattern* of breathing is distinguished by the substitution of hypopneas for apneas [19, 21]. In neurologic disorders, the Cheyne–Stokes type of breathing is mostly noted in bilateral cerebral hemispheric lesions [12, 13] and it worsens during sleep, whereas Cheyne–Stokes variant patterns of breathing may also be noted in brain stem lesions, in addition to bilateral cerebral hemispheric disease. In the AASM scoring manual [89], CSB is scored if there are at least 3 consecutive cycles of cyclical crescendo-decrescendo change in breathing amplitude accompanied by at least one of the following: five or more central apneas and hypopneas per hour of sleep; and a cyclic crescendo-decrescendo change in breathing amplitude and duration of at least 10 consecutive minutes. The cycle length is most commonly in the range of 60 s but must be at least 45 s in duration. The arousals typically occur in the middle of the hyperventilation cycle. This breathing pattern is most prominently seen in NREM sleep, particularly stages 1 and 2 and attenuates or disappears during REM sleep. Besides neurologic lesions, this pattern of periodic breathing is noted in patients with severe congestive cardiac failure and as an adverse effect of opiate intake.

Dysrhythmic Breathing

Dysrhythmic breathing [92, 94] is characterized by nonrhythmic respiration of irregular rate, rhythm, and amplitude during wakefulness with or without O_2 desaturation that becomes worse during sleep. Dysrhythmic breathing may result from an abnormality in the automatic respiratory pattern generator in the brain stem and is commonly seen in multiple system atrophy.

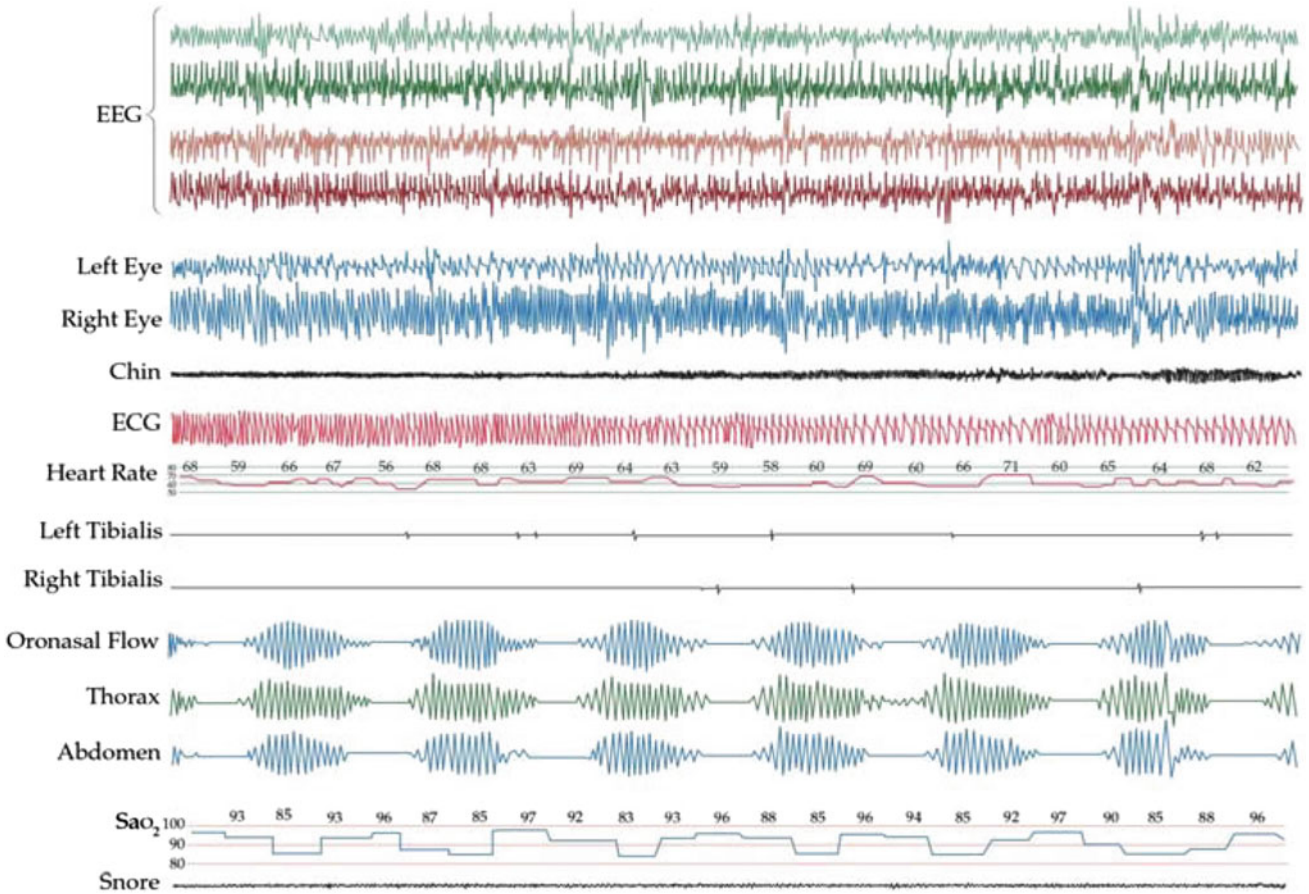

Fig. 41.11 A 500-second excerpt showing the classic Cheyne–Stokes breathing (CSB) crescendo-decrescendo pattern (*arrows*) from an overnight polysomnographic (PSG) recording of a 69-year-old man. The presence of CSB throughout most of the nonrapid eye movement sleep (with marked decrement or absence during rapid eye movement sleep) in this patient with a history of hypertension and excessive daytime sleepiness suggests occult left ventricular failure. ECG electrocardiogram; EEG electroencephalogram; SaO_2 oxygen saturation; Left Eye and Right Eye: Electro-oculograms; Chin: Electromyogram from mental and submental muscles; Left and Right Tibialis: Electromyograms from these muscles; Oronasal Flow: Respiratory flow from thermisters; Thorax and Abdomen: Respiratory effort

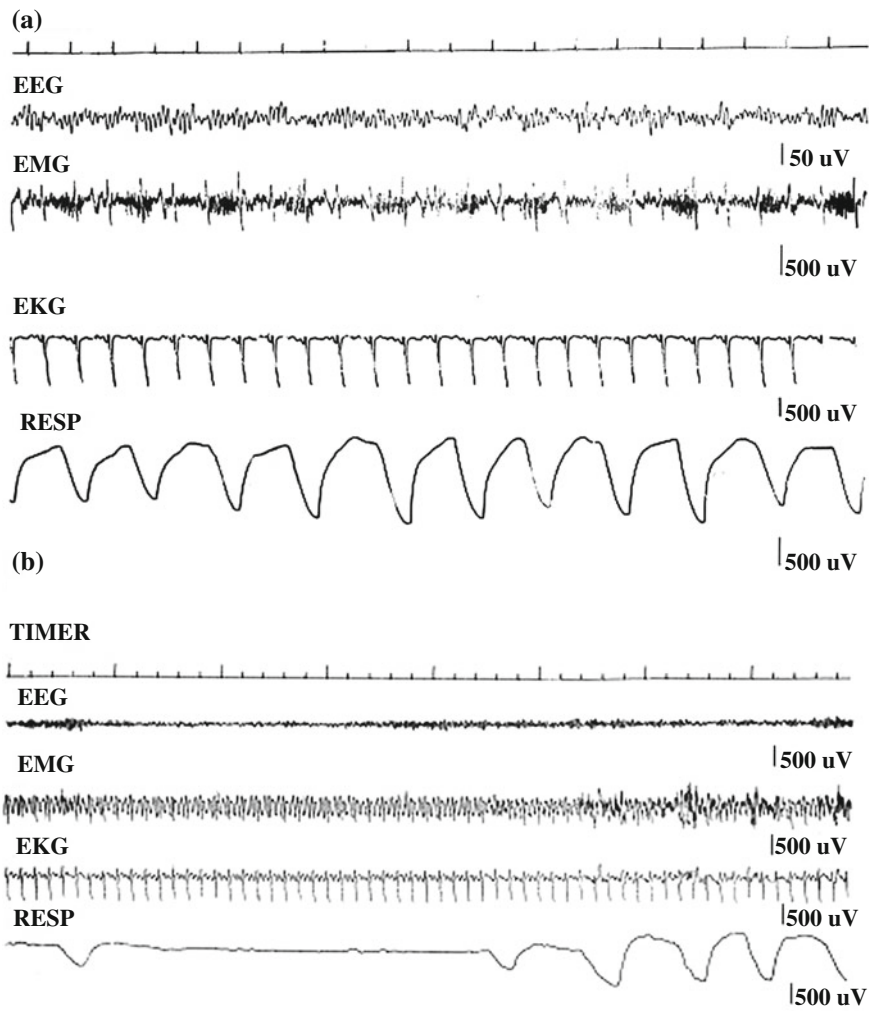

Fig. 41.12 Periodic central apnea in erect posture in a case of Shy–Drager Syndrome. **a** supine posture. **b** erect posture

Apneustic Breathing

Apneustic breathing is characterized by prolonged inspiration with an increase in the ratio of inspiratory to expiratory time [95–97]. This type of breathing may result from a neurologic lesion in the caudal pons that disconnects the so-called apneustic center in the lower pons from the pneumotaxic center (parabrachial and Kölliker–Fuse nuclei) in the upper pons in association with vagotomy [95–97].

Inspiratory Gasp

Inspiratory gasp is characterized by a short inspiration time and a relatively prolonged expiration (reduced inspiratory-expiratory time ratio) [97]. Gasping or irregular breathing has been noted after lesion in the medulla [16, 97].

Ataxic Breathing

This type of breathing is characterized by clusters of cyclic irregular breathing followed by recurrent periods of apnea. The apnea length is greater than the ventilatory phase. Ataxic breathing is often noted in medullary lesions [97] and after opiate ingestion [98].

Biot's Breathing

Biot's breathing is a special type of cluster breathing (ataxic breathing) characterized by two to three breaths of nearly equal volume separated by long periods of apnea [97]. This is really a variant of ataxic or cluster breathing and may be found in patients with medullary lesions.

Other Abnormal Breathing Patterns

The following abnormal breathing patterns have also been noted in neurologic disorders, particularly in patients with Shy–Drager syndrome (multiple system atrophy [MSA]) [87].

- Nocturnal stridor causing severe inspiratory breathing difficulty,

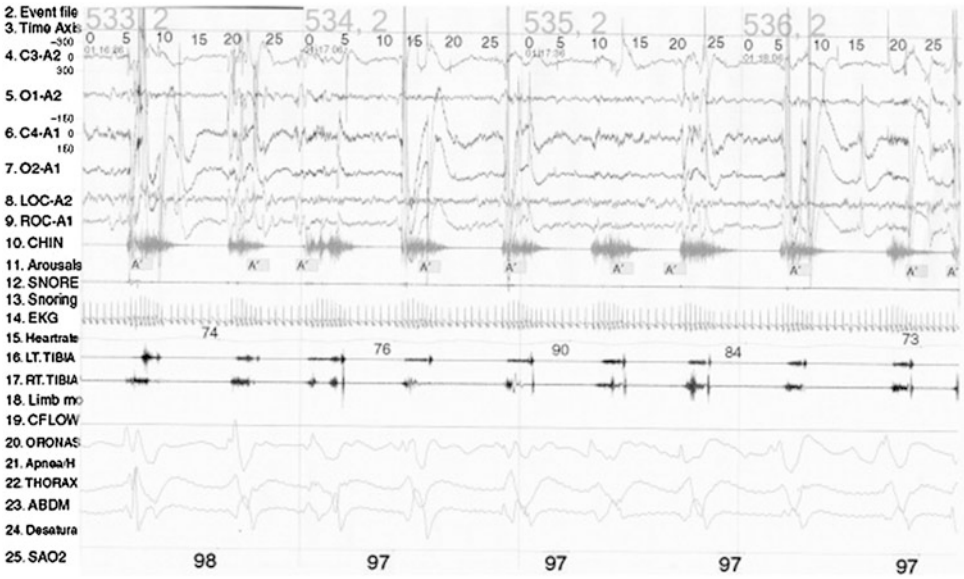

Fig. 41.13 Catathrenia (expiratory groan). A polysomnographic segment of a 120-s epoch showing the electroencephalogram (EEG: C3-A2, O1-A2, C4-A1, O2-A1); left and right eye movements (LOC-A2; ROC-A1); chin, left tibialis (LT.TIBI), and right tibialis (RT. TIBI) electromyograms (EMGs); snoring (SNORE); electrocardiogram (EKG); oronasal airflow (ORONAS); thoracic (THORAX) and abdominal (ABDM) effort channels; and oxygen saturation (SaO_2). Note prolonged expiration in the flow and effort channels followed by arousals without oxygen desaturation in stage 2 NREM sleep. Reproduced with the permission from Siddiqui et al. [100]

- Periodic central apnea in the erect position accompanied by postural fall of blood pressure in Shy–Drager syndrome (Fig. 41.12a and b) [99],
- Prolonged periods of central apnea accompanied by mild O_2 desaturation in relaxed wakefulness, as if the respiratory centers "forgot" to breathe [87, 91, 94],
- Transient occlusion of the upper airway or transient uncoupling of intercostal and diaphragmatic muscle activity [94],
- Transient sudden respiratory arrest,
- Catathrenia (bradypnea and groaning), characterized by prolonged expiration with the characteristic groaning noise. This is seen mostly in REM sleep but has also been noted in NREM sleep. This may be mistaken for a central apnea but is really not an apnea, and there is no oxygen desaturation during the episode [100] (Fig. 41.13). It is included in ICSD-3 under sleep-related breathing disorder section as an isolated symptom and normal variant. The etiology and mechanism are at present unknown.

Sleep-Related Hypoventilation

Finally, sleep-related hypoventilation [101], a type of respiratory dysrhythmia without any apnea or hypopnea, is seen commonly in neuromuscular and intrinsic pulmonary and thoracic restrictive disorders and sometimes in brain stem lesions. Sleep-related hypoventilation is characterized by an increase in the partial pressure of arterial carbon dioxide ($Paco_2$) of 10 mm Hg above the supine awake values during sleep. An abnormal rise in $Paco_2$ immediately on awakening from sleep is suggestive of sleep hypoventilation. Persistent oxygen desaturation is not sufficient to document hypoventilation.

Mechanism of Respiratory Dysrhythmias in Neurologic Disease

Several mechanisms may be responsible for the respiratory abnormalities in sleep associated with neurologic disorders [87, 91].

1 Direct involvement causing structural alterations of the medullary respiratory neurons (automatic or metabolic respiratory controlling system) may result in apnea or hypopnea during NREM and REM sleep. During REM sleep, this problem may be aggravated because of the additional complicating factor of oropharyngeal or other upper airway muscle hypotonia contributing to upper airway OSA.
2 Involvement of the voluntary respiratory control system causes respiratory dysfunction during wakefulness and may give rise to respiratory apraxia.
3 Functional or neurochemical alteration of the respiratory neurons may cause respiratory dysrhythmia.
4 Interference with the afferent inputs to the medullary respiratory neurons (e.g., compromise of the peripheral chemoreceptors located in the vagal and glossopharyngeal nerve endings), supramedullary pathways, and central chemoreceptors in the ventrolateral medulla may cause abnormal breathing.

5 Direct involvement of the efferent mechanism through respiratory muscle weakness may result from either direct involvement of the muscles, as in myopathies, or involvement of the lower motor neurons to the respiratory muscles. In patients with weakness of the principal respiratory and the accessory respiratory muscles, the central respiratory neurons may increase their rate of firing or recruit additional respiratory neurons during wakefulness to maintain ventilation at a level adequate to drive the weak respiratory muscles. Because of the normal vulnerability of the respiratory neurons during sleep, the central respiratory neurons may not be able to participate in such compensatory mechanisms during sleep in patients with respiratory muscle weakness. Ventilatory problems may thus be aggravated, causing more severe hypoventilation and even apnea during sleep. In addition, weakness of the upper airway muscles, which in fact are respiratory muscles and receive phasic inspiratory drive from the respiratory neurons in the brain stem, may cause obstructive apnea.

Sleep and Breathing Disorders Secondary to Somatic Neurologic Illness

Neurologic disorders may affect sleep/wake-generating neurons, causing profound sleep disturbances that may include insomnia, hypersomnia, parasomnia, circadian rhythm disorders, and abnormal movements in sleep at night. An adverse interaction between neurologic illness and sleep dysfunction exists. The sleep disturbances may adversely affect the natural course of the neurologic illness. Sleep dysfunction may result from central or peripheral somatic or autonomic neurologic disorders.

A complaint of insomnia may be related to sleep-onset or maintenance difficulties. Insufficient or fragmented night sleep may result in impaired quality of sleep, fatigue, muscle aches and pains, and poor attention and concentration as well as irritability, anxiety, depression, and impairment of daytime function with daytime somnolence. Most of the neurologic disorders cause hypersomnia, but sometimes insomnia is the predominant complaint [102–109]; an important but rare example, fatal familial insomnia (FFI), is described later in this chapter.

Hypersomnia is generally noted in patients with sleep-related respiratory dysrhythmias. Hypersomnia includes excessive daytime sleepiness (EDS) and irresistible sleep attacks. Associated complaints may include daytime fatigue, lack of concentration, impaired motor skills, morning headaches, and absence of symptom relief from additional sleep. In acute neurologic disorders, the clinical features of neurologic dysfunction may overshadow the sleep and sleep-related respiratory problems [91]. Furthermore, many patients with acute neurologic disorders are actually in stupor or coma. Neurologic lesions may disrupt the sleep architecture, for example, altering the percentage of different sleep stages, increasing awakenings, or causing sleep stage shifts. In addition, sleep apnea (which may occur in various neurologic diseases), intrusion of abnormal movements in sleep, and repeated seizures may disrupt the morphology of sleep and sleep stages. Sleep disturbances may impair memory, cognition, or behavior, or cause cardiopulmonary changes secondary to repeated hypoxemia. These effects, secondary to sleep disturbance, can aggravate the primary neurologic condition. Neurologic causes of hypersomnia have been described in Chap. 3.

The parasomnia (excessive motor activity and abnormal behavior intruding during sleep) most commonly noted in neurologic illnesses is REM sleep behavior disorder (RBD). This is characterized by intense motor activity related to dream-enacting behavior and absence of muscle atonia during REM sleep (see Chaps. 49 and 50). It has been suggested that in the setting of degenerative dementia or parkinsonism, RBD is a manifestation of evolving synucleinopathies (e.g., Parkinson's disease [PD], MSA, and diffuse Lewy body disease [DLBD] with dementia) but is rare in tauopathies (e.g., Alzheimer's disease [AD]) [105, 108]. Patients with RBD generally do not complain of EDS, and the multiple sleep latency test (MSLT) rarely documents increased somnolence. There is potential for injury to self and others in patients with RBD, and therefore, early recognition and treatment are very important. Circadian sleep-wake rhythm disturbances are noted in some neurologic disorders; most prominently, AD may present as a cyclic agitation syndrome [110]. An excessive amount of nocturnal motor activity may be related to the primary neurologic disease (e.g., dystonia in patients with torsion dystonia and nocturnal frontal lobe epilepsy).

Clinical Manifestations

The clinical manifestations of sleep and breathing disorders in chronic neurologic illnesses may be divided into specific and general features [87, 91]. The specific manifestations depend on the nature of the neurologic deficit. The general features that are relevant to the diagnosis of sleep-related hypoventilation and apnea include EDS, fatigue, early morning headache, unexplained pedal edema, disturbed nocturnal sleep, intellectual deterioration, personality changes, and, in men, impotence. Breathlessness is generally not an important feature of CNS disorders except those illnesses that affect the lower motor neurons to the respiratory muscles. The general symptoms of daytime fatigue, somnolence, and morning headache may be related to frequent arousals at night secondary to repeated apnea or hypopnea and carbon dioxide retention [108]. In patients with neurologic disorders, it is very important to recognize alveolar hypoventilation during sleep because assisted ventilation at night improves the symptoms and protects patients from fatal apnea during

sleep. Furthermore, such treatment may prevent the development of serious complications resulting from episodic or prolonged hypoxemia, hypercapnia, and respiratory acidosis in sleep, complications that may include pulmonary hypertension, cor pulmonale, congestive cardiac failure, and occasionally cardiac arrhythmias. Occasionally, neurologic disorders may cause an inversion of the sleep-wake rhythm that is manifested by excessive somnolence during the day and insomnia with agitation during the night [103, 108–110].

To make a clinical diagnosis of sleep disorders or sleep-related breathing disorders (SRBDs), a careful history—from the patient and the caregiver—and a physical examination are essential.

Mechanisms of Sleep Disturbances

Neurologic disorders can be metabolic or structural (e.g., head injury, tumor, infection, toxic-metabolic brain dysfunction, vascular and degenerative CNS disease, headache from any cause, painful peripheral neuropathy, or other neuromuscular disorder). The following are the suggested mechanisms of the sleep disturbances associated with neurologic disorders [87, 91, 105, 108]:

1. Direct involvement of the hypnogenic neurons. Hypofunction of the hypothalamic VLPO neurons or the lower brain stem hypnogenic neurons in the region of the NTS and dysfunction of the thalamus may alter the balance between the waking and the sleeping brain, causing wakefulness or sleeplessness. Similarly, a disorder of the posterior hypothalamic, ARAS, or other brain regions responsible for waking and alertness causes hypersomnolence.
2. Indirect mechanisms associated with the disorder, such as pain, confusional episodes, changes in the sensorimotor system, and movement disorders, can interfere with sleep.
3. Medications used to treat neurologic illnesses (e.g., anticonvulsants, antidepressants, dopamine agonists, anticholinergics, hypnotics, and sedatives) may have a direct effect on sleep and breathing.
4. Neurologic diseases (e.g., hyperkinetic movement disorders and Rett syndrome) may change the neurochemical environment of the sleep-generating and sleep-promoting neurons [107].
5. Comorbid depression or anxiety in neurologic illnesses may disrupt sleep.
6. Certain neurologic disorders may alter circadian rhythm in the suprachiasmatic nuclei (e.g., dementia, PD, and traumatic brain injury), causing insomnia.
7. Finally, neurologic disorders may cause sleep-disordered breathing (e.g., MSA, DLBD, and other neurodegenerative and neuromuscular disorders), resulting in sleep fragmentation and insomnia, and sleep apnea syndrome.

Sleep and Breathing Disturbances in Central Nervous System Disorders

Alzheimer's Disease and Related Dementias

Dementia is characterized by progressive deterioration of memory and cognition (as assessed by mental status and neuropsychologic testing), followed by language dysfunction, hallucinations, other psychotic features, depression, and sleep disturbances. In the advanced stage of the illness, the patient becomes bedridden, mute, and incontinent. Sleep dysfunction with or without abnormal motor activity during sleep is increasingly recognized in patients with irreversible chronic dementing illness. It has been estimated that approximately 10 % of the adult population over the age of 65 years suffer from some kind of dementing illness. The Delphi study in 2005 [111] estimated that there would be 24.3 million people with dementia in the world in 2001, and this was predicted to rise to 81.1 million by 2040. The same panel of experts in a systematic review and metanalysis in 2013 [112] estimated that 35.6 million people lived with dementia worldwide in 2010 with numbers expected to rise to 115.4 million in 2050. However, the Rotterdam study findings published in 2012 [113] provide an optimistic trend that the age-specific dementia incidence has declined between 1990 and 2005 as the population has lived progressively longer, probably as a result of increased use of treatment to minimize vascular risk factors and increased years of education. This observation was reinforced by recent report of robust evidence provided by Satizabal et al. [114] of declining incidence of dementia over three decades in the Framingham Heart Study participants. AD is the most common cause of chronic dementia, accounting for at least 60 % of all cases. Other conditions include DLBD, accounting for at least 15–20 % of the cases; PD with dementia and frontotemporal dementia (FTD) in about 10 %; and corticobasal degeneration (CBD), progressive supranuclear palsy (PSP), multi-infarct or vascular dementia, Huntington's disease (HD), Creutzfeldt–Jakob disease (CJD), and FFI (described later in the chapter), accounting for the rest of the cases.

Dementia can be classified according to location or according to molecular neurobiologic abnormalities (Box 41.1). In terms of location, dementia is classified into cortical dementia, consisting of AD, FTD, and vascular dementia; subcortical dementia, consisting of PD with dementia, PSP, and HD; and mixed cortical-subcortical dementia, including DLBD, CBD, CJD, and FFI. Most of the degenerative dementing illnesses are proteinopathies due to excessive protein misfolding and intracellular protein aggregation [108]. They are mainly classified into tauopathies, synucleinopathies, prion diseases, and polyglutamine disease. Tau proteins belong to the family of microtubule-associated proteins involved in maintaining the cell shape and serve as tracts for axon transport. The main tauopathies include AD, PSP, CBD, argyrophilic grain disease,

Pick's disease, and FTD with parkinsonism associated with chromosome 17. Alpha-synuclein is a presynaptic protein that helps transport dopamine-laden vessels from the cell body to the synaptic cleft. Synucleinopathies are a group of disorders with abnormal deposition of α-synuclein in the cytoplasm of neurons or glial cells and extracellular deposits of amyloid. The main synucleinopathies include PD, DLBD, and MSA, including Shy–Drager syndrome, striatonigral degeneration, and sporadic olivopontocerebellar atrophy.

Box 41.1 Classification of Dementia

According to Location

Cortical dementia

- Alzheimer's disease,
- Frontotemporal dementia,
- Vascular dementia.

Subcortical dementia

- Parkinson's disease,
- Progressive supranuclear palsy,
- Huntington's disease.

Mixed cortical-subcortical dementia

- Diffuse Lewy body disease,
- Corticobasal degeneration,
- Creutzfeldt–Jakob disease,
- Fatal familial insomnia.

According To Molecular Neurobiology

- Tauopathies
- Alzheimer's disease,
- Frontotemporal dementia,
- Progressive supranuclear palsy,
- Corticobasal degeneration.

Synucleinopathies

- Diffuse Lewy body disease,
- Parkinson's disease,
- Multiple system atrophy (Shy–Drager syndrome).

Prion diseases

- Fatal familial insomnia,
- Creutzfeldt–Jakob disease,
- Polyglutamine disorder,
- Huntington's disease.

Types of Sleep Disturbances in Dementia

The major sleep disturbances in dementing illness include insomnia, hypersomnia, circadian sleep-wake rhythm disorders, excessive nocturnal motor activity, "sundowning," and respiratory dysrhythmias. Circadian sleep-wake rhythm disturbances are noted, most prominently in AD, and may present as a cyclic agitation syndrome that is popularly known as sundowning syndrome. Commonly encountered excessive nocturnal motor activity that may occasionally cause sleep disturbance to the patient but very often causes sleep disturbance to the bed partner includes periodic limb movements in sleep (PLMS), which may be noted in many dementing illnesses. Respiratory dysrhythmias and loud snoring (see further on) during sleep occur in some of these conditions, particularly in AD, PD, and DLBD.

Sleep Dysfunction in Alzheimer's Disease

Diagnostic criteria for AD

AD or Alzheimer's dementia is characterized by progressive intellectual deterioration occurring in middle or later life associated with characteristic neuropathologic findings, including cerebral cortical atrophy and neuronal loss in the nucleus basalis of Meynert. There are also alterations in the forebrain cholinergic and noradrenergic systems [109]. Sleep disturbances in AD may be related partly to the severity of the loss of the cholinergic neurons in the basal forebrain regions, as well as to changes in the brain stem aminergic systems. Since the introduction of the criteria for clinical diagnosis of AD developed by the National Institute of Neurological and Communicative Disorders and Stroke–Alzheimer's Disease and Related Diseases Association (NINCDS-ADRDA) work group in 1984 [115], there have been significant advances in the development of reliable biomarkers for AD based on structural magnetic resonance imaging (MRI), molecular neuroimaging with positron-emission tomography (PET), and cerebrospinal fluid (CSF) analysis. Based on these advances, in 2011 the National Institute on Aging and the Alzheimer's Association (NIA-AA) revised the criteria for diagnosing AD (Table 41.1) [116–119]. In the revised criteria, the terminology was changed to Alzheimer's dementia rather than Alzheimer's disease. A diagnosis of dementia requires deficits in two of the following five features: episodic memory, executive function, visuospatial performance, language, and personality/behavior including activities of daily living (ADL) [117–119]. The new diagnostic criteria recognize that AD exists along a continuum and include three categories: preclinical (stages 1, 2, 3), mild cognitive impairment (MCI) due to AD, and AD dementia (probable, possible, unlikely). The biomarkers in the revised criteria include markers for amyloid (e.g., cerebrospinal fluid [CSF], low amyloid-β [A β 42], and abnormal amyloid PET imaging) and neuronal injury (e.g., increased levels of CSF tau protein and

Table 41.1 The NIA-AA revised criteria for the clinical diagnosis of Alzheimer's disease (AD) spectrum (modified from Refs. [120–122])

Category	Subcategory	Symptoms/Signs	Biomarkers
Preclinical	Stage 1	Asymptomatic	Amyloid beta (Aβ) (CSF or PET scan)
	Stage 2	Asymptomatic	Aβ + neuronal injury
	Stage 3	Asymptomatic	Aβ + neuronal injury
Mild cognitive impairment	Intermediate likelihood of conversion to AD	Impaired episodic memory	Aβ + neuronal injury
	High likelihood	Other cognitive impairment	Aβ + neuronal injury
	Unlikely	Mild functional impairment	Biomarker negative
AD dementia	Probable	Amnestic; impaired learning	Aβ + neuronal injury
		Nonamnestic executive dysfunction	Aβ + neuronal injury
	Possible	Meets clinical criteria for dementia	Aβ + neuronal injury
	Unlikely due to AD	Meets clinical criteria for typical or atypical AD dementia	Biomarkers negative

hippocampal atrophy on structural magnetic resonance imaging [MRI] or bilateral parietal hypometabolism on PET scan). The NIA-AA criteria incorporated many of the criteria proposed by the International Work Group (IWG) initially devised in 2007 and later revised in 2010 (Box 41.2) [116–119]. The IWG criteria recognize four diagnostic groups [119]: asymptomatic AD at risk stage showing positive biomarkers; preclinical early-onset AD with an autosomal dominant mutation (about 5 % of familial AD cases); prodromal AD with episodic memory loss and presence of a biomarker for AD; and AD dementia with impaired ADL (Table 41.1). In addition, diagnostic criteria have been established for non-AD dementias (e.g., FTD, DLBD with dementia, CBD, and vascular dementia). Many of these entities may fulfill the original NINCDS-ADRDA criteria, but the diagnostic accuracy of the original criteria ranges from 65 % to 96 %, and the specificity ranges from 23 % to 88 %. The new diagnostic criteria, however, need validation studies to optimize their sensitivity and specificity. Furthermore, current biomarkers have limitations (e.g., invasive or expensive). Recently, a group of investigators predicted phenoconversion of some elderly healthy individuals to mild cognitive impairment (MCI) or AD based on lower plasma levels of a set of plasma phospholipids [120]. Confirmation and replication of these findings will simplify preclinical diagnosis of AD and will stimulate research to prevent or halt the progression of the disease.

Box 41.2 International Work Group (IWG) Criteria for the Clinical Diagnosis of Alzheimer's Disease (AD)

Adapted from Dubois et al. [116].

Probable AD Criteria

Category A and one or more supportive features in B, C, D, or E

Core Diagnostic Criteria

(A) Presence of an early and significant episodic memory impairment with gradual and progressive alteration in memory function over the previous 6 months or more associated with the objective evidence of impaired episodic memory.

Supportive Features

(B) Presence of medial temporal lobe atrophy on MRI.
(C) Abnormal cerebrospinal fluid biomarker with low amyloid-β (1-42) concentrations with increased tau concentrations.
(D) Specific pattern on functional neuroimaging with PET showing reduced glucose metabolism in temporal parietal regions bilaterally.
(E) Proven AD autosomal dominant mutation within the immediate family.

Sleep dysfunction in AD

Sleep dysfunction in AD may occur even in the early stage but is more common and severe in advanced stages. In addition to sundowning, these patients often sleep early in the evening, waking up frequently and staying awake most of the night. Their sleep is fragmented and fractionated throughout a 24-h period. The patients remain somnolent most of the time and bedridden in the advanced stages of the illness.

Sleep dysfunction in AD is very common and includes insomnia and sleep apnea syndrome with sleep fragmentation, hypersomnia related to intrinsic disease process, comorbid medical or psychiatric disorders or ingestion of medications, circadian rhythm sleep disorders including inversion of sleep rhythm and "sun downing," excessive

nocturnal motor activity including occasional REM behavior disorder (Box 41.3).

Box 41.3 Summary of Sleep Dysfunction in Alzheimer's Disease

- May occur in the early stage,
- More common and severe in advanced stages,
- Sleep onset in the early evening; waking up frequently or staying awake most of the night,
- Sleep architectural changes, including decreased sleep efficiency, reduced slow-wave sleep with eventual disappearance as the disease advances, increased awakenings after sleep onset, and reduced REM sleep in later stages,
- "Sundowning,"
- Fragmented and fractionated sleep throughout the 24-hour period with increased daytime napping,
- Sleep apnea: 33–53 %; more with *APOE4* allele, possibly also with MAO-A 4 repeat allele,
- Visual hallucinations with nocturnal agitations.
- In advanced stage, somnolent most of the time.

Sleep disorders in AD may increase cognitive and behavioral dysfunction. Such sleep disorders may arise directly from the disease itself, as a consequence of the degeneration of the brain stem and other centers that regulate sleep [31, 109], or indirectly from changes in sleep associated with aging (see Chap. 51) and comorbid conditions or medications (see Chap. 47). Sleep disorders can have a number of undesirable consequences, including increasing cardiovascular and even cerebrovascular morbidity as well as impairing daytime alertness and functioning [91, 105, 108].

A number of studies have examined the differences between demented patients and normal elderly individuals and have demonstrated higher prevalence of sleep apnea and poorer sleep quality when patients are compared to age-matched controls [121–131]. Although the results vary somewhat from study to study, these investigations have shown deterioration of sleep parameters, including reduced total length of sleep, decreased REM and slow-wave sleep, loss of phasic components (spindles and K complexes) of NREM sleep, and sleep-wake rhythm disturbances, in demented patients. Montplaisir et al. [128] documented EEG slowing during both wakefulness and REM sleep in AD patients. The authors suggested that degeneration of the nucleus basalis of Meynert, which is the main source of cholinergic input to the cerebral cortex, may be responsible for EEG slowing and REM sleep changes. This pattern of disorder is different from that of depressed elderly patients, who most clearly show poor sleep maintenance, often with increased REM sleep [128]. Most of the studies, however, have not used current diagnostic criteria for dementia and have lumped together patients with different forms of it. When more accurate diagnostic groupings were made, similar results were found for AD patients, usually defined by clinical course. Some studies have shown a clear association between greater sleep disturbance and impaired mental functioning or severity of dementia [132–136].

Some of the inconsistencies noted in the sleep architecture in AD patients may be related to the fact that in many studies, mild, moderate, and severe AD patients were grouped together and not necessarily analyzed separately. Another point to remember is that it is often difficult to separate the effects of the disease on sleep from the effects of medication, PLMS or sleep apneas, which are common in elderly patients. Additionally, sleep architectural alterations noted during overnight laboratory sleep studies may be partly environmentally determined, as AD patients may become confused, displaying features of sundowning, in the artificial and foreign environment of the laboratory.

Vitiello et al. [133, 134] and others [123, 124, 135–138] reported sleep disturbances in AD associated with a decrease in slow-wave sleep and an increase in nighttime awakenings. In a study of 45 control subjects and 44 mild AD patients, Vitiello's group [139] confirmed their previous findings of disturbed sleep-wake patterns in AD patients, but the phenomenon of sleep disturbances was not diagnostically useful for discriminating between those with a mild stage of AD and control subjects.

A meta-analysis by Benca et al. [132] clearly showed significant sleep disturbances in dementia. Reduced sleep efficiency, increased stage 1 NREM sleep, and increased number of awakenings are some of the prominent findings noted in the various studies [127, 128, 131–144]. In some studies, there is a relationship between the severity of sleep disturbance and the severity of dementia [139]. Contradictory findings have been noted regarding decrement of slow-wave sleep. Reduction of sleep spindles is noted by Prinz et al. [135] as well as by Montplaisir et al. [145]. REM sleep abnormalities have given inconsistent results (decreased in some studies [131, 139] but not in others [142]), and this discrepancy may have been related to the degree of severity of dementia. It should be kept in mind that more severe sleep disturbances have been noted in depression than in dementia, and sometimes differentiating these two conditions, particularly in the early stage of AD, may be difficult. Other sleep architectural changes in AD include sleep-wake cycle [145] and sleep rhythm [146, 147] and disturbances and alterations in physiologic delta waves [148]. These sleep quality changes may cause EDS [148, 149].

Sleep may be disturbed early in the disease process, and sleep disturbances are noted even in the presence of mild cognitive impairment [139, 150–153]. It has been recently shown that sleep loss may even precede AD symptoms by

many years similar to CSF biomarkers [154–156]. It has been suggested that sleep disturbances and cognitive dysfunction are positively correlated in AD—that is, sleep disturbances increase with severity of disease process [157]. Disruption in sleep-wake patterns, circadian rhythmicity, increased amount and frequency of nighttime wakefulness, and reduction of slow-wave sleep occur at the early stages of AD and worsen with disease progression. In later stages of AD, there is a reduction of REM sleep, increased REM latency, and alteration of the circadian rhythm resulting in daytime sleepiness. The daytime sleep, however, consists essentially of NREM stages 1 and 2 and does not compensate effectively for the loss of slow-wave sleep and REM sleep. Thus, daytime napping and somnolence increase as the disease progresses.

The phenomenon of sundowning is noted in many AD patients, contributing to sleep disturbance. Sundowning can be described as cyclic nocturnal agitation syndrome [110, 151–153] with inversion of sleep schedule (wakefulness at night and somnolence in the daytime). It is a predictor of faster cognitive decline [157], is most likely related to the severity of dementia, and remains a common cause of institutionalization in AD patients. Factors such as going to bed early, increased use of sedatives, advanced cognitive impairment, associated medical conditions, and circadian rhythm disturbances may all contribute to sundowning. Circadian rhythm disturbances are frequently seen and pronounced in AD [110, 152, 153, 158–163]. It has been suggested that an alteration in the biologic clock in the SCN and the pineal gland is considered to be the biologic basis for the circadian rhythm disturbances in AD. Wu and Swaab [158] found disruption of pineal melatonin secretion and pineal clock gene oscillations in AD patients. They noted even in the earliest AD stage a functional disruption of the SCN as manifested by decreased vasopressin RNA, a clock-controlled major output of the SCN. The functional disconnection between the SCN and the pineal gland noted in the earliest stage of AD seems to account for the pineal clock gene and melatonin changes accounting for the circadian rhythm disturbances in AD. They also noted decreased melatonin MT_1 receptor in the SCN in late-stage AD patients and therefore suggested that in the advanced stages of AD, supplementary treatment with melatonin may not improve the circadian rhythm disturbances. Wu and Swaab [159] previously suggested that circadian disorders, such as sleep-wake cycle disturbances, associated with aging and advanced stages of AD causing disruptive melatonin production and rhythms may result from presumed degeneration of the retina-SCN-pineal axis. They further suggested that reactivation of the circadian system (retina-SCN-pineal pathway) by the use of light therapy and melatonin supplementation to restore the circadian rhythm and relieve clinical circadian disturbances has shown promising results.

However, there are contradictory reports [160, 161]. Dowling et al. [160] tested the effectiveness of time to bright-light therapy given in the morning and early afternoon in 70 institutionalized patients with AD and controls. They did not find any significant differences in actigraphy-based measures of nighttime sleep or daytime wakefulness between the groups. They therefore concluded that one hour of bright-light treatment in patients with AD in the morning or early afternoon did not improve nighttime sleep or daytime wakefulness compared to the control group. In another study, Dowling et al. [161] tested the effect of morning bright-light therapy in 46 AD subjects fulfilling the NINCDS-ADRDA criteria in two nursing home facilities in California. They gave one hour of bright-light exposure (≥2500 lx) to the experimental group and gave usual indoor light (150–200 lx) to the control group. By means of actigraphy, they assessed nighttime sleep efficiency, total sleep time, and number of awakenings. They also determined circadian rhythm parameters from the actigraphy data using core cosinor analysis and nonparametric techniques. They concluded that morning bright-light exposure did not induce an overall improvement in measures of sleep or rest activity in all treated patients compared to control subjects. However, they found that only subjects with the most impaired rest activity rhythm responded significantly and positively to a bright (one hour) light therapy. However, in a more recent study using randomized controlled trial, McCurry et al. [164] found that walking, light exposure, and combination are effective in improving sleep in community-dwelling AD patients. Singer et al. [162] conducted a multicenter, placebo-controlled trial of melatonin for sleep disturbance in 157 individuals with AD recruited by 36 AD centers. They measured nocturnal total sleep time, sleep efficiency, wake time after sleep onset, and day-night sleep ratio during a 2- to 3-week baseline and 2 months of treatment with melatonin. The sleep measures were obtained from the actigraphic data. They did not find any statistically significant differences in objective sleep measures between baseline and treatment for any of the group. Therefore, they concluded that melatonin is not an effective agent for treating sleep disturbances in patients with AD. This observation by Singer et al. [162] agrees with more recent conclusion based on a review of randomized controlled trials by McClury et al. [165] that there is no evidence of benefit from melatonin treatment in AD patients. The results of these studies, therefore, contradict the earlier findings of Mishima et al. [163] of altered melatonin secretion rhythms in patients with AD having disturbed sleep-wake patterns.

Sleep apnea has been observed in approximately 33–53 % of demented patients with probable AD [131, 133, 152, 153, 166–173] (Fig. 41.14). Although sleep apnea may be associated with disease severity, no longitudinal studies have been conducted to determine whether sleep apnea increases the severity of disease in individual patients and whether sleep apnea may be associated with more rapid progression of the disease. Such a deleterious effect of sleep apnea is to be expected, as it is thought to increase the intellectual deficit of demented patients [128, 129]. Because

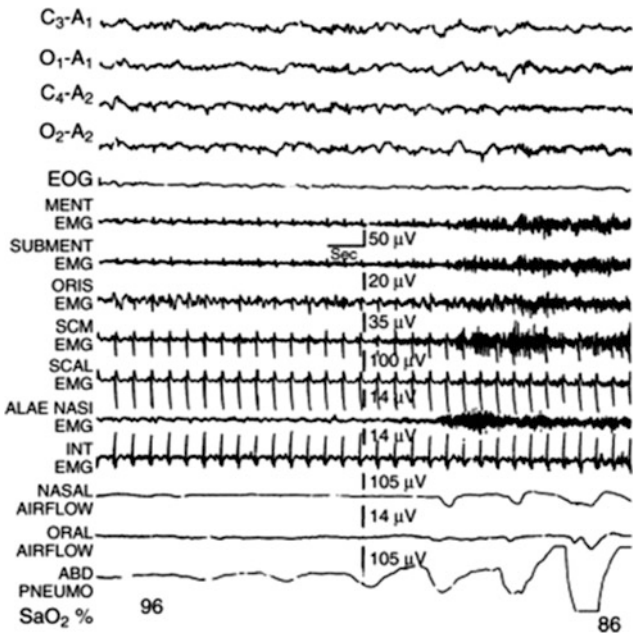

Fig. 41.14 Polysomnographic recording of a patient in an advanced stage of Alzheimer's disease shows a portion of mixed apnea during stage 2 NREM sleep accompanied by oxygen desaturation. Top four channels represent the electroencephalogram (EEG) (Key: international electrode placement system). Electromyograms (EMG) of mentalis (MENT), submental (SUBMENT), orbicularis (ORIS), sternocleidomastoid (SCM), scalenus anticus (SCAL), alae nasi, and intercostal (INT) muscles are shown. Also shown are nasal and oral airflow, abdominal pneumogram (ABD PNEUMO), and oxygen saturation ($SaO_{2\ \%}$). (EOG = electrooculogram.) Reproduced with the permission from Chokroverty [91]

sleep apnea may be treated by a number of modalities, it is possible that therapy may improve behavior and cognitive function. According to Smallwood et al. [131], the incidence of sleep apnea in male AD patients is similar to that in healthy elderly subjects. Reynolds et al. [167] reported a higher prevalence of sleep apnea in female AD patients during the later stage of the illness than in controls. These findings have been confirmed by Mant et al. [168]. The prevalence of sleep apnea is found to vary (70–80 % having an apnea-hypopnea index [AHI] of 5 or more and 38–48 % with an AHI of 20 or more in institutionalized demented patients) [174, 175]. However, in mild-to-moderate AD, the prevalence with AHI of 10 or more is up to 53 % of patients [176]. Bliwise [169] pointed out the high prevalence of comorbid cardiovascular, cerebrovascular, and pulmonary disease in the elderly population in the nursing home and outpatient memory clinics. These disorders may have played a causal role for sleep apnea and dementia. A key genotypic marker of AD is the apolipoprotein E4 (*APOE4*) allele. In recent years, the demonstration of an association between *APOE4*-genotype AD and sleep apnea has kindled interest in the possible association between sleep apnea and AD [169–173]. Gehrman et al. [172] suggested sleep apnea or sleep-disordered breathing (SDB) may be related to agitation in AD. These authors recorded sleep for one night and measured agitation with behavioral observations and ratings by nursing staff in 38 patients (29 women, 9 men) in a nursing home population. They found that SDB was very prevalent in this sample and was related to some types of agitation during the day but not in the evening and night. They further suggested that treatment of SDB may decrease agitation in these patients. In a later study by this group [173] utilizing 66 patients with mild-to-moderate AD in a home polysomnographic (PSG) study, the authors observed that the patients with SDB spent less time in REM sleep than those with no SDB, but they did not find any differences in other sleep stages. They concluded that decreased REM sleep may be due to the presence of SDB in AD. They further speculated that treating these patients' SDB may increase their amount of REM sleep, which may result in improved daytime functioning. Chong et al. [177] randomly assigned 39 community-dwelling elderly patients with mild-to-moderate probable AD with SDB to receive 6 weeks of therapy with continuous positive airway pressure (CPAP) titration or 3 weeks of sham CPAP followed by 3 weeks of therapeutic CPAP. They measured Epworth Sleepiness Scale (ESS) scores at baseline, 3 weeks, and 6 weeks to measure the changes in daytime sleepiness. Their results of reduction of ESS scores after therapeutic but not sham CPAP treatment supported the effectiveness of CPAP in reducing subjective daytime sleepiness in AD patients with SDB. Does CPAP slow cognitive decline in patients with comorbid Alzheimer diseases and sleep apnea? Preliminary studies support improvement or slowing of the progression of cognitive impairment as well as quality of sleep and architecture in AD patients [176, 178–181] although there are limitations [176, 182].

Ancoli-Israel et al. [176] studied 52 men and women with mild-to-moderate AD and OSA who were randomized to either therapeutic CPAP for six weeks or placebo CPAP for three weeks followed by therapeutic CPAP for three weeks in a double-blind placebo-controlled trial. The neuropsychologic test battery showed improvement in some of the cognitive functioning. The same group in a subsequent exploratory study [180] involving 10 patients with mild-to-moderate AD (five patients using CPAP for a mean of 13.3 months and five patients who discontinued CPAP use after the initial six-week randomized clinical trial of CPAP) showed less cognitive decline (based on a neuropsychologic test battery and sleep/mood questionnaires) in the group with sustained CPAP use. Recently, Troussiere et al. [181] in a single-blind, proof-of-concept trial involving 23 patients with mild-to-moderate AD and severe sleep apnea showed that those on CPAP (14 patients) had significantly slower decline in cognitive function over a three-year follow-up period. All these preliminary studies are encouraging but because of many limitations [176, 178, 182] (e.g., small sample size, too short a period of treatment exposure, selection bias, self-reported CPAP use, and failure

to adequately consider comorbid medical disorders), there is a need for a prospective randomized controlled trial including larger number of patients and a longer follow-up period.

Pseudodementia in elderly depressed patients presents a frequent diagnostic dilemma in differentiating depression from dementia of the Alzheimer's type. It has been noted that depressed elderly patients have shortened REM latency and increased REM density; in contrast, AD patients tend to have greater reduction in the amount of REM sleep and lower REM density [183, 184]. These findings, however, are not useful as a predictive indicator on a case-to-case basis.

Hallucinations may occur in AD patients but are noted much less frequently than in DLBD (see later). Sinforiania et al. [185] administered a sleep questionnaire in the presence of a caregiver to 280 patients in order to evaluate the relationship between hallucinations and sleep-wake cycle in patients with early-to-moderate AD. They noted hallucinations, mainly visual, in 12 % of the sample, and 69 % of the hallucinations occurred when the patient was awake. Vivid dreams were reported in 11 %, and violent sleep-related and dream-related behaviors (probable RBD episodes) were noted in 10 % of the subjects. The authors concluded that the higher occurrence of vivid dreams and RBD in AD patients with hallucinations compared with those without hallucinations indicates a potential role of disordered REM sleep in the occurrence of hallucinations in AD. It should be noted that in most of the reports, RBD has not been seen frequently in tauopathies such as AD. Although RBD is rare, REM sleep without atonia may be noted relatively frequently in patients with probable AD [186]. EDS is very common in AD, and in order to assess daytime sleep propensity in a cohort of patients with mild-to-moderate AD, Bonanni et al. [187] studied 20 drug-free AD patients meeting the NINCDS-ADRDA criteria for probable AD and a group of 12 healthy subjects free of dementia as controls. They used multiple sleep latency tests and overnight PSG recordings to evaluate daytime sleepiness. Their findings of significantly reduced daytime sleep latencies indicated an increased sleep propensity during the daytime in patients with mild-to-moderate AD. Park et al. [149] observed that AD patients with excessive daytime napping had more parkinsonian motor signs, suggesting that this subgroup may have an increased propensity for sleepiness resembling PD. The authors cautioned that longitudinal studies with objective measures are needed to determine whether a causal relationship exists between sleepiness and parkinsonism in AD.

The pathogenesis of sleep disturbances in AD is multifactorial, resulting from possible degeneration of neurons regulating sleep-wake cycles, SDB, and disruptive chronobiology. However, no longitudinal studies are currently available correlating sleep apnea with the severity or progression of the disease. Suprachiasmatic nuclei regulating circadian rhythm show degenerative loss of neurons in AD, which may explain inversion of rhythm in many patients. Other factors include normal age-related physiologic changes in sleep, medication effects, increased prevalence of PLMS causing arousal and sleep fragmentation in the elderly AD patients, comorbid RLS, environmental factors (e.g., artificial environment of the institution, laboratory, and nursing homes), and comorbid medical disorders (e.g., congestive cardiac failure, chronic obstructive pulmonary disease, pain from arthritis, nocturia, gastroesophageal reflux disease) or depression. Finally, there may be a genetically increased risk of sleep disruption in AD. Craig et al. [188] surveyed 426 AD patients diagnosed according to standard criteria and performed genotyping of APOE. They found that increased susceptibility to sleep disturbance is associated with genetic variation at the enzyme monoamine oxidase A.

In summary, it is known that sleep dysfunction is common in AD. It is unclear, however, whether a specific set of sleep abnormalities will be found to be associated with AD that are different from those observed in other dementias. Reynolds et al. [124] suggested that sleep dysfunction in AD may be related to the progression of the disease and may cause ongoing deterioration of the alertness, orientation, and cognitive function. Box 41.3 summarizes the sleep dysfunction in AD.

Dementia with Diffuse Lewy Body Disease

DLBD is a neurodegenerative disease characterized by onset of dementia (impaired executive function) within 12 months of onset of motor symptoms of parkinsonism such as akinesia or bradykinesia, postural instability, and rigidity without the characteristic parkinsonian tremor, associated with visuospatial dysfunction, recurrent visual hallucinations, fluctuating cognitive function, and hypersensitivity to neuroleptics. The clinical features of DLBD may be divided into three groups: core, suggestive, and additional features [189]. A recent international consortium on DLBD has resulted in revised criteria [190] for the clinical and pathologic diagnosis, incorporating new information about the core clinical features and improved measures for their assessment. The core features are typically cortical and subcortical cognitive impairment with worse visuospatial and executive dysfunction than AD [189]. In the early stage, the memory dysfunction may be relatively spared. Other core features include recurrent visual hallucinations, parkinsonism, and fluctuating attention. Suggestive features consist of RBD, severe neuroleptic sensitivity, and low dopamine transporter uptake in the basal ganglia on functional neuroimaging. Additional features supporting the diagnosis but occurring less commonly include repeated falls and syncope, transient loss of consciousness, severe

autonomic dysfunction, systematized delusions, olfactory and tactile hallucinations, depression, neuroimaging finding of relative preservation of medial temporal lobe structures, reduced occipital activity in functional neuroimaging, EEG slowing, and myocardial scintigraphy showing low uptake [189]. The pathologic criteria include the presence of Lewy bodies in limbic, paralimbic, and neocortical regions in addition to the midbrain substantia nigra, LC, and raphe nuclei. Senile plaques are present in the majority of individuals with DLBD, although neurofibrillary tangles are typically absent.

Studies inquiring about sleep disturbance in DLBD are few given its clinical overlap with AD and PD. Sleep disturbances in DLBD are very common and more prominent than in AD patients. The significant sleep disturbances in DLBD consist of insomnia, daytime hypersomnolence, RBD, sleep apnea, and nocturnal visual hallucinations. Presti et al. [191] in a recent postmortem examination of brains from DLBD patients observed that medullary respiratory neurons involved in respiratory rhythmogenesis and chemosensitivity are affected (decreased neuronal densities by immunocytochemical staining) in DLBD patients accounting for SDB [108, 191] including central apnea and sudden death during sleep and decreased ventilatory response [192] in these patients. Grace et al. [193] made a comparative study of sleep profiles in patients with DLBD and AD. They reported more overall sleep disturbances, more movement disorders in sleep, and more abnormal daytime sleepiness in DLBD patients in comparison with AD patients. RBD is very common in DLBD (present in 50–80 % of DLBD patients) and sometimes may be the initial presentation without other core diagnostic features [194–199]. Boeve and colleagues in a series of studies [40, 200–203] suggested that RBD is a manifestation of an underlying α-synucleinopathy (e.g., PD, DLBD, and MSA) and may be a forerunner or precursor of the disease. Neuropathologic studies by Uchiyama et al. [204] and Boeve et al. [197–203] supported the conclusion that idiopathic RBD may be a preclinical sign of DLBD. Disturbance of the circadian rhythm has been noted and is a potential factor underlying the nocturnal sleep fragmentation and daytime sleepiness in many AD and DLBD patients. Harper et al. [205] studied circadian variation of core body temperature and motor activity in a total of 32 institutionalized patients with probable AD by NINCDS-ADRDA criteria, nine of whom also met pathologic criteria for DLBD and in eight elderly male controls. They noted that patients with a postmortem diagnosis of DLBD manifested greater disturbances of locomotor activity circadian rhythms than patients with AD, which may reflect the greater sleep disturbances seen in this population. Bauman et al. [206] reported EDS with normal CSF hypocretin in 10 DLBD patients.

Sleep Disturbances in Frontotemporal Dementia

FTD is a type of cortical dementia and a tauopathy resembling AD, but there are many features differentiating these two entities. Sleep disturbances are noted in many FTD patients but have not been adequately characterized. The clinical features of FTD include core and supportive features [207]. Core features include insidious onset and progression, early loss of insight, social decline, personal conduct, and emotional blunting with relative preservation of perception, praxis, and memory. Supportive features include perseveration, hyperorality, impersistence, mental inflexibility, decline in personal hygiene, and altered speech and language dysfunction such as echolalia, mutism, reduced speech output, and lack of spontaneity in speech. Physical findings may include akinesia, rigidity, and appearance of primitive reflexes. Laboratory tests may include normal EEG, and neuropsychologic tests show frontal lobe impairment. Computed tomography (CT) and MRI of the brain may show frontal or temporal lobe atrophy.

In a retrospective review of the clinical records, Seeley et al. [208] studied the natural history of the temporal variant of FTD and divided FTD into three stages according to the progression of symptoms. Stage 1 is characterized by either semantic loss characterized by anomia with word-finding difficulties and repetitive speech or an early behavioral syndrome characterized by emotional distance, irritability, and disruption of sleep, appetite, and libido. In stage 2, appearing on an average after 3 years, patients have both semantic and behavioral syndromes. In stage 3, generally 5–7 years after onset, in addition to the above features, patients now have disinhibition, compulsions, impaired face recognition, altered food preference, and weight gain. The authors concluded that the temporal variant of FTD follows a characteristic cognitive and behavioral progression, suggesting early spread from one anterior temporal lobe to the other, and the latest symptoms implicate ventromedial frontal, insular, and inferoposterior temporal regions. However, they caution that precise anatomic correlates need to be confirmed. Liu et al. [209] compared the behavioral features in the frontal and temporal variants of FTD and performed volumetric measurements of the frontal, anterior temporal, and ventromedial frontal cortex and the amygdala in 51 patients with FTD and 20 normal controls as well as 22 patients with AD serving as dementia controls. They found that the group with the frontal variant of FTD showed more anxiety, apathy, and eating disorders, and the group with the temporal variant of FTD showed a higher prevalence of sleep disturbances, than patients with AD. The behavior between the two variants may be differentiated: There is greater apathy in the frontal variant and more sleep disturbances in the temporal variant of FTD. In 13 patients with FTD, actigraphic data suggested possible phase delay [210].

Some patients with FTD may have sleep-wake cycle abnormalities early in the course associated with sleep fragmentation and possible advanced sleep phase syndrome [211]. Coban et el [212] observed reduced orexin A plasma levels in cases of FTD possibly explaining EDS in these patients. Although RBD is rare in tauopathies, Lo Coco et al. [213] described a case of RBD (clinically and polysomnographically) in a case of FTD.

Sleep Dysfunction in Corticobasal Degeneration (CBD)

Corticobasal degeneration (CBD) is a rare tauopathy presenting with an atypical parkinsonian dementia syndrome characterized by asymmetric or unilateral rigidity, action or stimulus-sensitive myoclonus, apraxia, asymmetric or unilateral cortical sensory loss, and alien limb phenomenon, in which the patient cannot recognize his own affected limb, which may be performing apparently purposeful movements not intended by the patient. The pathologic hallmarks include large achromatic neurons and gliosis distributed asymmetrically in discrete frontal or parietal cortical and subcortical regions affected in PSP. Isolated case reports of sleep dysfunction such as insomnia, sleep-related respiratory disorders, PLMS, and RBD or REM without atonia are available [214–217].

Stroke and Sleep-Wake Disorders

Stroke is an acute neurologic deficit resulting from vascular injury to the brain and is the third leading cause of death and disability worldwide. Stroke is responsible for half of all acute neurologic hospital admissions in the USA [218]. Vascular injury could be ischemic (thrombotic or embolic) or hemorrhagic. In this section, we first describe sleep and breathing disorders as well as other sleep-wake dysfunction in cerebral hemispheric and thalamic strokes followed later by those resulting from brain stem stroke.

There are a few scattered reports of sleep complaints after stroke and several reports of SDB after cerebral infarction, but there is a dearth of well-controlled studies of the relationship between sleep disorders and cerebral vascular diseases [218]. Such studies are important from prognostic and therapeutic points of view.

Hemispheric Stroke

Sleep apnea or SDB and stroke

Sleep disruption and sleep complaints resulting from sleep-related breathing dysrhythmias have been reported in many patients with cerebral hemispheric stroke. Sleep apnea, snoring, and stroke are intimately related. Sleep apnea may predispose to stroke, and stroke may predispose to sleep apnea. There is increasing evidence based on case-control, epidemiologic, and laboratory studies that snoring and sleep apnea are risk factors for stroke. Confounding variables that are common risk factors for snoring, sleep apnea, and stroke (e.g., hypertension, cardiac disease, age, body mass index [BMI], smoking, and alcohol consumption) should be considered when attempting to establish relationships among snoring, sleep apnea, and stroke. A history of habitual snoring (established through questionnaire studies and interviews with a bed partner or other family members) is a clear risk factor for stroke. There is an increased frequency of sleep apnea in both infratentorial and supratentorial strokes. Sleep apnea may adversely affect the short-term and long-term outcomes in patients with stroke in terms of both morbidity and mortality. It is important to make the diagnosis of sleep apnea in stroke patients, as there is effective treatment for sleep apnea that can decrease the risk of future stroke.

Case-control and epidemiologic studies have established an association between hypertension and habitual snoring [219–222] and between habitual snoring and stroke [223–227]. The prospective study by Koskenvuo et al. [222], adjusting for other risk factors, found that habitual snorers have a significantly increased risk of new stroke or ischemic heart disease. Neau et al. [228] also found a significantly increased adjusted risk of stroke in habitual snorers. Spriggs et al. [229] found that in addition to increasing the risk for stroke, snoring adversely affected the prognosis after a stroke. In a prospective study, Bassetti et al. [230] used PSG to determine the frequency of habitual snoring and sleep apnea in 36 of 59 subjects within 12 days of acute hemispheric stroke or transient ischemic attack (TIA) and in 19 age- and sex-matched controls. Habitual snoring was reported in 58 % of patients with TIA or stroke, in addition to an increased frequency of sleep apnea in patients with TIA and acute stroke.

There is considerable evidence based on several recent large epidemiologic and many case-control studies showing an independent association between obstructive sleep apnea syndrome (OSAS) and stroke. Sleep apnea has been found in up to 72 % of patients with stroke. The pathogenesis is not clearly known, and most likely is multifactorial, involving sympathetic nervous system hyperactivity, activation of inflammatory molecular pathways, endothelial dysfunction, metabolic dysregulation, abnormal coagulation, dyslipidemia, and insulin resistance [231]. There are several well-established risk factors for the development of stroke, including arterial hypertension, cardiac disease, diabetes mellitus, smoking, and dyslipidemia. Although the evidence of association between OSAS and stroke is strong based on

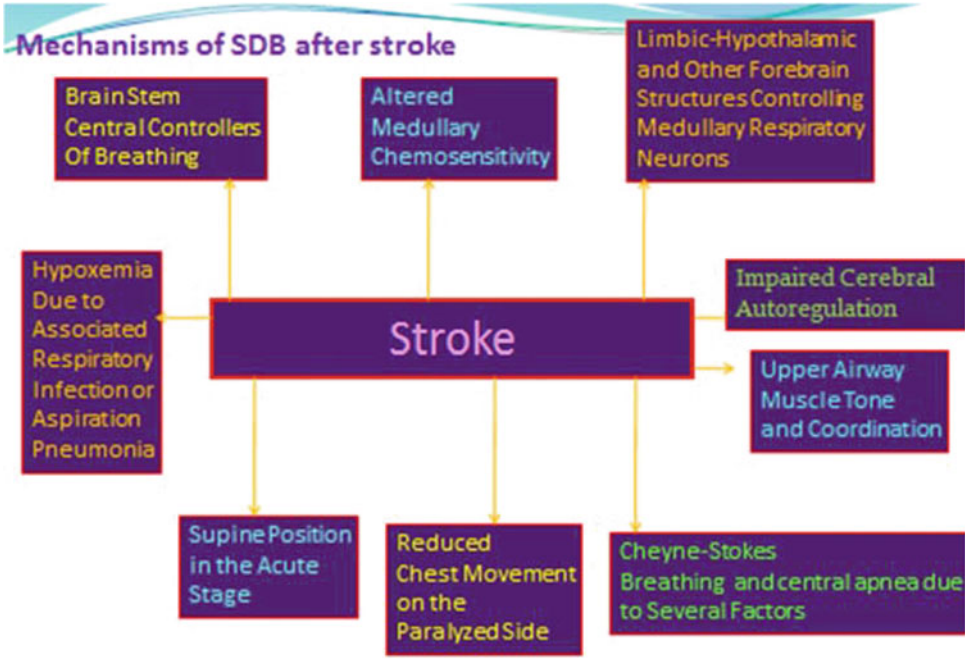

Fig. 41.15 Mechanisms of SDB after stroke

mainly cross-sectional, case-control, and some limited longitudinal studies, large-scale collaborative studies including patients with OSA controlled adequately for potential confounders are needed to evaluate the relationship between OSAS and stroke and the potential interactions between different basic mechanisms (Fig. 41.15). The Sleep Heart Health Study [232] is a cross-sectional study including a sample of 6424 individuals who underwent unattended overnight PSG at home. Sleep apnea was significantly associated with the development of stroke, coronary artery disease, and congestive cardiac failure independent of known cardiovascular risk factors.

As part of the Sleep Heart Health Study in a later report, Redline et al. [233] followed 5422 community-based subjects without stroke for a median of 8.7 years and reported in 2010 that 193 developed ischemic stroke with a significant positive association with AHI in men. Stroke risk was estimated to increase by 6 % for each one-unit increase in AHI in men with mild-to-moderate sleep apnea.

A higher prevalence of OSA has also been shown in patients with TIAs compared with controls by Bassetti and Aldrich [234]. Cross-sectional studies, however, cannot make a definite conclusion about the cause-and-effect relationship, and therefore, prospective longitudinal studies are needed. A prospective cohort study of patients admitted for stroke or TIA by Parra et al. [235] demonstrated a higher prevalence of OSA than in the general population. However, this was contradicted in a small case-control study involving 86 patients with TIA matched for age and sex with controls that showed no significant difference in the severity or prevalence of OSAS between the two groups [236]. A study by Wierzbicka et al. [237] involving 43 patients found a high prevalence of sleep apnea in patients with acute stroke and TIA. The authors suggested that overnight screening for SDB should be routinely performed in every patient admitted with stroke or ischemic attack. Grigg-Damberger [238], in a review article, made a similar suggestion and noted that such screening and treatment for OSAS should be incorporated into stroke prevention programs.

In an important observational cohort study, Yaggi et al. [239] performed PSG in 1022 consecutive patients enrolled in the study and verified subsequent events such as strokes and deaths. Proportional hazards analysis was used to determine the independent effect of OSAS on the composite outcome of stroke or death. At baseline, 697 patients (68 %) had a mean AHI of 35 as compared with 2 in controls. After a median follow-up period of 3.4 years, the OSAS syndrome was associated with stroke or death from any cause with a hazard ratio of 2.24. After adjusting for age, sex, smoking habits, alcohol consumption, BMI, and the presence or absence of diabetes mellitus, hyperlipidemia, atrial fibrillation, and hypertension, OSAS retained its statistically significant association with stroke or death with a hazard ratio of 1.97. The authors concluded that OSAS significantly increases the risk of stroke or death from any cause and the increase is independent of other risk factors. Several other studies confirmed an independent association between OSAS and stroke [240–244]. Harbison et al. [240] performed a prospective, uncontrolled observational study at week 2 and a repeat study in 50 patients at weeks 6–9 following stroke-utilizing sleep studies, modified ranking score, Barthel score, Scandinavian Neurological Stroke Scale, and

ESS score. They concluded that SDB improved in the first 6–9 weeks following stroke but remained highly prevalent. They made a surprising observation of the presence of SDB in patients with lacunar stroke. Marin et al. [241] did an observational study to compare the incidence of fatal and nonfatal cardiovascular events, including stroke, in simple snorers. They included patients with untreated OSAS, patients treated with CPAP titration, and healthy men recruited from the general population. The subjects were followed up at least once a year for a minimum of 10.1 years, and CPAP adherence was checked with a built-in meter. The study included 264 healthy men, 377 simple snorers, 403 patients with untreated mild-to-moderate OSAS, 235 with untreated severe disease, and 372 with the disease who were treated with CPAP. They found that patients with untreated severe disease had a higher incidence of both fatal cardiovascular events (deaths from myocardial infarction or stroke) and nonfatal cardiovascular events than did untreated patients with mild-to-moderate disease, simple snorers, patients treated with CPAP, and healthy participants. The authors concluded that in men, severe OSAS significantly increased the risk of fatal and nonfatal cardiovascular events and CPAP treatment reduced this risk. Munoz et al. [242]. performed a prospective 6-year longitudinal population-based study in subjects aged 70–100 years. After adjustment for confounding factors, the authors confirmed that patients with severe OSAS at baseline had an increased risk of developing stroke independent of known confounding factors. Artz et al. [243] also demonstrated after a cross-sectional longitudinal analysis of subjects from the general population that there was a strong association between moderate-to-severe SDB and prevalence of stroke independent of the confounding factors. These authors also provided the first prospective evidence that SDB preceded stroke and may contribute to the development of stroke. In a prospective 10-year follow-up study, Sahlin et al. [244] obtained overnight sleep recordings at a mean of 23 days after the onset of stroke in 132 patients. They found that the risk of death was higher among the 23 patients with obstructive apnea (AHI $\geq$ 15) than controls (AHI < 15), with an adjusted hazard ratio of 1.76 independent of all the confounding factors. There was no difference in mortality between central sleep apnea (CSA) patients and controls.

Several early studies [245–247] evaluated the role of CPAP in the treatment of patients with OSAS and found significant protection against new vascular events after ischemic stroke. Bassetti et al. [247] found a beneficial effect of CPAP in a small percentage of patients. In contrast, after a randomized controlled trial of CPAP in patients with stroke with an AHI of 30 or more, Hsu et al. [248] found no benefit from CPAP treatment. These authors advocated that CPAP treatment should be used for patients with stroke only if there are symptoms of SDB. Similar to the findings of Bassetti et al. [247], Palombani and Guilleminault [249] found that the majority of stroke patients with OSAS rejected CPAP treatment, and they suggested that better education and support of patients and families, and special training sessions, will be needed to improve adherence in such patients.

Obstructive sleep apnea is the most common form of SDB in stroke victims, and the prevalence in stroke patients exceeds the figure quoted for the general population [218, 236, 250–266]. Bassetti et al. [254] suggested that the presence of OSA should be suspected in men and elderly patients with diabetes mellitus and nighttime onset of TIA or stroke. The increased prevalence of OSAS in patients with TIA and stroke suggests that OSAS does not commonly precede but rather follows the onset of cerebrovascular events [255, 256]. It is notable that acute stroke may aggravate preexisting SDB or even may cause it de novo [255]. Improvement of SDB often occurs in the recovery phase after stroke [254, 256].

Mansukhani et al. [260] from Mayo Clinic in a prospective cohort study included 174 consecutive patients with acute ischemic stroke. Using Berlin Sleep Questionnaire, they identified 105 patients (60.4 %) with a high risk for OSA and seven patients (4 %) with a previous diagnosis of OSA. They found that those with a previous diagnosis of OSA were more likely to die within the first month after stroke and had worse functional outcome. Such comorbid OSA and stroke causing poor functional outcome [252, 257, 261] and increased poststroke mortality [231, 234] had been observed by earlier investigators.

In an important meta-analysis of 29 articles (2343 patients), Johnson and Johnson [262] observed that the percentage of stroke and TIA patients with OSA is up to 72 % (with an AHI of 5 or more) and up to 63 % (with an AHI of 10 or more), and the type of apnea is primarily obstructive (only 7 % had central apnea). They also made the following important observations: Comorbid OSA and stroke are more common in men than women and in older than younger subjects; nocturia may be a predictor and recurrent stroke may be an indicator.

In a recent review of stroke and sleep apnea, Davis et al. [263] cautioned that we may be neglecting a modifiable stroke risk factor. They provide evidence that sleep apnea is an important but under-recognized risk factor for incident and recurrent stroke which may adversely affect stroke recovery and that CPAP titration improves functional outcome after stroke. The authors further state that several preliminary randomized trials of CPAP therapy after stroke suggest diagnosing OSA in stroke patients may be best accomplished with portable devices, but these are less sensitive and specific for the diagnosis of OSA than a formal in-laboratory polysomnography (PSG). Many preliminary randomized trials of CPAP therapy for SDB in stroke

patients have shown improvement in stroke scales, motor recovery, symptoms of sleepiness, and depression, but some randomized trials have shown no difference in outcome [249]. Despite inconsistencies, Davis et al. [263] made the following important conclusions regarding CPAP therapy for sleep apnea in stroke: Increased CPAP adherence improves stroke recovery, but adherence remains a problem because of advancing age, severity of stroke causing facial paralysis, dysphasia, and impaired cognition [249, 254, 263–267]. However, better selection, patient education, and early CPAP treatment during hospitalization or as soon as the patient can tolerate may improve increasing adherence and treatment benefit.

In addition to OSA, patients with stroke may have central sleep apnea (CSA), including central periodic breathing and CSB Figure (Fig. 41.16) [268–272]. CSA and CSB may persist in 6–29 % of stroke patients and may adversely affect the recovery [252]. Nopmaneejumrusler et al. [272] suggested that in patients with stroke, CSA and Cheyne–Stokes respirations are associated with hypocapnia and occult left ventricular systolic dysfunction but are not related to the location or type of stroke. Hermann et al. [271] found central periodic breathing during sleep in 3 of 31 patients with first-ever stroke in the absence of cardiopulmonary dysfunction. They assessed the patients using PSG, MRI of the brain, and echocardiography. They concluded that central periodic breathing during sleep may be present in strokes involving the autonomic (insular) and volitional (cingulate and thalamus) respiratory networks and that breathing improved in all patients during stroke recovery. Bonnin-Vilaplana et al. [268] described CSB in patients with first-ever lacunar stroke. In a recent retrospective analysis of adaptive servoventilation (ASV) treatment for persistent CSA in postacute ischemic stroke patients without concomitant congestive cardiac failure, Brill et al. [269] observed that ASV was well tolerated and clinically effective in these patients.

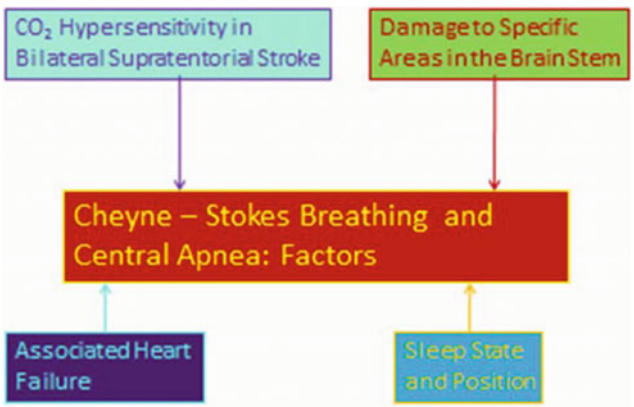

Fig. 41.16 Cheyne–Stokes breathing and central apnea: factors

Some studies have addressed circadian variations of stroke onset. In a study of 53 stroke patients, Kapen et al. [273] confirmed their previous reports of prevalence for the onset of stroke in the morning during a 6-hour period after awakening from sleep. This is similar to the peak incidence in the morning hours for myocardial infarction and sudden cardiac death. All of these conditions may be aggravated by a combination of circadian increase of corticosteroids and catecholamines, increased blood pressure and heart rate in the morning, and increased platelet "aggregability." (Normal subjects exhibit increased platelet aggregability in the early morning [274]. In several other studies, the incidence of stroke was highest during sleep at night [275] or during early morning hours after awakening from nocturnal sleep [276, 277]. In order to investigate circadian variations in situations at stroke onset, Omama et al. [278] analyzed 12,957 cases of first-ever stroke onset diagnosed from the Iowa Stroke Registry between 1991 and 1996 by CT or MRI of the brain. They noted that patients who had cerebral infarctions showed a bimodal pattern with a higher peak in the morning and a lower peak in the afternoon, whereas intracerebral hemorrhage and subarachnoid hemorrhage patients had the same bimodal pattern but with a lower peak in the morning and a higher peak in the afternoon. The authors concluded that sleep tends to promote ischemic stroke and suppresses hemorrhagic stroke. Another study from Japan [279] found that intracerebral hemorrhage during the sleep period may be more detrimental compared with the intracerebral hemorrhage during awake periods, causing larger hematoma and higher mortality rates.

Brain Stem Vascular Lesions

Brain stem vascular lesions include infarction, hemorrhage, arterial compression, and localized brain stem ischemia. Sleep disturbances have been described in brain stem infarction by Markand and Dyken [280] and several other authors [19, 21, 281, 282]. Polysomnographic findings generally consisted of increased wakefulness after sleep onset and decreased REM and slow-wave sleep. Several reports of EEG or PSG studies to document sleep disturbances have been described in patients with locked-in syndrome, which is characterized by quadriplegia associated with de-efferentation and results from ventral pontine infarction. Patients are generally aware of their surroundings and are conscious. They cannot speak because of facial muscle paralysis but can respond by moving the eyes, whose control is spared. Sleep EEG recordings of locked-in syndrome patients have been reported by Feldman [283], Freemon et al. [284], Markand and Dyken [280], Cummings and Greenberg [285], Oxenberg et al. [286], and Nordgren et al. [287]. The EEG findings in these reports generally

showed reduced or absent REM sleep and variable changes in NREM sleep, including reduction of slow-wave sleep and total sleep time. Oxenberg's group [286], however, described only minor alterations in the initial recording in contrast to the more marked alterations noted in the other reports. The authors thought that the difference could be related to the extent of the lesion. Feldman [283] found in his patient reduced REM, stage 4 NREM, and total sleep time. Markand and Dyken [280] noted in five of seven locked-in syndrome patients the total absence of REM sleep and variable changes in NREM sleep. Cummings and Greenberg [285] described one patient who had reduced slow-wave sleep and another with reduced NREM sleep and no REM sleep. Autret et al. [288] also found a reduction of REM and NREM sleep in four patients after medial pontine tegmental stroke.

The term, *Ondine's curse,* or the *syndrome of primary failure of automatic respiration,* was coined by Severinghaus and Mitchell [289] to describe three patients who experienced long periods of apnea even when awake but could breathe on command. They became apneic after surgery involving the brain stem and high cervical spinal cord and required artificial ventilation while asleep. When their consciousness was altered by nitrous oxide or thiopental, they became apneic. Carbon dioxide response to breathing showed low sensitivity. One patient died in apnea, and the two others improved in one week. The authors suggested that Ondine's curse resulted from damage to the medullary carbon dioxide chemoreceptors. It is notable that the term *Ondine's curse* was derived from the sea nymph in German mythology, whose curse rendered her unfaithful lover incapable of automatic respiratory function and caused his death. This eponymic syndrome generated considerable controversy and confusion [290]. The syndrome of Ondine's curse is usually caused by bilateral lesions anywhere caudal to the fifth cranial nerve in the pons down to the upper cervical spinal cord in the ventrolateral region. Levin and Margolis [282] described a 52-year-old man with unilateral medullary infarction, however, who lost automatic respiratory control. At autopsy, the lesion was found to extend from the left lower pons through the left lateral medullary tegmentum to the upper cervical spinal cord and to involve the left paramedian PRF. Thus, in some patients, automatic respiratory control can reside unilaterally in the pontomedullary tegmentum.

A case of inverse Ondine's curse syndrome in a patient with selective paralysis of voluntary respiration but preservation of automatic respiration was described by Munschauer et al. [291]. This was a 36-year-old man with sudden onset of quadriparesis and bulbar dysfunction in whom MRI demonstrated a well-demarcated lesion restricted to the ventral basilaris pontis. His hypercapnic ventilatory response and breathing during sleep were normal. Emotional stimuli producing laughter, crying, or anxiety appropriately modulated automatic respiration, but the patient could not voluntarily modify any respiratory parameters. The findings in this case suggested that descending limbic influences on automatic respiration are anatomically and functionally independent of the voluntary respiratory systems.

Bogousslavsky et al. [292] reported a clinical pathologic correlation in two patients who had central hypoventilation and unilateral infarct in the caudal brain stem. The authors suggested that unilateral involvement of the pontomedullary reticular formation and nucleus ambiguus is sufficient for generating a loss of automatic respiration, whereas associated lesion of the NTS may lead to more severe respiratory failure involving both automatic and voluntary responses [292].

Respiratory rate and pattern were studied by Lee et al. [19] by impedance pneumography in 14 patients with acute brain stem or cerebral infarction, and in a subsequent study, they reported on another 23 patients with acute brain stem infarction [21]. They found frequent abnormalities of respiratory pattern and rate in such patients, and these abnormalities became worse during sleep. The abnormal pattern included CSB and Cheyne–Stokes variant types of breathing, in addition to tachypnea and cluster breathing in some patients. In contrast to the observations of Plum et al. [11–13, 293] that such breathing patterns are associated with bilateral cerebral hemispheric and diencephalic lesions but rarely with lesions in the upper pons, Lee's group [21] observed Cheyne–Stokes respirations in patients with extensive bilateral pontine lesions. They suggested that the size and the bilaterality of the lesions determined the types of respiratory pattern abnormalities.

Devereaux et al. [281] reported sleep apnea that required ventilatory support in two women who breathed normally while awake. Aged 36 and 59 years, they had bilateral infarctions limited to the lateral medullary tegmentum. In one of these patients, the carbon dioxide response was markedly depressed. Although the authors stated that acute automatic respiratory failure did not generally evolve into a chronic alveolar hypoventilation syndrome, their second patient continued to have sleep-induced apnea after many months.

Sleep apnea after bulbar stroke was also described by Askenasy and Goldhammer [294]. Their patient had a left-sided Wallenberg syndrome (lateral medullary syndrome), and 2 nights' PSG recordings documented mostly obstructive or mixed apneas and hypopneas. This was a clinical diagnosis, and neuroimaging did not define the exact anatomy of the lesion. Their report, however, should direct attention to the possibility that unilateral brain stem lesions can cause sleep apnea syndrome. In such patients, it is important to diagnose and promptly treat ventilatory dysfunction during sleep.

Lassman and Mayer [295] described a 70-year-old woman with right lateral medullary infarction who developed recurrent episodes of life-threatening central

hypoventilation requiring diaphragm pacing with a phrenic nerve pacemaker and nocturnal mechanical ventilation via a tracheostomy.

Diencephalic Stroke

Freund [296] should probably be credited with the first report of patients with hypersomnolence following paramedian thalamic strokes. Thalamic stroke may cause ipsilateral loss of sleep spindles [297], and bilateral paramedian thalamic infarcts may be associated with hypersomnia [298, 299]. Bassetti et al. [299] evaluated 12 patients with MRI-proven isolated paramedian thalamic stroke and hypersomnia. The patients were evenly divided between groups of severe and mild hypersomnia. Nocturnal PSG findings included increased stage 1 NREM sleep, reduced stage 2 NREM sleep, and a reduced number of sleep spindles. Bassetti et al. [299], however, found intact REM sleep as well as circadian, ultradian, and homeostatic sleep regulation in their patients. The authors concluded that hypersomnia after paramedian thalamic stroke is accompanied by deficient arousal during the day and insufficient spindling and slow-wave sleep production at night. Their observation supported the hypothesis of a dual role of the paramedian thalamus for the maintenance of sleep-wake regulation.

In contrast, Guilleminault et al. [300] reported three patients with pseudohypersomnia and presleep behavior with bilateral paramedian thalamic lesions. These authors used long-term monitoring with an infrared video camera and polygraphic study to document that their patients did not develop the normal NREM cycling during the day; rather, the EEG indicated a mixture of low-amplitude theta and alpha frequency waves during the day, with "sleep-like behavior." The patients exhibited the behavioral aspects of sleep during the day, suggesting to Guilleminault et al. [300] that these subjects did not present hypersomnia but a "de-arousal" and were left in the transition between wakefulness and sleep. These authors [300] cited a report by Catsman-Berrevoets and von Harskamp [301] of a similar patient with compulsive presleep behavior and apathy due to bilateral thalamic stroke who responded to bromocriptine. There are a few other scattered cases reported of hypersomnolence following bilateral paramedian thalamic infarct [302–306]. Scammell et al. [307] described a narcolepsy-like syndrome with low CSF hypocretin-1 in a 23-year-old man after diencephalic stroke following the removal of a craniopharyngioma. Similar syndrome has been described by Castaigne et al. [298] after paramedian thalamic and midbrain infarcts.

Other Sleep-Wake Disorders in Stroke

Stroke may predispose to a number of other sleep disorders. Kleine–Levin syndrome can occur after multiple cerebral infarction [308]. Narcolepsy-cataplexy has been reported to follow cerebral hypoxia-ischemia [309].

Insomnia is commonly noted after cerebral infarction, but this may be partly due to the depression that typically follows stroke [310]. Bassetti and Hermann [264] reported an increased prevalence of sleep-wake disturbances in at least 20–40 % of stroke patients, mainly in the form of increased sleep need (hypersomnia), EDS, or insomnia. They listed several factors contributing to sleep-wake disorders in such patients, including depression, anxiety, SDB, complications resulting from stroke (e.g. nocturia, dysphagia, and urinary or respiratory infections), and medications. In another study by Palomaki et al. [311], the authors concluded that insomnia is a common complaint after ischemic stroke.

Total dream loss (Charcot–Wilbrand syndrome) after acute bilateral infarction of the deep occipital lobe as well as after parietal and deep frontal infarcts has been described by Bischof and Bassetti [312] and Solms [313].

Sleep architectural changes involving NREM and REM sleep have also been noted after cerebral hemispheric stroke [314–317].

There are a few scattered reports of cases of RBD and REM without atonia [318–320] after pontine stroke and rare cases of RLS/WED after lenticulostriate [321], lacunar [322], thalamic [323], and other subcortical and cortical stroke [324, 325].

Basal Ganglia Disorders

Sleep disturbances and sleep-related respiratory dysrhythmias are noted in many patients with basal ganglia disorders, but a systematic study to evaluate such dysfunction has not been undertaken in a large number of patients. A review of sleep and movement disorders is provided in Chap. 39.

Disorders of the Cerebellum

Cerebellar influence on the sleep-wakefulness mechanism has been clearly demonstrated in experimental animal studies by showing a mild decrement of NREM and an increment of REM sleep in cerebellectomized cats [326]. The role of the cerebellum in the respiratory control mechanism in sleep, however, is not known.

Olivopontocerebellar atrophy (OPCA) defines chronic progressive hereditary (usually dominant, occasionally recessive, rarely sporadic) cerebellar degeneration manifested by cerebellar-parkinsonian or parkinsonian-cerebellar syndrome and associated with atrophy of the pontine nuclei and cerebellar cortex and degenerative lesions of the olivopontocerebellar regions [327, 328]. There have been a few reports on sleep disturbances and sleep-related respiratory

dysrhythmias in OPCA (for sporadic OPCA or multiple system atrophy [MSA], see further on).

Cerebellar role in sleep has also been demonstrated by showing changes in the sleep-wake cycle after lesions of the fastigial nucleus and middle cerebellar peduncle as well as EEG changes after electrical stimulation or suppression of cerebellar nuclei [329, 330]. Further evidence is shown by significantly increased activity in the cerebellum during slow-wave sleep following functional magnetic resonance imaging [331]. Brain stem neurons, which are known to be degenerated in OPCA [328], lie close to the hypnogenic [67] and respiratory neurons [82–85]. Thus, dysfunction of respiratory control, in parallel with the somatic structural dysfunction in OPCA, may be expected. The known morphologic changes of OPCA [328] are adequate to explain the sleep disturbances and sleep apnea in this condition. Several authors [332–336] described EEG sleep alterations in degenerative cerebellar atrophy. Reduced or absent REM sleep, reduced slow-wave sleep, and increased awakenings are the essential PSG findings. In several cases of OPCA, REM sleep without muscle atonia accompanied by the typical features of RBD has been described [336, 337]. Jouvet and Delorme [38] produced REM sleep without atonia in cats by bilateral pontine tegmental lesions. A similar lesion in OPCA may be also responsible for RBD in this condition. OPCA has also been associated with hyposomnia [338].

Sleep apnea has been described in several cases of OPCA [335, 338–340]. Patients with sporadic OPCA associated with prominent autonomic failure are now classified as having MSA or Shy–Drager syndrome (see Sect. "Sleep and Breathing Disorders in Autonomic Failure" later in this chapter). Chokroverty et al. [339] described five patients with OPCA and sleep apnea. PSG study showed repeated episodes of central, upper airway obstructive, and mixed apneas during sleep; the apneic episodes lasted from 10 to 62 s, and the apnea index was 30–55. Pure central apnea was noted in three patients, but all three types of apnea were seen in two, and most of the apneic episodes occurred during NREM sleep stage 2. Thus, these findings suggested central neuronal dysfunction in an area where respiratory and sleep-waking systems are closely interrelated, such as the NTS and the pontomedullary reticular formation. Salazar-Grueso and associates [335] described a 37-year-old man with a 19-year history of autosomal dominant OPCA and EDS whose PSG demonstrated episodes of mixed and central (predominantly central) sleep apnea and no sleep spindles or REM sleep. Trazodone treatment normalized the sleep architecture and reduced the apneic episodes.

Occasionally, sleep disturbances are associated with other types of cerebellar lesions, although systematic studies are lacking. Bergamasco et al. [341] made a polygraphic study of a 13-year-old girl with a diagnosis of dyssynergia cerebellaris myoclonica (Ramsay hunt syndrome). An all-night sleep study showed no REM sleep and increased slow-wave sleep. The EEG showed multiple spike-and-wave discharges accompanied by myoclonic generalized seizures. There are reports of sleep disturbances including RLS and RBD in spinocerebellar ataxia (SCA) type SCA1, SCA2, SCA3, as well as increased prevalence of SDB in Friedreich's ataxia [329].

Brain Stem Tumor

Brain stem glioma with automatic respiratory failure was mentioned by Plum [13]. Ito et al. [342] described two children with brain stem gliomas and sleep apnea. Brain stem tumor may cause disorganization of the tonic and phasic events of REM sleep, as described in a patient whose pontine tumor caused a marked decrease in the atonia of REM sleep [343]. Lee et al. [344] reported a 74-year-old woman with recurrent acoustic neuroma at the cerebellopontine angle presenting as central alveolar hypoventilation. The patient had shallow breathing during sleep and had hypersomnolence during the daytime. Arterial blood gases showed increased $Paco_2$ and decreased partial pressure of arterial oxygen (Pao_2). Tumor resection eliminated hypersomnolence and respiratory failure. A patient seen by the senior author with a medullary tumor that caused severe hypoventilation during sleep required tracheostomy (unpublished observation). The central apneic episodes in the same patient became prolonged when the tracheostomy tube was occluded.

Other Brain Stem and Diencephalic Lesions

The metabolic and autonomic respiratory neurons and the lower brain stem hypnogenic neurons are located in the medulla. These neurons are influenced by the supramedullary respiration-controlling inputs and hypothalamic preoptic nuclei, as well as by the peripheral afferent inputs to the respiratory centers (see Chap. 9). Therefore, sleep and respiratory disturbances should be common manifestations of lesions in the brain stem, and many such cases have been described. Such disorders have included brain stem vascular lesions, tumors, traumatic lesions, multiple sclerosis (MS), bulbar poliomyelitis and post-polio syndrome, brain stem encephalitis, motor neuron disease affecting the bulbar nuclei, syringobulbia-syringomyelia, and Arnold–Chiari malformation [91]. In addition, several cases in which brain stem and diencephalic lesions caused narcolepsy-like syndrome have been described [307, 345–350]. All the characteristic features of narcolepsy are not seen in the cases. The causes have included infarction [307], trauma, tumors (including third ventricle tumor) [345], and arteriovenous malformation invading the third ventricle and affecting the

hypothalamus [347], and some cases have been associated with MS [348–350].

Brain stem ischemic damage may also cause respiratory dysfunction. Beal et al. [351] described a 19-year-old man who had failure of automatic respiration and other signs of brain stem dysfunction after nearly drowning. He had sleep apneas, and PSG study confirmed the presence of CSAs. During wakefulness, his breathing was normal. Hypercapnic ventilatory response was markedly impaired, but hypoxic ventilatory response appeared to be normal. Autopsy findings 8 months later, after sudden death, documented marked bilateral neuron loss in the tractus solitarius, ambiguus, and retroambigualis nuclei. This most likely resulted from anoxia or ischemia.

Parenti et al. [352] described two patients aged 38 and 53 years with CSA who died during sleep. At autopsy, the authors described acute bilateral hypoxic lesions at the level of the solitary tract nuclei.

Traumatic Brain Injury and Sleep Dysfunction

Traumatic brain injury (TBI) is defined as "an alteration in brain function or other evidence of brain pathology caused by an external force" [353]. It includes concussion, contusion, laceration, hemorrhage, and cerebral edema. After a severe TBI, brain stem function is severely compromised and the patient becomes comatose. There have been many EEG studies in patients with coma, and some patients may demonstrate sleep patterns such as spindles and K complexes. Such patterns are designated as *spindle coma* [354]. It is often stated that the presence of EEG sleep patterns indicates a favorable prognosis [355], but this may not be necessarily true. On recovering from the coma during this stage of rehabilitation, many patients may have sleep-wake disturbances. However, there have been no adequate studies addressing the sleep-wake abnormalities in such patients. This is surprising, considering that one editorial labeled TBI a silent epidemic [356]. There is a dearth of studies addressing sleep-wake abnormalities after minor brain injuries that did not result in coma but caused a transient loss of consciousness. Many of these patients experience the so-called postconcussion syndrome, characterized by a variety of behavioral disturbances, headache, and sleep-wake abnormalities.

Traumatic brain injury is a public health challenge and a leading cause of death and disability according to the World Health Organization (WHO) [357, 358]. There is a high prevalence of sleep-wake (S-W) dysfunction in TBI including mild TBI adversely impacting recovery, rehabilitation, and outcome [359], but unfortunately S-W dysfunction is not routinely screened in such patients [360]. An important point to remember is that TBI may trigger post-traumatic stress disorder (PTSD) and depression as well as increased sensitivity to pain in such patients promoting and aggravating sleep dysfunction [359]. TBI may cause insomnia, sleep-disordered breathing (SDB), hypersomnolence not due to SDB, circadian rhythm sleep disorders (CRSD), parasomnias, and sleep-related movement disorders (Fig. 41.17). In the past 15 years, there has been an explosion of studies using both self-report and objective methods to characterize sleep dysfunction in TBI [358–381].

In a meta-analysis involving 21 studies including 1706 subjects with mild, moderate, and severe TBI, Mathias and Alvaro [359] reported that overall, 50 % of subjects had some form of sleep disturbance and 25–29 % had a specific sleep disorder (insomnia [29 %], hypersomnia [28 %], obstructive sleep apnea [25 %], PLMS [19 %], and post-traumatic narcolepsy [4 %]). These rates are significantly higher than those seen in the general population. The authors suggested routine screening for sleep dysfunction in TBI patients for optimal treatment and favorable outcome and recovery. Similar suggestion was made by Mollayeva et al. [360] in a later review. In a prospective longitudinal study in 51 consecutive TBI patients, Kempf et al. [371] showed that three years after TBI, two out of three patients had a significant S-W disturbance, particularly post-traumatic hypersomnia, and only 10 % of patients had insomnia.

Verma et al. [365] studied 60 TBI patients (40 % mild, 60 % moderate-to-severe; three months to two years post-trauma) from a sleep clinic and observed the following S-W disorders: sleep apnea (30 %), parasomnias (25 %) including REM sleep behavior disorder (RBD) or increased EMG tone during REM sleep (13 %), sleepwalking (8 %), nightmares (7 %), sleep paralysis (5 %), nocturnal enuresis (5 %), nocturnal eating disorder (3 %), and post-traumatic narcolepsy (3.3 %).

There are several studies investigating the frequency of sleep disorders in TBI patients with hypersomnia and insomnia. Baumann et al. [381] prospectively assessed CSF hypocretin-1 levels in 44 consecutive patients with acute TBI. They found abnormally lower hypocretin-1 levels in 95 % of patients with moderate-to-severe TBI compared with controls. Later on, this group of authors [382] enrolled 96 consecutive patients within the first 4 days after TBI, attempting to delineate the frequency and clinical characteristics of post-traumatic sleep-wake disorders. Six months later, they studied 65 of these patients using questionnaire, CT scan of the brain, CSF hypocretin-1 levels, overnight PSG, and MSLT and actigraphy. They found new-onset sleep-wake disorders following TBI in 72 % of these patients, objective EDS in the MSLT in 25 %, post-traumatic hypersomnia (increased sleep need of 2 or more hours within 24 h compared to the pre-TBI period) in 22 %, and insomnia in 5 %. They found low CSF

hypocretin-1 levels in 4 of 21 patients 6 months after TBI compared to 25 of 27 patients in the first few days after TBI. The patients with post-traumatic sleep-wake disorders also had impaired quality of life. The authors suggested that sleep-wake disturbances are common and involvement of the hypocretin system is possible in the pathophysiology of post-traumatic hypersomnia.

Castriotta et al. [383] evaluated 87 adult patients at least 3 months after TBI using overnight PSG, MSLT, ESS, and neuropsychologic testing. They found a high prevalence of sleep disorders (46 %) and of EDS (25 %) in subjects with TBI. Sleep dysfunction in these patients included a high prevalence of OSA (23 %), post-traumatic hypersomnia (11 %), post-traumatic narcolepsy (7 %), and PLMS (7 %). Ouellet and coinvestigators [384] evaluated 452 subjects aged 16 years and older with minor-to-severe TBI utilizing a questionnaire related to quality of sleep. They found overall insomnia symptoms in 50.2 % and diagnostic criteria for an insomnia syndrome in 29.4 %. Risk factors for insomnia included mild TBI and high levels of fatigue, depression, and pain. Ouellete and Morin [385] studied 14 patients with mild-to-severe TBI compared to 14 healthy good sleepers using a sleep diary and 2 nights of overnight PSG. The authors found a higher proportion of stage 1 sleep in the TBI participants than in controls, but the percentages of stage 2, slow-wave, and REM sleep did not differ between the two groups. TBI patients, however, had more awakenings lasting longer than 5 min and a shorter REM sleep latency. The authors concluded that these results were similar to those found in patients with either primary insomnia or insomnia comorbid with depression.

Schreiber et al. [386] observed alterations in both timing and sleep architecture in 26 adult patients with a past history of minor head trauma (no structural brain imaging findings). In contrast, Gosselin and investigators [387] observed only subjective complaints but no objective sleep architectural abnormalities in 10 athletes with a history of sport-related concussion within the past year compared with 11 nonconcussed athletes. In a subsequent investigation, this group [388] confirmed their previous observations of a lack of abnormal sleep macroarchitecture in mild TBI patients but observed an increase of EEG beta power which could be attributed to brain injury or other factors such as anxiety or pain.

Post-traumatic hypersomnia has been listed in the third edition of the International Classification of Sleep Disorders (ICSD-3) under the heading "Hypersomnia due to a medical disorder" [389]. Guilleminault et al. [390] evaluated 20 patients with post-traumatic hypersomnia using PSG and the MSLT. The causes were multiple, including cases secondary to sleep apnea syndrome. TBI may cause central and upper airway obstructive sleep apnea by inflicting functional or structural alterations of the brain stem respiratory control system. It is important to remember, however, that many patients may have sleep apnea syndrome before sustaining TBI.

EDS in adults with TBI was also reported prospectively in case series of subjects by Castriotta and Lai [391]. These investigators found a high prevalence of sleep apnea-hypopnea syndrome, PLMS, and post-traumatic hypersomnia as well as post-traumatic narcolepsy. Post-traumatic narcolepsy in mild-to-moderate head injury in nine patients was also reported by Lankford et al. [392] utilizing overnight PSG and MSLT.

Hypersomnia or increased sleep need per 24 hours is noted in TBI in association with EDS, by the group led by Baumann [364] who suggested the term pleiosomnia for the increased need for sleep following TBI indicating an increased pressure for sleep. In a recent review of 12 cases of recurrent hypersomnia following TBI, Billiard and Podesta [370] attributed two directly to TBI. Collen et al. [374] retrospectively studied 116 soldiers with combat-related TBI and reported EDS in 85.2 % of the participants. These combat veterans also had a high rate (90.5 %) of comorbid psychiatric disorder (e.g., PTSD, anxiety, and depression).

Okawa et al. [393] described disturbance of circadian rhythms in severely brain-damaged patients. Patten and Lauderdale [394] reported a case of delayed sleep phase syndrome in a 13-year-old boy after a minor head injury sustained in a motorcycle accident (5 min' loss of consciousness followed by headache and drowsiness without other objective neurologic findings). Quinto et al. [395] reported a case of a delayed sleep phase syndrome (DSPS) in a 48-year-old man after TBI. There is another report of post-traumatic DSPS in a 15-year-old girl treated successfully with 5 mg melatonin [396]. In a more recent study, Ayalon et al. [397], using actigraphy, salivary melatonin, oral temperature measurement, and PSG, evaluated 42 patients with mild TBI and found circadian rhythm sleep disorders (DSPS in eight, irregular sleep-wake pattern in seven) in 36 % (15 patients).

The pathophysiology of post-traumatic S-W dysfunction remains unclear but most likely results from a complex interaction of anatomic, physiologic, environmental, and psychologic (e.g., anxiety, depression, and maladaptive habits) factors, as well as neurotransmitters and neuromodulators including hypocretin levels and hormonal changes, circadian rhythms, age, pain, and genetic predisposition.

In summary, TBI of any severity (mild, moderate, severe) may cause a variety of sleep-wake disorders with a much higher prevalence than in general population, impacting on quality of life and final outcome of rehabilitative and other therapies (schematically shown in Fig. 41.17).

Demyelinating Lesion in the Brain Stem

Sleep disturbances are very common in MS and may be seen in over 50 % of patients [398–454]. Surprisingly, there is a

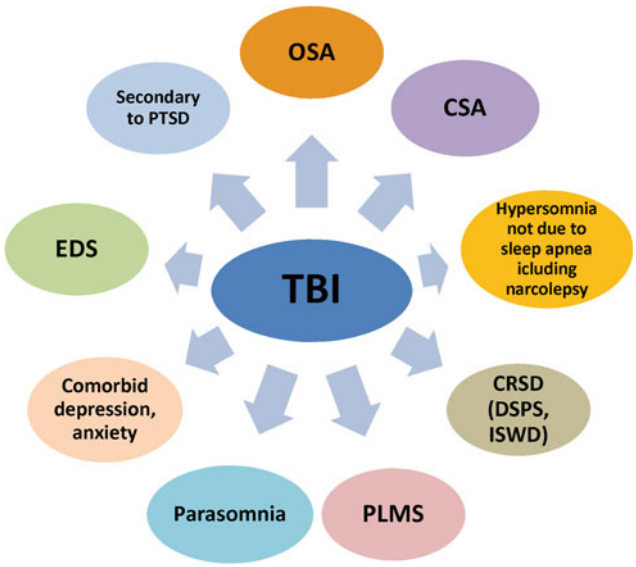

Fig. 41.17 Sleep dysfunction in traumatic brain injury TBI)

lack of adequate evaluation and characterization of such dysfunction in a systematic manner using subjective and objective measures in MS patients. Most MS patients suffer from an unexplained fatigue (see Chap. 42). An important reason for such fatigue may be an unsuspected sleep disorder, such as SDB or insufficient nocturnal sleep. Sleep disturbances in MS may include insomnia, hypersomnia, SDB, narcolepsy, restless legs syndrome (RLS)-PLMS, and RBD [398–454]. We do not know whether such sleep disturbances have an adverse impact on the natural history of MS (Fig. 41.18). Also, we have insufficient knowledge about the effects of treatment of MS with immunomodulating therapies on sleep-wake disturbances (see further on). It is not known whether sleep-wake disorder is related to the severity of the illness as there have not been adequate studies in a large number of MS patients complaining of sleep-wake disorder correlating with Kurtzke's expanded disability scale score.

Sleep-Disordered Breathing in MS

In individuals with MS, a demyelinating plaque may involve the hypnogenic and respiratory neurons in the brain stem, giving rise to sleep disturbance and SRBDs. A few such cases have been described in MS patients. An unusual patient, a 38-year-old man who had a clinical diagnosis of acute demyelinating lesion in the cervicomedullary junction, was described by Newsom Davis [398]. The patient had an autonomous breathing pattern, but he could neither take a voluntary breath nor stop breathing, thus illustrating the apparent independence of the mechanisms controlling metabolic and behavioral respiratory control systems. A patient reported by Rizvi et al. [399], whose brain stem dysfunction was consistent with MS, became apneic when asleep but was able to breathe when awake. His hypercapnic and hypoxic ventilatory responses were normal. Boor and associates [400] described a 40-year-old patient with paralysis of automatic respiration. During relaxation, the patient had recurrent apnea, but the breathing was stable when the patient was alert. The discovery at postmortem examination of a large, demyelinating lesion in the central medulla involving the medullary respiratory neurons explained the respiratory failure.

There are other reports of SDB [401–407] in MS, including failure of automatic respiration (Ondine's curse) [408] with sudden respiratory arrest and nocturnal death, CSA, hypoventilation, and paroxysmal hyperventilation. It is important to consider such a possibility when patients complain of EDS, fatigue, and disturbed sleep associated with snoring. Figures 41.19 and 41.20 show a sample of the hypnogram and overnight PSG recording from a 51-year-old woman with a history of MS showing frequent obstructive, mixed, and central apneas and hypopneas during both NREM and REM sleep associated with mild-to-moderate oxygen desaturation and frequent arousals, as well as REM sleep dysregulation with longer REM sleep in the early part of the night.

Fig. 41.18 Types of sleep dysfunction and factors: multiple sclerosis

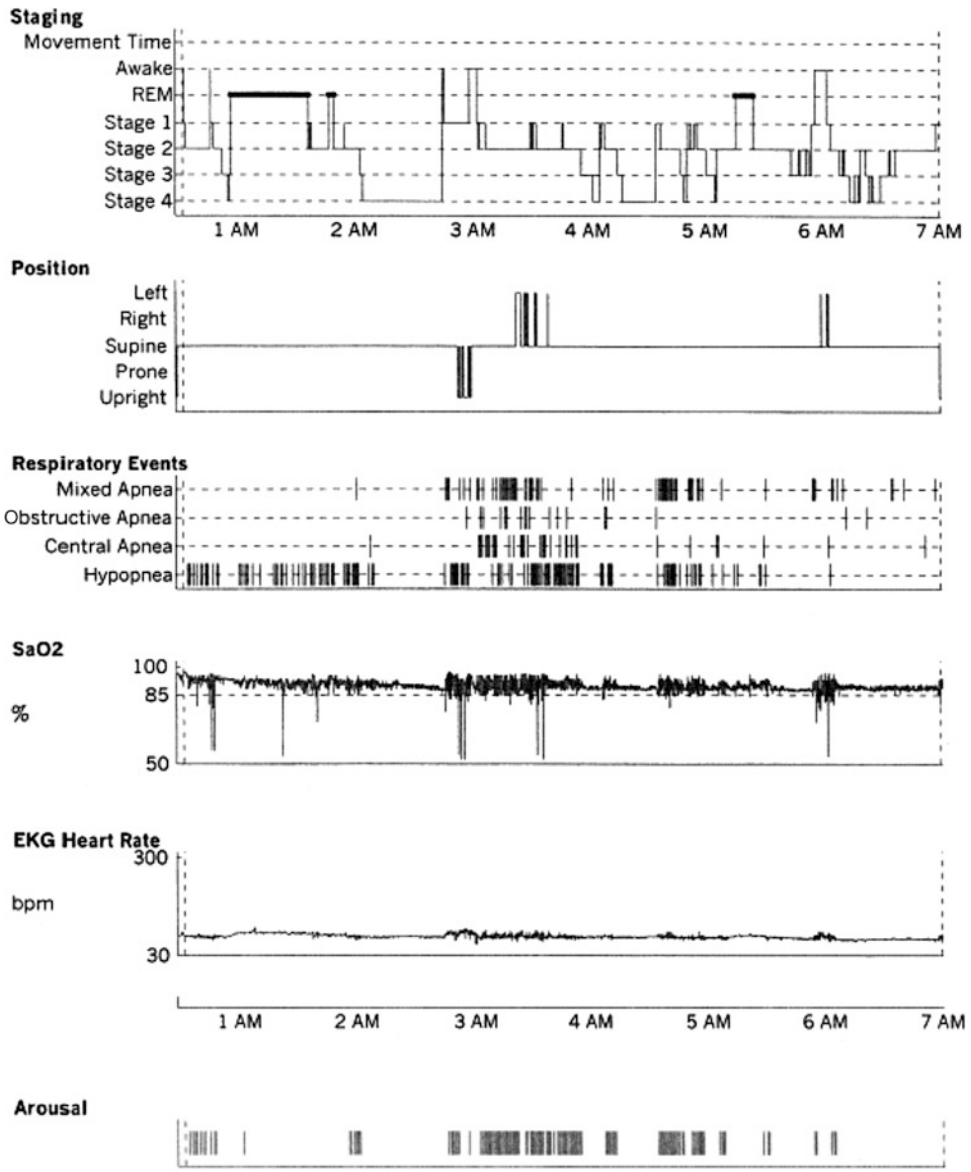

Fig. 41.19 A case of SDB in a 51-year-old woman with a history of multiple sclerosis diagnosed 7 years ago. Her sleep difficulties started approximately 3 years ago and are described as frequent night awakenings, sleepwalking, and brief episodes consisting of sudden sleepiness or impairment of consciousness resulting in falls and multiple fractures but never accompanied by jerky movements of the limbs, tongue biting, or incontinence, with spontaneous recovery in 5–10 min without residual confusion. These episodes occur during the early morning hours as well as during the day. Her neurologic examination is significant for the presence of decreased visual acuity and impaired saccades bilaterally, horizontal nystagmus on looking to the left, intention tremor (left more than right) on finger-to-nose testing, mild ataxia in the lower extremities on heel-to-shin testing, tandem ataxia, and impaired joint and position sense in the toes bilaterally. She was clinically evaluated with a differential diagnosis of SDB related to multiple sclerosis, narcolepsy-cataplexy secondary to multiple sclerosis, and sleepwalking. Unusual nocturnal seizures remained unlikely given the clinical features, the several negative electroencephalograms, and the negative long-term epilepsy monitoring. This hypnogram is significant for REM sleep distribution abnormality (the longest REM in the early part of the night); frequent, obstructive, mixed, and central apneas and hypopneas both during NREM and during REM sleep; mild-to-moderate O_2 desaturation; and frequent arousals. Sleep-related respiratory dysrhythmias due to brain stem involvement are a common finding in multiple sclerosis patients. Reproduced with the permission from Chokroverty et al. [455]

Insomnia in MS

In addition to sleep-related breathing abnormalities, other sleep difficulties have been commonly reported in MS patients, including insomnia and EDS [401, 402, 431–435, 440, 441]. Insomnia is the most common sleep problem in MS with an overall prevalence of more than 40 %. Tachibana et al. [431] evaluated 28 consecutive patients with MS,

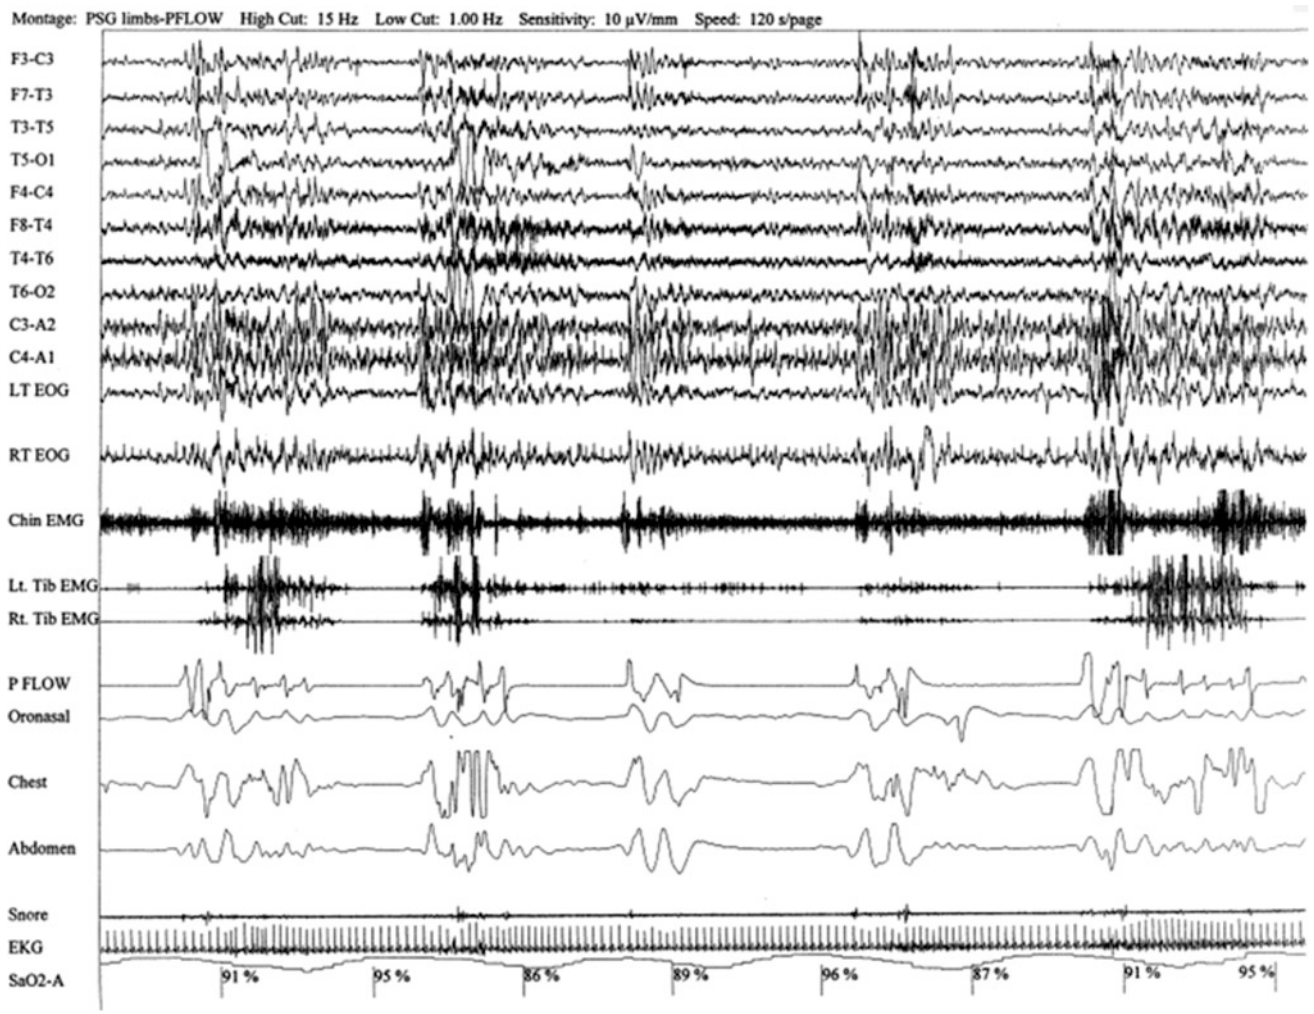

Fig. 41.20 A 120-s excerpt from an overnight polysomnographic recording (same patient as in Fig. 41.19) showing repeated central apneas with O_2 desaturation. An increase in muscle tone is noted on chin (chin EMG) and tibialis anterior (Tib.) electromyography (EMG) channels following some central events. Electroencephalogram (EEG): top 10 channels. *Lt.* left; *Rt.* right; *EOG* electrooculograms; *P Flow*, peak flow; oronasal thermistor; chest and abdomen effort channels; snore monitor; *EKG* electrocardiography; SaO_2, oxygen saturation by finger oximetry. Reproduced with the permission from Chokroverty et al. [455]

15 of whom had sleep problems that included difficulty initiating sleep, frequent awakenings, difficulty maintaining sleep, habitual snoring, and nocturia. All-night oximetric study showed sleep-related O_2 desaturation in three patients, two of whom had sleep apnea on PSG investigations. The authors concluded that sleep disturbance in MS is common but poorly recognized. Ferini-Strambi et al. [401] performed PSG studies in 25 MS patients and compared the results with 25 age- and sex-matched controls. They found reduced sleep efficiency with increased awakenings during sleep and an excess of PLMS in patients as compared with the controls. The cross-sectional study of Veauthier et al. [404] quoted 25 % prevalence of insomnia in MS patients, but most other studies in MS did not consider standardized diagnostic criteria confounding a methodological limitation. Sleep disturbance causing repeated arousals and sleep fragmentation is thought to be a contributing factor for MS-related fatigue [402, 436] (see also Chap. 42). An important cause of insomnia in MS is comorbid depression, which has a high prevalence (up to 50 %); it is important to recognize depression as treatment may improve sleep dysfunction and quality of life [417–419, 428, 430, 443–446, 454].

RLS-PLMS has a high prevalence in MS patients and in the general population [420, 435]. RLS-PLMS is an important cause of insomnia in these patients. Manconi et al. [435] studied 156 MS patients using a structured questionnaire and assessing the ESS; about one-third of their subjects satisfied the criteria for RLS. These authors noted that the primary progressive form of MS was more representative of the RLS group, which showed a higher ESS score than those without RLS. In a later multicenter Italian REMS study, Manconi et al. [447] reported that the prevalence of RLS was

19 % in MS and 4.2 % in controls. They identified the following risk factors: older age, longer duration, primary progressive MS form, higher disability, and the presence of leg jerks at sleep onset.

A recent meta-analysis by Schurks and Bussfeld [420] covering 24 studies estimated fourfold higher risk of RLS in MS patients than in those without MS. Manconi and collaborators [421] based on diffusion tensor MRI study suggested that cervical cord damage was a significant risk factor for RLS in MS which agrees with previous suggestion by Hartmann et al. [422]. A disconnection between brain stem and spinal cord due to interruption of ascending or descending pathways from the cervical spinal cord may be provided as an explanation for RLS in these patients [409].

Fatigue, Sleep Dysfunction, and MS

Most patients with MS suffer from an unexplained fatigue (see also Chap. 42). In the studies by Attarian et al. [436], Kaynak et al. [402], and others [415], there is a significant correlation between fatigue and disrupted sleep with sleep fragmentation, alteration of sleep macrostructure and microstructure, poor quality of life, and depression.

Other Sleep Disturbances in MS

Hypersomnolence with low CSF hypocretin-1 levels in primary and secondary narcolepsy [423–425, 438, 449, 450–453] and RBD [439] have also been observed in some MS patients. Plazzi et al. [439] described a 25-year-old woman with MS who presented with RBD as an initial presentation of MS, and this subsequently resolved after treatment with adrenocorticotrophic hormone. No MRI documentation, however, of brain lesions was provided. More recently, Tippmann-Peikert et al. [426] reported a 51-year-old woman with acute MS and RBD showing a large MS plaque (MRI T2 signal) in the dorsal pons similar to the lesion site causing RBD-like behavior in cats. One study [427] estimated prevalence of RBD in MS as 1.4 %.

Medications Causing Sleep Disturbance in MS

Treatment of MS with immunomodulating therapies such as interferon and methylprednisolone may cause sleep disturbances in the form of hypersomnolence, increasing fatigue, insomnia, and depression [454, 456]. The newer medications such as glatiramer acetate (Copaxone) or mitoxantrone (Novantrone) have not been found to cause sleep disturbance in MS, but adequate studies have not been undertaken. Insomnia, however, has been reported with laquinimod treatment in MS patients [457]. No specific information is available for natalizumab and fingolimod [409]. There is a report [458] showing that compared with oral baclofen, intrathecal infusion to treat severe spasticity in MS patients improved sleep continuity without affecting respiratory function.

Quality of Life and Sleep Dysfunction in MS Patients

Merlino et al. [440] studied 120 MS patients to assess the prevalence of sleep dysfunction in MS and to evaluate various factors affecting sleep quality and quality-of-life indicators. These authors found poor sleep in 47.5 % of the patients and concluded that poor sleep is an independent predictor of impaired quality of life, directing our attention to assessment and treatment of sleep dysfunction in MS patients to improve the quality of life. They also confirmed significantly higher mean Kurtzke MS disability scores among poor sleepers than among good sleepers, supporting an earlier report by Lobentanz et al. [446] but contradicting other reports [431, 432, 439] showing no correlation with these scores.

Mechanisms of Sleep Dysfunction in MS

Sleep-wake disturbances in MS may result from a variety of factors (see Fig. 41.18) as listed below: discomfort from immobility, spasticity and pain, nocturia, abnormal motor activities (e.g., RLS-PLMS, muscle spasms, and parasomnias), anxiety, depression, sleep-disordered breathing, anatomic locations of MS plaques (e.g., location of lesions affecting sleep-wake regulatory regions in brain stem, hypothalamus, and other brain areas), immunologic and cytokine abnormalities, and genetic predisposition (in some cases).

Bulbar Poliomyelitis and Post-polio Syndrome

In the acute and convalescent stages of poliomyelitis, respiratory disturbances commonly get worse during sleep. Some patients are left with the sequelae of respiratory dysrhythmia, particularly sleep-related apnea or hypoventilation requiring ventilatory support, especially at night. Another group of patients decades later develop symptoms that constitute *post-polio syndrome*. Sleep disturbances and sleep apnea or hypoventilation are also noted in post-polio syndrome. Medullary respiratory and hypnogenic neurons are involved directly in the poliovirus infection, and this explains the patients' symptoms.

Bulbar Poliomyelitis

Hypoventilation syndrome in bulbar poliomyelitis was first documented quantitatively by Sarnoff et al. [459]. They described four patients who could breathe voluntarily on

command but hypoventilated during periods of sleep and quiescence. The authors described irregular rate and rhythm of respiration, incoordination of the muscles of respiration, and hypoventilation resulting from decreased sensitivity of the respiratory center to $Paco_2$ as a result of direct involvement of the respiratory center by the poliomyelitis virus. Two of their patients benefited from electrophrenic respiration.

An extensive report on the clinical and physiologic findings in 20 of 250 poliomyelitis patients with central respiratory disturbances was given by Plum and Swanson [16]. These patients' respiratory disturbances could not be explained by involvement of the spinal motor neurons or airway obstruction. In acute bulbar poliomyelitis, the disordered breathing progressed through three successive stages. Stage I was characterized by disorder of respiratory rhythm during sleep, when breathing became irregular in rate and depth with periods of apnea ranging from 4 to 12 s. During stage II, normal breathing required increasing effort and concentration, and strong auditory or painful stimuli were necessary to maintain respiratory rhythmicity. At this stage, the patients had impaired chemosensitivity of the central respiratory centers as evidenced by a reduction in ventilation and carbon dioxide retention after O_2 inhalation. Sleep exacerbated the breathing difficulty, and there were longer periods of apnea. The respiratory homeostasis was lost entirely in stage III, and there was no ventilatory responsiveness to reflex, chemical, or other neuronal stimuli. The respiratory pattern was chaotic, with varying periods of apnea. The patients required ventilatory support to maintain respiratory homeostasis. Severe inflammatory changes and small areas of necrosis in the ventrolateral reticular formation of the medulla were noted in two patients on neuropathologic examination.

The breathing abnormalities in this series rarely lasted more than 2 weeks, but two patients had sleep-related irregular respiration that persisted many months after acute poliomyelitis. These two patients also demonstrated impaired hypercapnic ventilatory response and hypoventilation during administration of 100 % O_2. The physiologic abnormalities suggested severe and permanent dysfunction of the medullary respiratory neurons. In several convalescent spinal poliomyelitis patients, the authors also observed subnormal ventilatory response to carbon dioxide with reduction of maximum breathing capacity or vital capacity to less than 50 % of predicted normal values. These findings implied that peripheral mechanisms that cause restriction of chest movements may also contribute to impaired ventilatory response to carbon dioxide.

Post-polio Syndrome

Post-polio syndrome is manifested clinically by increasing weakness or wasting of the previously affected muscles and by involvement of previously unaffected regions of the body, fatigue, aches and pains, and sometimes symptoms secondary to sleep-related hypoventilation, such as EDS and tiredness [460, 461]. The exact mechanism of post-polio syndrome is not known. Some of the symptoms (e.g., EDS and fatigue) could result from sleep-related hypoventilation or apnea and sleep disturbances [462]. Thus, it is important to be aware of sleep apnea in such patients. This syndrome has been described in patients who had poliomyelitis decades earlier. Guilleminault and Motta [463] reported on five such men who had a history of bulbar poliomyelitis 16 years earlier. All had EDS, and PSG study documented numerous episodes of apneas, which were predominantly central but also mixed and upper airway obstructive types associated with O_2 desaturation. Their longest apneas were seen during REM sleep. It is important to know that these patients resemble those with primary sleep apnea syndrome. Presumably, the lesions in these cases involved the medullary respiratory neurons, and thus, central lesions were responsible for all three types of apneas. The patients' symptoms improved and daytime somnolence decreased after ventilatory assistance at night.

Steljes et al. [462] performed PSG examinations on 13 post-polio patients, 5 of whom used rocking beds for ventilatory assistance and 8 of whom had no ventilatory assistance. Patients who required ventilatory assistance demonstrated severe sleep disturbances with decreased total sleep time, reduced sleep efficiency, and decreased percentages of stage 2 NREM sleep, slow-wave sleep, and REM sleep, but increased awakenings and percentage of stage 1 NREM sleep. Respiratory abnormalities in these patients consisted of hypoventilation, apneas, and hypopneas associated with significant O_2 desaturation. These patients did not respond to CPAP treatment with the rocking bed, but they showed improvement in sleep structure and respiratory function after mechanical ventilation via nasal mask. Five of the eight patients who required no ventilatory assistance also showed impairment of sleep architecture similar to the other group, but the findings were less severe. All but one patient from the second group had obstructive or mixed apneas, which were treated successfully with nasal CPAP. One patient with mixed apnea and marked hypoventilation improved after treatment with nasal ventilation by mask.

Polysomnographic and pulmonary function studies by Bye et al. [464] and Ellis et al. [465] documented respiratory failure and sleep hypoxemia, particularly during REM sleep, in patients with post-polio respiratory muscle weakness. Sleep studies by Ellis' group [465] under controlled conditions without respiratory support showed repeated arousals with disruption and fragmentation of the REM-NREM cycle. In a retrospective review of medical records from 108 consecutive patients with post-polio syndrome and sleep

disturbances encountered during an 11-year period at the Mayo Clinic, Hsu and Staats [466] reported PSG findings from 35 patients fulfilling the inclusion criteria. All patients had hypersomnolence as the most common presenting symptom, and the authors identified three patterns of sleep disturbances: OSA, hypoventilation, and a combination of both. They concluded that SDB is a late sequela of poliomyelitis. Dean et al. [467] from the National Institutes of Health reported the PSG findings in 10 patients with clinical signs of post-polio syndrome. They noted disruption of sleep architecture due to sleep apnea (both central and obstructive), which was more frequent in patients with bulbar involvement who had more central than obstructive apneas. Bruno [468] reported abnormal movements during sleep studies (e.g., random myoclonus, brief ballistic and slow grasping movements, and PLMS) in seven poliomyelitis survivors. A physiologic study to understand the sequence of events during REM sleep in 13 patients with post-polio syndrome by Siegel et al. [469] from the National Institutes of Health measured latencies to the onset of the first occurrence of muscle tone reduction, the first sawtooth waves, and the first REMs in 13 patients with post-polio syndrome. The latencies for the entire group were longer than those of the normal volunteers, and the latencies for the bulbar group were significantly longer than those for the nonbulbar group of post-polio patients. The authors concluded that prolongation of these latencies may be due to prolonged recruitment time for neurons in the pontine tegmentum as a result of damage from the poliomyelitis virus in the past.

In a more recent report, Marin et al. [470] observed 10 fulfilling the diagnostic criteria for RLS/WED (2 men, 8 women; mean age of 42.5 years) among 35 post-polio patients in the outpatient clinics. They noted a concomitant occurrence of both RLS and post-polio patients suggesting a possible common underlying mechanism for both conditions. This is a small sample without controls, and epidemiologic studies including larger samples are needed to confirm this relationship. Silva et al. [471] in a brief report described some nonspecific sleep architectural changes, increased PLMS, and apnea-hypopnea index in overnight polysomnographic studies obtained from 60 randomly selected post-polio patients. The authors concluded these abnormalities reflected a dysfunction of the surviving motor neurons in the brain stem. There have been no new advances in the management of post-polio patients [472].

Syringobulbia-Syringomyelia

Some patients with syringobulbia-myelia may have alveolar hypoventilation and sleep-related apneas or irregular breathing and stridor. Haponik et al. [473] described such a case. The patient was a 35-year-old woman whose polygraphic examination showed 370 upper airway obstructive apneas lasting 10–170 s associated with hypoxemia during 7 h of NREM stages 1 and 2 sleep. The patient died 9 months after the onset of the illness, and neuropathologic examination disclosed a syrinx that extended from the lower third of the medulla to the upper thoracic spinal cord. Nogues et al. [474] studied 30 patients with syringomyelia, including 17 with syringobulbia, using overnight PSG and pulmonary function tests that also included hypercapnic ventilatory response; they found SDB (central, mixed, and obstructive apneas) in 1 of 13 patients with syringomyelia and 13 of 17 patients with syringobulbia. Impaired hypercapnic ventilatory response was noted in patients with syringobulbia. They found that symptoms of dysphagia and dysphonia rather than the size of the cavity on MRI or muscle weakness were predictive of SDB. These authors [475] also reported PLMS during NREM stages 1 and 2 in 16 of 26 patients with syringomyelia and periodic limb movements in wakefulness in three of these patients. The EMG latency delay between the upper and lower limb muscles suggested conduction along slowly conducting propriospinal pathways, indicating spinal cord hyperexcitability similar to the propriospinal propagation of PLMS in some RLS patients [476]. An occasional report [477] of postural tachycardia syndrome (see later) in syringomyelia and cardiovascular autonomic [478] impairment associated with sleep apnea in syringomyelia and syringobulbia suggest involvement of brain stem and spinal autonomic neurons. In a recent review published in 2012, Massimi et al. [479] stated that in the last three decades, only 41 cases of abrupt onset of syringomyelia associated with Chiari malformation type 1, respiratory failure (29 %), and cardiac autonomic dysfunction have been reported.

Sleep Dysfunction and Encephalitis

Cohn and Kuida [480] and White et al. [481] described alveolar hypoventilation, CSA, EDS, and subnormal hypercapnic ventilatory response after western equine encephalitis. The respiratory center was thought to have been damaged by the virus. Iranzo et al. [482] reported six patients with nonparaneoplastic limbic encephalitis associated with antibodies to voltage-gated potassium channels. Five of these patients had RBD associated with the onset of limbic encephalitis and in three of these immunosuppression resulted in the resolution of RBD in parallel with remission of the limbic syndrome. The authors suggested that RBD may be seen in the setting of voltage-gated potassium channel antibody-associated limbic encephalitis, which may be related to an autoimmune-mediated mechanism.

Sleep dysfunction, including total insomnia, NREM and REM parasomnia, has been described in many other types of autoimmune (antibody-mediated) encephalopathies [483–485] (e.g., anti-NMDA-receptor encephalitis and several limbic encephalitis subtypes). Distinctive clinical features including sleep disorders along with neuroimaging and

electrophysiologic findings may indicate specific antibody-mediated encephalitis. A novel encephalopathy (a tauopathy) associated with cell surface autoimmunity (IgLON5) causing a novel NREM and REM parasomnia (RBD) with OSA has been recently described [486].

Arnold–Chiari Malformation

Arnold–Chiari malformation, particularly types I and II, may cause SDB, predominately CSA but also upper airway OSA, and central hypoventilation, including sudden respiratory arrest during sleep or postoperatively [487–489]. A repeat PSG in 6 of 12 patients out of 16 consecutive patients with Arnold Chiari malformation type I showed a decrease in the central apnea index following decompression surgery [490]. In a study by Sergio et al. [491] reporting 103 patients with Arnold–Chiari malformation (36 with type I and 67 with type II), a video-PSG study showed RBD in 23 and SDB in 65 (predominantly with CSA syndrome in 61 of the 65 patients). More recently, PSG documented a high prevalence of sleep apnea (both central and obstructive) in 16 children with Chiari type II [492] and eight out of 22 children with Chiari type I [493] malformations who showed significant improvement of central apneas after surgical decompression. Figures 41.21 and 41.22 show a hypnogram and a 120-second excerpt from a PSG recording from a 52-year-old man with Arnold–Chiari malformation type I. The hypnogram findings suggest REM sleep-related hypoventilation, and the PSG tracing shows obstructive apneas and hypopneas.

Diseases of the Spinal Cord

In spinal cord disorders, sleep disturbances occur as a result of sleep-related respiratory dysrhythmias causing sleep apneas, hypopneas, or hypoventilation associated with hypoxemia and repeated arousals. The voluntary or behavioral respiratory control system descends via the corticospinal tracts, and the metabolic or automatic respiratory control system descends via the reticulospinal tracts; the two systems are integrated in the spinal cord (see also Chap. 11). The behavioral system is located in the dorsolateral quadrant of the cervical spinal cord [13, 14] and the automatic respiratory system in the ventrolateral quadrant. These two systems control the final common respiratory pathways of the spinal respiratory motor neurons, which send impulses along the phrenic and intercostal nerves to the main respiratory muscles. The anterior horn cells in the third, fourth, and fifth cervical spinal cord segments give rise to phrenic nerves, and the intercostal nerves originate from the ventral rami from the anterior horn cells in the thoracic spinal cord. It is known that transection of either the dorsolateral or the ventrolateral quadrant of the spinal cord may independently affect the voluntary and the automatic respiratory control systems [79]. Most reports, however, refer to transection of the ventrolateral tracts giving rise to dysfunction of the metabolic respiratory control system. Direct involvement of the lower motor respiratory pathways, either in the anterior horn or in the phrenic and intercostal nerves, may also give rise to respiratory dysfunction. Three patterns of respiratory dysfunction have been summarized by Krieger and Rosomoff [494]: (1) efferent motor impairment (e.g., phrenic nerve paralysis causing diaphragmatic weakness) associated with reduced vital capacity, (2) impaired hypercapnic ventilatory response without significant chest wall or diaphragmatic weakness and with normal vital capacity, and (3) a mixture of these two abnormalities. The lesions that cause such dysfunction in the spinal cord may include spinal surgery, spinal trauma, amyotrophic lateral sclerosis (ALS), syringomyelia, cervical spinal cord tumor, and cervical myelitis (demyelinating or nonspecific myelitis).

Spinal Surgery

Several cases of sleep apnea have been described after spinal surgery [494–496]. Krieger and Rosomoff [495] also described sleep apnea after high cervical cordotomy. These authors observed respiratory dysfunction within 24–48 h of bilateral percutaneous cervical cordotomy in 10 patients [494]. Although the authors concluded that the ascending reticular fibers in the ventrolateral segment of the spinal cord that relay afferent impulses to the medullary respiratory center had been damaged in their patients, it is most likely that selective damage to the descending automatic respiratory control fibers in the ventrolateral quadrant of the spinal cord was the lesion responsible. In two other patients, Krieger and Rosomoff [495] described sleep apnea that required assisted ventilation at night for several days after anterior spinal surgery at C3-4 interspace. Lahuerta et al. [496] performed high cervical cord percutaneous cordotomy for pain management in 12 patients, all of whom died during sleep postoperatively, presumably from respiratory dysrhythmia. These patients had lesions involving the anterolateral funiculus in the C2 segment, where respiratory fibers are intermingled with ascending pain fibers. Thus, these reports clearly document Ondine's curse as a sequela of high cervical spinal cord lesions.

Spinal Trauma

OSA has been described in patients with cervical spine fractures [497] or high spinal cord injury [498, 499]. Guilleminault [500] described eight victims of neck trauma who showed sleep apnea, hypoxemia, and EDS and suggested that mild compression of the lower medulla and upper cervical spinal cord might cause respiratory disturbances during sleep after severe whiplash injury or odontoid fractures. In another report, Stockhammer et al. [501]

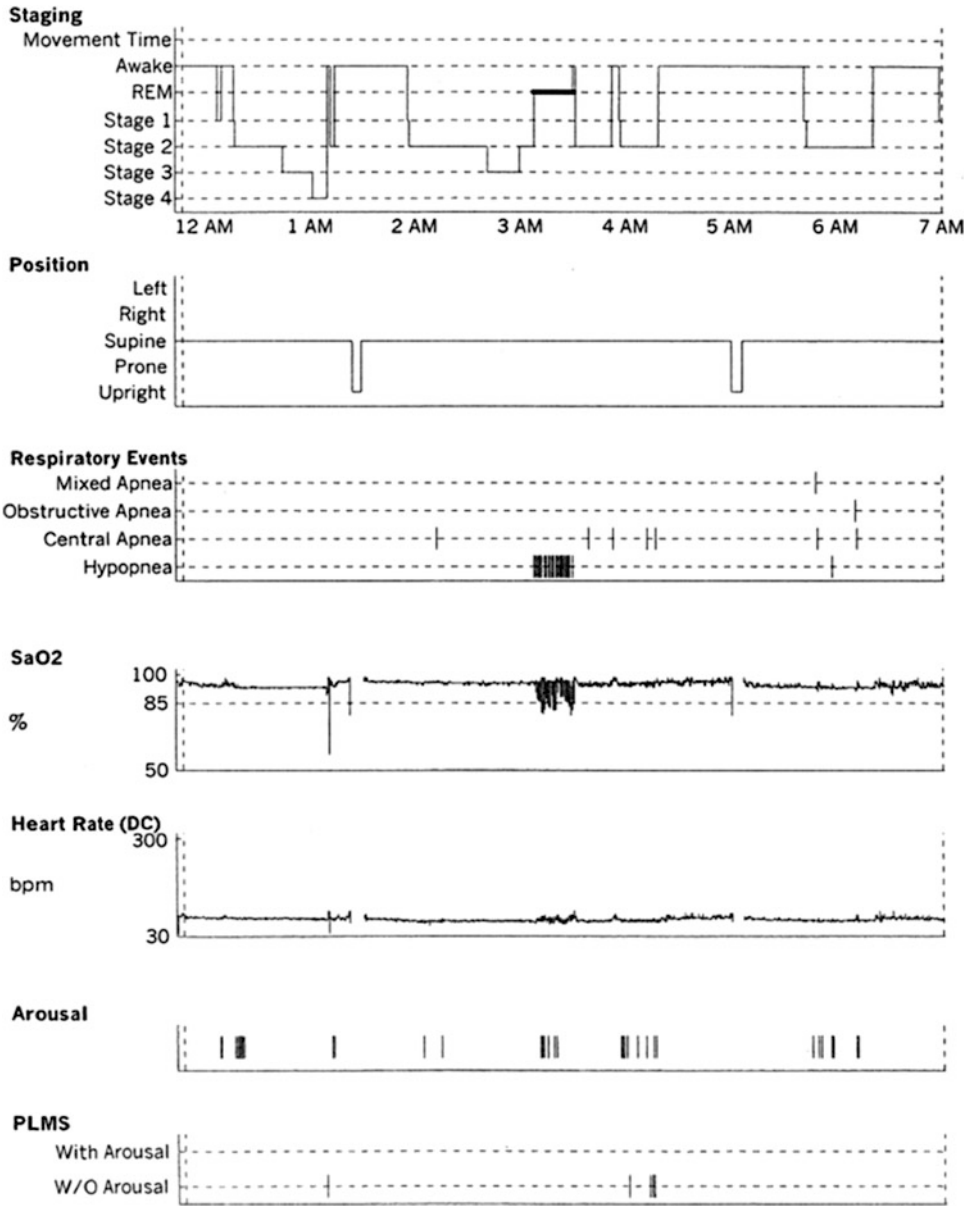

Fig. 41.21 A case of Arnold–Chiari malformation and SDB in a 52-year-old man with a history of tiredness and excessive daytime sleepiness for many years but no cataplexy, sleep paralysis, or hypnagogic hallucinations. At the age of 27 years, he complained of gait problems, and magnetic resonance imaging examination revealed Arnold–Chiari malformation type 1. His neurologic examination is significant for the presence of a coarse horizontal nystagmus, minimal right lower facial weakness, minimal right wrist extensor muscle weakness, minimal-to-mild ataxia in upper and lower extremities on coordination testing, and the presence of ataxia on tandem gait. This hypnogram shows a few periods of apneas and hypopneas accompanied by mild-to-moderate oxygen desaturation and arousals limited exclusively to a single REM sleep period recording during the night. A supine posture is maintained throughout the polysomnographic recording. These findings are suggestive of REM sleep-related hypoventilation. Central sleep apnea, obstructive sleep apnea, and hypoventilation have all been described in patients with Arnold–Chiari malformation, likely from brain stem involvement. Reproduced with the permission from Chokroverty et al. [455]

documented sleep apnea syndrome in 55 % men and 20 % of women in a series of 50 randomly selected patients with tetraplegia resulting from spinal cord injuries. The authors concluded that the incidence of sleep apnea syndrome is high in tetraplegia, especially in older men with large neck circumference and long-standing spinal cord injuries. More recent reports also emphasized a high prevalence of sleep dysfunction and sleep-disordered breathing (SDB) [502–506] in spinal cord injury. Sleep complaints are frequent in spinal cord injury patients and may include difficulty in falling asleep, repeated awakening, impaired sleep quality, increasing use of sleeping medication, snoring, and daytime

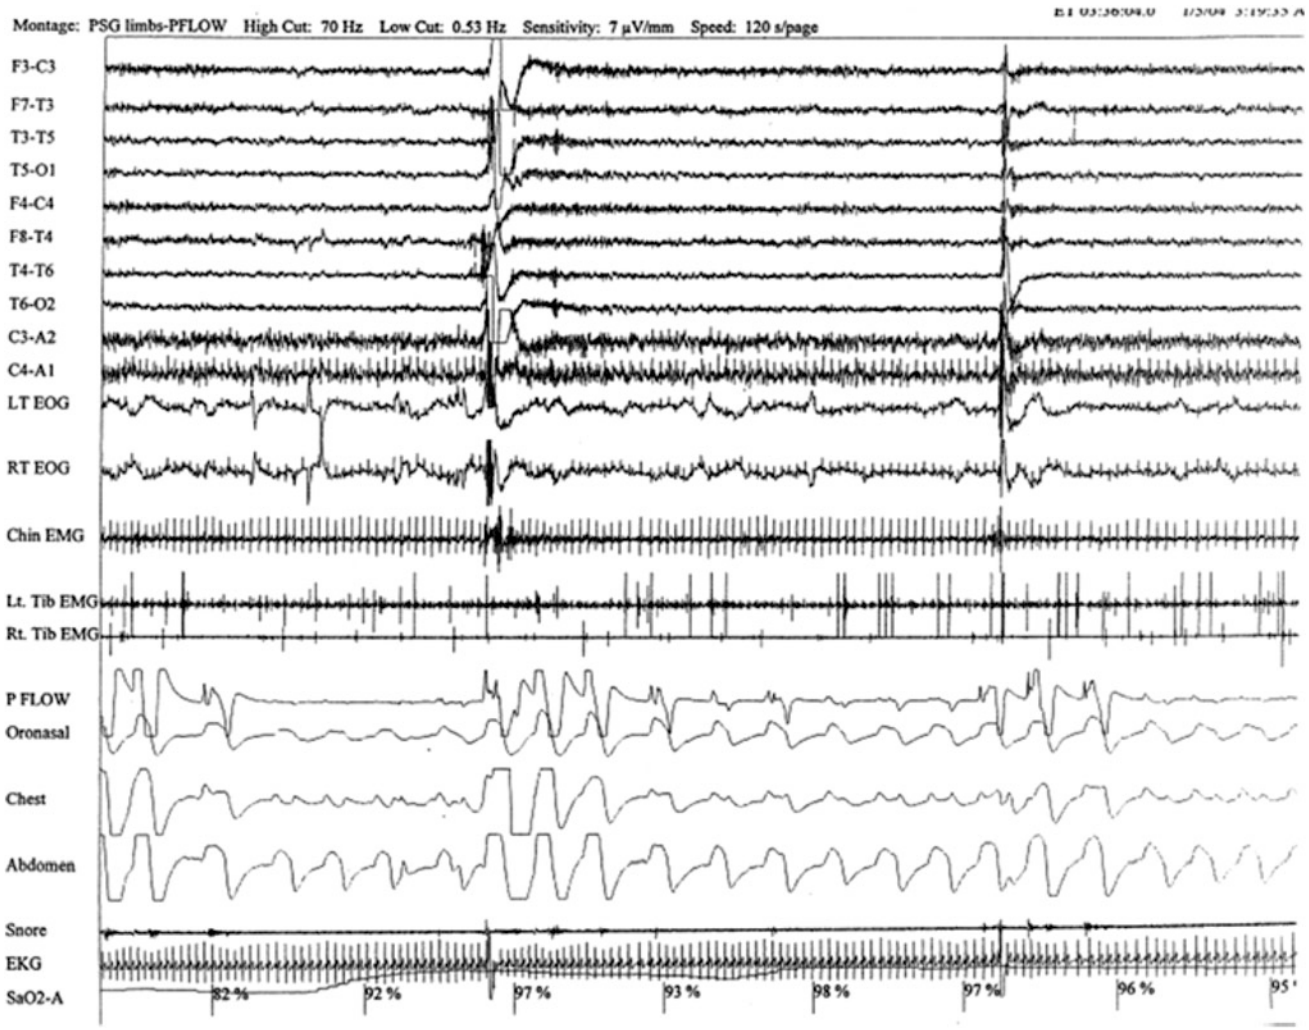

Fig. 41.22 A 120-s polysomnographic excerpt from REM sleep (same patient as in Fig. 41.21) showing one obstructive apnea followed by two sequential hypopneas. Oxygen desaturation of 82 %, likely from a prior respiratory event, is recorded at the onset of the epoch. The first two events are followed by an arousal response, and the epoch does not include the complete recovery phase of the third event. Phasic eye movements of REM sleep are noted on the electrooculogram (EOG) channels in the early part of the epoch. Phasic muscle twitches of REM sleep are noted on both tibialis anterior electromyography (Tib. EMG) channels. Chin EMG channel shows electrocardiography artifact. Electroencephalogram (EEG): top 10 channels. *Lt.* left; *Rt.* right; *P Flow* peak flow; oronasal thermistor; chest and abdomen effort channels; snore monitor; EKG, electrocardiography; SaO_2, oxygen saturation by finger oximetry. Reproduced with permission from Chokroverty et al. [455]

napping [503, 507]. Proserpio et al. [502] in a prospective observational study evaluated 35 patients with spinal cord injury (15 tetraplegics and 20 paraplegics) within the first year after injury. They noted OSA in nine (25.7 %) and PLMS in 10 (28.6 %) patients. In their patients, the frequency of OSA was higher in tetraplegics than paraplegics, similar to high prevalence of SDB in tetraplegics reported previously by Berlowitz et al. [508]. Another important observation in this study is the high prevalence of OSA after cervical cord injury. Finally, the absence of daytime sleepiness related to OSA in their patients is in line with similar previous observation [505] and that noted in heart failure patients with SDB [507].

There are a few scattered reports of PLMS associated with paraplegia due to spinal cord injury or other spinal cord lesions [509–512]. The authors of these papers concluded that the PLMS resulted from disinhibition of the spinal locomotor generator. It should be noted that the question of the spinal cord as the generator for PLMS remains highly speculative and controversial. In a recent preliminary neurophysiologic study in a subgroup of spinal cord injury patients, Ferri et al. [513] observed a cerebral and autonomic response to leg movements in 45 % of patients with acute spinal cord injury suggesting the potential presence of surviving spinal or extraspinal connections.

Sleep and Breathing Disturbances in Neuromuscular Disorders

Sleep disturbances in neuromuscular disorders are most commonly due to respiratory dysrhythmias secondary to involvement of the respiratory pump, which includes the diaphragm, the intercostal and other accessory muscles of respiration, and the upper airway muscles (genioglossus, palatal, pharyngeal, laryngeal, hyoid, and masseter muscles). Adverse effects on the motor neurons, the phrenic and intercostal nerves, or the neuromuscular junctions of the respiratory and oropharyngeal muscles, and primary muscle disorders affecting these muscles are responsible for respiratory dysrhythmia and sleep dysfunction [91, –519]. The most common complaint is EDS resulting from repeated arousals and sleep fragmentation due to transient nocturnal hypoxemia and hypoventilation in addition to sleep-related respiratory dysrhythmias. Some patients, particularly those with painful polyneuropathies, muscle pain, muscle cramps, and immobility due to muscle weakness, may complain of insomnia. The most common neuromuscular disorders causing SDB and sleep dysfunction include motor neuron disease (ALS); myasthenia gravis, including myasthenic syndrome; acute inflammatory demyelinating polyradiculoneuropathies (Landry/Guillain–Barré/Strohl syndrome); muscular dystrophies, including myotonic dystrophy; inflammatory myopathies; and congenital myopathies (Box 41.4 and Fig. 41.23). Many of these conditions are treatable; others show relentless progression, but even in these conditions, quality of life may be improved with prolongation of the natural course of the illness by timely and adequate treatment of SDB. It is therefore important for physicians taking care of patients with neuromuscular disorders to have a basic understanding of these disorders and a high index of suspicion for SDB in such patients so that patients can be either referred to specialists or treated adequately in a timely manner.

Box 41.4 Common Neuromuscular Disorders Causing Sleep-Disordered Breathing and Sleep Dysfunction

- Motor neuron disease (amyotrophic lateral sclerosis [ALS]),
- Polymyositis and post-polio syndrome,
- Myasthenia gravis,
- Myasthenic syndrome,
- Acute inflammatory demyelinating polyradiculoneuropathy (Landry–Guillain–Barré syndrome),
- Muscular dystrophies including myotonic dystrophies types 1 and 2 (DM1 and DM2),
- Inflammatory myopathies (polymyositis and dermatomyositis),
- Congenital myopathies.

Sleep-disordered breathing is commonly associated with insidiously developing chronic respiratory failure in neuromuscular disorders, especially in the advanced stages, but is often unrecognized and untreated [91, 513–519]. The most common SDB in neuromuscular disorders is sleep-related, especially REM-related, hypoventilation. Both central and upper airway obstructive apneas also occur. Bulbar muscle weakness in many patients may cause increased upper airway resistance, but adequate studies have not been undertaken to identify its true prevalence in neuromuscular

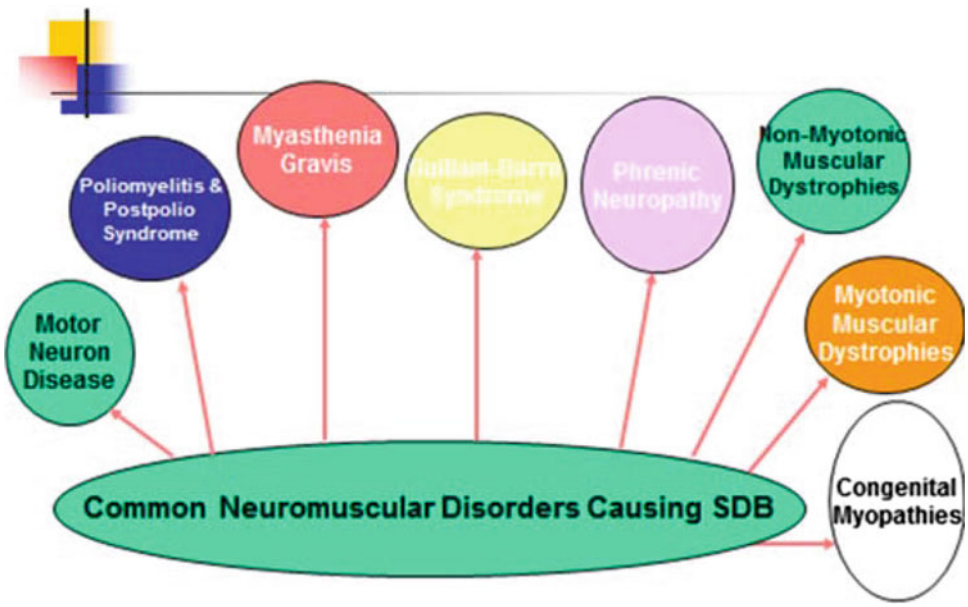

Fig. 41.23 Types of neuromuscular disorders

disorders. Paradoxical breathing (movements of the thorax and abdomen in opposite directions) may be seen in patients with upper airway OSA and upper airway resistance syndrome. This is different from paradoxical inward movement of the abdomen with epigastric retraction instead of protrusion during inspiration as seen in patients with diaphragmatic paralysis. Nocturnal hypoventilation giving rise to hypoxemia and hypercapnia during sleep in the initial stage of neuromuscular disorders causes chronic respiratory failure; the abnormal blood gases may later present even during the daytime.

Mechanism of SDB and Respiratory Failure in Neuromuscular Diseases

Respiratory failure is defined as an inability of the lungs to effectively exchange gas and maintain normal acid-base balance as a result of failure of the respiratory system anywhere from the medullary respiratory controllers to the chest bellows and the lungs, including the upper airways. As a result of this failure, there is reduction in Pao_2 and increased $Paco_2$. A Pao_2 of less than 60 mm Hg and a $Paco_2$ of more than 45 mm Hg at sea levels are commonly considered criteria for respiratory failure. Most neuromuscular disorders cause ventilatory failure, which is defined as inadequate alveolar ventilation with reduced tidal volume causing low Pao_2 and high $Paco_2$.

Respiratory failure in neuromuscular disorders begins during sleep, followed by gradual or relentless progression unless interrupted by ventilatory support at night. A variety of physiologic changes occur in the central control of breathing and in the respiratory muscles during sleep (see Chap. 11) that are responsible for initiating respiratory failure in sleep in patients with neuromuscular disorders. Additionally, there may be a comorbid upper airway obstruction not related to neuromuscular disorders. However, in many of these patients, the upper airway muscles are also affected, causing upper airway OSA. The accessory muscles of respiration maintain breathing during NREM sleep in patients with weakness of the diaphragm, the main muscle of ventilation; however, during REM sleep, there is hypotonia or atonia of these accessory muscles, and ventilation then depends exclusively on the diaphragm. Therefore, in patients with diaphragmatic weakness, ventilation is severely affected during REM sleep, causing REM hypoventilation. This is the first stage of respiratory failure in neuromuscular disorders (Fig. 41.24). As the disease advances to the second stage, the accessory muscles of respiration are affected severely, thus causing ventilatory disturbance during NREM sleep [513, 520]. In the final stage (stage 3) of neuromuscular disorders, ventilation is affected even during the daytime, causing altered blood gases (e.g., hypoxemia and hypercapnia) during wakefulness. Stage 2 of respiratory failure may be related to either progression of the neuromuscular disorder or superimposed intercurrent infection (e.g., pneumonia), or both.

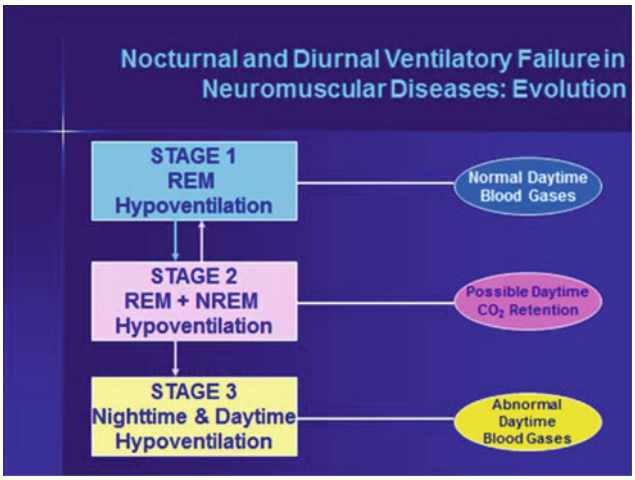

Fig. 41.24 Stages of NMD

Several authors aimed at identifying daytime predictors of SDB and nocturnal hypoventilation and its onset [521–523]. These authors concluded that progressive ventilatory restriction in neuromuscular diseases correlates with respiratory muscle weakness and can be predicted from daytime lung and respiratory muscle function. Inspiratory vital capacity (IVC) and maximum inspiratory muscle pressure (PI_{max}) are the two important predictors of the onset of respiratory failure [521, 522]. IVC of less than 60 % and PI_{max} of less than 4.5 kPa predicted onset of REM hypoventilation, IVC of less than 40 % and PI_{max} of less than 4.0 kPa predicted both REM and NREM hypoventilation, and IVC of less than 25 % and PI_{max} of less than 3.5 kPa predicted daytime respiratory failure. However, Lyall et al. [523] and Morgan et al. [524] suggested that the noninvasive maximal sniff pressure measurement is more sensitive than vital capacity and static maximal inspiratory muscle pressure in patients with ALS and in assessing the risk of ventilatory failure. Carratu et al. [525] in a later preliminary study in 31 ALS patients confirmed that maximal sniff nasal inspiratory pressure (SNIP) lower than 60 CMH_20 may be an early predictor of SDB in ALS. It has also been suggested that a significant fall of vital capacity from the erect to the supine position (70 % or less of the predicted value) indicates the presence of diaphragmatic weakness [526–528]. A fluoroscopy will confirm the weak movement of the dome of the diaphragm during inspiration. A serial blood gas determination is important in detecting impending respiratory failure. It should be remembered that a normal daytime Pao_2 and $Paco_2$ does not exclude REM-related hypoventilation.

In patients with weak respiratory muscles, regardless of cause, the waking breathing difficulties may worsen during

sleep. While patients are awake, both voluntary and metabolic respiratory controls are intact and central respiratory neurons increase the rate of firing or recruit additional respiratory neurons to maintain ventilation adequately to drive weak respiratory muscles [91]. During sleep, however, voluntary control is absent and respiration is dependent entirely on the metabolic control system. Respiratory neurons are thus vulnerable during sleep, aggravating the ventilatory problems and causing more severe hypoventilation and even apneas and hypopneas. Functional impairment of the sensitivity of the central respiratory neurons, causing decreased metabolic respiratory control, may also give rise to apnea-hypopnea during both REM and NREM sleep. Oropharyngeal (upper airway) muscle weakness coupled with REM-related hypotonia or atonia of the muscles may contribute to possible upper airway OSA.

In summary, breathing disorders causing sleep-related hypoventilation in neuromuscular disorders may be related to the following factors:

1. Weakness of the respiratory and chest wall muscles causing impaired chest bellows,
2. Increased work of breathing due to altered chest mechanics and reduced forced vital capacity caused by weakness of the chest wall muscles and diaphragm so that breathing is less efficient,
3. Hyporesponsive chemoreceptors, which may be secondarily acquired or related to altered afferent inputs from skeletal muscle spindles, causing functional alteration of the medullary respiratory neurons,
4. Weakness of upper airway muscles that increases upper airway resistance, adding respiratory muscle load or even upper airway OSA from complete closure of the upper airway,
5. Decreased minute and alveolar ventilation during sleep,
6. REM-related marked hypotonia or atonia of all the respiratory muscles except the diaphragm, causing increased diaphragmatic workload,
7. Respiratory muscle fatigue due to increased demand on the respiratory muscles during sleep, particularly REM sleep,
8. Kyphoscoliosis secondary to neuromuscular disorders, causing extrapulmonary restriction of the lungs with impairment of pulmonary functions, breathlessness, sleep apnea, and hypoventilation,
9. Failure of central control of ventilation,
10. Alteration of respiratory reflexes in upper airway and lung receptors and arousal responses.

All these factors may lead to ventilatory failure in neuromuscular disorders initially at night in the early stage. As a result of alveolar hypoventilation and ventilation-perfusion mismatching, hypoxemia and hypercapnia occur, giving rise to chronic respiratory failure even during the daytime at an advanced stage of the illness (Fig. 41.24).

Clinical Approach

The initial approach to clinical diagnosis of acute respiratory failure, as may occur in patients with acute inflammatory demyelinating polyradiculoneuropathies (e.g., Guillain–Barré syndrome) or myasthenic crisis, is quite obvious. Patients may have irregular, rapid, shallow, or periodic breathing, intermittent cessation of breathing, and cyanosis. However, recurrent hypoventilation in neuromuscular disorders may present insidiously and may initially remain asymptomatic [514, 515, 529–531]. A high index of clinical suspicion is needed. Clinical clues include the presence of EDS, nocturnal restlessness, frequent unexplained arousals, daytime fatigue, shortness of breath, orthopnea (breathlessness in supine position), morning headache, intellectual deterioration and failure to thrive and declining school performance in children. Signs of impending cor pulmonale include insomnia, morning lethargy, headache, and unexplained leg edema. Patients with neuromuscular disorders manifesting these clinical features should be investigated to uncover nocturnal hypoventilation in order to prevent adverse consequences of chronic respiratory failure, such as congestive cardiac failure and cardiac arrhythmia. Special attention during physical examination should be paid to uncover bulbar and respiratory muscle weakness, use of accessory muscles of respiration, and paradoxical breathing. Neuromuscular disorders causing SDB, respiratory failure, and sleep disturbance include ALS or motor neuron disease, primary muscle diseases, acute and chronic inflammatory demyelinating polyneuropathies, hereditary sensorimotor neuropathy, phrenic neuropathy, and neuromuscular junctional disorders (Fig. 41.23).

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis is the most common degenerative disease of the motor neurons in adults, affecting the spinal cord, brain stem, motor cortex, and corticospinal tracts. It is characterized by a progressive degeneration of both upper and lower motor neurons manifesting as a varying combination of lower motor neuron (e.g., muscle weakness, wasting, fasciculation, dysarthria, and dysphagia) and upper motor neuron (e.g., spasticity, hyper-reflexia, and extensor plantar response) signs. The readers are referred to the revised El Escorial and Awaji criteria for diagnosing ALS [532]. ALS can cause profound sleep disturbances associated with EDS as a result of repeated arousals and sleep fragmentation due to nocturnal hypoventilation, recurrent episodes of sleep apnea, hypopnea, hypoxemia, and hypercapnia. Insomnia related to other factors, such as

decreased mobility, muscle cramps, anxiety, and difficulty in swallowing, may be present in some patients. SDB in ALS may result from weakness of the upper airway, diaphragmatic, and intercostal muscles due to involvement of the bulbar, phrenic, and intercostal motor neurons. In addition, degeneration of central respiratory neurons may occur, causing central and upper airway OSAs. Generally, respiratory failure in ALS occurs late, but occasionally this may be a presenting feature requiring mechanical ventilation [529, 533]. Diaphragmatic weakness resulting from the degeneration of phrenic neurons is noted frequently in ALS and is mainly responsible for nocturnal hypoventilation, initially during REM sleep [514, 515]. Newsom Davis' group [534] described eight patients with diaphragmatic paralysis resulting from a variety of motor disorders. One of their patients had Kugelberg–Welander syndrome. The following features may be helpful in the diagnosis of diaphragmatic paralysis:

1. Breathlessness and EDS, suggesting alveolar hypoventilation,
2. Paradoxical inward movement of the abdomen with epigastric retraction instead of protrusion during inspiration,
3. An elevated diaphragm on chest radiography and paradoxical movement or decreased excursion of the diaphragm on fluoroscopy,
4. Documentation of a very sensitive measurement showing a lack of change in the transdiaphragmatic pressure during a maximum inspiration,
5. Diaphragmatic electromyographic (EMG) findings,
6. Respiratory function tests with the evidence of a restrictive pattern,
7. Blood gases showing hypoxemia and hypercapnia, suggesting alveolar hypoventilation,
8. Documentation of sleep-related breathing abnormalities on PSG.

Sleep-related respiratory dysrhythmia is a common complication of ALS causing central and obstructive sleep apneas, sleep hypoventilation, and respiratory failure associated with daytime hypersomnolence [514, 515, 535–538]. Overnight polygraphic recording documenting both central and upper airway obstructive apneas (Fig. 41.25) associated with severe oxygen desaturation, and alveolar hypoventilation taken from a PSG tracing of one of our (SC) ALS patients is shown here.

Ferguson et al. [535] studied 18 ALS patients with mild-to-severe bulbar muscle involvement and 10 age-matched control subjects. Most patients complained of difficulty initiating and maintaining sleep. All patients and controls had overnight PSG study, and 13 ALS patients had a second night of PSG study. ALS patients had more arousals and stage changes per hour, more stage 1 NREM sleep, and shorter total sleep time than controls. ALS patients had mild SDB with greater AHI than controls. It is notable that SDB was similar in ALS patients with or without respiratory muscle weakness. The SDB consisted of REM-related nonobstructive and central apneas. In an early study, Minz et al. [536] described PSG findings in 12 ALS patients, six men and six women. Four patients had both central and obstructive apneas. Sleep structure was normal in eight, but the others had frequent awakenings.

Howard et al. [537] described 14 patients with motor neuron disease associated with respiratory dysfunction. Eleven received respiratory support, including CPAP and intermittent positive pressure ventilation (IPPV) at night with considerable benefit. In a recent report, Lo Coco et al. [538] studied 100 consecutive ALS patients and 100 age- and sex-matched control subjects using PSQ and ESS as well as overnight PSG in 12 patients and the ALS Functional Rating Scale—Review (ALSFRS-R) in all patients. Fifty-nine percent of patients and 36 % of controls had sleep disturbances. The most common nighttime sleep complaints by patients with ALS included nocturia (54 %), sleep fragmentation (48 %), and nocturnal leg cramps (45 %). PSG showed decreased sleep efficiency and fragmented sleep architecture. These authors demonstrated that ALS patients had significant impairment of quality of sleep which correlated with the severity of illness (reduced ALSFRS-R score), daytime somnolence, ESS score, and depression. This is an important study challenging the clinicians to be aware of sleep-wake problems in ALS patients, because timely intervention could lead to better quality of life for these patients.

There have been several reports focusing on the role of noninvasive IPPV at night on the quality of life and the prognosis (see later in the Sect. "Treatment of Sleep and Respiratory Dysfunction Secondary to Neurologic Disorders").

Other Types of Motor Neuron Diseases

SDB causing sleep disturbance and daytime symptoms has also been noted in other types of motor neuron diseases, such as Kugelberg–Welander syndrome, a variant of juvenile-type motor neuron disease, as well as spinal muscular atrophy types 1 and 2 in children and adolescents [539–542].

Spinal muscular atrophy (SMA) consists of a group of recessively inherited neuromuscular disorders resulting from mutations of the survival motor neurons (SMN-1) gene on chromosome 5q [515]. Based on the age of presentation and

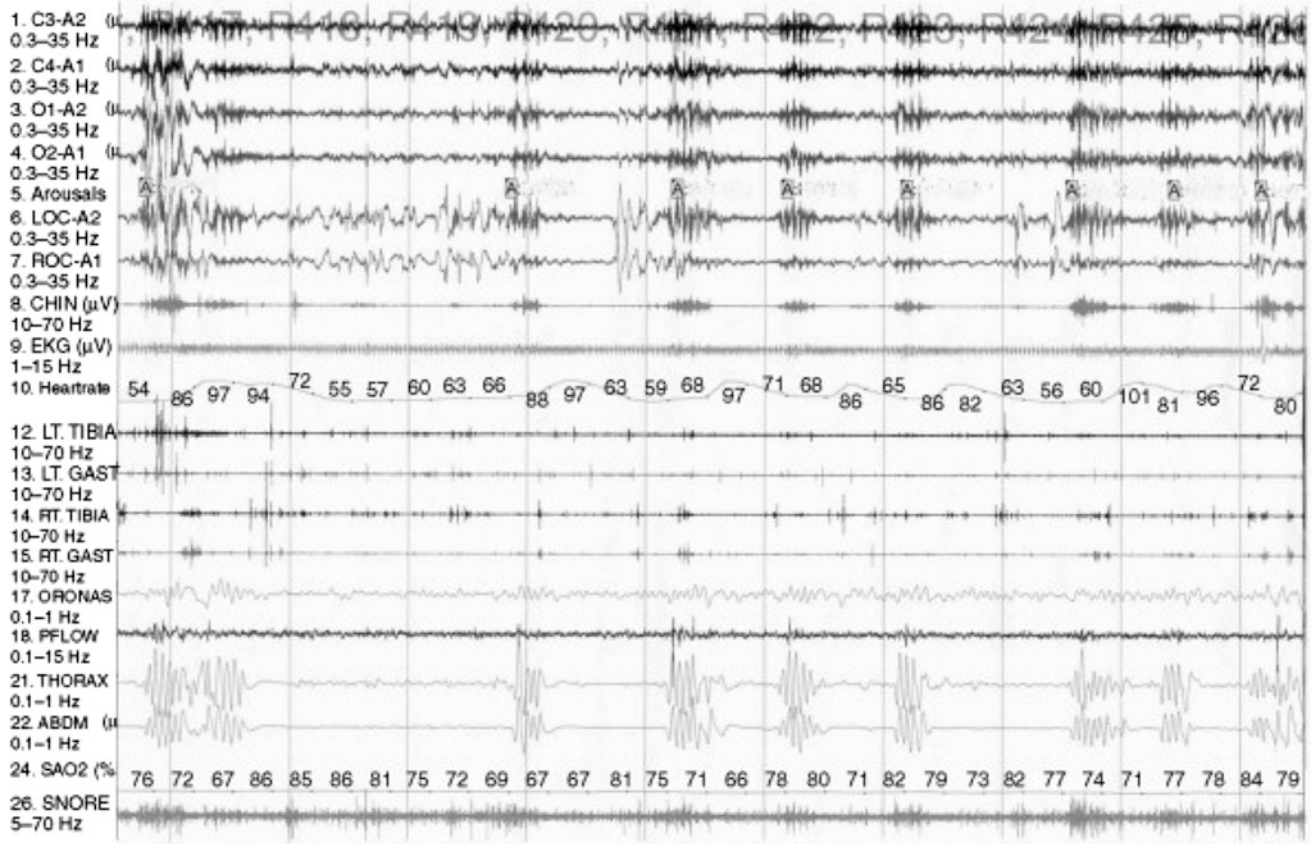

Fig. 41.25 Overnight polysomnographic recording from a patient with amyotrophic lateral sclerosis presenting with upper and lower motor neuron signs, including bulbar palsy, showing recurrent periods of central apneas many of which are prolonged, followed by irregular ventilatory cycles (resembling ataxic breathing; see Fig. 41.7) accompanied by severe oxygen desaturation and sleep hypoxemia during REM sleep. *Top four channels* represent the electroencephalogram. *EEG* international electrode placement system, *ABDM* abdominal breathing effort; *CHIN* submental electromyogram (EMG); *EKG* electrocardiogram; *LOC* left electrooculogram; *LT.GAST* left gastroenemius EMG; *LT.TIBIA* left tibialis EMG; *ORONAS* oronasal airflow; *PFLOW* nasal pressure recording for airflow; *ROC* right electrooculogram; *RT.GAST* right gastroenemius EMG; *RT.TIBIA* right tibialis EMG; *SAO_2%,* oxygen saturation [%] by finger oximetry; *SNORE* snoring recording; *THORAX* thoracic breathing effort

the number of functioning copies of the SMN-2 gene, SMA has been divided into four subtypes: SMA-1 (acute infantile type also called Werdnig–Hoffman disease), SMA-2 (chronic infantile form), SMA-3 (juvenile form or Kugelberg–Welander disease), and SMA-4 (adult onset). Those with a greater number of copies of the SMN-2 gene begin later in life and have less severe symptoms. Nocturnal noninvasive IPPV eliminates SDB, improves sleep quality, and prolongs survival in children with SMA types 1 and 2 [539, 541, 542].

Polyneuropathies

The cardinal manifestations of polyneuropathies are bilaterally symmetric, distal sensory symptoms and signs, and muscle weakness and wasting (affecting the legs more often than the arms). Peripheral neuropathies may be caused by a variety of heredofamilial and acquired diseases. Disorders of the phrenic, intercostal, and other nerves supplying the accessory muscles of respiration can cause weakness of the diaphragm, intercostal, and accessory respiratory muscles, giving rise to breathlessness on exertion, hypoxia, and hypercapnia. These respiratory dysrhythmias become worse during sleep. Sleep disturbances in polyneuropathies may result from painful neuropathies, partial immobility owing to a paralysis of the muscles, or SBD.

Acute inflammatory Neuropathy

The most common cause of respiratory dysfunction in polyneuropathy is acute inflammatory demyelinating polyradiculoneuropathy (Landry–Guillain–Barré–Strohl syndrome). The characteristic clinical manifestations consist of predominantly motor deficits associated with rapidly progressive ascending paralysis beginning in the legs and manifesting maximally in 2–3 weeks. In approximately 20–

25 % of cases, severe respiratory involvement has been reported, and the critical period is usually the first 3–4 weeks of the illness. It is important to recognize and treat the ventilatory dysfunction. Even the mild respiratory dysrhythmia during wakefulness may worsen during sleep, causing sleep apnea and hypoventilation. Patients with Guillain–Barré syndrome (GBS) may also have vivid dreams and hallucinations with abnormalities of sleep structure in the form of sleep-onset REM, REM sleep without atonia, RBD, and autonomic dysfunction, which have been described in approximately one-third of the GBS patients admitted to an intensive care unit [543]. In a prospective questionnaire-based study [544], more than half of GBS patients had sleep disturbance characterized by delayed sleep onset, sleep fragmentation, and decreased total sleep time, particularly during the first week of hospitalization with subsequent improvement. The question of long-term persistence of SDB in GBS remains undecided until further research [545].

Charcot–Marie–Tooth Disease

Charcot–Marie–Tooth (CMT) disease is the most common inherited neuropathy which has been separated into two main groups: a demyelinating form (CMT1) and an axonal form (CMT2) which has several subtypes (e.g., CMT2A…CMT 2G). Patients with CMT 2C are especially prone to develop vocal cord palsy, possibly due to laryngeal nerve involvement, as well as diaphragmatic dysfunction, hypoventilation, and sleep apnea [546], presumably due to phrenic neuropathy. Sleep dysfunction in CMT results mainly from comorbid sleep apnea [547–552] which may occur in both CMT1 and CMT2 subtypes and restless legs syndrome/Willis–Ekbom disease (RLS/WED) [549, 553–558].

RLS/WED, Polyneuropathies, and Sleep Dysfunction

RLS is seen most commonly in CMT2 but has also been noted in CMT1 type. Gemignani et al. [553, 555–558] observed that RLS associated with sleep dysfunction was more prevalent in subgroups of patients with painful polyneuropathies (both retrospective and prospective studies) compared with controls, suggesting small fiber neuropathy and central sensitization. In contrast, Lim et al. [559] based on their studies of 56 patients with primary RLS/WED and 36 age- and sex-matched controls, using quantitative sudomotor axon reflex test (QSART) and sensory testing concluded that abnormal sensory perception in RLS/WED patients resulted from an impairment of central somatosensory processing rather than small fiber neuropathy.

Other Neuropathies and Sleep Dysfunction

In addition to GBS, a high prevalence of RLS/WED with sleep dysfunction has been described also in chronic inflammatory demyelinating polyneuropathy (CIDP) [557, 560, 561] and those with painful polyneuropathies [556, 558, 559]. On rare occasion, multifocal motor neuropathy (MMN), a distinctive acquired demyelinating neuropathy with conduction block, may present with sleep hypoventilation (presumably due to bilateral phrenic neuropathy) which may be successfully treated with a combination of intravenous immunoglobulin (IVIG) and nocturnal bilevel positive ventilation therapy [562]. OSA associated with chronic sleep dysfunction itself may be a risk factor for axonal polyneuropathy due to recurrent intermittent hypoxemia [563, 564].

Phrenic neuropathies of diverse etiologies associated with neuropathies and plexopathies may cause SDB and sleep difficulty as a result of diaphragmatic dysfunction [514, 515]. Trauma, inflammatory polyneuropathy, and infiltrative lesions (e.g., neoplasms) may cause phrenic neuropathy. Phrenic nerve injury causing SDB with sleep dysfunction has also been noted as a complication of cardiothoracic surgeries [515, 565].

Primary Muscle Diseases (Myopathies)

Myopathies are primary muscle disorders characterized by weakness and wasting of the muscles resulting from a defect in the muscle membrane or the contractile elements that is not secondary to a structural or functional derangement of the lower or upper motor neurons [91, 514]. The characteristic clinical presentation consists of symmetric, proximal muscle weakness and wasting in the upper or lower limbs without sensory impairment or fasciculations. The causes include hereditary muscular dystrophies with or without myotonia; glycogen storage diseases; myoglobinuric myopathies; congenital nonprogressive myopathies with distinct morphologic characteristics; and various acquired metabolic, inflammatory, and noninflammatory myopathies. Some of these patients may report breathing disorders during sleep or worsening of the respiratory dysfunction during sleep. Generally, respiratory disorders show manifestations in the advanced stage, but a small number of patients may present with respiratory failure at an early stage. In many such patients, the true incidence of the sleep disturbances and sleep-related respiratory dysrhythmias cannot be determined without a systematic PSG study. Factors responsible for breathing disorders associated with hypoventilation and sleep apnea in these patients may be summarized as follows [91, 514, 515]: impairment of chest bellows owing to weakness of the respiratory and chest wall muscles,

increased work of breathing, and functional changes in the medullary respiratory neurons that could be due to hyporesponsive or unresponsive chemoreceptors acquired secondarily. The other suggestion for carbon dioxide hyposensitivity is altered afferent input from the skeletal muscle receptors [528]. Sleep disturbances generally occur in muscle disorders secondary to sleep-related respiratory dysrhythmias. Alveolar hypoventilation, both during wakefulness and sleep, should be diagnosed early in these patients to prevent dangerous or fatal hypoventilation during sleep or during administration of drugs, general anesthetic agents, and respiratory infections [91, 514]. Complaints of daytime hypersomnolence and breathlessness should direct attention to the possibility of SDB in these patients.

Muscular Dystrophy

The most common type of muscular dystrophy (nonmyotonic) associated with respiratory dysrhythmia-related sleep dysfunction is Duchenne's muscular dystrophy (DMD) and its variant, Becker muscular dystrophy (BMD). DMD is an x-linked recessive disorder with mutation of the dystrophin gene causing sarcolemmal membrane instability. Dystrophin is absent in DMD but is reduced in BMD. DMD is a relentlessly progressive disorder of muscle weakness, involving initially the pelvifemoral muscles resulting in an inability to stand and walk with confinement to a wheel chair within a few years. Respiratory failure with repeated awakenings at night and EDS occur in the late stage of the disease associated with alveolar hypoventilation and obstructive sleep apnea (OSA). Hypoventilation results from respiratory muscle weakness and scoliosis with restrictive pulmonary deficit, whereas OSA is secondary to upper airway muscle weakness.

Sleep-related respiratory dysrhythmias (both obstructive and central apneas) accompanied by O_2 desaturation and daytime hypersomnolence have been described in many patients with Duchenne's muscular dystrophy [517, 566–571]. Although respiratory failure is most commonly noted in Duchenne's muscular dystrophy, sometimes it also occurs in the more advanced stages of Becker's, limb-girdle, and facioscapulohumeral muscular dystrophies [514, 515, 517].

Smith and associates [567] described 14 patients with Duchenne's muscular dystrophy who had sleep apneas or hypopneas associated with marked O_2 desaturation. These authors stated that the severity of SDB in Duchenne's muscular dystrophy could not reliably be ascertained from daytime pulmonary function studies and asserted that sleep studies are essential.

Howard et al. [568] described nocturnal hypoventilation and respiratory failure in 84 patients with primary muscle disorders that included Duchenne's, Becker's, limb-girdle, and facioscapulohumeral muscular dystrophies; adult-onset acid maltase deficiency; myotonic dystrophy; polymyositis; congenital myopathies; and rigid spine syndrome. All patients needed ventilatory support in the form of negative or positive pressure ventilation or tracheostomy.

Khan and Heckmatt [569] studied 21 patients aged 13–23 years with Duchenne's muscular dystrophy and 12 age-matched controls using 2 consecutive nights of PSG. They noted apneas, 60 % of which were obstructive in nature, with hypoxemia in 12 patients. The respiratory care of patients with Duchenne's muscular dystrophy has been summarized in a consensus statement developed by the American Thoracic Society [534].

In a more recent study, Polat et al. [572] studied 35 children (12 with DMD and 23 controls) using PSG and they noted sleep-wake-related symptoms in 50 % of their patients. In an earlier study [517], similar symptoms were seen in up to 42 % and OSA in 16.6 %. These authors concluded that being wheelchair-bound or having scoliosis did not predict SDB, and so these patients should be investigated with PSG recording because if DMD patients are found to have SDB, treatment with nocturnal noninvasive positive pressure ventilation will improve the quality of life and longevity. In one of the largest studies [573] of 32 children with DMD by Suresh et al., OSA was noted in 31 % and these authors also recommended PSG for wheelchair-bound patients. They noted a bimodal presentation with OSA occurring in the first decade, whereas hypoventilation was seen more commonly in the second decade.

SDB including hypoventilation and OSA has been described in limb-girdle muscular dystrophy [574–576] (several subtypes are described based on distinct molecular abnormalities) and facioscapulohumeral muscular dystrophy [577, 578], the third most common form of muscular dystrophy after DMD and myotonic dystrophy, but not in a systematic manner.

Khan et al. [579] described eight children 6–13 years of age with congenital myopathy, congenital muscular dystrophy, and rigid spine syndromes with respiratory failure. PSG documented nocturnal hypoxemia and severe hypoventilation. Sleep disturbances included repeated awakenings. Sleep complaints and sleep-related periodic respiratory dysrhythmias are also common in other congenital myopathies such as nemaline rod myopathy, centrotubular and central core disease, merosin deficiency myopathy, and congenital muscular dystrophy [579–584]. Most of these present in childhood, but sometimes there is delayed presentation in adulthood [579–581] (see further on).

Myotonic Dystrophy

Dystrophica myotonica, or myotonic dystrophy type 1 (DM1), is an adult-onset, dominantly inherited muscular dystrophy associated with myotonia. DM1 is a multisystem disorder due to a trinucleotide expansion mutation (CTG

sequence) on the DMPK gene on chromosome 19, frontal baldness, cataract, endocrinopathy, and neuropsychologic deficit. Benaim and Worster-Drought [585] were most probably the first to describe alveolar hypoventilation in myotonic dystrophy. Alveolar hypoventilation associated with hypoxemia, as well as impaired hypercapnic and hypoxic ventilatory responses, may be present in both the early and the late stages of the illness. Several authors [517, 586–590] performed polygraphic studies that showed central, mixed, and upper airway obstructive sleep apneas, and sleep-onset REM was noted in some patients. The latter finding may have been due to sleep deprivation secondary to sleep-related respiratory disturbances. Two fundamental mechanisms account for the SDB in this illness: (1) weakness and myotonia of the respiratory and upper airway muscles and (2) an inherited abnormality of the central control of ventilation, most likely related to a common generalized membrane abnormality of the muscles and other tissues, including brain stem neurons that regulate breathing and sleep [587–591].

Sleep studies by Bye et al. [464] in four patients with myotonic dystrophy showed REM sleep-related O_2 desaturation and sleep disorganization. Several other authors have described alveolar hypoventilation, daytime somnolence, and periodic breathing in patients with myotonic dystrophy in single case reports and small and large series [517, 587–604].

Begin et al. [599] found a high prevalence of chronic alveolar hypoventilation in a series of 134 patients with myotonic dystrophy. The authors suggested that the central ventilatory control mechanism is abnormal in myotonic dystrophy patients, contributing to chronic alveolar hypoventilation. These authors concluded that the chronic alveolar hypoventilation resulted from a combination of inspiratory muscle weakness and loading. In addition, the presence of EDS suggested reduced central ventilatory drive or sleep apnea in these patients. The clinicopathologic study by Ono et al. [602] of one patient with myotonic dystrophy, alveolar hypoventilation, and hypersomnia supported the hypothesis postulated by Begin et al. [599]. On postmortem examination of this patient, Ono et al. [602] observed significant neuronal loss and gliosis in the midbrain and pontine raphe, as well as the pontomedullary reticular formation.

Park and Radtke [601] reviewed seven patients with myotonic dystrophy referred to their sleep disorder center. All patients had PSG. Five patients were subsequently given an MSLT. Each of the five who had an MSLT showed the evidence of moderate hypersomnia. Three of these five patients had two sleep-onset REM episodes, only one of whom showed the evidence of sleep apnea in the overnight PSG study. Human leukocyte antigen (HLA) typing was negative for DQW2, but DQW1 was present in two patients. The authors reviewed the literature available (they published their own paper in 1995) and found 86 patients, including their seven patients, with myotonic dystrophy who also had hypersomnolence. Ten percent of the reported patients with hypersomnolence had documented alveolar hypoventilation. Respiratory center hypoexcitability or myotonic muscle weakness is thought to be responsible for alveolar hypoventilation. Correction of hypoventilation does not always lead to improvement of EDS [597, 601]. SDB events were noted in 57 % of the reported patients with EDS, and both central and obstructive sleep apneas were observed. The presence of sleep-onset REMs in these patients supported the hypothesis of a primary CNS abnormality as the cause of EDS [601]. EDS in myotonic dystrophy patients often occurs in the absence of sleep apnea [600, 601]. EDS in their patients [601] responded to methylphenidate treatment. Martinez-Rodriguez et al. [603] measured CSF hypocretin-1 levels in six patients with myotonic dystrophy type 1 complaining of excessive daytime sleepiness who were HLA-DQB1*0602 negative and found to have significantly lower hypocretin-1 levels compared to the control values. The authors concluded that the dysfunction of the hypothalamic hypocretin system may be responsible for hypersomnia in myotonic dystrophy type 1. However, other authors [604, 605] did not find low CSF hypocretin levels in DM1 patients.

In summary, SDB including OSA and nocturnal hypoventilation, EDS, and REM sleep dysregulation are frequently noted in DM1 patients. There is reasonable explanation for the mechanism of sleep-related breathing disorder as stated above. However, an explanation for REM sleep dysregulation and EDS is not always obvious. In a case-control study including 40 DM1 patients and 40 controls, Yu et al. [590] observed EDS in 80 % of patients (ESS score was more than 10 in 31.4 %, and MSLT mean latency was less than 8 min in 12.5 %) and one SOREM in the majority of the patients, whereas two or more SOREMs were seen in about one-third of the patients. These authors also found higher REM density in patients than in controls. REM sleep dysregulation with two or more SOREMs or increased REM density in DM1 patients was also noted by Park et al. [601], Martinez-Rodriguez and coinvestigators [603], and Gibbs et al. [606]. It has been suggested that EDS and REM sleep dysregulation in DM1 patients are not necessarily related to SDB but may be due to an intrinsic CNS dysfunction involving sleep-wake-regulating neurons [590, 593, 600, 601, 604, 607].

Sleep disturbances have also been reported in proximal myotonic myopathy (PROMM), also known as myotonic dystrophy type 2 (DM2). PROMM is an autosomal dominant multisystem disorder caused by a CCTG repeat expansion in intron 1 of the zinc finger protein 9 gene (*ZNF9*), which is differentiated from myotonic dystrophy type 1 by the absence of a chromosome 19 CTG trinucleotide repeat that is associated with type 1 [608, 609].

DM2 has many overlapping clinical features with DM1 such as cataracts, myotonia, cardiomyopathy, autosomal dominant inheritance, diffuse muscle aches and pains, and insulin resistance, but differs from DMI in more proximal distribution of muscle weakness, later onset of the illness, slower progression, and genetic testing. Sleep disturbances including SDB and hypersomnolence have been described in many DMI patients (see above), but a description of sleep problems has been characteristically absent in DM2 until recently. In a brief report, the senior author described sleep disturbances in two sisters, aged 51 and 53, with PROMM [610, 611]. The patients had difficulty initiating sleep, EDS, snoring, frequent awakenings, and movements during sleep. Overnight PSG study showed decreased sleep efficiency, increased number of arousals, and sleep architecture abnormalities. One patient had absent REM sleep, and the other patient had dissociated REM sleep characterized by phasic REM bursts associated with EEG patterns showing sleep spindles and alpha intrusions. These sleep abnormalities in PROMM suggested involvement of the REM-NREM-generating neurons as part of a multisystem membrane disorder. Subsequently, our (SC) group reported more patients with DM2 showing SDB [612] and one with REM behavior disorder [613]. Many other investigators in case series and scattered case reports of DM2 reported a variety of sleep dysfunction including SDB, PLMS, EDS, RLS, and insomnia [614–618]. However, no systematic study involving a large number of DM2 patients with longitudinal follow-up is available. The MRI findings of white matter hyperintensity in T_2-weighted images in six patients from three families with PROMM described by Hund et al. [619] suggested brain involvement in PROMM, but the relationship between the sleep disturbances and the MRI abnormalities remains to be determined.

Acid Maltase Deficiency and Other Glycogen Storage Disorders

Alveolar hypoventilation has been described in several cases of mild-to-moderate myopathy associated with adult-onset acid maltase deficiency, a variant of glycogen storage disease, also known as Pompe disease. Pompe disease (or glycogen storage disease type II) is an autosomal recessive, serious, and often fatal disorder of glycogen metabolism. It is due to mutations in the acid alpha-glucosidase (GAA) gene, absence of which causes cardiorespiratory failure in the first year, whereas reduced GAA activity gives rise to progressive respiratory failure later in life [620, 621]. The disease may present in the early stage with diaphragmatic weakness causing hypoventilation, initially during REM sleep and later causing respiratory failure even during the daytime. Presence of macroglossia and significant tongue weakness should direct attention to upper airway dysfunction causing OSA. It is important to make the correct diagnosis early by performing electromyographic (EMG), biochemical, histochemical, or morphological examination of muscle biopsy samples, determination of low GAA activity in skin fibroblasts or blood samples, respiratory function, and genetic testing as specific treatment is now available. The Federal Drug Administration (FDA) in the USA and the European Authority recently approved alglucosidase alfa (recombinant human GAA, Myozyme, Genzyme Corporation, Cambridge, MA, USA) as enzyme replacement therapy (ERT) for the treatment of Pompe disease (biweekly intravenous infusion of 20 mg/kg body weight) [620, 621]. Subsequent clinical data suggest that ERT delays progression of symptoms, but many patients will require additional ventilator support, especially during sleep [620].

Bye et al. [464] described REM sleep-related hypoxemia and sleep disorganization in acid maltase deficiency. An adult patient with acid maltase deficiency with severe OSA and respiratory failure was reported by Margolis et al. [622]. Despite ventilatory support, the patient died. At postmortem examination, profound muscle replacement by fibrofatty tissue was noted in the tongue and diaphragm. The authors suggested that severe tongue weakness due to fatty metamorphosis associated with macroglossia contributed to the upper airway obstruction in this patient. The brain was not examined at the autopsy.

Other Varieties of Congenital Myopathies

Riley et al. [566] described alveolar hypoventilation in two patients with congenital myopathies (one with nemaline myopathy and the other with a myopathy of uncertain type). The patients' ventilatory response to carbon dioxide was absent, and the authors suggested that the alveolar hypoventilation may have been due to a primary defect in the central chemoreceptor control of breathing. Their other suggestion was that the sensory stimuli from skeletal muscle receptors (e.g., muscle spindles) may have played a role in the blunted hypercapnic ventilatory response by altering afferent input to the CNS. There are other reports of sleep hypoventilation in congenital myopathy [464, 579, 622– 624].

Miscellaneous Myopathies

Obstructive sleep apnea with sleep-related hypoxemia and sleep disturbances have also been described in patients with polymyositis [464, 517, 568, 625] including inclusion body myositis [626] and mitochondrial encephalomyopathy [627–630].

Neuromuscular Junction Disorders

Myasthenia gravis, myasthenic syndrome, botulism, and tick paralysis are several neuromuscular junction disorders

characterized by easy fatigability of the muscles, including the bulbar and other respiratory muscles, owing to failure of neuromuscular junctional transmission of the nerve impulses. The most important of these conditions is *myasthenia gravis*, an autoimmune disease characterized by a reduction in the number of functional acetylcholine receptors in the postjunctional region. Acute respiratory failure is often a dreaded complication of myasthenia gravis, and patients need immediate assisted ventilation for life support [91, 514, 515]. The respiratory failure, moreover, may be mild during wakefulness but may deteriorate considerably during sleep.

An important study by Quera-Salva et al. [631] reported the pulmonary function and PSG studies of 16 women and 4 men whose mean age was 40 years and who were diagnosed and treated for myasthenia gravis. Polysomnographic findings included moderately disturbed nocturnal sleep with an increase in stage 1 NREM and decreased slow-wave and REM sleep. Eleven patients had an RDI of 5 or higher. They had central, obstructive, and mixed apneas and hypopneas accompanied by decreased O_2 saturation. All patients with REM sleep-related apneas or hypopneas had disturbed nocturnal sleep with a sensation of breathlessness. Twelve patients had insufficient sleep owing to awakening in the middle of the night and early morning hours with a sensation of breathlessness. Four of the 12 patients also had daytime hypersomnolence. The authors suggested that those patients of advancing age, moderately increased BMI, abnormal pulmonary function results, and daytime abnormal blood gas concentrations are at particular risk for SDB. Since this report, there have been a few other reports of SDB in patients with myasthenia gravis [632–635].

Manni et al. [632] studied breathing patterns during sleep in 14 patients with mild generalized myasthenia gravis. Polysomnographic study documented infrequent central apneas, mainly during REM sleep, in five patients associated with O_2 desaturation. Putman and Wise [633] described a 54-year-old woman with myasthenia gravis and episodes of shortness of breath, which were more severe at night. The flow-volume loops suggested extrathoracic airway obstruction. They also surveyed a total of 61 myasthenia gravis patients referred to their pulmonary function laboratory during 42 months. They found a pattern of extrathoracic upper airway obstruction in 7 of the 12 patients who had flow-volume loops. Nicolle et al. [634] randomly selected 100 patients with myasthenia gravis out of 400 patients from their database. They found a prevalence of OSA of 36 % based on PSG study in 50 patients compared to an expected prevalence of 15–20 % of the general population. The prevalence of OSAS (those with daytime sleepiness) was 11 % compared to 3 % in the general population. The authors suggested that it is important to inquire about OSA symptoms in myasthenia gravis patients for adequate management of fatigue in these patients. Prudlo et al. [635] investigated sleep and breathing in 19 myasthenia gravis patients utilizing two consecutive overnight PSG studies. These authors found clinically relevant SDB in terms of OSA (defined as an RDI of > 0/h) in only four patients, who had also a few central apneas. The authors failed to confirm the high occurrence of central respiratory events during sleep and also failed to find a causal relationship between medically stable myasthenia gravis and OSA. Thus, some investigators observed more central than obstructive apneas [632], whereas others noted predominantly obstructive apneas. The final answer remains to be determined. Some investigators [636] reported a high prevalence of patient-reported sleep disturbance which was correlated with disease severity, while some other researchers [637] reported a high prevalence of RLS in MG compared with controls.

Fernandes Oliveira and coinvestigators [638] made a meta-analysis of 17 cross-sectional observational or clinical studies assessing the quality of sleep in MG patients published between 1970 and 2014. They found that the literature is limited and the evidence for sleep dysfunction in MG is inconclusive because some studies reported poor sleep quality, EDS, RLS, and SDB in patients with MG, whereas others did not report such associations. The authors recommended further research to investigate sleep dysfunction in MG.

Myasthenic syndrome, or Lambert–Eaton syndrome, is a disorder of the neuromuscular junction in the presynaptic region and is often a paraneoplastic manifestation, mostly of oat cell carcinoma of the lungs. Patients complain of muscle weakness and fatigue involving the limbs accompanied by decreased or absent muscle stretch reflexes and characteristic electrodiagnostic findings that differentiate this from myasthenia gravis. Very few data exist on SDB and sleep dysfunction in Lambert–Eaton myasthenic syndrome.

Botulism caused by *Clostridium botulinum* and tick paralysis caused by the female wood tick *Dermacentor andersonii* may also cause neuromuscular junctional transmission defects, which are due to released toxin, and may cause respiratory failure and sleep dysfunction, but adequate studies have not been performed.

Sleep and Breathing Disorders in Autonomic Failure

Anatomically and functionally, sleep, breathing, and the autonomic nervous system (ANS) are closely interrelated [91, 639–644]. To understand the sleep and breathing disorders in autonomic failure, it is important to understand the functional anatomy of sleep, control of breathing, and the central autonomic network. A brief review of the functional anatomy of sleep is given in the beginning of this chapter, and the neurophysiology of sleep is also described

extensively in Chaps. 5 and 8. Functional neuroanatomy of respiration, control of breathing during sleep and wakefulness, and the central autonomic network with its integration of sleep and breathing are reviewed briefly in Chap. 11.

In all of these conditions, respiratory muscles may be affected and patients may require assisted ventilation. They can exhibit sleep hypoventilation and sleep apnea. Profound functional changes occur during sleep in circulation, respiration, thermoregulation, and the gastrointestinal and urogenital systems due to alterations in autonomic outflow [639, 640] (see also Chap. 11). Thus, sleep has an important effect on the functions of the ANS, and dysfunction of the ANS may have significant impact on human sleep. Sleep and breathing disorders have in fact been described in many patients with autonomic failure. It is also important to remember that the peripheral respiratory receptors, the central respiratory neurons, and the hypnogenic neurons in the preoptic-hypothalamic area and the region of the NTS in the medulla are intimately linked by the ANS, making it easy to comprehend why sleep and breathing disorders should be associated with autonomic failure.

Autonomic failure (AF) may be classified into primary and secondary types. Primary autonomic failure (without known cause) includes pure autonomic failure without any somatic neurologic deficits (Bradbury–Eggleston syndrome), multiple system atrophy (MSA) formerly known as Shy–Drager syndrome, postural tachycardia syndrome (PoTS), familiar dysautonomia, and autoimmune autonomic neuropathy or acute pan-dysautonomia. The most well-known condition with autonomic failure in which sleep and respiratory disturbances have been reported and well described is MSA with progressive autonomic failure. In a consensus statement [645] in 1996 sponsored by the American Autonomic Society and the American Academy of Neurology, *multiple system atrophy* is the favored term, replacing *Shy–Drager syndrome.* MSA defines a sporadic, adult-onset progressive disorder characterized by autonomic dysfunction, parkinsonism, and ataxia in any combination. *Striatonigral degeneration* is the term used when the predominant feature is parkinsonism. The term *sporadic olivopontocerebellar atrophy* is used when cerebellar features are present. Finally, when autonomic failure is the predominant feature, the term *Shy–Drager syndrome* is often used. Familial dysautonomia, a recessively inherited primarily autonomic failure, is also known to be associated with disturbances of breathing and sleep. Congenital central hypoventilation syndrome (CCHS) (see Chap. 33), another autosomal dominant familial disorder due to mutations of PHOX 2B gene, has recently been considered to be a disorder of autonomic regulation, although classified in the ICSD-3 [101] under the category of "Sleep-related Hypoventilation Disorders." A large number of neurologic and general medical disorders are associated with prominent secondary autonomic failure. In many patients with diabetic autonomic neuropathies, amyloid neuropathy, and GBS, sleep and sleep-related respiratory disturbances have been noted. In many neurologic conditions, sleep and respiratory disturbances are secondary to the structural lesions involving the central hypnogenic or respiratory neurons. Some examples of neurodegenerative diseases with autonomic failure and sleep dysfunction are PD (see Chap. 39) and DLBD with dementia (see earlier section) and fatal familial insomnia (FFI), a rare prion disease with severe sleep disturbances and dysautonomia (see later in this chapter). Finally, some primary sleep disorders, such as chronic insomnia disorder, narcolepsy-cataplexy and upper airway OSAS, a very common primary sleep disorder, may be associated with autonomic deficits.

Multiple System Atrophy with Progressive Autonomic Failure (Shy–Drager Syndrome)

In 1960, Shy and Drager [646] described a neurodegenerative disorder characterized by autonomic failure and MSA. Since their description, there have been many reports [87, 91, 99, 640, 647–660] of the condition, which has generally come to be known as *Shy–Drager syndrome* or *multiple system atrophy with progressive autonomic failure.* MSA defines a sporadic adult-onset progressive disorder of multiple systems characterized by autonomic dysfunction, parkinsonism, and cerebellar ataxia in various combinations (Box 41.5). A second consensus conference held in 2007 published new diagnostic criteria for definite, probable, and possible MSA (Box 41.6) [656].

Box 41.5 Salient Clinical Manifestations of Multiple System Atrophy [77]

A. Autonomic Features

1. Cardiovascular
   - Orthostatic hypotension,
   - Postprandial hypotension,
   - Postural syncope,
   - Postural dizziness, faintness, or blurring of vision,
   - Orthostatic intolerance.

2. Genitourinary
   - Urinary bladder dysfunction (incontinence, hesitancy, frequency, nocturia),
   - Impotence in men.

3. Sudomotor
   - Hypohidrosis or anhidrosis,

4. Gastrointestinal
   - Gastroparesis,

- Intermittent diarrhea or constipation (intestinal or colonic dysmotility),
- Abnormal swallowing (esophageal dysmotility).

5. Ocular
   - Horner's syndrome,
   - Unequal pupils.

B. Nonautonomic Manifestations

1. Parkinsonism
   - Rigidity,
   - Bradykinesis or akinesis,
   - Postural instability.
2. Cerebellar dysfunction
   - Ataxic gait,
   - Scanning speech,
   - Dysmetria,
   - Dysdiadochokinesia,
   - Intention tremor.
3. Upper motor neuron signs
   - Extensor plantar responses,
   - Hyper-reflexia
   - Spasticity.
4. Lower motor neuron signs
   - Muscle wasting,
   - Fasciculations.
5. Respiratory
   - Sleep apnea-hypopnea,
   - Other respiratory dysrhythmias,
6. REM sleep behavior disorder
7. Cognitive decline (5–26 %)
8. Normal sensation.

Box 41.6 Criteria for the Diagnosis of Multiple System Atrophy (MSA) Based on Second Consensus Statement [617]

Definite MSA

- A sporadic, progressive adult-onset (>30 years of age) disease with neuropathologic demonstration of α-synuclein-positive glial cytoplasmic inclusions in the CNS,
- Evidence of neurodiagnostic changes in striatonigral or olivopontocerebellar structures.

Probable MSA

- A sporadic, progressive adult-onset (>30 years of age) disease with the evidence of autonomic dysfunction (e.g., orthostatic fall of blood pressure by at least 30 mm Hg systolic or 15 mm Hg diastolic within 3 min of standing, urinary incontinence, or erectile dysfunction in men)
- Parkinsonian features (e.g., bradykinesia, rigidity, tremor, and postural instability) that are poorly levodopa responsive, or
- Cerebellar features (e.g., gait and limb ataxia, scanning dysarthria, and cerebellar type of oculomotor dysfunction).

Possible MSA

- A sporadic, progressive adult-onset (>30 years of age) disease with parkinsonian features or cerebellar features or
  evidence of at least one autonomic dysfunction (orthostatic fall of blood pressure should be significant, which may not meet the level required for probable MSA).
- Presence of at least one of the following additional features (either a clinical or a neuroimaging abnormality):
  – stridor and hyper-reflexia with Babinski sign.

Possible MSA-P

- Parkinsonian or cerebellar features; dysphagia within 5 years of motor onset; olivopontocerebellar or putaminal atrophy on brain MRI; FDG-PET hypometabolism in putamen, brain stem, or cerebellum.

Possible MSA-C

- Cerebellar features; presynaptic nigrostriatal dopaminergic denervation on SPECT or PET scan; olivopontocerebellar or putaminal atrophy on MRI; FDG-PET hypometabolism in putamen, brain stem, or cerebellum.

CNS central nervous system; *FDG-PET* fluorodeoxyglucose positron-emission tomography; *MRI* magnetic resonance imaging; *PET* positron-emission tomography; *SPECT* single-photon-emission computed tomography.

Patients frequently manifest sleep and respiratory disturbances. Initially, they present with autonomic failure of both the sympathetic and the parasympathetic systems. They may present with symptoms related to orthostatic hypotension (e.g., postural dizziness and faintness or even frank loss of

consciousness in the erect posture), urinary sphincter dysfunction (e.g., frequency, urgency, hesitancy, dribbling, and overflow incontinence), hypohidrosis or anhidrosis, and impotence in men. After 2–6 years, patients lapse into the second stage, showing some combination of cerebellar, extrapyramidal, upper motor neuron, and lower motor neuron dysfunction, including bulbar deficits. Most patients manifest a parkinsonian-cerebellar syndrome. In some, atypical parkinsonian features (e.g., bradykinesia, rigidity, and postural instability) predominate; in others, pancerebellar dysfunction predominates. There has been an increasing evidence of cognitive decline in MSA [661, 662]; however, cognitive deficits are poorly recognized in this condition and in fact are listed as nonsupportive diagnostic features in the latest consensus diagnostic criteria [656] for MSA. In the later stages of the illness, a variety of respiratory and sleep disturbances add to the progressive disability. Occasionally, respiratory dysfunction, particularly dysrhythmic breathing in wakefulness that becomes worse during sleep, manifests in the initial stage of the illness [663]. In the final stage, progressive autonomic and somatic dysfunctions are compounded by respiratory failure. Ventilatory disturbances now may be present in both wakefulness and sleep. Pathologically, there are various combinations of striatonigral degeneration, OPCA, and degeneration of the autonomic neurons. A distinctive neuropathologic alteration in MSA is thought to be the presence of argyrophilic oligodendroglial cytoplasmic inclusions in the cortical motor, premotor, and supplementary motor areas; extrapyramidal and corticocerebellar systems; brain stem reticular formation; and supraspinal autonomic systems and their targets [653]. This inclusion-bearing oligodendroglial degeneration may cause or contribute to the manifestations of clinical symptoms in MSA. In fact, Wenning et al. [654] recently hypothesized that MSA is a primary oligodendrogliopathy, followed by the secondary selective neurodegeneration. In fact, a prion-like transfer of α-synuclein from neurons to oligodendrocytes has been suggested to be playing a crucial role in the pathogenesis and progression of MSA [659].

Sleep Disturbances

Patients with autonomic failure (primary or secondary) often have sleep dysfunction. There is a bidirectional relationship between disorders of ANS and sleep [644, 664, 665]: Sleep disorders may affect ANS functions, and ANS disorders may affect physiology of sleep. Because of this close associated, every patient presenting with AF should be questioned about sleep dysfunction; similarly, one should be vigilant about a possible autonomic impairment in a primary sleep disorder and look for clues to AF.

Sleep dysfunction is very common in MSA and includes insomnia with sleep fragmentation; EDS and RBD, which may occasionally be the presenting feature [666, 667]; and sleep-related respiratory dysrhythmias. RBD is very common, being present in 80–95 % of MSA patients [200, 664–677]. The characteristic clinical features of RBD include intermittent loss of REM-related muscle atonia and appearance of a variety of abnormal motor activities during sleep. The patient presents a violent dream-enacting behavior during REM sleep, often causing self-injury or injury to the bed partner. RBD may precede the illness or may present concomitantly or after the onset of MSA [664–677]. Positron-emission tomography (PET) and single-photon-emission computed tomography (SPECT) studies by Gilman et al. [671] suggested that RBD in MSA is related to nigrostriatal dopaminergic deficit. In other cases, RBD in MSA may be due to the neuropathologic changes in the brain stem REM-generating neurons.

The most common sleep disorders in MSA result from a variety of sleep-related respiratory dysrhythmias similar to those described in other neurologic conditions (see Fig. 41.9). The most common types of respiratory dysrhythmias consist of sleep apnea and hypopnea associated with repeated arousals and hypoxemia [85, 87, 91, 663, 664, 671, 678, 692], dysrhythmic breathing [87, 91, 663], and laryngeal stridor due to laryngeal abductor paralysis [647, 648, 684, 689–692]. Less commonly, apneustic breathing [679] and inspiratory gasping [85, 90, 647, 684] may occur. Hypersomnia often results from nocturnal sleep disruption. Sudden nocturnal death in patients with MSA in some cases probably is due to respiratory arrest and other cardiorespiratory abnormalities. Sleep-related respiratory dysrhythmias in MSA are present in almost 100 % of the cases in the advanced stages of the illness. Polysomnographic studies may show the following: a reduction of total sleep time, decreased sleep efficiency, increased number of awakenings during sleep, a reduction of slow-wave and REM sleep, absence of muscle atonia in REM sleep in those with RBD, and a variety of respiratory dysrhythmias. Laryngeal stridor and excessive snoring resulting from laryngeal abductor paralysis have been described in cases of MSA by several groups [648, 680, 682–684, 689–692]. The nocturnal stridor can be inspiratory, expiratory, or both and can cause upper airway obstruction during sleep. The stridor may result in a striking noise likened to a donkey's braying [87, 648]. Williams's group [682] noted this abnormality in 8 of 12 cases. The stridor can be relieved by tracheostomy. The group led by Guilleminault [685–687] described eight patients with predominantly upper airway OSA associated with O_2 desaturation.

In our early study of four patients with MSA [99], we observed periodic central apnea in the erect position

(Fig. 41.12) and CSB in one patient during the last stage of the illness. Impaired hypercapnic ventilatory response and mouth occlusion pressure response in the supine position in one patient suggested impairment of the metabolic respiratory system, whereas normal hypercapnic and hypoxic ventilatory responses in another patient (in the presence of an abnormal respiratory pattern resembling that noted by Lockwood [678]) suggested that the chemoreceptor control and respiratory pattern generator were probably subserved by different populations of neurons rendered selectively vulnerable in MSA. The neuropathologic findings in the same patient with impaired chemoreceptor response—neuronal loss and astrocytosis in the pontine tegmentum—suggested involvement of the respiratory neurons in the brain stem. In a later study [85, 87], we described 10 other patients with MSA who showed central apnea, including CSB or Cheyne–Stokes variant type breathing and upper airway obstructive and mixed apneas accompanied by O_2 desaturation, predominantly during NREM sleep stages 1 and 2 and REM sleep (Fig. 41.26). During sleep, seven patients had central apnea, two had upper airway OSA, and three had mixed apneas. The AHI varied from 20 to 80; the duration of apneas ranged from 10 to 65 s. The variation in the heart rate during apneic and eupneic cycles was not seen in these patients with the evidence of cardiac autonomic denervation. This finding was in contrast to the bradyarrhythmias and tachyarrhythmias noted during apnea and immediately after resumption of normal breathing in patients with primary sleep apnea syndrome [88]. Four patients had several episodes of central apneas during relaxed wakefulness; it was as if the respiratory center "forgot" to breathe. Two patients had inspiratory gasps and two required tracheostomy for respiratory dysrhythmia. All-night PSG studies in two patients revealed the following sleep abnormalities in addition to recurrent episodes of sleep apneas accompanied by O_2 desaturation: marked reduction of NREM sleep stages 3 and 4 and REM sleep, increased awakenings after sleep onset, snoring, and excessive body movements and frequent arousal responses in the EEG. In 8 of 10 patients, dysrhythmic breathing occurred mostly during sleep, although in 4 of these 8 it was also present during wakefulness; this finding suggests that this type of respiratory dysrhythmia is very common in MSA. These observations are in agreement with the suggestion of McNicholas et al. [663] that such findings imply an impaired respiratory pattern generator in these patients.

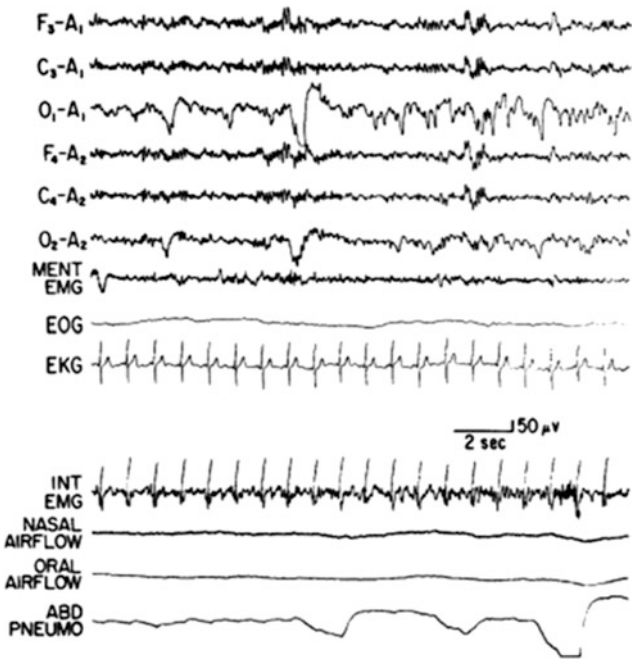

Fig. 41.26 A portion of an episode of mixed apnea during stage 2 NREM sleep associated with oxygen desaturation in a patient with multiple system atrophy. The electroencephalogram (EEG) is shown in the top six channels. Also shown are electromyography (EMG) of the mentalis (MENT) and intercostal (INT) muscles, electrocardiogram (EKG), nasal and oral airflow, and abdominal pneumogram (ABD PNEUMO). Reproduced with the permission from Chokroverty [91]

Mechanisms of Ventilatory Dysrhythmia

There is ample evidence in the literature [85, 87, 108, 646–648, 653–655, 657, 659, 660] of pathologic involvement of the pontine tegmentum, reticular formation, NTS, nucleus ambiguus, hypoglossal nucleus, and, in some patients, anterior horn cells of the cervical and thoracic spinal cord. Lockwood [678] and Chokroverty et al. [99] correlated the physiologic and clinical findings of respiratory dysrhythmias with a direct involvement of the regions of the brain stem that contain the respiratory neurons. In addition, physiologic studies of respiratory control [99, 663] showing impairment of hypercapnic and hypoxic ventilatory and mouth occlusion pressure responses indirectly suggested an impairment of the metabolic respiratory control system. Vagal and sympathetic denervation in these patients is firmly established [327, 644, 646, 659, 660]. The pathogenic mechanisms for the respiratory dysrhythmia include all that had been postulated in the beginning of this chapter for the respiratory dysrhythmias in neurologic disorders. Additional mechanisms for the respiratory dysrhythmia in MSA have been suggested [85]: interference with the forebrain, midbrain, and pontine inputs to the medullary respiratory neurons causing dysrhythmic and apneustic breathing; involvement of the direct projections from the hypothalamus and central nucleus of the amygdala to the respiratory neurons in the NTS and nucleus ambiguus; affection (loss of neurons) [644, 693] of the parabrachial nucleus (PBN) and the adjacent Kölliker–Fuse nucleus (KFN) in the pons which are responsible for respiratory rhythmogenesis and control of upper airway

resistance and have reciprocal connections with the medullary respiratory neurons including laryngeal motoneurons of the nucleus ambiguus; involvement of the vagal afferents from the lower and upper airway receptors, which would reduce the input to the central respiratory neurons, causing respiratory dysrhythmia; sympathetic denervation of the nasal mucosa causing increased nasal resistance, thus promoting upper airway obstructive apnea; and discrete neurochemical alterations that may interfere with the normal regulation of breathing.

There is experimental evidence that noradrenaline, serotonin, and dopamine play distinct roles in the control of breathing [644, 694]. Patients with MSA have been found to have low levels of dopamine and noradrenaline in the basal ganglia, the limbic-hypothalamic regions including the septal nuclei, and the LC [695]. Furthermore, these patients may also have specific catecholamine enzyme deficits in the brain and sympathetic ganglia [696]. SPECT findings by Gilman et al. [697] suggested decreased pontine cholinergic projections to the thalamus contributing to OSA in MSA. Finally, in a series of postmortem studies of brains obtained from patients with MSA, Benarroch and colleagues reported depletion of catecholaminergic neurons in the ventrolateral medulla [698], A5 noradrenergic neurons [699], cholinergic neurons in the medullary arcuate nucleus [700], corticotrophin-releasing factor neurons [701] in the putative pontine micturition center, mesopontine cholinergic neurons in the PPT and LDT nucleus [702, 703], ventrolateral medullary neurokinin 1 receptor-like immunoreactive neurons [704], chemosensitive glutamatergic and serotoninergic neurons in the arcuate nucleus in the ventral medullary surface as well as serotoninergic neurons in the medullary raphe [705], serotoninergic neurons in the pontomedullary raphe [706], and neurons in the ventrolateral nucleus ambiguus innervating the heart and dorsal vagal nucleus-innervating enteric neurons [707], loss of hypocretin (orexin) hypothalamic neurons [708], and loss of PBN and KFN in the pons [709]. Loss of these cell groups may contribute to the respiratory disturbances, including loss of automatic respiration and other autonomic dysfunction involving various systems in MSA [644, 693, 709].

Vetrugno et al. [710] performed video-PSG study in 19 consecutive MSA patients and documented RBD in 100 % of the patients, stridor in 42 %, OSA in 37 %, and PLMS in 88 %. Plazzi et al. [668] documented RBD in 90 % of 39 consecutive MSA patients. RBD preceded in 44 %, appeared concomitantly in 26 %, and followed the onset of MSA symptoms in 30 % of the patients. They also noted OSA, stridor, and PLMS in some patients. Ghorayeb et al. [711], based on a standard sleep questionnaire, reported a variety of sleep disorders in 70 % of 57 unselected patients with MSA: sleep fragmentation (52.5 %), vocalization (60 %), RBD (47.5 %), and nocturnal stridor (19 %). They noted that severity of motor symptoms, disease duration, comorbid depression, and the duration of levodopa treatment correlated with sleep problems. Silber and Levine [712], after reviewing 42 patients with MSA (17 with nocturnal stridor and 25 without stridor), concluded that survival is shorter in those with stridor than in those without stridor. There are several other reports of stridor, particularly nocturnal stridor and sudden nocturnal death resulting presumably from laryngeal obstruction, in some MSA patients. Iranzo et al. [713] reported sleep disturbances in all 20 patients with MSA and vocal cord abduction dysfunction in 14 (70 %) of their 20 patients in a prospective study. Following CPAP treatment, laryngeal stridor and obstructive apneas were eliminated in three patients. Iranzo et al. [714] followed 13 MSA patients with stridor for months and reported beneficial effects of long-term CPAP therapy. In addition to improvement in the quality of sleep, these authors found similar median survival in patients with and without stridor. In a later study of 22 MSA patients, Ghorayeb et al. [715] found 3 with OSA without stridor and 15 with stridor alone or accompanied by apnea. They administered CPAP treatment in 12 of these patients. Two, however, died shortly after CPAP titration and one died 17 months later. Five patients discontinued the use of CPAP because of discomfort, and only four continued CPAP with improvement of sleep and daytime alertness. The authors concluded that the severity of motor impairment at the time of initial CPAP is the most significant factor for long-term CPAP acceptance.

Postural Tachycardia Syndrome

PoTS, also known as orthostatic intolerance syndrome, is an entity still in search of an identity, and the clinical manifestations are still evolving. Sleep dysfunction, which is often an important complaint of patients with PoTS, has largely been neglected in the literature [716]. The clinical diagnostic criteria for PoTS include symptoms of orthostatic intolerance accompanied by heart rate of 120 beats/min or more, or a heart rate increment of 30 beats/min or more on changing from supine to upright position within 5 min of standing or head-up tilt [717]. The symptoms of orthostatic intolerance include faint feelings, dizziness, palpitations, nausea, tremulousness, anxiety, and visual blurring on standing without significant orthostatic hypotension. The other symptoms of these patients include extreme fatigue, diffuse muscle aches and pains, and upper and lower gastrointestinal symptoms, as well as sleep dysfunction [718, 719]. Some patients may complain of sleep-onset or maintenance insomnia, whereas others may have daytime hypersomnolence or circadian rhythm disorders. Some patients may complain of fatigue, which is a very common

manifestation and may be difficult to differentiate from EDS. Sleep-onset and maintenance insomnia in patients with PoTS may be related to inadequate sleep hygiene, diffuse muscle aches and pains, and anxiety. Daytime hypersomnolence may be secondary to OSA, sleep deprivation at night, or depression in some patients. Circadian rhythm disorder in an occasional patient suggests a dysfunction of the circadian clock in the SCN.

Bagai et al. [720] using only a battery of questionnaires without any objective data in 44 patients with PoTS and 46 controls reported higher subjective daytime sleepiness, fatigue, and poor health-related quality of life. In a subsequent study [721], the same group using wrist actigraphy as an objective measure of sleep studied 36 patients with PoTS and equal number of healthy controls and observed significantly reduced sleep efficiency (SE), self-reported (subjective) sleep problems (restless sleep), and morning tiredness in PoTS patients. The authors suggested that sleep-onset latency mismatch between subjective and objective data is indicative of paradoxical insomnia (sleep state misperception). Furthermore, their other observations of increased upright plasma norepinephrine levels correlating with actigraphic sleep-onset latency may have contributed to a hyperarousal state and consequent insomnia.

In an important study, Mallien and coinvestigators [722] obtained overnight PSG and heart rate variability (HRV) using a fast Fourier transform (FFT) algorithm in addition to subjective scales in 38 PoTS patients and 31 healthy controls. The only significant abnormality in the PSG is higher percentage of stage N2 in patients than in controls; one patient had predominantly REM-related obstructive sleep apnea. The authors suggested that the increased amount of stage N2 is similar to that noted in patients with insomnia disorder which they provided as a supportive evidence for PoTS patients having a primary sleep disorder. This suggestion, however, may not be acceptable to the entire sleep community. Their other finding of reduced HRV during different sleep stages in PoTS patients may have indicated either a cardiac dysautonomic neuropathy or a hyperadrenergic state [719].

In contrast, Pengo and collaborators [723] did not find any abnormal PSG findings in 37 patients with PoTS seen in a single sleep clinic nor any objective daytime sleepiness assessed by MSLT. However, HRV studied by the FFT analysis showed an association between enhanced parasympathetic nervous system activation at night and subjective daytime sleepiness assessed by ESS, implying an altered ANS in PoTS patients.

Previously, Thieven et al. [724], after retrospectively reviewing 152 medical records, noted that 31.6 % of PoTS patients had sleep disturbances and 48 % had severe fatigue.

Thus, objective data (PSG finding) have been inconsistent. The subjective findings, however, of EDS and fatigue have been noted consistently in PoTS patients. Similar to pathophysiologic mechanisms, the pathogenesis of fatigue and subjective EDS in patients with PoTS remains controversial.

It is important to pay attention to sleep dysfunction in these patients as treatment combining pharmacologic therapy (short-term hypnotic or selective serotonin reuptake inhibitor) and nonpharmacologic treatment (sleep hygiene, stimulus control therapy, relaxation techniques, appropriately timed bright-light exposure, or CPAP in appropriate patients) may be beneficial in such patients. An adequate number of patients with PoTS using both subjective and objective (e.g., PSG and actigraphy) data with longitudinal follow-up have not been studied prospectively to understand the pathophysiology of sleep dysfunction in this syndrome.

Familial Dysautonomia (Riley–Day Syndrome)

Riley–Day syndrome is a recessively inherited disorder associated with autonomic failure. The condition usually presents in childhood and is peculiar to the Ashkenazi Jewish population. This neurodevelopmental disorder results from IKBKAP gene mutation [725] causing marked reduction of IKAP protein in the CNS which is responsible for the clinical manifestation. The clinical features consist of a variety of autonomic and somatic manifestations [726–728]: autonomic, neuromuscular, cardiovascular, gastroesophageal, skeletal, renal, and respiratory abnormalities; absence of the fungiform papillae of the tongue; defective lacrimation and sweating; vasomotor instability and fluctuation of blood pressure (postural hypotension and paroxysmal hypertension); relative insensitivity to pain; and absent muscle stretch reflexes. Sleep dysfunction, associated with both CSAs and OSAs, has been described in most of these patients [729]. Sleep abnormalities consist of increased awakenings; delayed sleep onset, including prolonged REM sleep onset (but reduced REM sleep time); and sleep apneas. Patients with familial dysautonomia often have prolonged breath-holding spells, owing to defective responses of central respiratory neurons to changes in $Paco_2$.

Gadoth et al. [729] performed PSG recordings in 13 patients (7 women and 6 men aged 5–31 years) with familial dysautonomia to investigate the role of ANS in sleep and breathing disorders in this condition. All had sleep apneas (an average of 73.5/night), 11 had central apnea, and 2 had OSA. REM latency was prolonged, with decreased amount of REM in some patients, and adults also had increased sleep latency. All had orthostatic hypotension, and cardiac responses during apnea were absent, indicating cardiac autonomic denervation.

Guilleminault et al. [687] described two adolescent girls with familial dysautonomia who had respiratory

irregularities. One also had esophageal reflux during sleep that gave rise to sleep disturbances due to frequent awakenings. McNicholas et al. [94] described dysrhythmic breathing in a patient with familial dysautonomia similar to the irregular breathing noted in patients with MSA. Carroll et al. [730] obtained cardiorespiratory home monitoring during sleep and wakefulness in 25 children with familial dysautonomia and 25 age- and sex-matched controls. They found higher daytime respiratory variability compared with controls, suggesting alterations in central rhythm generating circuits associated with reduced parasympathetic drive in patients. An infant with familial dysautonomia with episodic somnolence lasting for 4–15 h during the neonatal period has also been reported [731].

Secondary Autonomic Failure

Many medical and neurologic conditions have associated autonomic neuropathies with or without peripheral neuropathies, but in most of these conditions, sleep and respiratory dysfunctions have not been adequately studied [87, 732–734]. However, there are many reports of such studies in diabetic polyneuropathies associated with autonomic neuropathy. This combination of somatic and autonomic neuropathies has been observed in some patients with acute inflammatory polyradiculoneuropathy (GBS), amyloidosis, and paraneoplastic autonomic neuropathy.

Rees et al. [735] observed 30 or more apneic episodes (in two patients mainly central and in one predominantly obstructive) during sleep at night in three of eight patients with diabetic autonomic neuropathy. In contrast, eight diabetes patients without autonomic neuropathy exhibited no sleep-related respiratory dysrhythmias. The authors speculated that sudden cardiorespiratory arrests that have been noted in some patients with diabetes may be related to autonomic failure and sleep apneas.

Mondini and Guilleminault [736] obtained PSG recordings for 12 type 1 and seven type 2 diabetes. They found obstructive and central apneas and an irregular pattern of breathing in five of 12 type 1 patients. They noted OSA in only one of seven type 2 diabetes. Autonomic neuropathy was present in all three type 1 patients with diabetes.

The findings of Catterall et al. [737], however, do not support the findings reported above of patients with diabetic autonomic neuropathy. They studied eight patients who had autonomic neuropathy and eight who did not and found no significant difference in frequency of apnea between the two groups.

Bottoni et al. [738] described obstructive sleep apnea/hypopnea with a frequency of more than 30 % in adult, nonobese diabetes with autonomic neuropathy independent of the severity of their dysautonomia.

Neurodegenerative Disease with Autonomic Failure and Sleep Dysfunction

Two neurodegenerative diseases, PD and DLBD, are associated with autonomic failure and sleep disturbances [739–745]. They are considered synucleinopathies, which are a group of disorders with abnormal deposition of α-synuclein in the cytoplasm of neurons or glial cells.

In PD, sleep dysfunction is present in 70–90 % of cases, with progressive impairment with the progression of the disease (see Chap. 39). Sleep disturbances and sleep-related respiratory dysrhythmias are common in patients with PD, especially those with the evidence of autonomic failure [103]. Distinguishing L-dopa-responsive idiopathic PD with autonomic failure from L-dopa-nonresponsive MSA with predominant parkinsonism and dysautonomia may be difficult but important for prognosis and treatment.

Symptomatic orthostatic hypotension, including syncope, occurs in up to 30 % of patients with DLBD [739–744], sometimes as the presenting feature. Other dysautonomic features in DLBD may include urogenital disturbance.

Fatal familial insomnia (see further on) is also associated with significant dysautonomia, particularly sympathetic hyperactivity.

Cardiac Arrhythmias and Autonomic Deficits in Obstructive Sleep Apnea Syndrome

Several varieties of cardiac dysrhythmias are noted in patients with OSAS as a result of changes in the ANS. These are described in Chap. 47.

Other Primary Sleep Disorders with Autonomic Dysfunction

Autonomic dysfunction has been reported in insomnia disorders, narcolepsy-cataplexy, idiopathic RBD (iRBD), sleep terror, RLS/WED, and idiopathic hypersomnia. In all of these conditions, autonomic dysfunction is mild generally and is not a major contributor of morbidity.

In insomnia, sympathetic hyperactivity (as manifested by increased LF component in the EKG spectral analysis, increased urinary excretion of catecholamine, and increased resting pulse rate) may partly account for the hyperarousal hypothesis in this condition [102].

Klein et al. [746] studied autonomic function in 15 consecutive patients with narcolepsy and 15 matched controls prospectively using a variety of scales (e.g., SCOPA-AUT, Parkinson's disease nonmotor symptoms [PDNMS], and others) and found frequent dysautonomia in all domains except sexuality in the patients. Limitations of this study

include small sample size, inability to exclude medication effect, and the absence of objective autonomic function tests. An impaired autonomic control of the cardiovascular system in narcolepsy has been mentioned in a review chapter by Calandra-Buonaura and Cortelli [664].

Patients with idiopathic hypersomnia may have symptoms suggestive of autonomic dysfunction, such as orthostatic intolerance, perception of temperature dysregulation, cold hands, and feet [101]. The presence of ANS abnormality has often been quoted as a differentiating feature from narcolepsy, but as stated above, narcoleptics may also have subtle ANS dysfunction.

Mahowald and Schenck [747] first directed our attention to the possibility of ANS dysfunction in iRBD by pointing out that the heart rate did not rise appropriately during abnormal movements and stage transitions in RBD patients. Subsequently, several studies have documented ANS dysfunction in scattered case series. Ferini-Strambi et al. [748] in a multicenter case-control study reported the presence of autonomic symptoms in the largest series covering PSG-confirmed 318 cases of iRBD and 137 healthy controls from 13 centers in 10 countries. They used a validated scale (SCOPA-AUT) consisting of 25 items to assess the autonomic function in multiple domains and concluded that iRBD patients have significantly more problems with gastrointestinal, urinary, and cardiovascular functioning than controls. These data may be used as prodromal markers for eventual neurodegeneration in these patients.

Miscellaneous Neurologic Disorders

Sleep Apnea in Narcolepsy Syndrome

The narcolepsy syndrome is manifested by an irresistible desire to fall asleep at inappropriate times. Such attacks last a few seconds to as long as 20–30 min. They are often accompanied by cataplexy or other characteristic ancillary manifestations of narcolepsy (see Chap. 38). Narcolepsy may be associated with other comorbid sleep disorders such as RBD, OSA, PLMS, sleep-related eating disorder, sleepwalking, and nightmares. It is often associated with an increased BMI, which predisposes to the development of OSA. Narcoleptics have on average a BMI 10–20 % higher than the normal population [749]. A reduced metabolic rate, decreased motor activity, and abnormal eating behavior [750] have been suggested as possible explanations. SDB is found in 10–20 % of patients [751, 752].

Guilleminault's group [753] first reported CSA that lasted 20–90 s (during REM and NREM sleep) accompanied by O_2 desaturation in two patients with pure narcolepsy. In a later report, Guilleminault et al. [754] described 20 additional cases of narcolepsy with sleep apnea, which was predominantly central, although 5 also had mixed and obstructive apneas. The authors speculated that a dysfunction of the CNS structures that control sleep and respiratory centers was responsible for the combined syndrome of sleep apnea and narcolepsy. Laffont et al. [755] also described central, obstructive, and mixed apneas in 5 of 18 narcolepsy patients. Chokroverty [752] made polygraphic observations in 16 patients with narcolepsy syndrome, 11 of whom showed central apneas and 5 upper airway OSAs during both REM and NREM sleep stages associated with O_2 desaturation (Figs. 41.10 and 41.27).

Sansa et al. [756] in a later report made an important observation after studying 133 consecutive patients in a university sleep clinic with narcolepsy diagnosed with PSG and MSLT. They noted that 33 patients (24.8 %) had OSA with an AHI of > 10. Ten of these patients were initially diagnosed with only OSA, and narcolepsy diagnosis was delayed by several years until evaluation for residual sleepiness after adequate CPAP therapy. In the remaining 23 patients, both OSA and narcolepsy were diagnosed concurrently. The authors concluded that OSA occurs frequently in narcolepsy and this may delay the diagnosis of narcolepsy by several years, and the physicians should be vigilant about comorbid narcolepsy in OSA patients in whom EDS persists

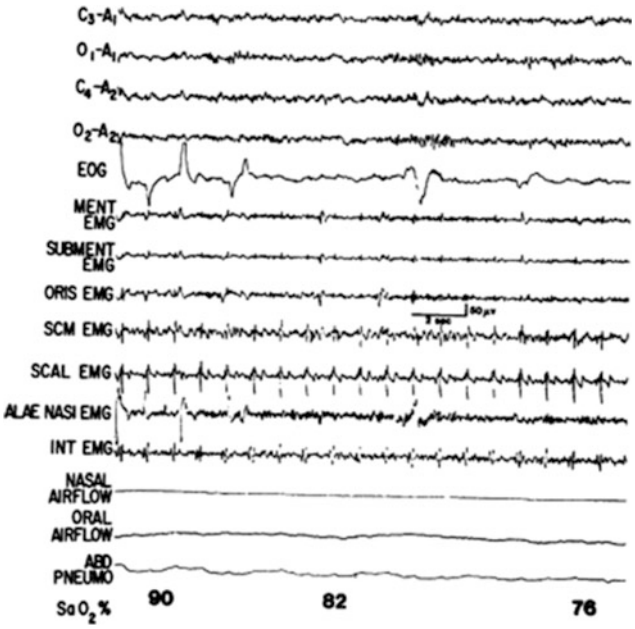

Fig. 41.27 Polysomnographic recording of a patient with narcolepsy showing four channels of the electroencephalogram (EEG); vertical electrooculogram (EOG); electromyograms (EMG) of mentalis (MENT), submental (SUBMENT), orbicularis oris (ORIS), sternocleidomastoid (SCM), scalenus anticus (SCAL), alae nasi, and intercostal (INT) muscles; nasal and oral airflow; abdominal pneumogram (ABD PNEUMO); and oxygen saturation (SaO_2%; ear oximeter). The patient has central apnea during REM sleep (only 18–30 s are shown). Note decrease of SaO_2 from 90 to 76 % during apnea

despite adequate CPAP therapy. Pizza et al. [757] also documented a high prevalence of SDB (11 out of 35 consecutive patients, i.e., 31 %) in narcolepsy type 2. The authors listed older age and higher BMI compared with those without SDB as the risk factors for OSA.

The possibility of coexisting sleep apnea should be considered in a patient with narcolepsy, particularly when the patient is again complaining of EDS after initial improvement on stimulant therapy. OSA should be suspected in such a patient, particularly with increasing age as prevalence of OSA increases in the elderly. Patients with comorbid narcolepsy and sleep apnea should receive treatment for both conditions.

Kleine–Levin Syndrome

An episodic disorder characterized by periodic hypersomnolence and bulimia was described first by Kleine [758] and later by Levin [759] occurring mostly in adolescent boys (but also described in girls). Critchley [760, 761] gave a comprehensive description after analysis of 15 cases from the literature and 11 personal cases. The episodes usually occur three to four times per year, and each episode lasts days to weeks. During the sleep "attacks," patients sleep 16–18 h a day or more, and on awakening, they eat voraciously. Other behavior disturbances during the episode may include dull appearance, withdrawal, confusion, hallucinations, inattentiveness, memory impairment, and hypersexuality. In a later report, Billiard and Cadilhac [762] in 1988 reviewed 123 cases collected from the literature. The condition is generally sporadic and self-limited (although not always) and disappears by adulthood. Occasional familial cases have been described [763, 764]. Polysomnographic studies show normal sleep cycling or nonspecific findings, and MSLTs show the evidence of pathologic sleepiness without sleep-onset REM [765–767]. In a report on 10 patients, Huang et al. [768] observed a reduction of slow-wave sleep in the initial half of the symptomatic period and mild sleepiness in the MSLT, with two or more sleep-onset REM periods (SOREMPs) in 7 of 17 patients. Occasional atypical presentations with episodic alteration in sleep (hypersomnia and insomnia) and appetite (hyperphagia and anorexia) responding to carbamazine treatment have been reported [769].

In the third edition of ICSD [101], the eponym Kleine–Levin syndrome is considered the preferred name for recurrent and periodic hypersomnia which now includes menstrual related hypersomnia which is very rare and may be a variant of Kleine–Levin syndrome except that it occurs just before or during menses. Box 41.7 lists the ICSD-3 criteria for Kleine–Levin syndrome all of which must be fulfilled to meet the diagnostic criteria of Kleine–Levin syndrome. In a recent review, Arnulf [770] summarized Kleine–Levin syndrome as a rare neurologic disorder affecting adolescent boys more frequently than girls, manifested by relapsing-remitting episodes of hypersomnolence, apathy, cognitive impairment, psychiatric and behavioral disturbances (e.g., anxiety, delusions, and hallucination), and altered environmental perception characterized by derealization. The authors considered these as core symptoms superseding previously emphasized triad of hypersomnia, hyperphagia, and hypersexuality (the latter two symptoms are noted in about 50–70 % of cases). Functional imaging studies (e.g., SPECT and PET scans) have shown hypoperfusion of hypothalamus, mesial temporal and frontal lobes consistently, and less frequently of thalamus [771, 772]. EEG has shown diffuse slowing in 70 % and normal findings in 30 % of cases during episodes. Arnulf's group published the data from their most recent analysis of a new series of 120 patients with typical primary Kleine–Levin syndrome seen between 2006 and 2012 [773]. This analysis essentially confirmed their previous [770, 774, 775] conglomeration of symptom in addition to some new features (e.g., more frequent birth and developmental abnormalities than controls and those with prolong episodes lasting longer than one month [seen in 34 patients]), had shorter sleep time with higher anxiety level and agitation during the episodes, but in between these episodes needed more naps, felt tired, and had higher anxiety-depression score. They analyzed the evolution of the disease in 53 patients and found that the frequency of episodes decreased in 63 % but increased in 10 % of the patients after five years. Almost half of the patients had decreased performance at school or at work, and some especially those with prolonged episodes were left with some long-term residual symptoms challenging the concept of Kleine–Levin syndrome being a benign disorder.

Box 41.7 ICSD-3 Diagnostic Criteria for Kleine–Levin Syndrome: All five must be met [101]

1. At least two recurrent episodes of hypersomnolence, each lasting for two days to five weeks,
2. Episodes recur at least every 18 months,
3. In between the episodes, alertness, mood, and cognitive function are normal,
4. During episodes, one of the following must be present:
   - Cognitive dysfunction,
   - Altered perception,
   - Hyperphagia or anorexia,
   - Behavioral disinhibition (e.g., hypersexuality).
5. The above behavior is not better explained by another sleep, neurologic, medical, or psychiatric disorder or ingestion of medication.

The pathophysiology [770, 771, 774, 775] is unknown but points to a localized but multifocal encephalopathy during recurrent episodes as evidenced by EEG and functional imaging findings (see above). Another intriguing neuroimaging finding is the demonstration of interictal thalamic hyperactivation using functional magnetic resonance imaging (fMRI) during working memory performance [776] on a group but not on an individual basis. The authors suggested that this might be considered a compensatory mechanism in those with high working memory capacity. The syndrome may have been caused by genetic, environmental, autoimmune, inflammatory, or metabolic factors singly or in combination. CSF hypocretin-1 levels have been essentially normal [770] as are serum cytokine levels [777].

Drug treatment of Kleine–Levin syndrome has been unsatisfactory [770]. All the drug trials had been nonplacebo-controlled open-label, but there have been no randomized controlled trials (RCTs) for this condition. For symptomatic treatment during episodes, stimulants and wake-promoting agents (e.g., amphetamines, methylphenidate, modafinil, and armodafinil) had been tried with minimal success in eliminating or shortening the hypersomnolence episodes. For eliminating the recurrent episodes, prophylactic treatment has been tried with some success. Lithium (requires close monitoring as the range of therapeutic and toxic doses is narrow) has been most successful in about 50–60 % of cases followed by the treatment with valproic acid [770, 778, 779]. Carbamazepine was successful in occasional patients. Amantadine, an antiviral agent which is also used in Parkinson's disease, had been successful in some patients if given at the beginning of an episode. There is a single case report of success with sodium oxybate (4 g) treatment [780]. In view of the reports of Kleine–Levin syndrome being triggered by upper respiratory or other infections, clarithromycin, an antibiotic with GABA A receptor antagonistic properties, was tried in an occasional patient with success [781], but further studies in larger number of patients are needed to verify the usefulness of this approach.

Idiopathic Recurrent Stupor

In 1992, Tinuper et al. [782] coined the term *idiopathic recurrent stupor* (IRS) for a condition characterized by recurrent episodes of stupor in all of these patients, in whom no metabolic, toxic, or structural brain dysfunction was noted. A characteristic EEG during an episode of stupor in these patients showing nonreactive, diffusely distributed fast rhythms (14–16 Hz) was described. Benzodiazepine-like activity identified as endozepine-4 in plasma and CSF was markedly elevated in all patients. The clinical manifestations and the EEG abnormalities rapidly reversed to the normal state after administration of flumazenil (0.5–1.0 mg intravenously), a benzodiazepine receptor antagonist. Endozepines also accumulate in hepatic coma, in which flumazenil injection causes transient arousal [783]. In 1998, however, the original authors who described IRS [784] reported a case of covert lorazepam intoxication misdiagnosed as endozepine stupor and called attention to the need to perform refined toxicologic analyses (mass spectroscopy with high-performance liquid chromatography) in order to exclude with certainty the presence of exogenous benzodiazepines, in particular lorazepam, that may mimic the action of endozepines. Subsequent reports also highlighted the need to exclude fraudulent exogenous benzodiazepines, in particular lorazepam administration, in cases of comas associated with fast EEG activities and response to flumazenil [785], and have cast doubts on the true existence of a syndrome of recurrent comas due to endozepine accumulation. Since 1998 report casting doubt on the true existence of this syndrome, no new cases of apparent IRS have been attributed to an endrogenous molecule with benzodiazepine-like bioactivity [785]. The Bologna group who first described IRS warned in a recent report [786] that a diagnosis of IRS should not be made without performing sophisticated toxicological tests to exclude exogenous benzodiazepines; otherwise, this may lead to inappropriate treatment which may have legal implications for the treating physicians.

Idiopathic Hypersomnia

Idiopathic hypersomnia (IH), a condition of excessive somnolence, has no known cause. A disorder of the CNS has been suspected but not proved [787]. The syndrome has been described under a variety of labels, including nonrapid eye movement narcolepsy; idiopathic central nervous system hypersomnia; and mono- or polysymptomatic idiopathic hypersomnia; *idiopathic hypersomnia* is the preferred term. IH closely resembles narcolepsy syndrome. The ICSD-3 [101] defines the disorder as a condition characterized by EDS or irrepressible need to sleep without cataplexy lasting for at least three months that is associated with a total 24-h sleep time of 660 min or more (typically 12–14 h) documented by 24-hour PSG monitoring or by wrist actigraphy for seven days and sleep log. Bedrich Roth [788], who actually coined the term *idiopathic hypersomnia*, described a monosymptomatic form manifested only by EDS and a polysymptomatic form characterized by EDS, nocturnal sleep of abnormally long duration, and signs of "sleep drunkenness" upon awakening. The onset of the disease is generally around the same age as narcolepsy (15–30 years). The sleep pattern, however, is different from that of narcolepsy. The patient generally sleeps for hours, and the sleep is not refreshing. Because of EDS, the condition may be mistaken for sleep apnea or narcolepsy. However, the patient does not give a history of cataplexy, snoring, or repeated awakenings throughout the night. Sleep drunkenness is often

seen in these patients and may manifest as sleep inertia or automatic behavior with amnesia for the events. Physical examination uncovers no abnormal neurologic findings. The condition is disabling and generally lifelong, although spontaneous remissions have been noted in a few patients [101]. In a retrospective review of 77 patients with IH, Anderson et al. [789] stated that clinical features were heterogeneous and of variable severity, similar to the suggestion made by Aldrich [790]. It has been suggested [791] that occasional patients with IH may be misdiagnosed as having adult-onset attention deficit/hyperactivity disorder (ADHD) based on a self-reported ADHD questionnaire. The condition may be familial, but in the absence of rigorous studies, mode of inheritance cannot be determined [101].

The differential diagnosis of the condition should include other causes of EDS (see Chap. 3) including insufficient sleep syndrome. Polysomnographic monitoring shows generally normal sleep structure and sleep cycling with normal REM latency and prolonged total sleep time. Sforza et al. [792] based on the spectral analysis of the EEG found reduced power of slow-wave activity due to reduced amount of slow-wave sleep, suggesting that the homeostatic sleep regulatory mechanism is preserved, but the sleep pressure indicated by slow-wave activity is reduced. The MSLT shows mean sleep latency of 8 min or less but typically longer than in narcolepsy and less than 2 SOREMPs or none if a SOREMP was noted on the preceding overnight PSG. A recent report [793] of actigraphic assessment of patients with drug naïve narcolepsy type 1 (39), idiopathic hypersomnia (24), and controls (30) documented some distinguishing features among these central disorders of hypersomnolence based on significant differences in nighttime and daytime parameters. CSF hypocretin-1 levels are normal, in contrast to reduced levels in the majority of patients with narcolepsy-cataplexy syndrome [101, 794].

In this condition, no consistent HLA association has been found in contrast to narcolepsy [101]. The treatment of IH is unsatisfactory and is somewhat similar to the stimulant treatment for narcolepsy. The behavioral approach of sleep hygiene techniques has been advised, but these do not have a significant impact on the disease. Compared with patients with classic narcolepsy with cataplexy, stimulants are less effective in those with IH. There are still unresolved and pending issues in terms of precise clinical characteristics, treatment response, and neurobiology of idiopathic hypersomnia [101].

Central Sleep Apnea and Sleep Hypoventilation Syndromes

These entities including sleep and breathing at high altitudes have been described in Chap. 33.

Sleep and Increased Intracranial Pressure

Increased intracranial pressure (ICP) may result from a variety of neurologic disorders (e.g., tumor, large infarction, intracranial hemorrhage, head trauma, focal abscess, and diffuse encephalitis). Cooper and Hulme [795, 796] found that the ICP of patients with intracranial lesions rose during REM and stage 2 NREM sleep. This was probably due to a combination of factors [797–799] (e.g., variations in cerebral blood flow, neurogenic reflex, cerebral vasoconstriction, and enhanced brain metabolism). These observations have been confirmed by the findings of Munari and Calbucci [800] in 16 head trauma patients. In a study of children with craniosynostosis, Gonzalez et al. [801] observed both increased ICP and upper airway obstruction. They performed PSG studies along with continuous monitoring of ICP during sleep in 13 children with the syndrome of craniosynostosis and 7 control patients with isolated unicoronal synostosis only. In 11 of 13 patients with this syndrome, they found upper airway obstruction, and 8 of those 11 had frank OSAs. The other group of children showed no signs of upper airway obstruction during sleep. The causal relationship between upper airway obstruction and raised ICP in these children, however, remains undetermined. In a later report, Stephensen et al. [802] measured ICP levels during wakefulness and sleep in 29 adults with noncommunicating and 26 adults with communicating hydrocephalus. They found that ICP is normal in most adults with hydrocephalus; however, ICP is higher during sleep than during periods of wakefulness in the supine position and is not correlated with either symptoms or the rate of improvement after surgery. In idiopathic intracranial hypertension (IIH) in adults, SDB may be noted in many patients [803–808]. The conclusion in some studies is based on the findings from nonconsecutive case series [807], Berlin questionnaire without a control group, and retrospective, validated questionnaire-based study with matched controls. It is notable that OSA itself may cause increased intracranial pressure during apneic episodes due to associated hypoxia and cerebral vasodilation, and this has been thought to play a role in the pathogenesis of IIH in men with coexisting OSA [806]. Many of these prior studies did not have a control group. However, in a more recent study, Thurtell et al. [807] reversed their prior [808] conclusion based on overnight PSG study in 24 patients (20 women and 4 men) with coexisting IIH and OSA, and controls derived from population-based model matched for age, sex, and menopause status. These authors noted OSA in 8 patients (33.3 %) which is not significantly different from the control group. It was, however, unclear whether the presence or treatment of OSA would have influenced the clinical course of IIH. The authors recommended larger prospective, controlled study to evaluate the relationship between OSA and IIH.

Headache Syndromes

Headaches and sleep complaints are common and have a bidirectional relationship [809]. Sleep disturbance (e.g., OSAS) may cause headache, and headache itself may cause sleep disturbances. The relationship between headache and sleep disorders is somewhat complex and remains ill-understood [810]. Sleep-related headaches include most daytime headache conditions, which also occur during sleep or on awakening in the morning. The ICSD-3 [101] includes migraine, cluster headache, chronic paroxysmal hemicrania (CPH), and hypnic headache syndrome (HHS) under "Sleep-related Headaches." Other causes of sleep-related headaches (secondary headaches) include medical (e.g., hypertension), neurologic (e.g., tumor and head trauma), psychiatric (e.g., depression), and primary sleep disorders (e.g., OSAS). Migraine headache can, of course, occur during both the day and night. There are several reports on headache and sleep disorders in the literature, but many of them are retrospective analyses and do not clearly eliminate other confounding factors.

Migraine headaches are common episodic headaches characterized by nausea, vomiting, photophobia, and phonophobia; they are generally unilateral and associated with throbbing pain. Dexter and Weitzman [811] made the first PSG recording in patients with chronic migraine and cluster headaches and found a clear relationship between REM sleep and attacks of headache. Attacks occurred during REM or within 9 min after it terminated. In later studies, Dexter [812] also found a relationship between NREM stages 3 and 4 and REM sleep and arousals with migraine headaches. Kelman and Rains [813] evaluated 1283 migraineurs from 1480 consecutive headache patients attending a tertiary headache clinic. They reported that over half of the migraineurs reported difficulty in initiating and maintaining sleep, and the migraine headaches were triggered by sleep disturbance in 50 % of patients. "Awakening headaches," or headaches awakening them from sleep, were reported by 71 % of patients. The authors concluded that there is a substantial sleep-migraine relationship, those patients who slept 6 h per night exhibited more severe headache, and sleep complaints were more frequent during chronic episodic attacks. Gori et al. [814] after evaluating 100 patients suffering from migraine without aura noted a preferential timing for occurrence of migraine attacks during the night and early morning hours. Engstrom et al. [815] evaluated sleep quality by sleep questionnaires and diaries, and PSG from 53 migraine and 20 tension-type headache (TTH) patients as well as 34 controls in a blinded exploratory study. They reported more sleep-related symptoms and anxiety in all headache groups: TTH and migraineurs with daytime onset had more daytime tiredness and increased slow-wave sleep as seen after sleep deprivation, whereas those with migraine headache during sleep had increased awakening during sleep.

Cluster headaches are unilateral severe headache in the periorbital or temporal region lasting for 15 min to 3 h. As the name suggests, the headaches occur in clusters of one to three per day over a period of 1–2 months. Most of the patients have one cluster period each year, and the headache tends to occur at the same hour each day. A characteristic feature of cluster headache is the presence of autonomic features such as lacrimation, conjunctival injection, nasal congestion, rhinorrhea, and the evidence of Horner's syndrome (e.g., the absence of forehead and facial sweating, ptosis, and small pupils). Cluster headaches are thought to be REM-related [812, 816, 817], by some but not by all investigators [818]. Sometimes, cluster headaches may be triggered by NREM sleep [819].

CPH [101, 820, 821] is probably a variant of cluster headache. CPH is grouped under trigeminal autonomic cephalalgias [822] which are primary headache disorders associated with cranial parasympathetic autonomic symptoms (e.g., conjunctival injection, lacrimation, rhinorrhea, nasal congestion, ptosis, and eyelid edema). This is chronic in 80 % but episodic in 20 % of cases [820]. The attacks of CPH occur unilaterally involving orbital, supraorbital, or temporal region and are briefer (2–30 min) and more frequent (1–40 per day) and more in women (3 W:1 M) than cluster headaches. CPH is most commonly associated with REM sleep [101, 821], and it responds to indomethacin but in some cases may respond to calcium channel blockers [820, 823]. Significant disruption of sleep architecture (decreased total and REM sleep time accompanied by increased number of awakenings during REM sleep) has been described in patients with CPH [101, 821]. After a nocturnal polygraphic study, Conelli et al. [824] reported that CPH headache episodes were preceded by a sustained increase in blood pressure. There are occasional reports of the coexistence of OSAS and cluster headache with improvement of headache after CPAP titration [825, 826]. An earlier report by Kudrow et al. [827] also found a high prevalence of CSA or OSAS in patients suffering from cluster headaches, especially episodic headaches.

The relationship between chronic headache and early morning headache has remained somewhat controversial. Patients with upper airway OSAS are thought to have an increasing incidence of morning headache as compared with controls [828–830], and improvement in morning headache has been reported after treatment of OSAS [831]. Dexter [828] reported PSG-documented sleep apnea in 11 patients with chronic recurring headache syndrome. After surgical reconstruction in six patients with obstructive apneas, PSG demonstrated marked improvement in sleep apnea and

considerable improvement in headache symptoms. In contrast, Aldrich and Chauncey [832] as well as Poceta and Dalessio [833], after a survey, found that the complaint of morning headache was no different in patients with OSAS than in those with other sleep disorders. The Copenhagen Male Study [834] (included 3323 men aged 54–74 years), however, found that heavy snoring was an independent risk factor for headache. Ulfberg et al. [835] confirmed the association between heavy snoring, OSA, and headache in both men and women based on a questionnaire survey as well as sleep apnea screening that included 4 h of sleep on the back of a static charge-sensitive bed and finger oximetry. In a later report of 432 patients with a variety of sleep disorders studied with two nights of PSG comparing with 30 controls, Goder et al. [836] noted an increased frequency of morning headaches not only in OSAS but also in other sleep disorders. The authors concluded that morning headache might be associated with decreased total sleep time, sleep efficiency, and amount of REM sleep and an increase in the wake time during the preceding night.

Paiva et al. [837] evaluated 49 subjects successively seen in a headache clinic during a 6-month period with the predominant complaints of nocturnal or early morning headache. Based on the questionnaire and overnight sleep recordings, the authors found that headache was related to a specific sleep disorder (e.g., OSAS, PLMS, sleepwalking, and sleep paralysis) in 55 % of these subjects. They also found that treatment of these sleep disorders ameliorated the headaches. These findings confirmed the earlier observations of Paiva et al. [838] that morning or nocturnal headaches were frequent indicators of a sleep disturbance.

HHS is a rare benign headache syndrome of the elderly that usually occurs after the age of 50 years and awakens the patient from sleep at a consistent time each night like an alarm clock and hence the name alarm clock headache [101, 839–841]. The headache is either generalized or lateralized, lasting for at least 15 min (with range up to 180 min) and occurring at least 15 times per month. This may occur one to three times during the night and tends to occur during REM sleep but may also occur during stage N3 sleep [101]. In a recent serial PSG study [842] on four consecutive nights in six patients with hypnic headache capturing 22 attacks, six arouse from REM sleep and 16 from different NREM sleep stages. Five patients had an increased apnea-hypopnea index indicating OSA on some nights but not the majority of nights. The underlying pathophysiology of HH is unknown, but a hypothalamic involvement seems likely [843]. HHS is differentiated from chronic cluster headache by its generalized distribution, age of onset, and the lack of autonomic manifestations. The disorder often responds to lithium, indomethacin, or caffeine treatment.

Another variety of unusual headache syndrome is "exploding head syndrome," which usually occurs in the transition from wake to sleep, abruptly arousing the patient with a feeling of an explosion or a sensation of bursting of the head [844–846]. The condition is benign, and most likely represents a type of "sleep starts" and is classified in ICSD-3 under "Other Parasomnias" [101]. Polysomnographic recordings [847, 848] showed that the syndrome occurred during both wakefulness and REM sleep. In occasional cases, treatment with clomipramine may be effective [847].

The exact pathophysiologic mechanism for association of headache and sleep is not known, but Dodick et al. [849] suggested a role for the hypothalamus, serotonin, and perhaps melatonin. The PET scan finding of hypothalamic activation in cluster headache [850] and the therapeutic response of melatonin [851] in migraine and other headache types lend some support to the suggested mechanism of Dodick et al. [849]. The principles of treatment of sleep-related headaches include first the correct diagnosis of the type of the headache, investigations (including PSG recordings) to exclude other causes of headaches, practice of commonsense measures for sleep hygiene, treatment of underlying sleep disorders, and symptomatic treatment for specific headache using standard medications [852].

Familial and Sporadic Fatal Insomnia

Lugaresi and associates [853] originally described FFI in a family (14 affected members in three generations) as an autosomal dominant, rapidly progressive neurologic illness characterized by insomnia and dysautonomia that terminated in death. Later, they found that two families with FFI harbored a mutation (associated with the substitution of aspartic acid with asparagine) at codon 178 of the prion protein (PrP) gene *PRNP,* located on chromosome 20 [854, 855]. FFI therefore belongs to the so-called prion diseases, characterized by the accumulation of a pathologic isoform of the PrP that becomes resistant to the action of the proteases and called PrPres or PrPsc (sc for scrapie). It should be noted that the same mutation at codon 178 of *PRNP* is present in both FFI and familial CJD (178fCJD). These two conditions, however, are separated by the methionine-valine polymorphism at codon 129 on the mutated allele of *PRNP,* a common polymorphism that codes either for methionine or for valine: FFI is invariably associated with methionine, while 178fCJD is associated with valine [856–859]. This genetic difference is expressed in a different type of PrPres being accumulated in the brain of affected individuals, whereby FFI brains accumulate a 19-kDa (type 2) PrPres, while 178fCJD brains accumulate a 21-kDa (type 1) PrPres [856].

Prion diseases can occur as infectious, sporadic, and hereditary forms and are transmissible. Accordingly, FFI has been transmitted to experimental animals [860, 861], in

particular to transgenic mice expressing a chimeric human-mouse *PRNP* [862]. A sporadic form of fatal insomnia (called sporadic fatal insomnia [SFI]) has also been described, characterized by the same clinicopathologic features of FFI and by type 2 PrPres and also transmissible, but in the absence of the defining *PRNP* 178 codon mutation [863, 864]. Upon transmission of either FFI- or SFI-derived brain inoculates, the experimental animal accumulates the same type of PrPres and displays pathologic features comparable to those found in the donor brain, thus demonstrating that prion strains encipher and propagate the diversity of prion diseases [862]. FFI represents the third most frequent hereditary prion disease and has been reported worldwide [865, 866]. Age of onset of FFI is at about 51 years, but cases with young age of onset (23 and 24 years) are described. The clinical course runs from 7 to 72 months, with a mean of 18 months. A two- to threefold longer disease course (together with some differing clinical features) has been related to the presence of a valine 129 *PRNP* codon polymorphism on the *non*mutated allele (heterozygote methionine/valine 129 *PRNP* codon FFI patients) [867].

Clinical manifestations of FFI and SFI include impaired control of the sleep-wake cycle, including circadian rhythms; autonomic and neuroendocrine dysfunction; and somatic neurologic, cognitive, and behavioral manifestations [868, 869]. Profound sleep disturbances and, in particular, severe insomnia are noted from the very beginning of the illness. Patients seldom complain of drowsiness and may look drowsy with expressionless faces and lowered eyelids but present an inability to nap during the day and to fall asleep at night. Moreover, at the onset of the disease, patients become increasingly taciturn and apparently indifferent to their surroundings and even their fate (apathy). Neuropsychologic studies reveal an early progressive impairment of attention and vigilance, leaving relatively intact intellectual skills so long as consciousness is preserved [870]. Polysomnographic study [853, 871, 872] shows the early loss of sleep spindles and K complexes which are markedly and progressively reduced and are absent in the later stage of the illness. The loss of sleep spindles and slow-wave sleep is so severe and permanent that these EEG activities cannot even be induced by IV administration of barbiturates or benzodiazepines, drugs that usually cause spindles and slow waves to appear in the EEG [873]. The sleep cycle organization and stage shifts are altered from the very beginning, and there is no orderly transition from wake to sleep or from one sleep stage to the other. The dominant EEG pattern until the most advanced disease stages is characterized by a mixed stage between stage 1 (dominant theta activity and slow eye movements) with interspersed short, often recurring in clusters, REM sleep episodes, lasting for a few seconds or minutes only with or without muscle atonia. When left alone, both during the day and during the night, patients present stereotyped, simple, calmer, automatic, well-organized motor gestures mimicking daily life activity such as eating, drinking, dressing, combing the hair, washing, or manipulating nonexistent objects. If questioned at the end of these behaviors, patients often link these gestures to an oneiric scene, and the motor activity appears to be clearly related to the oneiric content (oneiric stupor) [869, 874]. The terminal stage of the illness is characterized by progressive slowing of the EEG, and the patients remain in a coma. It is remarkable that the quasi-periodic sharp-wave EEG activities typical of CJD are not recorded in FFI, except in some patients with long evolution just before death.

Insomnia is associated with sympathetic activation in the form of hypertension, tachypnea and tachycardia, hyperhidrosis, and slight pyrexia. Autonomic function tests show the evidence of sympathetic hyperactivity with preserved parasympathetic activity [853, 874–876], resulting in persistent elevation of plasma catecholamines with further increase after upright tilt of the table [877]. There is consistent elevation of blood pressure, heart rate, and core body temperature, and the nocturnal fall in blood pressure that occurs in normal individuals is lost from the early stages of the illness [876, 877].

Neuroendocrine functions [875, 876, 878, 879] in FFI show a dysfunction of the pituitary-adrenal axis as manifested by striking elevation of serum cortisol but normal adrenocorticotrophic hormone and persistently elevated serum norepinephrine levels, associated with abnormal secretory patterns of growth hormone, prolactin, and melatonin: Growth hormone showed no nocturnal secretory peaks, while the circadian rhythm of prolactin persisted. Circadian fluctuations of prolactin, however, tended to disappear with disease progression, and likewise, the nocturnal rise in melatonin was progressively lost [878]. Fifty-two days of actigraphic monitoring in one patient showed up to 80 % increased motor activity with a loss of circadian rhythmicity, and indirect calorimetry revealed a remarkable 60 % metabolic increase in 24-h energy expenditure [880].

The somatic neurologic manifestations are present in all cases, particularly in the later stage of the illness, and consist of dysarthria and dysphagia, ataxia [881], the evidence of pyramidal tract dysfunction, and myoclonus. The disease progresses rapidly, and in the final stage of the illness, the patients may also have breathing disturbances and mutism and then end in coma and death. CSF analysis for the 14-3-3 protein, a good marker of prion diseases, detects increased levels in only half of FFI patients. CSF hypocretin-1 levels are normal in FFI [882].

Neuropathologically, the hallmark of FFI is severe atrophy of the thalamus, particularly the anterior ventral and dorsomedial thalamic nuclei, and of the inferior olives, associated with variable involvement of the cerebral cortex, striatum, and cerebellum [853, 883, 884]. In the thalamus,

the loss of neurons is particularly striking, averaging 80 % of neurons and associated with reactive astrogliosis [883, 884]. There are no prominent spongiform changes, which are usually found in prion diseases, but a mild-to-moderate spongiform degeneration in the cerebral cortex has been noted in subjects with the longest duration of symptoms. These pathologic features in FFI are at variance with those found in 178fCJD, where spongiosis and cortical involvement predominate [858]. Moreover, deposition of PrPres in FFI brains is also characteristic, occurring to a much lesser degree than in sporadic CJD, especially in the neo- and limbic cortex and in those patients with prolonged disease course [885]. The amounts of PrPres indeed correlate with disease duration, though not in the thalamus, where deposition of PrPres is only moderate and unrelated to disease duration. This could probably reflect a selective thalamic vulnerability in FFI [886]. Severe hypometabolism of the thalamus along with a mild hypometabolism of the cingulate cortex was shown also by means of an in vivo fluorodeoxyglucose PET study in seven FFI patients by Cortelli et al. [887]. Hypometabolism of other brain regions depended on the duration of symptoms, being more widespread in the methionine-valine heterozygotes at *PRNP* codon 129, who also had a more prolonged course. Comparison with the neuropathologic changes showed that the metabolic changes were more widespread than the pathologic alterations, correlating with the amount of abnormal PrPres deposited in the different brain areas [887]. In a fluorodeoxyglucose PET study [888] of 9 asymptomatic carriers of the FFI mutation, 10 noncarriers belonging to the same family and 19 age-matched controls studied over several years, together with spectral EEG and PSG, the PET, and all other examinations, were normal at the beginning of the study. Four of the mutation carriers developed typical FFI during the study, but PET and other results remained normal for 63, 56, 32, and 21 months before disease onset. Selective thalamic hypometabolism was found in the thalamus 13 months before the onset of symptoms, while spectral EEG analysis disclosed changes indicative of impaired thalamic sleep spindle formation. Following clinical disease onset, hypometabolism was found in the thalamus in all three patients examined. These findings were considered to demonstrate that the neurodegenerative process associated with FFI begins in the thalamus at close to one year before the clinical presentation of the disease [888].

The study of FFI has opened a new era in the molecular biology of the prion proteins and their genes, being instrumental in the discovery of different prion strains in humans [856] and in establishing that prion strains alone encode prion disease diversity [862, 889]. FFI has also been proposed as a model disease for sleep pathophysiology [890], rekindling the role of the thalamus in sleep-wake-regulating mechanisms [871–873, 886, 891] Geminiani et al. [891] by demonstrating that the thalamus is essential for the generation of slow-wave sleep and also suggesting a role for prions in sleep regulation. The consideration that FFI has clinical features in common with diseases such as delirium tremens and Morvan's chorea, an autoimmune limbic encephalitis, has finally led to the concept of "agrypnia excitata" [892], a clinical condition characterized by disruption of the sleep-wake cycle, a continuous day and night motor, sympathetic and aminergic overactivity, and episodes of oneiric stupor, related to changes in the thalamolimbic circuitry [893, 894]. In agrypnia excitata, loss of slow-wave sleep occurs in the face of preserved light stage 1 NREM sleep (stage N1), a fact that has been taken as evidence that NREM sleep is not a continuous process starting from stage 1 and progressing to stage 3, but that light sleep probably represents an independent state of sleep and should not be combined with deep sleep into a unique NREM sleep process [892, 895].

Laboratory Investigations

The laboratory tests should be directed at a diagnosis of the primary neurologic disorder and an assessment of sleep disturbances resulting from the neurologic illness.

Laboratory Tests for the Primary Neurologic Disorders

It is beyond the scope of this chapter to delve into details of neurodiagnostic tests to assess the neurologic condition that gives rise to sleep and SRBDs, so readers are referred to some excellent neurologic texts available [896–899]. Laboratory tests must subserve the findings of the history and physical examination, as discussed in Chap. 26. Laboratory tests are essential for diagnosis, prognosis, and treatment of the primary neurologic disorders. These investigations can be broadly divided into neurophysiologic tests, neuroimaging studies, examination of the cerebrospinal fluid, and general laboratory tests, including blood work and urinalysis. Special procedures such as tests to uncover autonomic deficits; neuroimmunologic, neurovirologic, or neurourologic investigations; and brain biopsy are required to detect some neurologic disorders.

Neurophysiologic Tests

Neurophysiologic tests include electroencephalography (**EEG**), evoked potential, nerve conduction studies (NCS), and electromyography (EMG). EEG, including 24-h ambulatory and video-EEG examinations, is necessary to detect seizure disorder and may also be useful in

metabolic-toxic-nutritional encephalopathies and dementing illnesses (e.g., AD and CJD). Evoked potential studies include sensory (somatosensory, brain stem auditory, and visual evoked responses) and motor-evoked potentials and may be indicated in certain neurologic disorders, particularly demyelinating diseases such as MS. NCS and EMG are necessary for diagnosis of various neuromuscular disorders, including neuromuscular junction diseases.

Neuroimaging Studies

These studies include anatomic and physiologic studies which are essential when a neurologic illness is suspected to cause sleep disturbance.

Cerebral angiography, including digital subtraction arteriography and magnetic resonance angiography (MRA), may be necessary to investigate for strokes. Computer tomography (CT) and magnetic resonance imaging (MRI) are important studies for structural lesions of the CNS (e.g., tumors, infarctions, and vascular malformations). CT and MRI are also helpful in patients with demyelinating and degenerative neurologic disorders that can be responsible for sleep and SDBs. Diffusion tensor MR imaging, MR tractography, functional MRI (fMRI), DAT scanning used with single-photon-emission computed tomography (SPECT) for detecting dopamine transporter (DAT) uptake in the basal ganglia in suspected parkinsonian syndromes, and MR spectroscopy are other imaging studies which may be helpful in diagnosing and monitoring neurologic diseases responsible for sleep dysfunction.

Positron-emission tomography (PET) dynamically measures cerebral blood flow, O_2 uptake, and glucose utilization and is helpful in the diagnosis of dementing, degenerative (e.g., PD), and seizure disorders. It is very expensive, however, and is not available in most centers. SPECT, which dynamically measures regional cerebral blood flow, may be useful for patients with cerebral vascular disease, AD, or seizure disorders. PET and SPECT studies can also be performed to investigate D_2 receptor alterations in RLS-PLMS as well as narcolepsy and RBD [900–906], which may show reduced striatal presynaptic dopamine transporter uptake. Functional MRI can be useful to study the generators and the areas of activation in RLS-PLMS [907]. Doppler ultrasonography is an important test for investigation of stroke due to extracranial vascular disease. Myelography other than CT and MRI is important for diagnosis of diseases of the spinal cord.

In selected patients, fiber-optic endoscopy may be performed to locate the site of collapse of the upper airway, and cephalometric radiographs of the cranial base and facial bones may be obtained to assess the posterior airway space or maxillomandibular deficiency (see Chap. 32). These are important when surgical treatment is planned. For research and clinical investigations, cross-sectional areas of the upper airway during wakefulness may be measured by CT and MRI [908–915]. Some imaging studies measured upper airway during sleep dynamically [916, 917].

Finally, MIBG cardiac scintigraphy [918] may show reduced cardiac uptake, and midbrain transcranial sonography [919, 920] may show hyperechogenicity as preclinical markers for neurodegeneration in RBD.

Cerebrospinal Fluid Examination and Other Laboratory Tests

Cerebrospinal fluid examination is important for the diagnosis of meningoencephalitis, Lyme disease, and MS, all of which may give rise to sleep disturbances. Hematologic tests and biochemical studies of blood and urine, as well as tests to assess the endocrine, pulmonary, and cardiac disorders, are essential to uncover general medical disorders that may result in metabolic or toxic encephalopathies.

Laboratory Tests to Investigate Sleep and Sleep-Related Breathing Disorders

Polysomnography

The importance of PSG in the diagnosis of sleep and SDBs is discussed in Chaps. 26 and 32. Sleep can adversely affect breathing, and conversely, respiratory dysrhythmias can have deleterious effects on sleep (see Chap. 11). Both alterations can affect the severity and course of a neurologic illness, causing such sleep disturbances, and so the sleep architecture should be studied. The technique of PSG is described in detail in Chap. 17. For indications and PSG findings in sleep disorders, see Chap. 26.

Video-PSG is important for monitoring patients suspected of having epilepsy or parasomnias that may be associated with certain neurologic disorders (see Chaps. 26, 44 and 50).

Electroencephalography, Including 24-h Ambulatory EEG

Multiple channels of EEG recordings are essential to document focal and diffuse neurologic lesions and to accurately localize epileptiform discharges in patients with seizure disorders (see Chap. 18). Electroencephalography, including 24-h ambulatory EEG, is essential if epilepsy is suspected, as it can cause sleep disturbances that may sometimes be mistaken for parasomnias or sleep apneic episodes. For further details, see Chaps. 26 and 32. If the results of the EEG recording, including long-term monitoring, and neuroimaging findings are discordant in localizing the focus or in making a

diagnosis of seizure in a patient strongly suspected to have it, the patient should be referred to a specialized epilepsy center for intracranial recordings. Recently, for better localization and identification of the epileptic focus as part of presurgical screening, high-density EEG (HD-EEG) technique has been introduced [921]. HD-EEG or dense-array EEG can overcome the spatial limitation of standard EEG in more precise localization of an epileptic focus.

Electrodiagnosis of the Respiratory Muscles

Electromyography of the upper airway, diaphragmatic, intercostal, rectus abdominis, or other abdominal accessory expiratory muscles (see Chaps. 11 and 18) may detect effects on these muscles in neurologic diseases [88, 922–927]. In patients with MSA with laryngeal stridor, it is important to perform laryngeal EMG to detect laryngeal paresis [928].

Phrenic nerve [929] and intercostal nerve conduction study [930] may detect phrenic and intercostal neuropathy, which may cause diaphragmatic and intercostal muscle weakness in some patients with neurologic disorders. Needle EMG of the diaphragm may reveal diaphragmatic denervation, which would suggest neurogenic dysfunction of the diaphragm [931–933].

Multiple orofacial muscle EMGs, in addition to the standard chin EMG, may help assess upper airway muscle hypotonia (see Chap. 18). Multiple muscle EMGs, including tibialis anterior, additional forearm, other limb, and trunk muscle EMGs, are essential for diagnosis of RLS, PLMS, some parasomnias (e.g., RBD), and other sleep-related physiologic and pathological movements.

Multiple Sleep Latency Test

The MSLT is an important test to effectively document EDS, and narcolepsy is the single most important indication for performing MSLT. The presence of two sleep-onset REMs (SOREMs) on four or five nap studies (SOREMs in the preceding overnight PSG may substitute for one MSLT SOREMs) and sleep-onset latency of 8 or less minutes strongly suggest a diagnosis of narcolepsy [101, 934] (see Fig. 41.3). Abnormalities of REM sleep regulatory mechanisms (e.g., OSAS, insufficient sleep syndrome, and use of REM-suppressant medications) or circadian rhythm sleep disturbance may also lead to REM sleep abnormalities during MSLT. Further details about the recording technique and the indications of MSLT are described in Chap. 22.

Maintenance of Wakefulness Test

The maintenance of wakefulness test (MWT) is a variant of the MSLT measuring the subject's ability to stay awake. It also consists of four to five trials of remaining awake recording every 2 h. Each trial is terminated if no sleep occurs after 40 min or immediately after the first 3 consecutive epochs of stage 1 NREM sleep or the first epoch of any other stage of sleep [934]. If the mean sleep latency is less than 8 min, it is then considered an abnormal test; values greater than this but less than 40 min are of uncertain significance. The MWT is less sensitive than the MSLT as a diagnostic test for narcolepsy but is more sensitive in assessing the effect of treatment (e.g., CPAP titration in OSAS and stimulant therapy in narcolepsy). The MWT 40-minute protocol is also indicated to assess an individual's ability to remain awake when his/her inability to remain awake constitutes a public or personal safety issue. For further details, see Chap. 23.

Actigraphy

Actigraphy is an activity monitor [935] or motion detector, designed to record acceleration or deceleration of body movements, that indirectly indicates the stage of sleep or wakefulness (see Fig. 41.27). This complements the sleep diary or sleep log data. It is a small watch-like device generally worn on the wrist, but that can also be worn at the ankle, for 1–2 weeks. The actigraph stores the activity data in epoch-by-epoch samples in its internal memory until the end of the recording period, when it is downloaded to a computer to pool the data graphically and generate a report of the sleep-wake pattern. It is assumed that sleep is represented by long periods with very little to no movement. Actigraphy is a cost-effective method for the assessment of sleep-wake pattern. It can assess sleep-wake schedules in normal and sleep-disordered patients. Actigraphy is very useful in the diagnosis of circadian rhythm sleep disorders (see Fig. 41.28), paradoxical insomnia (sleep state misperception; see Fig. 41.12), and other types of insomnia. It also can be used to detect and quantify PLMS and other sleep-related movements. However, it is not suitable for the assessment of SDB events. Sometimes, it is difficult to assess the sleep-wake schedule in subjects who may feign a sleep problem. Several models are commercially available. Actigraphy and overnight PSG sleep measures are highly correlated in clinical studies. For additional information about actigraphy, see Chap. 39.

Pulmonary Function Tests

Pulmonary function tests (PFTs) assess respiratory and ventilatory muscle function. PFTs include measurement of lung volumes (quantities of air within the lungs) and lung capacities (derived from lung volumes), arterial blood gases, Pa_{O_2} and Pa_{CO_2} obtained by arterial (radial or femoral) puncture, arterial oxygen saturation by finger oximetry, and end-tidal CO_2 or

transcutaneous CO_2. Spirometry is the most important pulmonary function test, measuring most of the lung volumes and capacities except residual volume, functional residual capacity, and total lung capacity, which require nonspirometry techniques (e.g., gas dilution technique). The important spirometric measurements [525–530, 620, 621, 936] are forced vital capacity (FVC), forced expiratory volume in 1 s (FEV_1), and the ratio of FEV_1 to FVC. In order to obtain valid spirometric measurements, it is important to have patient cooperation and good patient-technician interaction. Values are expressed as percentage of predicted. Values of FVC, FEV_1, and peak expiratory flow of less than 80 % predicted are considered abnormal. A value of less than 70 % predicted for the ratio of FEV_1 to FVC is abnormal. The characteristic abnormalities in neuromuscular disorders include decreased FVC, FEV_1, and total lung capacity but increased residual volume. The airway obstruction shows less-than-predicted values of the ratio of FEV_1 to FVC, whereas restricted lung disease will show an increase in the ratio of FEV_1 to FVC combined with an absolute reduction in FVC and FEV_1. Box 41.8 lists the lung volumes and lung capacities, which are schematically shown in Fig. 41.28.

Box 41.8 Lung Volumes and Capacities

Lung Volumes

- Tidal volume (TV): volume (ml) of air per normal inspiration or expiration,
- Inspiratory reserve volume (IRV): volume of air during maximal inhalation following a normal breath,
- Expiratory reserve volume (ERV): volume of air during maximal exhalation following a normal breath,
- Residual volume (RV): volume of air remaining after maximal exhalation.

Lung Capacities (derived from lung volumes)

- Vital capacity (VC): volume of air that can be exhaled maximally after maximal inspiration (IRV + TV + ERV),
- Inspiratory capacity (IC): inspiratory reserve volume plus tidal volume (IRV + TV),
- Functional residual capacity (FRC): volume of air remaining after a normal expiration (ERV + RV),
- Total lung capacity (TLC): vital capacity plus residual volume (VC + RV).

Before a significant reduction in lung volume is appreciated, respiratory muscle strength must be severely reduced because pressure/volume characteristics of the respiratory system are not linear. Thus, static respiratory pressure measurements are often used to assess the respiratory muscle strength: for example, maximal inspiratory pressure (PI_{max}) and maximal expiratory pressure (PE_{max}) [937]. However, these measurements require the cooperation of patients, and the normal values have large ranges and variability that may be related to factors such as lung volume, type of mouthpiece, variable effort, and learning. In patients with bulbar muscle weakness, it may not be possible to measure PI_{max} and PE_{max}. In order to reduce the effects of these variables in the measurements of PI_{max}, investigators have used respiratory pressures during the maximal sniff maneuver [523, 524]. The maximal sniff pressure may be measured using transdiaphragmatic, esophageal, or nasal methods. Nasal pressure is often measured rather than esophageal pressure because it is much less invasive.

The definitive test for alveolar hypoventilation is an analysis of arterial blood gases showing hypercapnia and hypoxemia [518, 531]. In the early stage of neuromuscular disorder, awake arterial blood gas values remain normal; only in advanced stages with chronic respiratory failure, will these values be abnormal. To detect abnormal nocturnal arterial blood gases and hypoventilation, an indwelling arterial catheter needs to be placed throughout the night, which is invasive and rather impractical. Therefore, some investigators advocate noninvasive monitoring of arterial oxygen saturation and $Paco_2$ only to detect hypoventilation; however, there are pitfalls to this line of investigation [531]. There is limitation to the usefulness of finger oximetry alone because of the hyperbolic shape of the oxyhemoglobin dissociation curves, which may show minor oxygen desaturation in the presence of significant hypoventilation and reduced Pao_2. The noninvasive end-tidal and transcutaneous carbon dioxide tension measurements are also unreliable and correlate poorly with actual $Paco_2$.

Chemical control of breathing may be impaired if neurologic disease causes dysfunction of the metabolic respiratory controllers [9]. Such impairment may be detected by hypercapnic ventilatory response ($VE/Paco_2$), hypoxic ventilatory response (VE/Pao_2), and mouth occlusion pressure ($P_{0.1}$) response, with or without loading [9]. Central respiratory drive and the inspiratory muscle strength independent of pulmonary mechanical factors are reflected in the $P_{0.1}$ response.

PFTs can exclude intrinsic bronchopulmonary disease, which may affect SDBs [936]. For additional detail on PFTs, see Chap. 20.

Chest Fluoroscopy

In patients suspected to have diaphragmatic paralysis, chest fluoroscopy in addition to the measurement of transdiaphragmatic pressure using esophageal and gastric balloons

inserted through the nasogastric route may be necessary [938–940]. The chest radiography is noninvasive and permits visualization of the diaphragm dome but provides little information regarding diaphragm function. Chest fluoroscopy of the diaphragm provides real-time examination of the start of diaphragm dome motion but carries the disadvantage of exposure to ionizing radiation and poor sensitivity and specificity.

Other Laboratory Tests

Any suspected medical disorders that may be causing patient's insomnia or hypersomnia should be investigated with appropriate laboratory tests which may include blood and urinalysis, ECG including Holter monitoring, echocardiogram, chest radiography, and other tests to exclude pulmonary, cardiovascular, gastrointestinal, endocrine, and renal disorders. Autonomic function tests may be required in autonomic failure cases causing SDB and other sleep disturbance.

Narcolepsy patients may require histocompatibility leukocyte antigen (HLA) typing as most of the patients with narcolepsy are HLA DR2DQI and DQB1*0602 antigen positive (see Chap. 38). This is, however, not a specified test for narcolepsy as a high percentage of rheumatologic disorder, and some (12–21 %) normal individuals are also DR2 positive. Another important test for diagnostic problem cases of narcolepsy is the measurement of CSF hypocretin-1 levels which are found to be low (<110 pg/ml) in narcolepsy type 1 patients who are DQB1*0602 positive (see also Chap. 38). In patients with narcolepsy type 2 and in some other neurologic disorders, CSF levels may be low normal.

Minnesota Multiphasic Personality Inventory (MMPI) testing may be needed to assess the baseline personality trait in some psychiatric patients complaining of EDS.

In patients with RLS, in addition to neuroimaging tests as described above, EMG and NCS are important to exclude polyneuropathies or lumbosacral radiculopathies, and other lower motor neuron disorders that may be associated with RLS or cause symptoms resembling idiopathic RLS. Other important laboratory tests in patients with RLS include those necessary to exclude diabetes mellitus, uremia, anemia, and other associated conditions. It is particularly important to obtain levels of serum iron (including serum ferritin and transferrin), serum folate, fasting blood glucose, blood urea, and creatinine. In a subgroup of patients with RLS, serum iron and ferritin levels are found to be low (ferritin < 50–70 mg/ml), and correction of these abnormalities may improve the condition. The role of nerve biopsy remains controversial, and in the vast majority of patients, it is not necessary, but may be obtained for research purpose and when there is a strong suspicion of polyneuropathy.

Box 41.9A and Box 41.9B outline the laboratory tests to assess the sleep disorders.

Box 41.9A Diagnostic Tests to Assess the Sleep Disorder

- Diagnostic workup for the primary or comorbid condition causing sleep disturbance
- Laboratory tests for the diagnosis and monitoring of sleep disorders:
  - Overnight polysomnography (PSG),
  - High-definition video-PSG,
  - Multiple sleep latency tests (MSLT),
  - Maintenance of wakefulness test (MWT),
  - Actigraphy.
- Video-PSG with multiple muscle montage
