- Laboratory tests for suspected seizure disorders
  - Standard electroencephalography (EEG),
  - Video-EEG monitoring for suspected seizure disorders,
  - Video-PSG with special seizure montage.
- Imaging studies:
  - Upper airway imaging for obstructive sleep apnea syndrome,
  - Neuroimaging studies of the brain (e.g., computed tomography, magnetic resonance imaging [MRI], MR angiography, diffusion tensor MRI, and MR tractography) and cerebral angiography in cases of suspected neurologic illness causing sleep disorder,
  - Positron-emission tomography and single-photon-emission computed tomography of the brain in special situations,
  - Cardian MIBG scintigraphy and midbrain transcranial sonography in idiopathic RBD to uncover preclinical markers for neurodegeneration,
  - Fiber-optic endoscopy and cephalometric radiographs of the cranial base and facial bones to locate site of the upper airway collapse and to assess the posterior airway space in OSA patients.
- Miscellaneous tests:
  - Standard blood and urine analysis,
  - Pulmonary function tests including arterial blood gases (ABGs) in cases of suspected bronchopulmonary and neuromuscular disorders causing sleep-disordered breathing,
  - Histocompatibility leukocyte antigen for suspected narcolepsy (HLA DQB1*0602),
  - Cerebrospinal fluid hypocretin-1 levels in suspected narcolepsy,
  - Serum iron, ferritin levels, and transferrin for patients with RLS/WED,

- Electromyography and nerve conduction studies to exclude comorbid or secondary RLS/WED,
- Cardiological investigations including electrocardiogram (EKG), Holter EKG, and echocardiogram,
- Endocrine tests,
- Autonomic function tests in patients with suspected autonomic and sleep-related breathing disorders.

Box 41.9B Home Sleep Apnea Testing (HSAT)

- Indications
  - May be alternatives for the initial diagnosis of OSA in patients with a high pretest probability for the condition.

- Contraindications to HSAT
  1. Patient is 18 years of age or younger,
  2. Moderate or severe chronic obstructive pulmonary disease (COPD)—FEV1/FVC less than or equal to 0.7 and FEV1 less than 80 % of predicted,
  3. Moderate or severe congestive heart failure (CHF)—NYHA class III or IV,
  4. Cognitive impairment (inability to follow simple instructions),
  5. Neuromuscular impairment,
  6. Suspicion of a sleep disorder other than OSA (e.g., central sleep apnea, narcolepsy, restless legs syndrome, circadian rhythm disorder, parasomnias, and periodic limb movement disorder),
  7. Previous technically suboptimal home sleep study (2 nights of study attempted),
  8. Previous 2-night home sleep study which did not diagnose OSA in a patient with ongoing clinical suspicion of OSA,
  9. Patient is oxygen dependent for any reason,
  10. History of cerebrovascular accident (CVA) within the preceding 30 days,
  11. History of ventricular fibrillation or sustained ventricular tachycardia.

Treatment of Sleep and Respiratory Dysfunction Secondary to Neurologic Disorders

Treatment is discussed under two broad categories: (1) therapy for the primary neurologic illness and (2) therapy for the secondary sleep disturbance.

Treatment of Primary Neurologic Illness

First and foremost is accurate diagnosis of the primary neurologic disorder. This is followed by vigorous treatment and monitoring of the neurologic illness. Such treatment may improve the sleep disturbances. It is beyond the scope of this volume to discuss the treatment of primary neurologic disorders, and readers are referred to some excellent texts [896–899].

Treatment of Sleep Disturbances Including Sleep-Related Breathing Disorders

Sleep disturbances in neurologic disorders include hypersomnia, insomnia, circadian rhythm sleep disturbances, parasomnias, and other sleep-related movement disorders. Treatment of these complaints is discussed in several chapters in this volume (see Chaps. 32–38, 40–42, 44, 46–50, and 55). In this section, treatment of hypersomnia that results mainly from sleep-related respiratory dysrhythmias in neurologic disorders is discussed. In the following sections, general principles of treatment for sleep disturbances in dementias and PD not related to the respiratory dysrhythmias are briefly reviewed.

The objective of treatment of SRBDs is twofold: (1) to improve the quality of life by improving the quality of sleep and (2) to prevent life-threatening cardiac arrhythmias, pulmonary hypertension, and congestive cardiac failure related to SDB. The quality of sleep may be improved by eliminating repeated apneas during sleep and thus preventing repeated arousals, sleep fragmentation, nocturnal hypoxemia, and daytime hypersomnolence. The treatment modalities for sleep-related respiratory dysrhythmias resulting from neurologic illness may be divided into five categories: (1) general measures, (2) pharmacologic agents, (3) mechanical devices, (4) supplemental O_2 administration, and (5) surgical treatment (Box 41.10).

Box 41.10 Treatment of Sleep-Related Breathing Disorders in Neurologic Illness

General Measures

- Avoid alcohol and sedative hypnotics, especially in the evening.
- Reduce body weight if overweight.
- Avoid sleep deprivation.
- Avoid supine sleeping position.
- Participate in regular exercise program if possible.

Pharmacologic Agents

- Protriptyline, medroxyprogesterone acetate, or SSRIs in mild cases (mostly ineffective),
- Nasal corticosteroids for OSA in children (minimal benefit),
- Acetazolamide in central apnea at high altitude,
- Modafinil as an adjunct treatment in a subset of OSA patients with residual sleepiness and in some patients with myotonic dystrophy.

Mechanical Devices

- Continuous positive airway pressure (CPAP) titration,
- Bilevel positive airway pressure (BPAP) titration,
- Auto-CPAP,
- Assisted servoventilation,
- Intermittent positive pressure ventilation,
- Dental appliances, including mandibular advancement device,
- Tongue retaining device.

Supplemental O_2 Administration

Surgical Treatment

- Bariatric surgery,
- Diaphragm pacing or electrophrenic respiration,
- Hypoglossal nerve stimulation,
- Tracheostomy (rarely performed nowadays).

OSA obstructive sleep apnea; *SSRIs* selective serotonin reuptake inhibitors.

General Measures

General measures of treatment include reduction or elimination of risk factors that can aggravate sleep-related respiratory dysrhythmias. Avoidance of alcohol and sedative hypnotic drugs [941] (e.g., benzodiazepines, barbiturates, and narcotics) that can depress breathing during sleep is an important step in eliminating the risk factors. Alcohol is known to increase the frequency and duration of apneas, probably by two mechanisms [942–944]: (1) selective depression of the genioglossus and other upper airway muscles and (2) impairment of the arousal response by raising its threshold. For obese patients, weight loss is another important step in eliminating risk factors for sleep-related respiratory dysrhythmia. Other general measures include avoidance of sleep deprivation and supine sleep position and maintenance of a regular exercise program as much as possible from a practical point of view in the neurologically afflicted patient.

Pharmacologic Treatment

This therapy remains unsatisfactory [945]. The agents that have been tried with partial success for mild-to-moderate sleep apnea are protriptyline, medroxyprogesterone acetate, acetazolamide, selective serotonin reuptake inhibitors (SSRIs), and nasal corticosteroids for children. Protriptyline may be used in a dose of 5–20 mg at bedtime. Suppression of REM sleep; a specific alerting property; increased upper airway muscle tone; and conversion of apnea to hypopnea are cited as mechanisms of action of this drug [941, 946]. Anticholinergic effects and cardiac arrhythmias are the limiting side effects of this drug.

Medroxyprogesterone acetate has been tried in many patients with sleep apnea, but the results have been

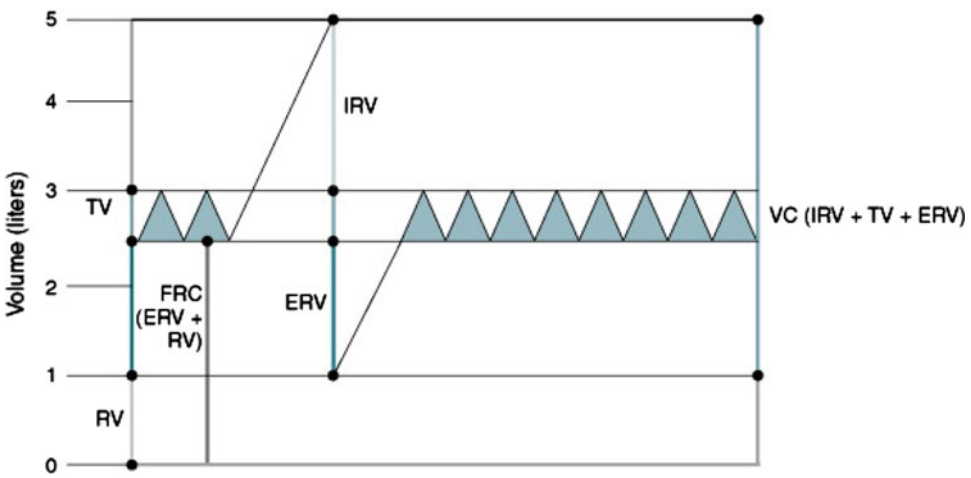

Fig. 41.28 Schematic diagram to show lung volumes and capacities. *ERV* expiratory reserve volume; *FRC* functional residual capacity; *IRV* inspiratory reserve volume; *RV* residual volume; *TV* tidal volume; *VC* vital capacity.)

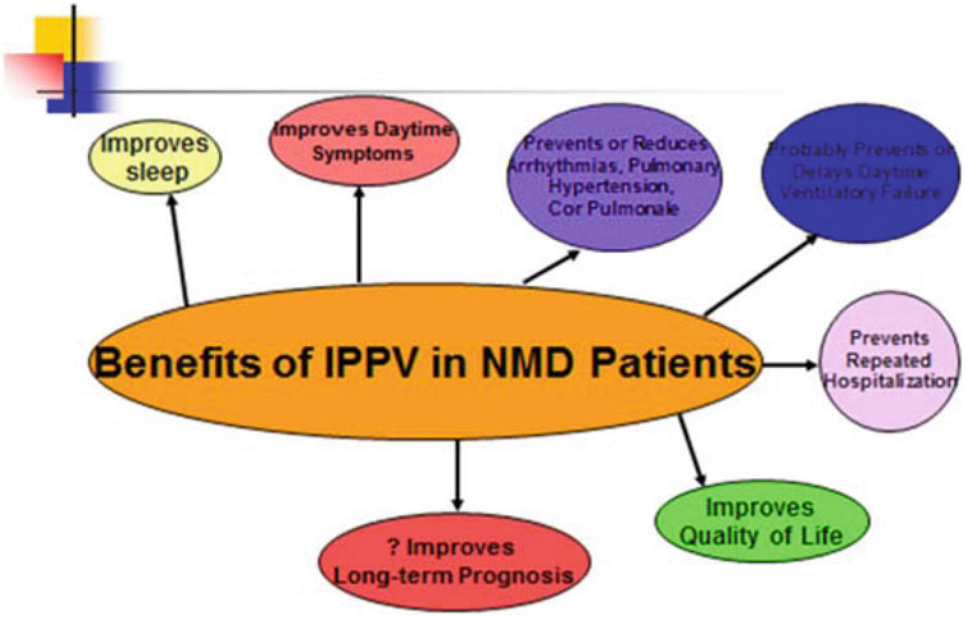

Fig. 41.29 Schematic to show benefits of IPPV

disappointing [947–949]. It is thought to act by increasing ventilatory drive. Impotence in men is a limiting side effect, and there are other side effects [950].

Acetazolamide has been used with some success in central apnea, but development of obstructive apnea or aggravation of orthostatic hypotension owing to its diuretic and natriuretic effects should be kept in mind during treatment. Acetazolamide is a carbonic anhydrase inhibitor and will produce metabolic acidosis, causing a shift in the P_{ACO_2} apnea threshold, and it has been used with some success to treat central apnea at high altitude [951–955].

There have been isolated reports of the use of selective serotonin reuptake inhibitors in mild cases and topical nasal corticosteroids for OSAS in children with minimal benefit. In a subset of OSAS patients on CPAP titration (see later), complaining of residual daytime sleepiness, modafinil or armodafinil, a novel wake-promoting agent, has been used with success as an adjunct treatment [956–964]. Modafinil has also been used successfully for myotonic dystrophy patients with hypersomnia unrelated to alveolar hypoventilation or sleep apnea [965–967]. Modafinil may be initiated at 100 mg/day, increasing to a maximum of 400 mg/day to be taken in two divided doses. Armodafinil may be used as a single dose (longer-acting agent than modafinil of 150–250 mg one totwo hours before or after breakfast). Methylphenidate and amphetamines may also be used if modafinil is not effective.

CSA, including CSB, associated with heart failure requires aggressive pharmacologic treatment for heart failure (e.g., beta-blockers, digoxin, and diuretics) and, if needed, heart transplantation (see Chap. 47).

Mechanical Devices

Nasal Continuous Positive Airway Pressure

An important therapeutic advance in the treatment of OSAS, CPAP is described in detail in Chap. 34. It should be given a trial in neurologic disease patients with upper airway OSAs associated with intermittent CSAs or with mixed apneas. Such treatment often improves the quality of sleep and reduces daytime symptoms by eliminating or reducing sleep-related obstructive or mixed apneas and O_2 desaturation. The role of nasal CPAP for CSA is highly controversial. The Stanford University group [968] found CPAP helpful for central apnea patients who had associated OSA or who showed sleep fragmentation and repeated sleep-wake changes. In a subgroup of patients with CSA with insomnia who may show narrowing or occlusion of the upper airway via fiber-optic scope, nasal CPAP reversed the CSA [969, 970]. In addition to nasal or full-face CPAP with or without expiratory pressure relief (1–3 cm), other devices that found to be useful include bilevel positive airway pressure (BiPAP) delivering higher pressure during inspiration and lower pressure during expiration, auto-CPAP, and auto-BiPAP titration. Auto-CPAP and auto-BiPAP machines automatically titrate pressure according to specific algorithms set by each manufacturing agency to detect abnormal breathing events. The role of these autodevices in better adherence than standard CPAP remains to be determined despite reducing mean pressure requirement by 2 cm compared to fixed pressure CPAP. For further details, see Chap. 34.

Treatment of Cheyne–Stokes Breathing and Central Sleep Apnea

Patients with CSB-CSA should be given a trial with CPAP or BIPAP titration to improve ventilation in addition to pharmacologic treatment with acetazolamide or theophylline. Some patients may require oxygen inhalation and gas modulation with inert carbon dioxide through the nasal mask or with added dead space to positive pressure titration [971, 972]. Another treatment besides CPAP-BIPAP that has been found to be useful in patients with CSB-CSA and complex sleep apnea includes adaptive servoventilation [973–983]. The role of adaptive servoventilation in terms of long-term prognosis, however, remains to be determined. Recent European trial suggested increased mortality after ASV titration for CSA-CSB in systolic heart failure with reduced (≤45 %) ejection fraction [984]. See also Chap. 47 and contradictory correspondence with response from the original authors [985].

Neuromuscular Disorders and Other Ventilatory Supports

In the past, the mainstay of treatment for patients with neuromuscular disorders associated with SDB including hypoventilation was invasive ventilation through a tracheostomy (see later in this section), but this has now been largely replaced by noninvasive measures of ventilatory support consisting of negative and positive pressure ventilators [531, 986, 987]. These ventilators were developed during the early polio epidemics in the 1950s and the 1960s. Negative pressure ventilators include "iron lung" or tank respirators, the "rain coat" or "pneumowrap ventilator," and the cuirass or "tortoise shell" [986, 988–992]. Although the tank respirator is the most effective negative pressure ventilator, applying negative pressure to the entire body below the neck, it is bulky and limits the patient's acceptance [986, 990]. Furthermore, negative pressure ventilators may cause upper airway OSA with oxygen desaturation both in normal subjects [993] and in patients with neuromuscular diseases [994]. The contemporary standard of care for chronic ventilatory failure in neuromuscular disorders is noninvasive intermittent positive pressure ventilation (IPPV) using a nasal mask or prongs. Positive pressure ventilation includes CPAP, BiPAP, and IPPV. For upper airway OSAS, nasal CPAP is the ideal treatment. Following such treatment, sleep quality and daytime hypersomnolence often improve due to the reduction or elimination of sleep-related obstructive or mixed apneas and oxygen desaturation. However, such treatment has not been very useful in patients with relentlessly progressive disease; therefore, the role of CPAP in such diseases requires additional study. Some patients may not be able to tolerate the same high pressure during both inspiration and expiration and feel comfortable using BIPAP, which uses higher inspiratory than expiratory positive airway pressure.

The beneficial effect of nocturnal IPPV may be summarized as follows: improved nocturnal gas exchange as reflected in Sao_2 and transcutaneous CO_2 as well as improved daytime arterial blood gases; mild improvement of total sleep duration without significant improvement of quality of sleep; improved FVC and PI_{max}; reduced number of days of hospitalization; and improved quality-of-life measures and long-term survival. Figure 41.29 schematically outlines the benefit of IPPV in neuromuscular disorders.

The benefits of noninvasive ventilation through a nasal mask for 6–8 h during sleep in neuromuscular disorders have been clearly shown in many studies [464, 519, 530, 995–1025]. IPPV generally uses no expiratory positive pressure, but in some patients, positive end-expiratory pressure up to 5 cm may be required. In some patients during initial nights of IPPV, there may be upper airway closure for the first time [520, 1026] during the expiratory phase. The mechanism for such closure may include driving CO_2 below the inspiratory threshold and marked reduction of muscle tone as a result of REM rebound. Treatment of these patients is by the addition of a positive end-expiratory pressure valve by maintaining a positive pressure (up to 5 cm) during expiration. Noninvasive IPPV can be used even in those patients with bulbar muscle weakness utilizing the full-face mask. Either pressure-cycled ventilators delivering air at a fixed pressure or volume-cycled ventilators delivering a fixed volume of air may be used. Many clinicians prefer pressure-cycled ventilators to deliver IPPV, but there is variation in individual patient response [1025]. There does not seem to be a difference between these two types of ventilators in terms of long-term survival [1027] and short-term studies showing correction of hypoventilation [1028]. The volume-cycled ventilators deliver tidal volume, and pressure-cycled ventilators deliver fixed pressure (usually 10–20 cm H_2O) set by the clinician. One of the following three ventilator modes may be used: control mode, wherein the ventilator starts and ends inspiration according to prescribed settings; assist-control mode, wherein either the patient's effort or a programmed setting initiates inspiration; and spontaneous assist, wherein the patient's effort starts and ends inspiration. In the spontaneous mode, a backup respiratory rate is set up.

Cochrane Database updated review in 2014[1023] noted two trials comparing pressure-cycled ventilation (PCV) with volume-cycled ventilation (VCV). VCV was associated with less sleep time spent with an arterial O_2 saturation below

90 % and a lower apnea-hypopnea index per hour. There was only one trial in this report [1029] with 16 participants which found no difference in mortality between PCV and VCV.

Long-term follow-up and prospective randomized controlled trials in neuromuscular disorders such as ALS are limited. In one of the largest prospective, although not randomized, blinded studies, Mustafa et al. [1008] proved the efficacy of noninvasive ventilation in ALS patients. There were striking improvements in blood gases and a variety of quality-of-life measures following noninvasive ventilation within one month that were maintained for up to 12 months in 26 patients with ALS showing respiratory muscle weakness. These authors also studied in parallel 15 age-matched patients without respiratory muscle weakness but with similar severity of ALS. These ALS patients showed improvement in quality-of-life measures despite progression of the disease. It was also shown that noninvasive ventilation in patients had no impact on most quality-of-life measures for caregivers and did not increase caregiver burden or stress. In another study [1011], 26 patients with congenital neuromuscular or chest wall diseases having daytime normocapnea and nocturnal hypercapnia were randomized either to nocturnal noninvasive ventilation or to a control group without ventilatory support. These authors found increased mean Sao_2 and decreased mean percentage of the night with peak transcutaneous CO_2 tension in the group using noninvasive ventilation as compared with controls. The authors suggested that such patients may benefit from nocturnal IPPV before daytime hypercapnia ensues. In the only randomized controlled trial, Bourke et al. [998] assigned 22 patients to noninvasive ventilation and 19 patients to standard care when these ALS patients developed orthopnea with PI_{max} less than 60 % of predicted value or symptomatic hypercapnia. They found a median survival benefit of 205 days with improvement in quality-of-life measures in patients receiving noninvasive ventilation. In patients with severe bulbar involvement, however, survival benefit was not noted, but there was improvement in sleep-related symptoms. A survival benefit was also observed by Pinto et al. [999] and Kleopa et al. [1005]. Improvement in nocturnal ventilation and sleep quality following IPPV has been noted by several authors in patients with nocturnal respiratory failure as a result of restrictive or neuromuscular disorders [1026, 1030, 1031]. In the Cochrane Database updated review covering 10 eligible trials with 179 participants, Annane et al. [1029] stated that there is a clear evidence of alleviation of chronic hypoventilation in neuromuscular disorders in the short term. In their review covering four small studies involving mainly motor neuron disease, prolonged survival and reduced number of hospitalizations were noted. In both motor neuron disease and Duchenne's muscular dystrophy, survival benefit after using mechanical ventilation versus no ventilation is established. However, the authors concluded that further larger studies are needed to assess the long-term benefit of different types and modes of ventilation to determine morbidity, mortality, and quality of life in all other neuromuscular and chest wall disorders. Sancho et al. [1032] also observed prolonged survival of 22 patients with amyotrophic lateral sclerosis following both noninvasive and tracheostomy IPPV.

Indications for Intermittent Positive Pressure Ventilation

A European consensus conference in 1993 listed the following criteria for long-term noninvasive nasal ventilation for patients with neuromuscular disorders [1033]: presence of clinical symptoms associated with $Paco_2$ level of ≤45 mm Hg, Pao_2 <60 mm Hg in the daytime arterial blood gas analysis, or pronounced nocturnal oxygen desaturation. The patient's obstructive symptoms and arterial blood gases should be monitored. A later US consensus conference in a 1999 report listed the criteria for IPPV for patients with neuromuscular disorders (Box 41.11) [1034]. First, the diagnosis must be established via history and physical examination followed by appropriate laboratory tests. The patients should have received treatment for associated (e.g., OSAS diagnosed by performing PSG studies) or underlying conditions. The suggested indications for use of noninvasive ventilation include clinical symptoms and one of the three physiologic criteria (see Box 41.11). A follow-up in 1–3 months for the assessment of compliance and monitoring awake arterial blood gases is also suggested. Overnight oximetry may be helpful for monitoring such patients.

Box 41.11 1999 US Consensus Conference: Indications for IPV in Chronic respiratory failure [1034]

- Appropriate clinical symptoms

- PLUS one of the three physiologic criteria:
  - $PaCo_2$ ≥45 mmHg,
  - Nocturnal oxygen desaturation (by finger oximetry) of ≤88 % for five consecutive minutes,
  - PImax of <60 % cm H_2O or FVC <50 % of predicted value in cases of progressive neuromuscular diseases.

Abbreviations: *$PaCo_2$* arterial partial pressure of carbon dioxide; *PImax* maximum inspiratory muscle pressure; *FVC* forced vital capacity.

In 2009, the American Academy of Neurology published updated practice parameter [1035] for initiation of IPPV in the care of patients with amyotrophic lateral sclerosis (Box 41.12). The American Academy of Sleep Medicine (AASMS) Task Force made recommendations for titration guidelines for noninvasive positive pressure ventilation

[1036]. It should be remembered that different neuromuscular disorders evolve and progress at different and varying speeds depending on the etiology of the disease process and other associated variables, and therefore, the setup guidelines may need further modifications depending upon the disease process involved.

Box 41.12 American Academy of Neurology Practice Parameters updated (2009) for IPPV in the care of ALS patients [1035]

- PImax of <60 cm H_2O,
- FVC <50 % of predicted value,
- Pnsn <40 cm H_2O,
- Nocturnal SaO_2 <90 % for a cumulative time of >1 min in the presence of orthopnea.

Abbreviations: *PImax* maximum inspiratory muscle pressure; *FVC* forced vital capacity; *Pnsn* nasal sniff pressure.

There have been some attempts to document daytime predictors that will indicate nocturnal hypoventilation and hence the need for IPPV, and these have been discussed previously in this chapter. Katz et al. [1037] studied 46 children with progressive neuromuscular diseases and observed that subjects (15 %) with nocturnal hypoventilation had FVC <70 % and FEV_1 <65 % which the authors considered as predictors of nocturnal hypoventilation. In a recent study of obesity hypoventilation syndrome from Saudi Arabia, Bahammam [1038] concluded that serum sodium bicarbonate (HCO_3) may be a predictor of nocturnal hypoventilation. There is no controlled study implementing these predictors to evaluate the progression of disease and efficacy of treatment, but finger oximetry is the most widely used. In addition, transcutaneous or end-tidal CO_2 concentration can also be used. Electromyography of the accessory respiratory muscles may help in indicating the evidence of ventilatory failure; however, repeat PSG study remains the best test for evaluating quality of sleep and effectiveness of IPPV. Guilleminault and Shergill [516] suggested that even if there is no change in clinical symptoms, a PSG is recommended at least once a year as respiratory changes can occur without accompanying clinical symptoms. There are, however, no standard guidelines for this recommendation.

The complications of IPPV are similar to those noted with CPAP or BIPAP (see Chap. 34). One particularly annoying complication is nasal stuffiness or rhinorrhea, which may be relieved by using a warm humidifier or nasal corticosteroids. Some patients complain of claustrophobia when using a nasal mask, particularly those with breathing problems. In such patients, a nasal pillow instead of a nasal mask may be useful. Leaks around the mask causing arousals, sleep fragmentation, and subsequent decrease in efficacy of IPPV are also common, and correction of these leaks is important to improve the sleep quality and architecture. Long-term use of a nasal mask can lead to a maxillary hypoplasia in young subjects. Children using nasal ventilation should be seen monthly to adjust mask size, particularly in the first 2 years of life, as a child's face grows quickly during infancy and childhood. Furthermore, airways develop and remodel during this time, and repetition of nocturnal PSG has been suggested approximately every 3 months [516].

Mechanism of Improvement Following IPPV

Several mechanisms have been suggested but not proven for improving SDB and related symptoms in patients with neuromuscular disorders following noninvasive IPPV [518, 530, 531, 1039, 1040]. Improvement of respiratory muscle fatigue and restoration of the sensitivity of the respiratory center to carbon dioxide are the two important mechanisms cited. Changes in pulmonary mechanics (e.g., increasing lung volumes, improvement of lung compliance, and reduction of dead space) may also contribute to improvement in symptoms and gas exchanges (Fig. 41.29).

Oxygen Supplementation

The role of supplemental oxygen therapy using low-flow oxygen (1–2 L/min) in the treatment of SDB in neurotomy-muscular diseases remains controversial. According to most investigators, oxygen therapy in restrictive thoracic disorders caused by neuromuscular diseases is ineffective and may be dangerous, leading to marked CO_2 retention [1041].

Supplemental O_2 therapy may decrease the severity of OSA in certain patients [1042]. The recommended treatment of nocturnal hypoxemia is the administration of O_2 at a low flow rate (1–2 L/min) via a nasal cannula (see Chap. 47). Oxygen administration may not be safe for all patients with sleep apnea syndrome. Motta and Guilleminault [1043] and Chokroverty et al. [1044] observed prolongation of apneas after O_2 administration during sleep in patients with OSAS and obesity hypoventilation syndrome. Gay and Edmonds [1045] directed our attention to the possible exacerbation of hypercapnia after administration of low-flow O_2 in patients with neuromuscular disorders. In eight patients with neuromuscular disease and diaphragmatic dysfunction (patients with polymyositis, ALS, or inflammatory motor neuropathy), mean $Paco_2$ increased considerably after administration of low-flow supplemental O_2 (0.5–2.0 L/min). Four patients needed subsequent nocturnal assisted ventilation. The authors suggested that nocturnal assisted ventilation can be considered for patients with O_2-sensitive hypoventilation. In such patients, it may be possible to safely administer O_2 during the daytime. AASM made recommendations [1036] for supplemental oxygen during noninvasive IPPV titration.

Surgical Treatment

This consists of bariatric surgery, hypoglossal nerve stimulation, diaphragmatic pacing or electrophrenic respiration and tracheostomy (see Box 41.10).

Hypoglossal Nerve Stimulation

Recently, hypoglossal nerve stimulation by an implanted device has been tried in 126 patients who had difficulty in accepting or toleratin CPAP with reduction of mean AHI from 32 to 15.2/hour at 12 months' follow-up. Aderse effects included and soreness and abrasions of the tongue [1046].

Diaphragmatic Pacing or Electrophrenic Respiration

Sarnoff et al. [1047] first used electrophrenic stimulation in patients with poliomyelitis in 1951, but the technical difficulties at that time prevented its regular use for such treatment. Glenn and associates [1048] improved the technique and extensively studied electrophrenic respiration by diaphragm pacing (DP). This form of treatment is used successfully in patients with respiratory center involvement with CSA syndrome. Superimposed OSA may complicate the procedure, which may then require both electrophrenic respiration and tracheostomy for treating such patients. Glenn's group [1048] used such treatment successfully in three groups of neurologic disease patients: those with respiratory center involvement, either direct or through interruption of the afferent or efferent neurons to the respiratory center; those with high cervical spinal cord lesions; and those with primary alveolar hypoventilation (PAH). Chervin and Guilleminault [1049] reviewed the topic of DP. The authors stated that the "gold standard" of treatment of hypoventilation due to neurologic (including neuromuscular) disorders is BIPAP or IPPV. For those patients who require ventilatory assistance during both the day and the night, however, DP is advantageous. The indications for DP include those patients with partial or total ventilatory failure, either during sleep or continuously. The causes for hypoventilation include neurologic disorders proximal to the phrenic motor neurons. The causes include both idiopathic CSA syndrome and CCHS in infants. Most of the patients on long-term DP require minimal or no additional ventilatory support, and most show improvement in the quality of life.

Complications of DP include precipitation of upper airway OSA requiring CPAP or tracheostomy in many patients, damage to the phrenic nerve, diaphragmatic damage due to fatigue, equipment malfunction, surgical complications, neuromuscular junction failure, local infection, and interference with cardiac pacemakers. Finally, DP is an invasive procedure. Despite the complications and disadvantages, DP is the preferred procedure for those requiring ventilatory assistance during both the day and the night. In June 2008, the US Food and Drug Administration (FDA) approved the $NeuR_x$ Diaphragm Pacing System (DPS) only for spinal cord injury (SCI) patients who depend on ventilators because of a paralyzed diaphragm. This approval was based on data obtained from a multicenter clinical trial [1050]. In September 2011, the FDA approved DP for amyotrophic lateral sclerosis (ALS) patients under a "Humanitarian Device Exemption" provision [1051]. In a 2009 multicenter study report involving laparoscopic diaphragm pacing in 88 patients (50 SCI and 38 ALS), Onders et al. [1052] have shown freedom from ventilators in SCI patients and delayed need for ventilators in ALS patients increasing their survival. In later studies, the same group [1053, 1054] demonstrated that DP can be used to overcome instability of breathing, improve sleep, and positively influence survival in ALS patients. The FDA subsequently approved DP for ALS patients.

Tracheostomy

Tracheostomy remains the only effective measure for emergency treatment of patients with marked respiratory dysfunction with severe hypoxemia, patients with sudden respiratory arrest after resuscitation by intubation, and patients with severe laryngeal stridor due to laryngeal abductor paralysis. This used to be the definitive treatment for patients with severe OSAS, but it has been largely replaced by CPAP or BIPAP since they became available. On improvement after emergency tracheostomy, patients may later be weaned from the tracheostomy. Permanent tracheostomy may still be needed for patients with neuromuscular diseases: those with central respiratory drive abnormalities showing persistently elevated $Paco_2$ despite using noninvasive IPPV; those who are unable to handle oropharyngeal secretions and show continued deterioration of neuromuscular disorders with very brief periods of spontaneous ventilation; and those patients with sleep apnea who fail to improve after nasal CPAP and nasal ventilation [528, 986]. In such patients, ventilatory assistance is provided at night with plugging of the tracheostomy tube during the daytime, or the patient may use a commercially available portable ventilator continuously if needed, using the assist-control mode [979]. Potential complications of tracheostomy and the care needed for maintenance of the tracheostomy should be discussed in detail with the patients and their families. Besides its invasiveness, the complications of tracheostomy include disfigurement, difficulty with speaking, tracheal stenosis, and tracheomalacia [531, 1055].

Treatment of Sleep Disturbances in Alzheimer's Disease and Related Dementias

Treatment of acute confusional states associated with dementia is described in Chap. 51. In this section, general principles of

treatment of sleep disturbance in patients with dementia are outlined [1056]. Box 41.13 lists certain general principles of treatment. Medications that could have an adverse effect on sleep and breathing should be reduced in dose or changed. Associated conditions that could interfere with sleep (e.g., pain due to arthritis and other causes) should be treated with analgesics. Depression is often an important feature in patients with AD, and a sedative antidepressant may be helpful. Frequency of urination in such patients may result from infection or enlarged prostate and may disturb sleep at night. Appropriate treatment should be directed toward such conditions. Patients should be encouraged to develop good sleep habits. They should be discouraged from taking daytime naps and should be encouraged to exercise (e.g., walking during the day). They should not drink caffeine before bedtime or in the evening. For sleeplessness, a nonbenzodiazepine agonist such as zolpidem (including zolpidem CR) and eszopiclone as well as a melatonin receptor agonist (e.g., ramelteon) are commonly prescribed for a short period (see Chap. 37). For nocturnal agitation and sundowning, the patient should be treated with antipsychotics, including the newer agents (haloperidol, 0.5–1.5 mg; thioridazine, 10–100 mg; risperidone, 1–1.5 mg; olanzapine, 5–10 mg; quetiapine, 12.5–100 mg) (see Chap. 46). In a recent review, McCleery et al. [1057] found no RCTs (and therefore, presumed to have no clear evidence) for commonly prescribed hypnotics (e.g., benzodiazepine and nonbenzodiazepine drugs) in patients with AD. However, after analyzing all RCTs, these authors found three drugs (e.g., melatonin, trazodone, and ramelteon) which had undergone RCTs to treat sleep dysfunction in AD. They found no evidence of benefit on sleep for melatonin in AD with moderate-to-severe dementia and ramelteon in AD with mild-to-moderate dementia, but noted some evidence of benefit on sleep for low dose (50 mg) of trazodone at bed time.

Box 41.13 Treatment of Sleep Disturbance in Alzheimer's Disease and Related Dementias

- **General Measures**
  - Reduce or eliminate medications that may contribute to sleep disturbance or sleep apnea.
  - Treat associated depression or anxiety and other comorbid conditions (e.g., pain causing sleep disturbances).
  - Eliminate alcohol and caffeine in the evening.
  - Institute regular sleep-wake schedule and sleep hygiene as much as possible.
  - Avoid daytime naps.
  - Encourage regular exercise (e.g., walking).
  - Attend to environmental factors.
- **For insomnia**, try a nonbenzodiazepine agonist (e.g., zolpidem and eszopiclone) or melatonin receptor agonist (e.g., ramelteon).
- **For insomnia associated with depression**, sedative antidepressants (e.g., mirtazapine and trazodone) may be used.
- **For extreme agitation or nocturnal confusional episodes**, try small doses of antipsychotics, such as haloperidol (0.5–1.0 mg/day), risperidone (1–1.5 mg/day), or quetiapine (12.5–100 mg/day).
- **Timed exposure** to bright light in the evening and in the morning may be helpful.

In some patients, timed exposure to bright light may be helpful [1058–1061]. In limited studies, Satlin et al. [1058] and Okawa et al. [1059, 1060] reported improvement in nighttime sleep and a decrease in daytime sleepiness after bright-light exposure in the evening. These findings were confirmed in some later reports [158, 159, 1062–1066]. In contrast, Dowling et al. [1067] did not find any improvement in nighttime sleep or daytime wakefulness (actigraphically documented) following morning exposure to bright light (2500 lx) for 1 h in a group of institutionalized AD patients compared to controls. However, in a later study, Dowling et al. [1067] observed that a combination of nighttime melatonin (5 mg) and bright-light (2500 lx) exposure for 1 h the next morning improved daytime activity levels and wake time in a group of institutionalized AD patients but not those receiving placebo and bright light only. Further studies are needed to confirm these observations. In a RCT of exercise (walking), light therapy, and combination in 132 AD patients, McCurry et al. [1068] evaluated sleep by wrist actigraphy. They concluded that walking, light exposure, and combination of both walking and light therapy were all effective in improving sleep. Salami et al. [1065] reviewed 38 studies (majority included mild-to-moderate AD) which used PSG, actigraphy, sleep logs, and rating scales as outcome measures to evaluate sleep. These authors concluded that most treatments for sleep disturbance were ineffective. Pharmacologic agents produced inconsistent results, but bright-light therapy (BLT) among all nondrug treatments had the best results. In a RCT evaluating effect of BLT versus standard light therapy on agitation and sleep in demented patients, Burns et al. [1066] concluded that BLT was a potential alternative to drug treatment in agitated dementia.

Treatment of Sleep Disturbances in Patients with Parkinson's Disease

Sleep has not been consistently improved in patients with PD following antiparkinsonian medications. In those patients with reactivation of parkinsonian symptoms during sleep at night, adjustment in the timing and choice of

medication may be helpful. Dopamine agonists or longer-acting preparations of levodopa at bedtime may benefit sleep in some patients. Antihistamines such as diphenhydramine may promote sleep in addition to their modest antiparkinsonian effect. A small dose of carbidopa-levodopa at bedtime with a second dose later at night when the patient awakens may sometimes help those with insomnia. Nocturnal dyskinesias related to levodopa causing insomnia may respond to a reduction in the dopamine agonists or the addition of a small dose of a benzodiazepine or nonbenzodiazepine agonist as mentioned previously. In patients with psychosis and severe nocturnal hallucinations, clozapine or newer drugs such as olanzapine may be used with considerable benefit. During clozapine treatment, the usual precautions of monitoring blood counts and testing liver functions should be taken. Sleep disorders (e.g., insomnia, hypersomnia, RBD, OSA, and RLS-PLMS) are common but have been a challenge to treat these; however, several options are available for many of these [1069]. Patients with PD associated with RBD should be treated with a small dose of clonazepam (0.5–1 mg) or melatonin (3–12 mg) nocte. Patients with PD with OSAS associated with oxygen desaturation and repeated arousals should be treated with CPAP titration. In some patients with insomnia, judicious short-term use of hypnotics may be recommended. Rios et al. [1070] conducted a randomized pilot study in 18 patients with insomnia (divided into three groups: six on doxepin 10 mg; six on CBT with BLT; and six on placebo). Using insomnia scales, clinical global impression, sleep diaries, and actigraph as outcome measures, the authors concluded that doxepin and CBT improved insomnia in PD; however, the authors cautioned that these results must be confirmed in future full RCTs. Some patients with PD showing the phenotype of narcolepsy with EDS not associated with OSAS may be treated with a small dose (100 mg in the morning) of modafinil or armodafinil (150–250 mg) one to two hours before or after breakfast (not approved by the FDA), although the results have been inconsistent [1071–1074]. Modafinil data regarding treatment of EDS in PD in several small controlled studies generated conflicting results, but data from open trials and case reports suggested limited benefit [1075]. Some of these studies showed improvement in subjective sleep ratings, but the results have been inconsistent or without any benefit in objective sleep studies. The American Academy of Neurology [1076], the American Academy of Sleep Medicine [1077], and European Federation of Neurological Society [1078] guidelines all recommended the use of modafinil in PD for treating EDS to improve subjective perception of sleepiness based on conflicting data from modafinil clinical trials in PD [1075].

Conclusion

The science of sleep is beginning to advance and probe even deeper into the significance and pathogenesis of sleep and its disorders. Dement [1079] stated aptly that sleep medicine focuses on the sleeping brain and on all phenomena and pathologic effects that derive therefrom. Progress in research involving molecular neurobiology and neurophysiology of sleep, chronophysiology, chronobiology, and functional imaging of the brain (e.g., functional MRI, PET, and SPECT scanning) holds great promise to unravel the mysteries of sleep even further and to direct our attention to finding more promising therapies for the unfortunate millions suffering from chronic disorders of sleep and wakefulness.

Fatigue in Clinical Practice

42

Sushanth Bhat and Sudhansu Chokroverty

Introduction

Practitioners of sleep medicine often encounter patients complaining of fatigue. Patients and clinicians may use the terms "fatigue" and "sleepiness" interchangeably, but while fatigue may be secondary to excessive daytime sleepiness, and both symptoms may result from disorders of sleep, they are distinct and often have different causes, significances, and treatments. Fatigue is often described as a pervasive sense of tiredness or lack of energy impacting quality of life, and excessive daytime sleepiness (EDS) signifies a pressure to sleep or an inability to stay awake. In contrast, a patient with EDS complains of episodes of involuntarily eye closure, lapses into episodes of microsleep with inattention, yawning, and succumbing to irresistible attacks of sleepiness. It falls to the practitioner to distinguish between these two symptoms, so that appropriate investigations can be performed and management strategies initiated.

Fatigue is underreported by patients, underrecognized by clinicians, and often lumped together with other symptoms of the underlying disease. Fatigue-related complaints are often nebulous and vague, and therefore dismissed as psychosomatic [1, 2]. Treatment strategies for fatigue are not standardized, making management challenging. Prevalence rates for chronic fatigue in the general population vary, ranging from 13.6 to 30.5 % [3, 4] and suffer from a lack of a universally accepted standard definition [5]. While fatigue has generally been thought of as trouble initiating and sustaining motor tasks despite intact motor strength, patients complaining of fatigue may be describing this as muscle weakness, inability to sustain muscle contraction (muscle fatigability), exercise intolerance, inability to concentrate, perceived cognitive deficits (mental fatigue), excessive daytime sleepiness (EDS), apathy, and a loss of motivation. Many of these symptoms suggest underlying medical, neurological, sleep-related or psychiatric etiologies that may only be identified by eliciting a thorough history and performing a detailed physical examination. Several validated and reliable tools (e.g., the Fatigue Severity Scale [FSS] in Table 42.1 [6], the Checklist Individual Strength and the Abbreviated Fatigue Questionnaire [AFQ] [7, 8]) are available for identification of fatigue in the clinical setting.

This chapter focuses on the causes and management of fatigue in primary sleep, neurological, and general medical and psychiatric disorders, with a brief overview of the proposed mechanism (the neurophysiological basis) of fatigue.

Identifying the Sites of Fatigue

Classification of fatigue as being of peripheral or central origin has aided the development of neurophysiological models [9]. Both peripheral and central fatigue can be demonstrated using models that measure the force generated by muscle during maximum voluntary contraction (MVC) (Fig. 42.1).

Peripheral fatigue occurs as a result of failure of the motor unit (the anterior horn cell, the motor axon, the neuromuscular junction, and the muscle fibers innervated by this). The recording and comparison of force generated by electrical stimulation of muscle before and after exercise helps identify peripheral fatigue. Typically, after a pre-exercise electrical stimulation, the subject performs a maximum voluntary contraction (MVC) for a pre-determined period of time, generally 30–60 s, which is measured with a force transducer. A subsequent post-exercise electrical stimulation is then performed, and the force generated is compared to the pre-exercise tracing. Lower amplitudes of the waveform and slower relaxation phases as compared with pre-exercise findings are characteristic of peripheral fatigue [10,

Table 42.1 Fatigue severity scale

Patients choose a number from 1 to 7 that shows their degree of agreement with every statement, where 1 indicates strongly disagree and 7 indicates strongly agree
• My motivation is lower when I am fatigued • Exercise brings on my fatigue • I am easily fatigued • Fatigue interferes with my physical functioning • Fatigue causes frequent problems for me • My fatigue prevents sustained physical functioning • Fatigue interferes with carrying out certain duties and responsibilities • Fatigue is among my three most disabling symptoms • Fatigue interferes with my work, family, or social life

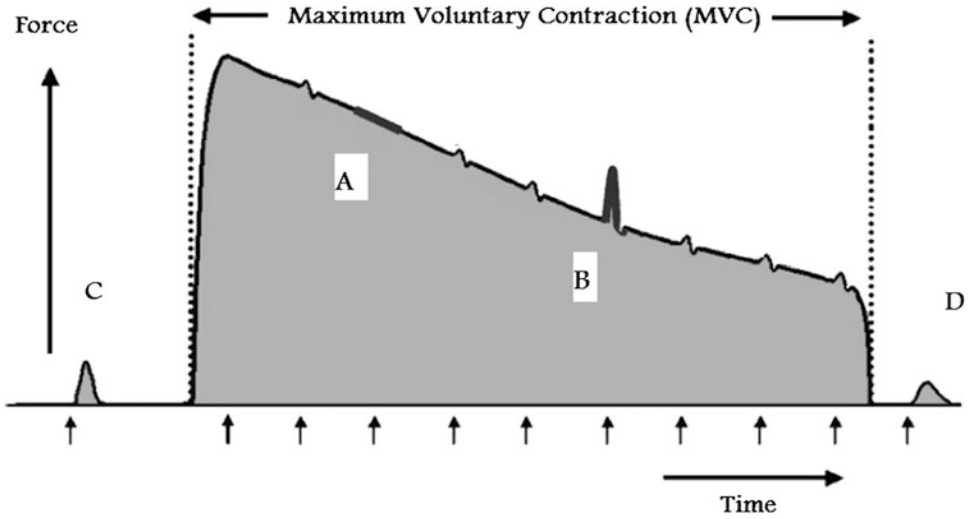

Fig. 42.1 Peripheral fatigue can be studied by measuring the maximum voluntary contraction (MVC) of muscle as recorded by a force transducer. Note the normal linear decrease in force generated is attributable to peripheral fatigue. Superimposed tetanic stimulation (denoted by the *arrows*) is used to detect the presence of central fatigue. Absence of significant twitch amplitude (*A*) suggests the absence of central activation failure (CAF), whereas a large twitch amplitude (*B*) suggests the presence of CAF. A pre-MVC tetanic contraction (*C*) and post-MVC tetanic contraction (*D*) are compared. The lower amplitude and slower relaxation phase of the post-MVC contraction is suggestive of the development of peripheral fatigue. (Reprinted with permission from Bhat and Chokroverty [44] and modified with permission from Zwarts et al. [11]

11]. On the other hand, central fatigue is generated in the central nervous system (CNS), namely the brain, spinal cord and descending central motor pathways, or at unidentified "pre-motor cortex" sites. This is assessed by measuring central activation failure (CAF), which suggests suboptimal CNS output to the motor unit. CAF can be measured by analyzing the force generated during MVC and providing superimposed electrical stimulation. The resulting twitch interpolation is then analyzed; the absence of significant change in twitch amplitude suggests full voluntary contraction and no central fatigue, whereas a large superimposed twitch amplitude suggests significant CAF. Several studies using transcranial magnetic stimulation (TMS) in patients with CNS lesions support the concept of a supraspinal site of fatigue in these conditions [12–14], and some authors have proposed a focal reduction in cortical excitability following a fatiguing motor task as the basis for such central fatigue [15, 16].

The localization of the seat of central fatigue remains elusive, and many diverse areas influencing motor output, such as the prefrontal cortex, multiple subcortical areas including the hypothalamus, the brainstem, the cerebellum, and neuronal systems subserving arousal and attention (i.e., ascending reticular activating system and the limbic system) have been investigated in this regard. Neuroimaging has not been able to identify a single anatomical substrate correlating with fatigue [17–20]. Functional magnetic resonance imaging (fMRI) studies in patients with fatigue have shown greater motor task-related activation of the contralateral cingulate area and more diffuse cervical cord recruitment [21–23] compared to controls, whereas positron emission tomography (PET) scans in patients with fatigue have demonstrated cerebral hypometabolism [24]. The clinical significance of these early findings remains unclear, and most patients with fatigue likely have involvement of multiple central and peripheral areas.

Cognitive or mental fatigue, defined as a failure to endure sustained mental tasks, a deficit of self-motivation, and

overall debilitation not attributable to motor weakness, may occur with or without concomitant physical fatigue and is more challenging to identify, measure, and localize than physical fatigue. While a recent report suggested that the posterior hypothalamus may be involved in cognitive fatigue [25], this finding has yet to be replicated by other studies. Similarly, while several authors have proposed various cognitive and motor-task processing parameters to measure cognitive fatigue, large-scale validation studies are lacking [26–28].

Fatigue in Specific Conditions

Chronic Fatigue Syndrome (see also Chapter 47)

Chronic fatigue syndrome (CFS), also known as myalgic encephalomyelitis, is a poorly understood, ill-defined and yet potentially debilitating condition characterized by severe chronic fatigue lasting a minimum of six months and usually accompanied by myriad nonspecific systemic symptoms. Its full impact is difficult to estimate, with prevalence reports varying greatly from 0.002 to 11.3 % in primary care practices [29]. Most reports indicate that it is more common in women than in men, minority groups, and lower socioeconomic and educational classes, and is often comorbid with psychiatric and personality disorders [30, 31]. Our understanding about this condition is constantly evolving, and at present there is no uniform agreement about the criteria for diagnosis of CFS; while the Center for Disease Control (CDC) diagnostic criteria (Table 42.2) are generally widely accepted, they are limited by being highly dependent on patient self-reporting. The US Institute of Medicine recently recommended that the disorder be renamed "systemic exercise intolerance disease" and has proposed new diagnostic criteria, including three core symptoms that must be present: Impaired day-to-day functioning because of fatigue, malaise after exertion (physical, cognitive, or emotional) and unrefreshing sleep, and at least one of the following two additional symptoms: cognitive impairment or orthostatic intolerance [32]. This proposal awaits acceptance by the medical community at large.

Attempts to identify the etiology of CFS have been futile. A post-viral etiology has long been proposed, and many patients complain of relatively acute onset of fatiguing symptomatology after a flu-like illness, but no organism has been consistently identified [33]. A few early studies provided some evidence for both central and peripheral immunological dysfunction in CFS [34–36], but more research is necessary to determine the clinical significance of these preliminary results [37]. The anatomical site of dysfunction in CFS is similarly uncertain. Numerous neurophysiological studies have failed to establish a peripheral cause of fatigue in CFS [38]. While studies have shown that there is a delay in information processing speed in patients and central dysfunction with CFS [39], MRI and single-photon emission computerized tomography studies have not identified consistent structural or functional markers [40].

Nearly half of the patients with CFS have a coexistent primary sleep disorder (mainly obstructive sleep apnea syndrome [OSA], as well as chronic insomnia and periodic leg movements during sleep [PLMS]), and 45 % have a coexistent psychiatric disorder (mostly mood and anxiety disorders) [41]. The diagnosis of either a sleep or psychiatric disorder, however, does not rule out coexistent CFS [42]. While sleep complaints such as unrefreshing sleep, EDS, and insomnia are common in patients with CFS, objective sleep architectural abnormalities are usually not demonstrable on polysomnography [43].

The optimal treatment of CFS is unclear. Immunological treatments (e.g., high-dose glucocorticoids and intravenous immunoglobulin [IVIG] therapy) have not been found to be beneficial [44]. Similarly, evidence for benefit from stimulants, antidepressants, and wakefulness-promoting agents (e.g., modafinil) is mixed [45]. Several studies, however, have consistently shown the superiority of nonpharmacological interventions in CFS, such as cognitive behavioral therapy (CBT) and low impact, graded aerobic exercise [46].

Fatigue in Primary Sleep Disorders

One of the unique challenges in treating patients with primary sleep disorders is distinguishing between fatigue and EDS [47]. Both symptoms are common bedfellows; nevertheless, as stated before, the distinction is important, because the two symptoms warrant different investigations and management strategies. The practitioner must help the patient to distinguish between fatigue and EDS based on historical clues. Several validated questionnaires, however, are available, aiding the distinction, such as the Epworth Sleepiness Scale (ESS) for EDS and the FSS for fatigue.

Most patients with untreated primary sleep disorders experience fatigue. Younger age, female gender, and a high number of awakenings and arousals have been shown to be predictive characteristics for fatigue [48]. Fatigue occurs in up to 42 % of patients OSA [49] and improves with continuous positive airway pressure (CPAP) treatment [50]. While fatigue in patients with OSA is related to the presence of depressive symptoms [51], it has not been found to correlate with the severity of OSA or with objective measures of EDS (such as multiple sleep latency testing [MSLT]), demonstrating once again that sleepiness and fatigue are distinct symptoms [52]. Similarly, although fatigue occurs in up to 63 % of patients with narcolepsy [53], it does not correlate with the degree of EDS; however, both symptoms respond to treatment with modafinil [54]. Both restless legs syndrome (RLS, recently renamed

Table 42.2 Center for Disease Control (CDC) criteria for the diagnosis of chronic fatigue syndrome (CFS)

In order to be diagnosed with chronic fatigue syndrome, a patient must satisfy two criteria:
1. Have severe chronic fatigue for at least six months or longer with other known medical conditions (whose manifestation includes fatigue) excluded by clinical diagnosis and 2. Concurrently have four or more of the following symptoms: • post-exertional malaise • impaired memory or concentration • unrefreshing sleep • muscle pain • multi-joint pain without redness or swelling • tender cervical or axillary lymph nodes • sore throat • headache

Willis-Ekbom disease [WED]) and PLMS have been found to correlate with sleep disruption and fatigue [55]. Circadian rhythm disorders, especially shift work disorder, are associated with both EDS and fatigue, independent of mood disorders [56], possibly related to lower morning serum cortisol levels [57]. Insomnia, either as a primary disorder or as a symptom of another sleep disorder or medical condition, is commonly associated with fatigue. Nonpharmacological interventions, such as CBT and exercise programs, improve sleep quality as well as fatigue-related symptoms [58].

Fatigue in Neurological Disorders

Fatigue in Peripheral Nervous System (PNS) Disorders

Fatigue in Neuromuscular Junction Disorders

Neuromuscular junctional disorders are characterized by the failure of transmission across the neuromuscular junction and may be presynaptic (e.g., Lambert-Eaton myasthenic syndrome) or postsynaptic (e.g., myasthenia gravis). This results in muscle fatigue of peripheral origin. However, patients with myasthenia gravis experience additional cognitive fatigue following completion of demanding cognitive work, suggesting a component of central fatigue [59]. Supplementation of Vitamin D may benefit fatigue in patients with myasthenia gravis showing Vitamin D deficiency [60].

Fatigue in Neuropathies and Myopathies

Chronic, persistent fatigue occurs in many patients with acquired immune-mediated neuropathies (e.g., Guillain–Barre syndrome, chronic inflammatory demyelinating polyradiculoneuropathy, and monoclonal gammopathies). Some authors have suggested that fatigue in these patients is related to axonal loss [61], but neurophysiological studies of the peripheral nerves are often normal, suggesting that central mechanisms are at play [62]. Medically supervised home exercise programs may be beneficial in these patients [63]. Modafinil has shown some benefit in alleviating fatigue in patients with hereditary motor sensory neuropathy type 1 (also known as Charcot–Marie–Tooth Disease-1), the most common inherited neuropathy [64]. Metabolic myopathies are characterized by the occurrence of "exercise intolerance," cramping, painful contractions, and myalgias after exercise, while being asymptomatic at rest. This exercise intolerance may occur in the absence of motor weakness or abnormal physical findings, and may be perceived as fatigue by patients. Genetic testing is often required for diagnosis. Similarly, patients with inherited channelopathies (hypokalemic and hyperkalemic periodic paralysis, myotonia congenita, paramyotonia congenita, and Andersen–Tawil syndrome) present with paroxysmal attacks of periodic generalized weakness as well as muscle fatigability brought on by exposure to cold, carbohydrate-rich meals, exercise or rest, depending on the exact disorder. Except for the hypokalemic periodic paralysis, these patients also have myotonia on EMG and can be diagnosed by genetic testing. Muscle weakness in these disorders may last from a few minutes to a few hours during each attack, with a normal neurological examination finding including normal strength testing in between the attacks. The symptoms are often treated with acetazolamide, although the exact mechanism of action of this agent in these conditions is unknown [44]. Fatigue has also been described in a large number of patients with a variety of inherited myopathies such as facioscapulohumeral dystrophy and myotonic dystrophy [65]. Both fatigue and excessive daytime sleepiness are common with myotonic dystrophy type 1 (DM1), most likely due to prominent sleep dysfunction that accompanies sleep-disordered breathing, numerous microarousals, and PLMS. DM1 patients have short sleep latencies on MSLT as well as sleep onset REM periods (SOREMPs), suggesting a narcoleptic phenotype [66].

Fatigue in CNS Disorders

Fatigue in Anterior Horn Cell Disorders

Fatigue is very common in disorders of the motor unit and pyramidal cells. In patients with amyotrophic lateral sclerosis (ALS), both central and peripheral fatigue seem to be present.

Patients with ALS show evidence of CAF on MVC studies, as well as less intramuscular phosphocreatine depletion and less fatigue of stimulated tetanic force during exercise compared to controls, suggesting that central fatigue plays a major role in this condition [67]. Peripheral fatigue has been demonstrated in muscles that show no evidence of denervation-related injury, suggesting that motor weakness and fatigue in ALS are distinct entities. Maladaptation of cortical processes related to degeneration of inhibitory GABAergic intracortical circuits is a feature of ALS that significantly correlates with the development of fatigue and weakness [68]. Sleep disruption is a contributory factor as well [69].

Fatigue occurs in over three quarters of patients with post-polio syndrome (PPS); young patients with PPS with shorter polio duration, more pain, and higher body mass index tend to be more fatigued and have a lower quality of life [70]. Both central and peripheral causes seem to be at play, with neuromuscular junction failure as well as defects of attention and information processing having been demonstrated [71, 72]. Neuroimaging studies have also shown that more than half of the patients with PPS-related fatigue have CNS white matter lesions [73]. EDS (causing secondary fatigue) may also result from sleep fragmentation, PLMS, OSA, hypoventilation, or a combination of these factors [74]. Treatment is unsatisfactory; amantadine, modafinil, and IVIG have all been studied, but no consistent benefit has been found [75]. The role of CBT and exercise programs is currently being investigated [76].

Fatigue in Multiple Sclerosis

Fatigue is a cardinal feature of multiple sclerosis (MS), reported by over 80 % of patients [47], but its etiology remains a matter of debate. Hypothalamic dysfunction, hypothalmo-pituitary axis hyperactivity, elevated adrenocortoctrophic hormone levels, lower waking cortisol levels and dopamine imbalance, and increased circulating proinflammatory cytokines have been all been implicated in causing fatigue in MS [77–81]. While certain agents used to treat MS, in particular interferons, may themselves worsen fatigue, glatiramer acetate and natalizumab have shown some efficacy in alleviating MS-related fatigue [82, 83]. The role of sleep dysfunction in MS patients with fatigue is being increasingly recognized. Insomnia, OSA, RLS, and PLMS are all very common in patients with MS and, when present, are associated with fatigue. Treating comorbid sleep disorders in MS patients improves fatigue [84]. Management of fatigue in MS has proven to be challenging. Pharmacological agents such as modafinil and amantadine have been tried with varying success. As with fatigue in general, MS-related fatigue improves with nonpharmacological measures (e.g., exercise programs and CBT) [85].

Fatigue in Parkinson's Disease

A majority of patients with Parkinson's disease (PD) complain of sleep disturbances and fatigue, which is associated with several motor and nonmotor symptoms [86]. Positron emission tomography (PET) scan findings in PD suggested that fatigue in this disorder is associated with reduced serotonergic function in the basal ganglia and limbic structures, and probably also dopaminergic dysfunction in the insular cortex [87]. Sleep dysfunction is common in PD (including insomnia, circadian rhythm abnormalities, RLS/PLMS, nocturnal bradykinesia and discomfort, sleep fragmentation, comorbid sleep apnea, and REM behavior disorder), and both sleep disorder and depression appear to be independent predictors of PD-related fatigue and EDS [88]. Fatigue may respond to treatment of comorbid mood disorders, levodopa therapy [89] as well as nonpharmacological interventions such as (e.g., CBT and exercise programs) [90].

Post-stroke Fatigue

Post-stroke fatigue affects more than half of the patients who suffer strokes and is associated with poor long-term functional outcome and physical health [91]. While post-stroke fatigue is often accompanied by depression, deficits in processing speed and memory appear to be independent of depressive symptoms [92]. It has been proposed that post-stroke fatigue is related to decreased motor cortex excitability [16], and serum glucose and homocysteine levels may play a role [93]. No neuroimaging findings predict post-stroke fatigue, and it does not appear to correlate with degree of neurological deficit. Younger patients with infratentorial infarctions and concomitant post-stroke depression appear to be most at risk for developing post-stroke fatigue [94]. There are no guidelines for treating post-stroke fatigue. Antidepressants, though commonly prescribed to post-stroke patients, have not been conclusively proven to be beneficial, and the role of CBT, exercise, and medications like modafinil and amantadine remains uncertain in this setting [95, 96].

Fatigue in Traumatic Brain Injury

Traumatic brain injury (TBI) results in a variety of long-term consequences, including sleep complaints such as insomnia and daytime sleepiness, cognitive impairment, mood disorders and fatigue, with the degree of initial injury being a poor predictor of the severity of post-TBI impairment [97, 98]. Fatigue, in particular, is present in nearly half of all patients post-TBI, does not appear to significantly improve with time, and seems to be independent of depression or EDS [99]. The natural history of fatigue in TBI remains unclear, but CBT,

lifestyle modification, pharmacologic treatments with modafinil and melatonin, and light therapy have been suggested as possible interventional strategies [100].

Fatigue in General Medical Conditions

Chronic fatigue occurs in a wide variety of medical conditions such as anemia, autoimmune disorders (e.g., systemic lupus erythematosus [SLE], sarcoidosis), chronic infectious diseases such as HIV and Lyme's disease, cardiopulmonary disorders (chronic obstructive pulmonary disease [COPD], congestive heart failure [CHF], interstitial lung disease), rheumatological disorders like fibromyalgia, and cancer. Endocrinological disorders such as hypothyroidism and hypothalamo-pituitary axis dysfunction are other causes of chronic fatigue. In addition, it may be a side effect of a wide variety of medications, most commonly beta-blockers, anxiolytics (e.g., benzodiazepines and barbiturates), antiepileptics (valproic acid, carbamazepine, and levetiracetam), antipsychotics, dopaminergics, proton pump inhibitors, chemotherapeutic agents, and beta interferons.

Fatigue in Cardiopulmonary Disease

Fatigue in COPD

The prevalence of daily fatigue in COPD has been reported as high as 80 %, and nearly half of COPD patients describe it as their most disabling symptom, affecting cognitive, physical, and psychosocial well-being and quality of life. It worsens with underlying disease severity and predicts higher hospitalization rates [101, 102]. The etiology of fatigue in COPD is incompletely understood, but is most likely multifactorial. Exercise intolerance in patients with COPD has been shown to be predictive of fatigue [103]. In addition, coexistent mood disorders and sleep disorders such as RLS [104] and sleep-disordered breathing (in particular the combination of COPD and OSA, known as the "overlap syndrome," a common cause of severe nocturnal hypoxemia, sleep disruption, and subsequent EDS) increase the likelihood of fatigue. Severe COPD is also associated with complaints of insomnia and nonrestorative sleep [105]. Treatment of fatigue in COPD is closely linked to the improvement of pulmonary status and comorbid sleep and mood dysfunction. Multidimensional programs that include pharmacotherapy to improve lung function, pulmonary rehabilitation, and CBT for insomnia have shown promising results [106].

Fatigue in Heart Failure

Fatigue is an important symptom in patients with heart failure (HF) including approximating 70–90 % of all patients which adds to the overall debilitation caused by orthopnea, peripheral edema, nocturnal cough, and exertional dyspnea. Fatigue is indicative of a poor prognosis in HF, but a consistent relationship between fatigue and degree of cardiac dysfunction has not been demonstrated [107, 108]. The proposed causes of fatigue in HF include impaired peripheral perfusion during exercise, reduced oxidative capacity of skeletal muscle, impaired muscle strength, and possibly reflex mechanisms associated with alterations in the metabolism of skeletal muscle. However, fatigue may persist despite optimization of cardiac output [109]. Comorbid sleep disorders contribute to fatigue in HF, with sleep-disordered breathing (including primary central apneas and Cheyne–Stokes respirations), nocturia, and insomnia being the most common. In addition, pharmacotherapy of HF, especially with beta-blockers, has been linked to fatigue. Fatigue and depression occur independently in HF [110]. Nonpharmacological interventions such as individualized exercise training programs for all patients with stable CHF may combat fatigue [111].

Fatigue in Chronic Renal Failure

The debilitating fatigue experienced by patients with chronic renal failure and end-stage renal disease (ESRD) is likely due to multiple chronic metabolic and physical derangements, such as anemia, cachexia, and abnormal calcium and phosphate metabolism. Nearly half of the patients on hemodialysis complain of major fatigue, often associated with depression and poor sleep quality [112]. Primary sleep disorders such as OSA and RLS/PLMS may lead to both insomnia and EDS, worsening fatigue [113]. Optimal treatment of fatigue in ESRD patients on hemodialysis is unclear, but may include strengthening of social support, exercise programs, erythropoietin, and L-carnitine supplementation [114].

Fatigue in Other Medical Conditions

The fatigue seen with chronic anemia often responds to erythropoietin-stimulating agents and blood transfusions as necessary. In several autoimmune conditions such as SLE and Sjögren's syndrome, fatigue is a prominent syndrome that is resistant to treatment and may be caused by underlying inflammatory states [4]. Chronic fatigue is a major symptom of fibromyalgia, along with abundant musculoskeletal and joint pains, depressive symptoms, and sleep disturbances, and as thus significant clinical overlap with CFS, with which it often coexists [115].

Cancer-Related Fatigue

Cancer-related fatigue is frequent, often severe and multifactorial. Its etiology is poorly understood and possibly related to changes in the underlying cytokine profile [116]. Older patients as well as those undergoing chemotherapy or radiation therapy, bone marrow transplantation, and treatment with biological response modifiers are particularly at risk [117]. Nutritional status and comorbid sleep and mood disorders play a significant role [118], and addressing these issues may alleviate fatigue to a certain extent. Anemia is a major underlying cause of fatigue in cancer patients, and several studies have shown that fatigue responds to improvements in hemoglobin levels in anemic patients with a variety of malignancies, both on and off chemotherapy [119]. Erythropoietin-stimulating agents, antidepressants, wakefulness-promoting agents, and psychostimulants have all been shown to improve subjective fatigue [120]. Daily exercise and CBT may also be beneficial [121, 122]

Fatigue and Psychiatric Disorders

Patients with primary psychiatric disorders (such as attention deficit-hyperactivity disorder, major depressive disorder, bipolar disorder, generalized anxiety disorder, substance intoxication and withdrawal, and post-traumatic stress disorder) usually suffer from significant fatigue. Sleep dysfunction, particularly insomnia and daytime somnolence, is also very common with psychiatric disorders, worsening fatigue. In addition, depression is a comorbid condition in a variety of neurological and medical conditions as discussed above, and when present, tends to be a risk factor for the development of fatigue. Unfortunately, fatigue in this setting is often resistant to treatment with antidepressants. The exact role of graded exercise therapy, CBT, psychostimulants, and wakefulness-promoting agents such as modafinil remains unclear [123].

Abbreviations

DOC	Disorders of consciousness
REM	Rapid eye movement
NREM	Non-rapid eye movement
VS/UWS	Vegetative state/unresponsive wakefulness syndrome
MCS	Minimally conscious state
EMCS	Emergence from minimally conscious state
LIS	Locked in syndrome
MRI	Magnetic resonance imaging
PET	Positron emission tomography
EEG/TMS	Electroencephalography/transcranial magnetic stimulation
DMN	Default mode network
BOLD	Blood oxygen level-dependent
SWS	Slow-wave sleep

Introduction

Consciousness is a multifaceted and ambiguous concept, which is often the focus of passionate philosophical, ethical, social, religious and medical discussions. Even though there have been many attempts to define consciousness, no definition has been universally accepted [1, 2]. Here, we will define consciousness as what is lost during dreamless sleep and what is gained after waking up [3]. As such, consciousness is a matter of both waking states and experience, so that the less awake we get, the less aware we become of our surroundings and ourselves. From the scientific point of view, consciousness has been simplistically reduced into two main components: awareness and wakefulness [4] (Fig. 43.1). Awareness refers to the ability to live experiences of any kind, and these subjective experiences comprise sensations, thoughts, emotions, memory, imagination and other major psychological processes [2]. Awareness seems to be anatomically related to structures in the fronto-parietal cortex [4]. However, at present, there is no singular marker of conscious awareness but its presence can be clinically deduced from a range of behaviours and motor outputs (e.g. responses to command, visual pursuit) which indicate that an individual can perceive self and surroundings [5]. Wakefulness (also referred to as vigilance or arousal) is related to the level of alertness, and it can be considered as the potential to experience awareness. It is anatomically related to structures in the brainstem, hypothalamus and basal forebrain, and it is clinically evidenced by opening of the eyes [2]. Wakefulness holds considerable control over awareness; an increase in arousal is usually accompanied by an increase in conscious

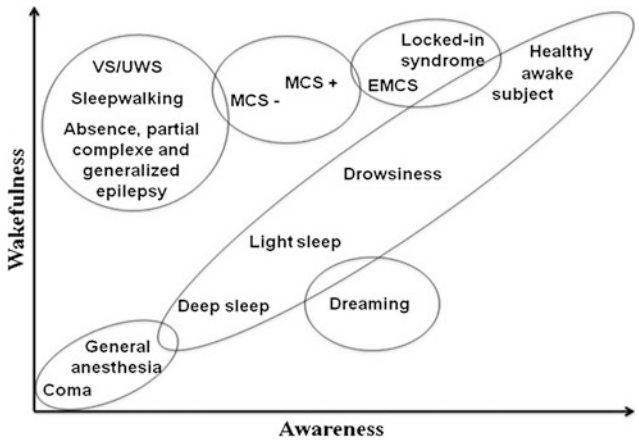

Fig. 43.1 The two main components of consciousness: wakefulness and awareness. In most pathological and physiological states, the two components are linearly correlated along the spectrum of consciousness. In some cases, however, they are dissociated. Vegetative state/unresponsive wakefulness syndrome, VS/UWS; minimally conscious state, MCS and emergence of MCS (EMCS). Adapted from [4]

experience, leading to a linear correlation of the two components along the spectrum of consciousness [2]. However, in some cases, these two components are dissociated. On the one hand, during vivid dreams, wakefulness is impaired, whereas awareness is spared. On the other hand, in the vegetative state (VS), now also called the unresponsive wakefulness syndrome (UWS) [6], in the minimally conscious state (MCS) and also in some more transient altered states of consciousness such as some kind of seizures and somnambulism, wakefulness is spared, while awareness is impaired [7–9]. These latter dissociated states, as opposed to unconscious states like deep sleep, acute coma and general anaesthesia (which are characterized by the absence of both wakefulness and awareness), offer us an important opportunity to disentangle the components of consciousness, and hence, to identify the neural correlates of (un)awareness [4].

Here, we review the clinical entities of disorders of consciousness (DOC) following brain injury (coma, VS/UWS and MCS) and the knowledge on (un)consciousness obtained by studying these patients, mainly focusing on functional neuroimaging and neurophysiological studies. We will then see how these neuroimaging techniques can detect covert awareness in this challenging patient population and, finally, we will further consider the converging points between loss of consciousness in pathological states such as DOC and in physiological states such as deep sleep.

Disorders of Consciousness

In the last decades, the development of emerging medicine and life-saving techniques has resulted in a progressively increased number of patients surviving after sustaining severe brain damage. Ever since, we witnessed a range of clinical entities of DOC never encountered before. DOC are among the most challenging and poorly understood conditions of modern medical care. The main difference between DOC and other states of unconsciousness, such as sleep, pharmacological anaesthesia and epileptic seizures, stems in the prolonged impaired awareness following severe brain damage. After a severe brain injury, a patient can spend some time in a coma, a condition characterized by the lack of both awareness and wakefulness, as evidenced by the closed eyes. Coma may arise after structural or metabolic lesions of the brainstem reticular system or after widespread bilateral cerebral damage [10]. The condition of coma usually does not last longer than 4 weeks, after which patients either evolve to brain death (i.e. permanent loss of brainstem functions), or completely recover consciousness or evolve to a VS/UWS [11]. VS/UWS is a condition of wakefulness, as evidenced by the opened eyes, without clinical evidence of awareness. This means that patients in a VS/UWS show only reflex behaviour, without any sign of voluntary conduct [4]. VS/UWS can be acute and reversible, as a transition before progressing to higher levels of awareness, or chronic and irreversible [12]. It has been proposed that the VS/UWS is permanent after 12 months following traumatic brain injury (TBI) and 3 months following non-traumatic insults, and therefore, chances for recovery are poor [13]. However, patients with late spontaneous recoveries have challenged these proposed time boundaries, and as such, the connotation of the VS/UWS has been revisited [14]. It has been recently recommended to substitute the term 'permanent' by the aetiology of the injury (traumatic or non-traumatic) and the length of time since onset, as these factors have been shown to influence outcome [15]. Patients from VS/UWS may evolve into a MCS, which may be the endpoint of their improvement or a temporary stage on the way to further recovery of consciousness [16]. MCS is a related diagnostic category recognized in 2002 [16]. It differs from the VS/UWS by the presence of discernible, yet inconsistent, non-reflex behaviours as a response to visual, auditory, tactile or noxious stimuli [16]. Although some patients in MCS may show intentional signs of communication [17], by definition they are not able to communicate accurately with their environment. The typical lesion profile consists of grade II or III diffuse axonal injury with multifocal cortical contusions, sometimes accompanied by thalamic involvement. In comparison with patients with VS/UWS, these patients show relatively preserved long-range thalamo-cortial pathways, which could explain why patients in a MCS retain some capacity for cognitive processing [15]. Diagnosis of MCS is clinically based on discernible and reproducible evidence of conscious awareness such as visual pursuit, simple command following, intelligible yes-no response and/or behaviours that are selected triggered by specific environmental stimuli. Example of the latter is the smiling of a patient only when looking at

his/her mother and not other persons. The responses of these patients are typically inconsistent. That is, as the behaviour of interest may occur infrequently or may be ambiguous, serial assessment is often required to capture signs of awareness. The heterogeneity of MCS has been recently recognized, and it has been proposed to subcategorize this entity into MCS PLUS and MINUS [18]. The differentiation was based on the level of complexity of the observed behavioural responses, such as the ability to understand language and therefore to follow simple commands [19]. Patients may emerge from MCS (EMCS) once they regain the ability to reliably communicate and/or use objects in a functional manner [16]. The temporal limits of irreversibility have not been proposed yet for MCS. Although there is some evidence suggesting that patients in a MCS have better chances of recovery than patients in VS/UWS, at present we are not in a position to possibly refer to chronic MCS [20]. Some patients, mainly after a focal brainstem injury, may evolve from coma to a locked-in syndrome (LIS). This is not properly speaking a DOC; however, it is worth to be mentioned in this context, as it is easily and often misdiagnosed as a DOC. This clinical entity results from a lesion in the brainstem extensively impairing the cortico-spinal and cortico-bulbar tracts, which classically leads to complete paralysis of voluntary muscles except for oculomotor muscles in a fully regained consciousness. These patients, therefore, are able to communicate solely through their eyelids movements [21]. Rarely, all voluntary muscles are impaired, including extrinsic eye muscles (complete LIS) making even more challenging the diagnosis of this patient category [22].

Neural Correlates of Awareness

Studies using conventional brain structural imaging have shown highly variable and heterogeneous results in patients with DOC, suggesting that awareness cannot be unequivocally related to a specific brain region [23]. Nonetheless, neuropathological findings seem to associate VS/UWS to profound damage to the subcortical white matter and the major relay nuclei of the thalamus [24, 25], supporting a role of the thalamus and cerebral cortex in the genesis of awareness. Using positron emission tomography (PET) during resting state, it has been shown that awareness is not related to a global brain metabolism [26], but instead to the preservation of a large-scale fronto-parietal network encompassing the polymodal associative cortices [27], and its connections with thalamic nuclei. This was suggested by the recovery of this thalamo-cortical activity in a VS/UWS patient who had recovered consciousness [26]. In VS/UWS, where awareness is impaired while wakefulness is spared, PET studies showed that patients were characterized by a reduced global metabolism compared with healthy subjects, but notably, the recovery of consciousness did not necessarily coincide with resumption of global metabolic activity [17]. Resting-state PET voxel-based studies have further demonstrated that impairment of awareness was related to impairments in specific brain areas, consisting of a large-scale fronto-parietal network encompassing the polymodal associative cortices (Fig. 43.2) [27]. In addition, a peculiar disconnection between primary sensory areas and higher order associative cortices, which are thought to be required for conscious perception [4], has been demonstrated in VS/UWS patients during passive auditory and noxious stimulations [28]. In contrast, function in known arousal structures including the reticular formation in the brainstem, the hypothalamus and the basal forebrain appeared to remain relatively intact in patients with VS/UWS [10]. In this context, recent PET studies during resting-state and passive paradigms have detected relative hyperactivity in the reticular formation of the brainstem in VS/UWS in contrast to hypo-activity between the reticular formation and the precuneus compared to controls, suggesting the existence of a functional link between the arousal system and the associative cortices in the genesis of perception awareness [29]. In line with their clinical condition, MCS patients showed a partial preservation of this large-scale associative fronto-parietal network [30]. More important, PET studies employing passive noxious stimuli have elicited the activation of association areas related to pain processing in MCS patients in a similar network as in normal controls, suggesting a potential pain perception capacity in this patient category [31]. Similar findings of fronto-parietal deactivation have been found in other conditions of impaired awareness, such as in somnambulism as well as in absence and complex partial (mainly in the temporal lobe) seizures [7–9], whereas temporal lobe seizures without loss of consciousness were not accompanied by these widespread changes [8]. The above-mentioned studies have suggested a key role of an extensive fronto-parietal associative cortex for the emergence of awareness. The higher order associative fronto-parietal network mentioned above, commonly impaired during altered states of consciousness, has been recently functionally subdivided into two different networks: external awareness and internal awareness network [32]. The first one, also called task-positive network, is a lateral fronto-parietal network routinely exhibiting activity increases during attention-demanding cognitive tasks. The second, better known as default mode network (DMN), is a mesial fronto-parietal network commonly involved in self-related processes [33]. These two networks are functionally anti-correlated, (that is, when one network is activated the other one is not, and vice versa) and clearly linked to spontaneous mentation [32]. Several studies using even-related functional magnetic resonance imaging (fMRI) experiments have, in fact, demonstrated that awareness of the environment and awareness of the self have different

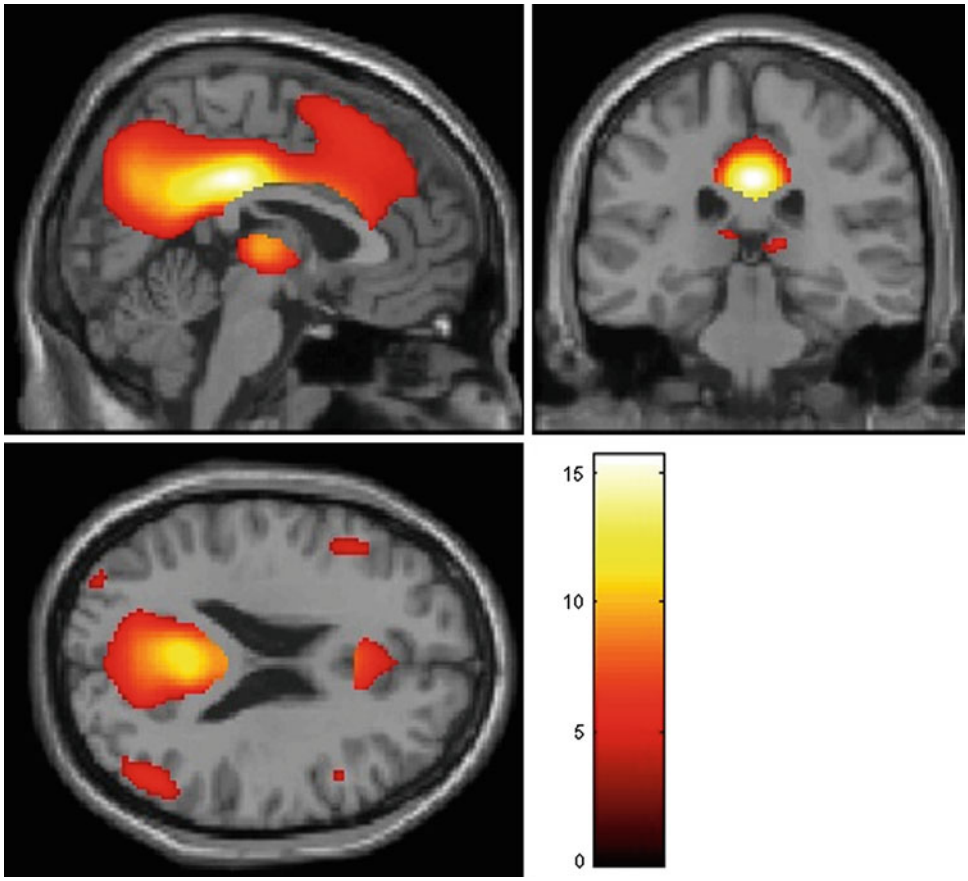

Fig. 43.2 Brain areas where metabolism is impaired in vegetative/unresponsive wakefulness syndrome (VS/UWS) patients compared to controls (areas in *red*), superimposed in a 2D image, axial, coronal and sagittal view. FWE p 0.05 corrected

anatomical substrates, namely the external and internal awareness network, respectively. For example, by giving subjects somatosensory laser stimuli on the back of their hand, it has been shown that at a certain intensity, one stimulus could be perceived only when the external awareness network was activated. Conversely, a stimulus at the same intensity could not be consciously perceived when the internal awareness network was activated, suggesting a role for the baseline brain activity fluctuations in the consciousness perception of the external world [34]. A number of auto-referential stimuli, furthermore, pointed to the critical role of the midline structures (DMN) for self or internal awareness [35–38]. In addition, the decreased anti-correlation of these two networks in unconscious states, such as anaesthesia [6], deep sleep [39] and DOC patients [40, 41], suggests somehow the functional contribution of this anti-correlated pattern to conscious cognition [42]. Frequently and increasingly used in the analysis of DOC, resting-state fMRI is a non-invasive technique which investigates the spontaneous temporal coherence in blood oxygen level-dependent (BOLD) fluctuations related to the amount of synchronized neural activity existing between different location of the brain (i.e. functional connectivity or correlation) in the absence of input or output tasks [43]. Besides the external and internal awareness networks mentioned above, several other resting-state networks of high spatial consistency across subjects have been detected, such as the auditory network, visual network, salience network and cerebellum network [44]. Among those, the DMN is the one that has mostly attracted the scientific attention. The DMN, in fact, has been thought to be implicated in cognitive processes and consciousness, probably because of its link to internally oriented cognitive content, such as mind wandering and autobiographical memory recall [45–47]. Recent resting-state fMRI studies have detected decreased DMN connectivity in patients in coma, VS/UWS and MCS [48]. Such reduced connectivity was shown to be correlated to the level of consciousness, mostly affecting the precuneus, a brain area considered to be a critical hub within this network [10]. Similar decreases in DMN connectivity were observed in healthy controls during sedation, general anaesthesia [6] and deep sleep [49]. However, other studies have shown the persistence of coherent DMN connectivity in some patients with VS/UWS as well as in a case of anesthetized monkey [50], in contrast with its complete absence in a case of brain death [41]. The above evidence suggests that the DMN may not be a mere reflection of conscious mental activity and that other phenomena may indeed play a role in the relation between consciousness and the DMN. For example, it was recently reported that along

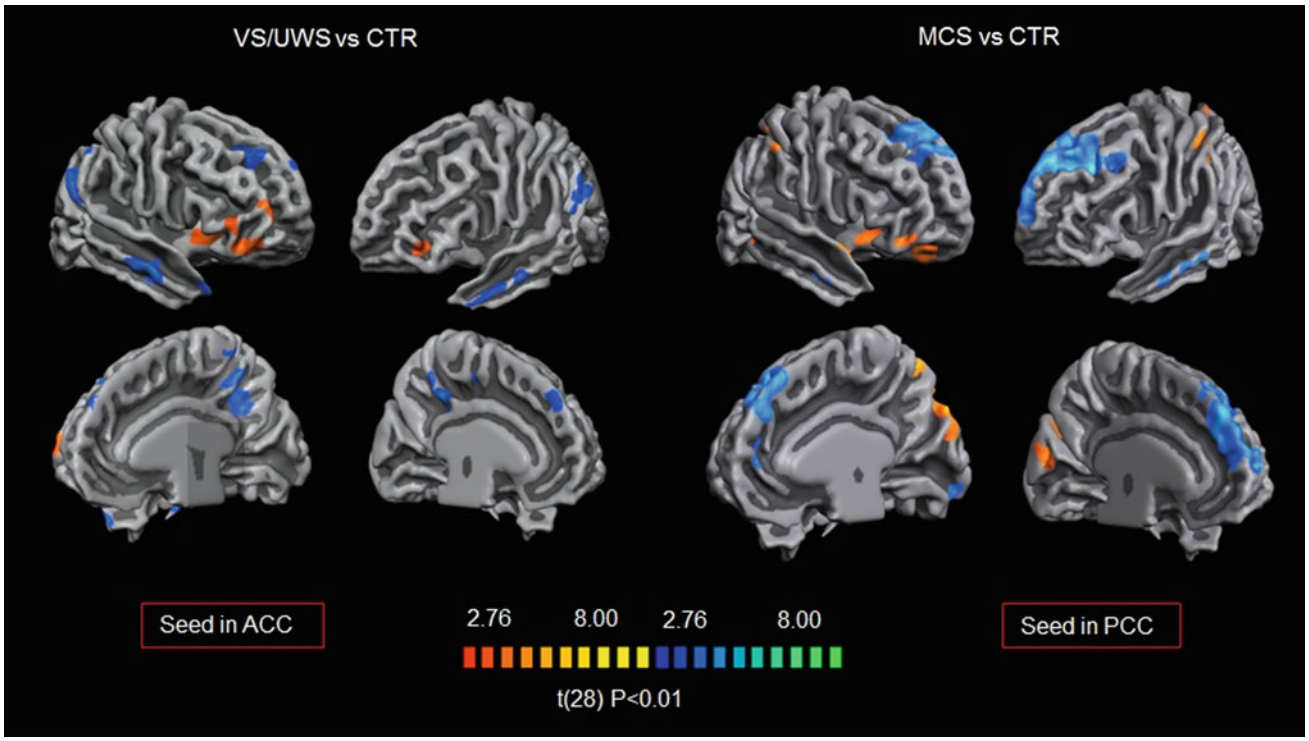

Fig. 43.3 In vegetative state/unresponsive wakefulness syndrome (VS/UWS), the anterior cingulate cortex (ACC) and posterior cingulate cortex (PCC) are hypo-connected to the default mode network (DMN, in *blue*) and hyper-connected to the fronto-insular cortex (in *red*). Superimposed on a 3D template, lateral and mesial sagittal view. Correlation from random effect ($p < 0.01$) and clustered corrected ($p < 0.05$) results based on general linear model maps with seed region of interest comparing VS/UWS to healthy controls. Adapted from [51]

with decreased DMN connectivity, DOC patients showed an increased "pathological" correlation, compared to healthy controls, between the DMN and regions belonging to the external awareness network (hence normally anti-correlated in conscious controls), such as the insula and dorsolateral prefrontal cortex (Fig. 43.3), and stronger in VS/UWS than in MCS patients [51]. This pathological hyper–connectivity suggests the role of a network unbalance sustaining unconsciousness possibly caused by a natural brain topology reorganization strategy of functional connectivity [51]. Taking this into account, hypo–connectivity is therefore only an aspect of a possibly multifaceted and more complex dysfunctional architecture of brain connectivity in altered consciousness, and not necessarily the global hallmark of these conditions. This being also recently supported by the detection of hyper-connectivity patterns also in states of pharmacological coma, such as general anaesthesia [52]. Recently, more networks at resting state have been investigated in DOC, such as the bilateral fronto-parietal or executive control networks, salience, sensorimotor, auditory, visual systems and the cerebellar network. It was found that besides the DMN, the bilateral executive control networks and the auditory system were also significantly less identifiable (in terms of spatial and neural properties) in patients with DOC compared to healthy controls and showed consciousness-level-dependent decreases in functional connectivity across the spectrum of DOC. Furthermore, with machine learning classification trained on the identification of these ten networks as neuronal or not, it was even possible to separate healthy controls from patients in DOC and VS/UWS with high accuracy [53, 54]. One of the near-perspective future challenges will be to interpret resting-state patterns according to studied population in order to unravel the relationship (correlation and anti-correlation) between the resting-state networks in different level of consciousness, and to better comprehend its functional and clinical meaning in general and at also at single-subject level, leading to a more accurate diagnosis [42].

Functional Neuroimaging and Detection of Awareness in Disorders of Consciousness

Detection of potential awareness in uncommunicative brain-damaged patients raises important ethical and medical concerns, regarding end-of-life decisions and palliative treatment [5]. Clinicians are offered with various clinical scales to detect sings of awareness at the bedside [55]. The Coma Recovery Scale-Revised (CRS-R) [17] is one of the most sensitive tools to diagnose and differentiate between patients in VS/UWS and MCS because it assesses all the defining criteria for MCS, such as visual pursuit and

command following [56]. Nonetheless, not only is it made of different behavioural components, but it also includes directives to look for these behaviours. For example, when visual pursuit was tested by means of a moving object, a moving person and a moving mirror, more patients tracked their image in the mirror compared to the other two stimuli and were hence considered to be in a MCS [57]. Similarly, to score sound localization with the CRS-R, the patients need to orient their head or eyes towards the source of the sound. When the patients' own names were used, more patients oriented their head or eyes towards the examiner compared to the meaningless sound of a ringing bell [58]. These studies imply that self-referential stimuli are more effective to explore patients' responsiveness and can influence the diagnostic process [also see 59]. Nevertheless, it is worth stressing that what one can actually assess at the bedside of the patient is responsiveness. As responsiveness represents only an indirect evidence of consciousness (i.e. the lack of responsiveness does not necessarily imply lack of consciousness) reliance on these behavioural markers presents significant challenges and may lead to misdiagnoses. Clinical studies have shown that up to 40 % of patients with a diagnosis of VS/UWS may in fact retain some level of awareness [60–62], and the main causes of misdiagnosis are associated with patient's disabilities, such as paralysis and aphasia, fluctuation in arousal level, difficulty differentiating reflexive from involuntary movements, the presence of drugs' side effects and the non-use of standardized and sensitive clinical scales such as the CRS-R. One way to approach the problem is to detect awareness independently of responsiveness, that is to measure patients' brain responses and activation during sensitive experimental manipulations (which do not require motor responsiveness) and compare them with that of healthy controls. If the cerebral activation pattern is indistinguishable between the two groups, then one has good reasons to believe that the extracted statistical maps reflect the same construct [63]. Possible concerns about the degree of confidence on functional neuroimaging results are recently raised, especially when one considers that it is not possible to have subjective reports by the patients [e.g. 64]. In addition, our limited understanding of the complex dynamic neuronal mechanisms underlying consciousness and its reluctance to quantification in the absence of communication [65] makes it difficult to establish any strong claim about consciousness in non-communicating patients. Nevertheless, the use of these technologies (such as neuroimaging and electrophysiology) has shed light on the grey zones between the different clinical entities of consciousness and has revealed that not all patients considered as VS/UWS are actually unaware [20, 66]. Due to the excellent spatial resolution that is offered by functional magnetic resonance (fMRI) and PET, here we will focus on studies employing these neuroimaging methods referring to the main paradigms used to detect residual consciousness in patients with DOC: active and passive paradigms.

Active paradigms refer to mental imagery tasks which measure wilful modulation of brain signal in specific brain areas, aiming to detect ability to follow command. Command-following abilities in patients with DOC is of major importance as its presence or not can distinguish, respectively, the clinical entities of MCS and VS/UWS, with related ethical and medical issues. Hence, active paradigms in fMRI can be used to detect potential command-following abilities in those patients that are not able to show it through their motor behaviour, improving possible misdiagnosis in this category of patients that could occur when based only on the clinical approach.

In the fMRI setting, two main paradigms have been shown to activate robustly and reproducibly specific brain regions, namely imaging of playing a tennis match (encompassing mainly supplementary motor areas) and imaging visiting his/her own house (encompassing mainly parahippocampal cortex) [67]. When these paradigms were employed in a behaviourally unresponsive patient, the activation pattern of this patient was indistinguishable from that in a healthy control, showing that this patient was actually capable of understanding and following these mental imagery commands [67]. Thus, the behavioural diagnosis was challenged and the patient was no longer considered to be in a VS/UWS. Moreover, a few months after the fMRI finding of activation pattern, the same patient emerged out of the VS/UWS also clinically. We can say, therefore, that in this case functional imaging could detect signs of awareness in the patient earlier than the bedside clinical assessment. Nevertheless, this was the first evidence of dissociation between extreme behavioural motor impairment and identifiable preserved higher cognitive abilities detectable only by functional imaging techniques. A further study examined this phenomenon on a much larger cohort of patients, aiming at detecting the frequency of preserved awareness in behaviourally unresponsive patients [68]. It turned out that of 54 patients with DOC, five (3 VS/UWS and 2 MCS—two which did not show any signs of consciousness at behavioural assessment) were able to wilfully modulate their brain activity; furthermore, one behaviourally diagnosed VS/UWS patient was able to use this technique to communicate by correctly responding with yes (by imagining playing tennis) or no (by imagining visiting the rooms of his house) to autobiographical questions during the fMRI scanning [68]. Thus, this study showed that the case described by Owen et al. in 2006 was not an isolated case, and that approximately 17 % of patients diagnosed as in VS/UWS after behavioural assessment can follow commands when such commands showed a change in BOLD response, rather than overt motoric behaviour. Other mental tasks for detecting response to command in patients with

DOC have been employed. For example, by employing fMRI during covert picture naming as a command-following task in a cohort of patients with DOC, complete network expected for the task as in normal controls was evidenced in the patient with LIS, in two of five MCS patients and in one of two VS/UWS patients [69]. By instructing patients behaviourally considered in a VS/UWS to move their hand, Bekischtein et al. [70] detected activation in the premotor cortex contralateral to the instructed hand, consistent with movement preparation. Similarly, by employing a hierarchical mental imagery (imaging playing tennis and swimming) fMRI approach, Bardin et al. [71] detected residual cognitive capacities in patients with DOC, confirming the dissociation between bedside and fMRI-based command-following and communication abilities. More recently, a further study using selective auditory attention showed that three behaviourally unresponsive patients (two MCS and one VS/UWS) were able to convey their ability to follow commands, and one in VS/UWS was even able to use attention to correctly communicate answers to several binary questions [72], pointing out how different tasks, which allow to overcome the motor unresponsiveness of brain-injured patients by tackling different cognitive aspects, might detect residual covert awareness in this patient category. However, legitimate concerns about the degree of confidence in these methods have emerged. Mental imagery paradigms rely on the fact that a patient can understand the commands and is able to wilfully execute them. In fact, there are many cases when this is not possible, even if the patient retains some degree of consciousness. For example, a patient might not understand the task because he is deaf or aphasic, a patient might not be compliant due to the side effect of medications interfering with vigilance or motor ability or simply because he is sleepy at the moment of the mental imagery task, given that the fluctuation level of vigilance is very often shown in several cases of MCS. Indeed, out of 31 MCS patients described in the study by Monti et al. [68], only one was able to wilfully modulate his brain activity, and out of six cases of behaviourally MCS described by Bardin, only four showed contingent brain activation in the fMRI. Hence, it is worth stressing that absence of command-related brain activation does not allow to infer that awareness is not present [71], and this could lead to possible false-negative results [73]. In order to overcome some of the above-mentioned limitations, residual cognitive function in patients with DOC can be further assessed employing passive and resting-state paradigms.

Passive paradigms measure brain responses to external sensory stimulation (e.g. auditory, somatosensory and visual) while the subject is not performing any task. As previously mentioned, the administration of auditory stimuli in VS/UWS patients elicited PET activation in the primary auditory cortex of these patients, whereas a wider spread of activation in the secondary auditory cortex and associative cortices, contingent to their clinical condition, was detected in MCS patients [74]. By using PET, painful stimulation of the median nerve elicited the entire 'pain matrix' (including the anterior cingulate cortex and insular areas) in patients with MCS, whereas only activation in the lower level subcortical areas was detected in VS/UWS patients [28, 31], indicating that MCS patients are more likely to experience the administered stimuli as painful, with related practical and clinical issues regarding the use of painkillers in this patient category. Similarly, in a passive visual fMRI task, that is presenting pictures of different emotional valences, visual activation similar to healthy controls was found in MCS patients [75]. More recently, a visual cognition study applied to a MCS patient showed brain activations undistinguishable from those observed in healthy and aware controls, suggesting that the patient retained the ability to access his own visual representations [76]. The above studies once again confirm the importance of the associative areas for the emergence of awareness and showed an overlap between clinical and neuroimaging findings. However, the possible dissociation between clinical and neuroimaging assessment has been also shown by means of passive paradigms. For example, a study combining PET and fMRI and using a more complex auditory task (manipulating words at different levels of auditory intelligibility and semantic ambiguity) detected a residual auditory and speech processing in a patient behaviourally considered to be in a VS/UWS [77]. Also, a passive auditory fMRI study using narratives played forward and backwards showed one of three patients in a VS/UWS, and one of four MCS patients showed similar brain activation as that elicited in normal controls [78]. Another salient auditory stimulus which has been preferred because of its attention-grabbing properties is the patient's own name. It has been in fact reported that the subject's own name (SON) activated the cerebral cortex more extensively than non-self-referential emotional stimuli in patients with MCS [30] and the SON spoken by a familiar voice (SON-FV), as opposed to an unfamiliar voice, elicited stronger event-related potential (ERP) responses [79]. Furthermore, it is shown that the SON showed higher sensitivity to elicit sound localization reflex in DOC patients [58]. The SON-FV, therefore, has been used in order to maximize the chances of detecting residual brain function in DOC patients using fMRI. With a SON-FV paradigm, two of seven patients in UWS and all four patients in MCS not only showed activation of the primary auditory cortex but also in higher order associative auditory areas, which are thought to be implicated in the conscious processing of the incoming stimuli. Notably, these two patients in UWS subsequently recovered to MCS, as observed three months after their fMRI scan. This pointed out the possible prognostic value of such fMRI paradigm [80]. Taken together, these paradigms

have shown that auditory, visual and somatosensory activation is restricted to lower level sensory regions in patients in UWS, while brain activation is widespread in MCS reaching higher level associative areas. In some cases, they have shown activation in higher level associative areas in patients behaviourally diagnosed as VS/UWS, suggesting the potential of this tool to detect covert awareness in behaviourally unresponsive patients or, at least in some cases, before the clinical manifestations of the recovery. The passive paradigms can often overcome some limitation of the previously described active task, such as the possibility that a patient is aphasic and therefore unable to understand a task. However, in other cases, such as when a patient has sensory deficits (e.g. deafness or impaired vigilance possibly related to drug side effects), these paradigms might bring false-negative results and other acquisitions should be used, such as the resting-state fMRI. The use of neuroimaging techniques during resting state in patients with DOC has been more specifically described in the previous paragraph.

Electroencephalography (EEG) and transcranial magnetic stimulation (TMS)

Like fMRI, EEG recordings in patients with DOC can evaluate different aspects of cognitive residual function and provide means to communicate with the outside world without motor output. Standard recordings in the neurological department offer a first global view of the brain function of a patient and can detect abnormal activity and therefore guide treatment [81]. In resting conditions, various EEG paradigms have made an effort to differentiate between the clinical entities of patients with DOC. After a severe brain injury, of whatever origin, the EEG can be altered and may display abnormalities. A visible common effect is a slowing of the brain activity proportional to the severity of the injury. Therefore, the predominant rhythm is no longer posterior alpha (related to the awake stages in healthy adult individuals) but diffuse theta or delta (normally present in the slow stages of sleep in healthy adult individuals). In some cases, alpha or theta activity can be observed, but its activity differs from a normal adult alpha activity [82]. Measures of signal complexity such as the bispectral index (a measure of the depth of anaesthesia) were shown to discriminate between unresponsive and MCS patients at the group level [83]. The bi-spectral index was also positively correlated with behavioural scores of awareness at the time of testing and was associated with outcome at one-year post-trauma. However, at the single-subject level, establishing a diagnosis solely based on a single standard EEG is difficult since the patterns are not specific to the aetiology and the same subject can have different patterns in a short interval of time. A study based on patients in persistent VS/UWS concluded that it was not possible to reliably use EEG as a diagnostic tool due to its heterogeneous and varying aspects [84]. Despite the limited diagnostic role of standard EEG recordings, prognostic statements are possible but challenging as the same pattern can be found in varying brain pathologies. EEG information needs to be constantly integrated by the clinical information in order to have plausible insights into the prognosis [81]. In this context, active command mental paradigms combined with EEG [85–87] appear to be useful in the diagnosis of DOC. They have, in fact, allowed both detection of voluntary brain function in VS/UWS and functional communication in patients with complete LIS. A recent study showed that out of 16 studied patients, three were in VS/UWS on the basis of repeated specialist behavioural assessments, and were found to be aware and capable of substantially and consistently modulating their EEG responses upon command [87]. However, as pointed out above, no diagnostic information can be inferred from a negative result, as it does not necessarily imply the lack of consciousness. Indeed, patients behaviourally in a MCS might still not be able to understand and follow instructions. In this context, EEG combined with TMS (TMS/EEG) may be especially useful to assess the level of consciousness in DOC patients, because it does not rely on a subject's ability to process sensory stimuli, or to understand and follow instructions. TMS/EEG allows to stimulate a subset of cortical neurons in a non-invasive way, and to measure the effects produced by this perturbation in the whole brain [88, 89]. For patients in VS/UWS, when stimulating a superficial region of the cerebral cortex, TMS induced either no response or a simple response and a local EEG response, indicating an impairment of effective connectivity [90, 91], similar to the one observed in deep sleep and anaesthesia [89, 92]. In contrast, for patients in MCS, TMS triggered more complex EEG activations that sequentially involved different cortical areas, similar to activations showed in healthy awake subjects. Of note, an MCS patient assessed during a period of no responsiveness still showed complex and widespread brain responses to TMS, even though he did not demonstrate any behavioural sign of consciousness during clinical assessment [91]. Furthermore, an empirical measure of brain complexity, the perturbational complexity index (PCI), which measures the amount of information contained in the integrated response to a direct TMS perturbation, has recently been introduced [88]. The PCI was tested on a large data set of TMS-evoked potentials recorded from healthy subjects during wakefulness, dreaming, non-rapid eye movement (NREM) sleep, and different levels of sedation induced by different anaesthetic agents as well as from brain-injured patients who had emerged from coma (overall, 208 sessions in 52 subjects). PCI provided a data-driven metric that can discriminate level of

consciousness in single subjects under different conditions of consciousness: wakefulness; dreaming; the LIS; the MCS; the EMCS; intermediate levels of sedation; NREM sleep; midazolam-, xenon- and propofol-induced loss of consciousness; and the VS/UWS [88]. It appears that not a single unconscious subject (regardless of its aetiology) has a PCI above 0.31, and no awake healthy subject has a PCI below 0.44. This allows a single-subject approach, necessary for a clinical use of this tool. Because this technique is handy, not invasive, does not require patients' cooperation and works at the single-subject level, it appears to be a promising tool for the diagnosis of patients with DOC [88].

Sleep and Disorders of Consciousness: Differences and Crossing Points

Sleep and consciousness are intimately connected in several ways, showing many neurophysiologic and neuroimaging similarities and differences. Sleep disruption is very common after a TBI [93], often affecting quality of life and outcome/prognosis. Although numerous studies have been conducted on the association between sleep disorders and individuals with TBI, sleep is not routinely assessed in this population [94], and there are paradoxical reports regarding factors associated with sleep disturbance in TBI population [95]. Estimates of the prevalence of post-TBI sleep disturbances range between 30 and 84 % [93]. This so wide range is probably due to differences in the criteria (e.g. formal diagnosis or not), definitions (i.e. broad vs. specific) and measures (e.g. subjective vs. objective) used to assess sleep alterations, as well as heterogeneity of the samples studies, including symptomatic/asymptomatic individuals, or different severity of TBI [93]. Moreover, defining sleep in severely brain-injured patients is a problematic issue, considering the wide spectrum of neurophysiologic and imaging alterations in these patients [96], often irrespective of the injury severity [93, 97]. As for DOC assessment, neurophysiologic evaluation represents a valuable tool for clinical characterization and prognosis evaluation, being sometime more accessible than functional imaging modalities [73]. However, the definition of wakefulness and sleep in DOC is tricky because instrumental findings recorded in these patients may be correlated to different cellular mechanisms than those found in normal physiological sleep. Moreover, recording good-quality signals is not easy due to artefacts caused by skin and skull lesions, involuntary movements, vegetative or autonomous deregulation and electrical artefacts from life-supporting devices [96].

In healthy subjects, sleep is typically led by the search for a safe place and a progressive reduction of alertness and motor tone/activity. In DOC, the occurrence of these conditions is often unavailable. In particular, environmental factors in the intensive care unit like ventilator modes, the continuous exposure to light, noise and nursing activities or the chronic pain and discomfort suffered by these patients can cause considerable sleep disruption. As far as EEG patterns, normal sleep is characterized by well-defined cycles and microstructures (e.g. K-complexes, spindles), and is finely and continuously checked by homeostatic and circadian factors. In DOC, the existence of such elements and such regulators are a matter of debate [96]. Although these existing differences between normal and DOC sleep, and the lack of sleep staging criteria for DOC patients, several clinical and electrophysiological evidences like eye opening and the presence of a sleep–wake cycle suggest the importance of sleep disruption in the DOC spectrum [98]. The occurrence of phasic REMS [99] or the presence and density of sleep spindles [96] represent important parameters to define different comatose states and to speculate on the prognosis [100–102].

The transition from coma to VS/UWS is defined by spontaneous eye opening and the reappearance of sleep–wake cycles. According to this statement, several studies have analysed the presence of sleep–wake cycles in DOC, reporting their presence/absence in persistent VS/UWS patients, with no obvious difference in their clinical status [98]. REM sleep appeared to be the one sleep element that most adequately correlated with clinical scores, and a significant prognostic sign in DOC [103]. In a recent study [99], all of the 10 MCS patients enrolled show phasic REM sleep, a pattern associated with dreaming in healthy subjects, and therefore, with a differential diagnosis value in the VS/UWS. In another study [104], all MCS patients showed an alternating NREM/REM sleep pattern, though no slow-wave sleep or REM sleep stages could be identified in VS/UWS patients. Other authors focused on REM sleep in VS/UWS showing the presence of nystagmus in wakeful and REM stages [105] or the degradation of REM events [106]. As far as sleep microstructure, the presence of K-complexes has a marginal role, considering their high prevalence in these patients; sleep spindles, instead, showed a higher correlation with clinical scores and with DOC outcome [100, 107]. These NREM elements can possibly be present, slowed or absent in both MCS and VS/UWS patients, independently from their aetiologies. The correlation between the number of standard spindles and DOC outcome remains speculative, although several studies support the potential prognostic value of sleep spindles in comatose and vegetative patients [96, 107]. For instance, several authors have reported the occurrence of spindles in 11 out of 20 traumatic and 3 out of 10 hypoxic VS/UWS patients, relating their density increase in the follow-up to the clinical recovery of traumatic patients [108]. In conclusion, several prognostic markers have been identified in DOC patients, such as sleep spindles and preservation of REM stages. This would justify the use of neurophysiologic assessment in the clinical routine, although

adapted and validated standardized behavioural scales are rarely used in sleep research in DOC.

Concerning imaging techniques, several similarities have been detected between normal sleep and DOC patients. PET imaging has demonstrated a significant reduction in cerebral blood flow during NREM stage, to 60 % of normal waking values [10, 109, 110]. Similar findings have been mainly reported for VS/UWS patients with values reduced to 40–50 % of normal ones [27, 74, 111, 112]. Cerebral metabolism in comatose patients is reduced to approximately 55 % of normal values [10], whereas in patients with a LIS, overall supratentorial cerebral metabolism has been shown to be partially [111] or fully [10] preserved. As far as regional variations, precuneus region is less active than the rest of the brain during both slow-wave sleep (SWS) [113] and REM sleep [114, 115]. This region has been suggested as a crucial actor in conscious processes, and identified as a principal node in the DMN by fMRI [42]. Of note, connectivity in this region was shown to be indistinguishable between controls and LIS patients, relatively preserved in MCS, significantly reduced in VS/UWS patients [48] and could not be identified in brain death [41].

Resting-state investigations have also been attempted using other modalities, such as EEG [81] and arterial spin labelling techniques [116].

Conclusions

In the last decades, the development of life-saving medical techniques resulted in a major interest in patients surviving severe brain injury. Ever since, the scientific advances have changed neuroscientists' and clinicians' view of severely brain-injured patients, promoting both a deeper understanding of brain functions in impaired consciousness and a better diagnostic and prognostic assessment in patients with DOC. We here provided an updated overview of the contribution of functional neuroimaging and EEG techniques in the assessment of patients with DOC, by further highlighting the parallels and gaps between impaired consciousness in sleep and in DOC. The use of this technology-based assessment appears to be imperative when assessing this challenging patient population, especially when one considers that bedside behavioural assessment is not always accurate [60]. However, despite the progresses of these techniques and the deeper understanding we have achieved over these conditions, much still needs to be done. The neuroimaging and electrophysiological tools that permit most of the recent discoveries cannot yet be routinely included in the clinical setting until they can be reliably used at the single-subject level, hence allowing us to translate the results of such studies into clinical decisions relevant to the individual patient under our care.

Sleep and Epilepsy

44

Sudhansu Chokroverty and Lino Nobili

Introduction

The relationship between sleep and epilepsy has intrigued researchers and thinkers since antiquity. Passouant [1] mentioned Hippocrates' description of "fears, rages, deliria, leaps out of bed, and seizures during the night." Aristotle observed that in many cases, epilepsy began during sleep. Despite these early observations, the intriguing relationship between seizure and sleep was neglected by the medical profession until the end of the nineteenth century. Echeverria [2], Fere [3], and Gowers [4] gave clear descriptions of the relationship of epilepsy to the sleep-wake cycle. In a study of hospitalized epileptics, Fere [3] noted that in more than two-thirds of 1985 patients, the attacks occurred between 8:00 PM and 8:00 AM. It is interesting to note that even in those days, Fere mentioned the effect of epilepsy on sleep—he noted apparently associated difficulties with falling asleep and impairment of sleep efficiency, suggesting the facilitation of seizures by sleep deprivation. In the beginning of the twentieth century, Turner [5], Gallus [6], and Amann [7] emphasized that many seizures were nocturnal and occurred at certain times of the night. These reports were followed by those of Langdon-Down and Brain [8], Patry [9], Busciano [10], and Magnussen [11].

All of these early observations were made on the basis of clinical features alone and without the benefit of electroencephalography (EEG), which was not described until 1929. The observation of Gibbs and Gibbs [12] in 1947 of the occurrence of paroxysmal discharges in the EEG twice as often during sleep as during the waking state marks the beginning of the modern era in the study of the relationship between epilepsy and sleep. Combining clinical with EEG observations, those authors showed that indeed, a distinct relationship between epilepsy and sleep exists. This report was followed by many original observations, notably those of Janz [13], Passouant [14], Gastaut et al. [15], Cadilhac [16], Niedermeyer [17], Montplaisir [18], Broughton [19], Billiard [20], Kellaway [21], and other researchers.

This chapter provides an overview of the effect of sleep on epilepsy as well as the effect of epilepsy on sleep. The usefulness of sleep in the diagnosis of epilepsy and the practical relevance to understanding the relationship between sleep and epilepsy are also discussed.

Interrelationship Between Sleep and Epilepsy: Physiologic Mechanisms

There is a reciprocal relationship between sleep and epilepsy: Sleep affects epilepsy, and epilepsy in turn affects sleep. To understand this relationship, it is important to review briefly the mechanism that generates paroxysmal EEG discharges and clinical seizures as well as the mechanism of initiation of sleep.

Basic Mechanism of Epilepsy

An understanding of the basic mechanism of epilepsy is derived primarily from studies of animal models and human clinical epilepsy [22, 23]. Experimental animal models of focal

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_44

epilepsy are produced by topical application of agents or focal electrical stimulation to the neocortex and limbic cortex to provoke partial seizures, whereas electric shock or systemic injection of convulsants and penicillin have been used for generalized epilepsy models [23]. Over the years, these models have been used to study the basic mechanisms of epilepsy and seizure generation as well as to test potential disease-modifying or antiepileptogenic therapies [22]. More recently, a number of genetic animal models have also been developed such as the genetic absence epilepsy rat from Strasbourg (GAERS) [24], the Wistar Albino Glaxo/Rijswijk rat (WAG/Rij) [25] and the *Stargazer* mice [26] models for human absence epilepsy and the Nav1.1 [27] and Kv7.2/7.3 [28] mouse models that reproduce many of the phenotypic and pharmacologic features of human severe myoclonic epilepsy of infancy (SMEI) and benign familial neonatal convulsions (BFNCs) [28], respectively. These models have contributed to the molecular and genetic knowledge of epilepsy and will aid in identifying and validating novel targets for the treatment and prevention of epilepsy [22, 29]. Finally, this translational approach to studying human epilepsy can also be used to study the relationship between sleep and epilepsy [30].

Neuronal synchronization and interactions between neurons and neuronal populations are the basic features of brain function [31]. Alteration of synchronization and neuronal hyperexcitability are also central factors in epilepsy that may transform an interictal to an ictal state [23]. Factors enhancing synchronization are conducive to active ictal precipitation in susceptible individuals. These factors include nonspecific influences, such as sleep, sleep deprivation, and others. In addition, seizure itself may produce sleep disturbance.

Neuronal mechanisms of focal and primary generalized epilepsies differ. An understanding of the basic mechanism of human focal epilepsy is derived from studying patients with mesial temporal lobe epilepsy associated with hippocampal sclerosis (MTLE) [23, 32] and from patients with focal cortical dysplasia (FCD), a malformation of cortical development [33–35]. A fundamental mechanism in generating focal epileptiform discharges (spikes or sharp waves) is a paroxysmal depolarization shift (PDS) in the epileptic neurons [36], originally described by Matsumoto and Ajmone-Marsan [37], followed by post-hyperpolarization [38]. PDS can be considered a giant excitatory postsynaptic potential (EPSP) caused by an abnormally prolonged depolarization of millions of neurons with positivity inside and negativity on the surface (spikes or sharp waves). The oscillation of a PDS involving a large area of cerebral cortex causes an alteration of behavior, manifesting as focal or secondarily generalized jerking movements.

In generalized epilepsy, nonspecific thalamic reticular nuclei are responsible for recruiting, and specific thalamic nuclei are responsible for augmenting responses; both are also responsible for triggering generalized seizures by synchronizing afferent inputs to the cortex from these nuclei [39, 40]. This thalamocortical interaction is responsible for changing the name of centrencephalic epilepsy to corticoreticular epilepsy for petit mal absence seizure [41]. According to the corticoreticular hypothesis, spike-and-wake discharges are linked to the thalamocortical mechanisms that generate spindles. A synchronous burst-pause firing pattern of the thalamocortical volleys of alternating EPSPs and inhibitory postsynaptic potentials (IPSPs) generates sleep spindles [42, 43]. It is believed that these thalamic rhythmic oscillations are transformed into generalized epileptic spike-and-wave discharges when the cortex is hyperexcitable [44], with enhancement of the discharges from the potentially epileptic neurons in the cerebral cortex generating spikes or multiple spikes followed by a prolonged γ-aminobutyric acid (GABA)-mediated inhibitory mechanism causing slow waves. Currently, the corticoreticular hypothesis on the origin of generalized absence epilepsy seems to be the most widely accepted [45]. However, contrary to the long-established principle that absence seizures are generalized from the onset, recent clinical and animal data suggest a cortical "initiation site" of spike-and-wave discharges (SWDs) [46, 47]. Indeed, high-density EEG, magnetoencephalography, and functional magnetic resonance imaging studies in patients with different idiopathic generalized epilepsy have shown the appearance of spike-and-wave discharges in discrete, mainly frontal and parietal cortical regions, immediately before their diffusion over the rest of the cortical mantle [48–50]. The immediate bilateral spread of generalized epileptiform discharges depends on a genetically determined diffuse cortical hyperexcitability [51, 52]. Furthermore, although considerable attention has been given to the complex bidirectional interactions between sleep spindles and SWDs, it remains unclear whether the temporal association between these events implies a causal relationship between these two EEG oscillations [46]. Current evidence suggests that although the corticothalamocortical circuit is the main network responsible for generating pathological SWDs and the naturally occurring sleep spindles, their initiation site is different: SWDs initiate in the cortex, and sleep spindles are of thalamic origin [46].

Epileptogenesis of the neurons is dependent on several factors, both genetic and acquired, that maintain increased neuronal hyperexcitability and increased neuronal synchronization as well as factors encouraging failure of inhibitory mechanisms [23]. Examples of some of these factors are decreased dendritic spines and branches, cortical sprouting of surviving axons to cause increased synchronization, altered ionic microenvironment in and around the epileptic neurons, attenuation of inhibitory influences causing enhanced synchronization, and alteration of calcium and chloride ion channel distribution [23].

It is important to understand the interictal and ictal states as well as the mechanism of ictal termination and postictal state. The hallmark of an interictal state from the physiologic

point of view is the focal or diffuse interictal EEG spike-and-wave discharge (SWD) [23]. These patterns are diverse and variable. Highly reproducible interictal spikes are typical of cryptogenic and benign forms of epilepsy such as childhood absence epilepsies or benign epilepsy with centrotemporal seizures (BECTSs) [53]. On the contrary, focal epilepsies secondary to brain lesions, especially FCD, have more irregular features that include sharp waves, fast oscillations, and bursts of repetitive spike-and-wave and polyspike-and-wave, frequently associated with short bursts of fusiform micro polyspikes, defined as brushes [54]. This electrographic pattern is enhanced during non-REM sleep and also associated with well-localized, brief, low-voltage activity [55, 56]. The epileptic neuronal aggregates producing interictal spikes show increased synchronization but with a decrease in firing rates, which may explain hypometabolism of the interictal focus as noted on positron-emission tomography using [18] F-fluorodeoxyglucose scans [23]. Prevention of ictal spread and maintenance of the interictal state are determined by strong inhibitory influences that also keep the neurons in an excessively synchronous state [23].

The ictal onset is determined by a combination of a failure of inhibitory interictal mechanisms and enhancement of excitatory synaptic activities, which may be initiated by an excess of subcortical synchronizing afferent input, as in generalized seizures or focal hypersynchronous discharge [23]. The true ictus in a generalized seizure, initiated in the cortex, may depend on a failure of inhibitory mechanism coupled with synchronizing thalamocortical input, as well as the influence of the reticular formation of the brain stem, particularly in the pontine region for the tonic phase [23]. A combination of diminution of synaptic inhibition, nonspecific excitation, propagation along the efferent projection pathways, and trans-synaptic alteration in excitation determines the appearance of partial ictus [23]. Investigations into both human and animal studies have revealed the presence of abnormal high-frequency (200- to 600-Hz) oscillations, named "fast ripples," which are seen in interictal spikes and are capable of precipitating ictal onset [57–59]. Electrical synapses (gap junctions) seem to play a crucial role in the propagation of abnormal high-frequency oscillations [60]. For the ictal termination, the two most important mechanisms are active inhibition and the failure of synchronization [23]. If these mechanisms fail, the patient may develop status epilepticus. Postictal phenomena (neuronal depression, neuronal deficit, EEG slowing, etc.) are sequelae to events that cause termination of the ictus. In the postictal state, there is neuronal hyperpolarization and neuronal depression causing termination of seizure and postictal EEG slowing.

Mechanism of Sleep

In humans, there are two sleep states: desynchronized or rapid eye movement (REM) sleep and synchronized or non-REM (NREM) sleep. These sleep states are determined by two different mechanisms [61]. NREM or synchronized sleep seems to act as a convulsant because this state is characterized physiologically by an excessive diffuse cortical synchronization mediated by the thalamocortical input [62, 63]. This predisposes to activation of seizure in an already hyperexcitable cortex. In REM or desynchronized sleep, there is inhibition of thalamocortical synchronizing influence as evidenced by depression of recruiting rhythms generated by low-frequency electrical stimulation of the nonspecific thalamic nuclei [62]. Thus, there is attenuation of bilaterally synchronous epileptiform discharges at this stage of sleep. During REM sleep, there is also a tonic reduction in the interhemispheric impulse traffic through the corpus callosum [64]. This also contributes to the limitation of propagation of the generalized epileptiform discharges.

Cortical excitability for epileptogenesis is higher during sleep than during wakefulness [62]. This observation was based on the finding of a significant drop in the threshold for electroconvulsive shock in the sleep deprivation (specifically desynchronized sleep deprivation) experiments in rats, suggesting heightened neural excitability. The increase of cortical excitability during NREM sleep seems to depend on the peculiar pattern of activity of neurons during this vigilance state [65, 66]. In fact, in the transitions from wakefulness to NREM sleep, neurons enter in a so-called state of "bistability," changing their activity from a tonic- to a burst-pause firing mode. In particular, during NREM, slow-wave sleep neuronal activity alternates between two distinct states: one characterized by depolarized membrane potential with burst of action potentials (upstate, on period) and the other associated with hyperpolarized membrane potential and neuronal silence (downstate, off period) [67, 68]. Recent experimental studies have shown that during sleep deprivation, cortical neurons of awake rats may become transiently bistable, with local populations of neurons undergoing brief off periods similar to those observed in NREM sleep [69]. These changes are accompanied by stronger and more synchronous responses to cortical electrical microstimulation reflecting an increased neuronal excitability during sleep deprivation [65]. Studies in human epilepsy [70, 71] utilizing a paired-pulse technique during transcranial magnetic stimulation, showing an increased cortical excitability following sleep deprivation, support the previous observations in rats [62, 65]. This factor of cortical excitability coupled with the fact that the inhibitory mechanism (e.g., postspike hyperpolarization and afferent inhibition) may be less effective during sleep favors activation of focal cortical epileptiform discharge.

Physiologic synchronization can be defined as a state during which there is appearance of the same frequency in two or more oscillators due to coactivation of a large number of neurons [43]. In NREM sleep, spindles and slow waves result from synchronization. As stated earlier, a synchronous burst-pause firing pattern of the thalamocortical volleys of alternating EPSPs and IPSPs generates sleep spindles [42]. Extensive study by Steriade and colleagues [43, 72–81] has shown the importance of thalamocortical participation in the genesis of sleep spindles, delta waves, and very slow (infraslow) oscillations. Sleep spindles are generated in the thalamic reticular nucleus, resulting from synaptic interactions in a network involving the GABAergic reticular thalamic nucleus, glutamatergic thalamocortical neurons, and cortical pyramidal neurons [82]. Cortical pyramidal neurons project to the thalamic reticular nucleus, which in turn has two-way connections with thalamocortical neurons of the dorsal thalamus, which in turn projects to the cerebral cortex. Sleep spindles are abolished after isolation of the reticular nucleus from the rest of the thalamus and cerebral cortex [83]; however, spindle oscillations persist in the reticular thalamic nucleus disconnected from dorsal thalamic and cortical inputs [84]. Delta waves are generated at both cortical and thalamic levels. Hyperpolarization of thalamocortical pathways causing functional deafferentation from the sensory input is responsible for generation of delta waves [79]. Very slow oscillations (<1 Hz) are generated in the cortex (see also Chap. 5). The very slow oscillations must be generated in cortical networks because these are present in athalamic preparations [76, 77] and absent from the thalamus of decorticate animals [75, 85]. It has been proposed that the vast majority of K complexes appearing during sleep are generated by the very slow (<1 Hz) cortical oscillations.

Lesions and stimulation experiments have shown the existence of structures responsible for cortical synchrony in the forebrain as well as in the hindbrain [43, 86]. More than 70 years ago, Morison [87] observed recruiting synchronizing cortical responses after low-frequency electrical stimulation of the midline thalamic nuclei, evidence of an intimate thalamocortical relationship. In 1944, Hess [88] even suggested the existence of a thalamic sleep center. Later studies, however, have shown that the thalamus is responsible for the genesis of spindles and not for sleep slow waves or the behavioral aspect of sleep [43, 86].

The theory about REM or desynchronized sleep suggests that there are anatomically distributed and neurochemically interpenetrated "REM-on" and "REM-off" cells in the brain stem [89] (see also Chaps. 5 and 41). REM sleep is dependent on an interaction between REM-on cells and REM-off cells in the brain stem. Thus, the interaction and oscillation between the REM-promoting and REM-inhibiting neurons generate the REM-NREM cycle. The various chemical mechanisms (e.g., cholinergic, aminergic, GABAergic, and glutamatergic) participating in NREM and REM sleep may also be responsible for activation or inhibition of epileptiform discharges during sleep [90].

An understanding of the basic mechanism of epilepsy and sleep helps us understand the mechanism of activation and suppression of seizure discharges during sleep and in particular during different stages of sleep. Sleep-induced seizures result from an altered interaction among sleep-generating neuronal networks, arousal systems, and the generators for epileptogenesis. In other words, there is a complex interaction between cortical and subcortical mechanisms. The activation of ictal and interictal seizures during NREM sleep seems to be related to the existence of a thalamocortical synchronizing mechanism, whereas suppression during REM sleep is due to depression of the thalamic synchronizing mechanism and a tonic reduction of interhemispheric transmission during REM sleep [62, 64]. The role played by the arousal mechanisms in facilitation of seizures remains somewhat controversial. According to some investigators [91, 92], arousal mechanisms are important in facilitating the seizures, whereas other investigators [93] postulate that arousal mechanisms, particularly the posterior hypothalamic histaminergic system, exert an antiepileptic effect. In support of the arousal mechanism, facilitating seizures is the suggestion [91] that sudden bursts of excitatory inputs from the wake-promoting neurons in the histaminergic posterior hypothalamic neurons and basal forebrain cholinergic neurons to the already hyperexcitable neocortical neurons might exacerbate the cortical hyperexcitability precipitating seizures [51]. Seizures occurring shortly after awakening in juvenile myoclonic epilepsy (JME) and generalized tonic-clonic seizures on awakening may be cited as clinical examples in support of the role of the arousal mechanisms facilitating sleep-related seizures [94].

Frontal lobe epilepsy is predominantly nocturnal, and the presence of strong thalamocortical projections to the frontal lobes might be a straightforward anatomical explanation to the preferential occurrences of nocturnal seizures in frontal lobe epilepsy. Because infraslow oscillations such as slow oscillations, delta waves, and spindles are mainly evident in the frontal lobe region, we can hypothesize that an epileptogenic focus (either secondary to an anatomic lesion or by a functional alteration) localized in the frontal lobe could be more prone to be activated by these oscillatory mechanisms. Furthermore, the strong presence of nACh receptors in both cortical and subcortical structures, known to modulate sleep and arousal oscillations at the cortical and subcortical levels [95], could facilitate the occurrence of an unbalanced excitation/inhibition circuitry within the GABAergic reticular thalamic neurons [96] and, subsequently, facilitate nocturnal seizures through the synchronizing effect of spontaneous oscillations in the frontal thalamocortical connections.

Interrelationship Between Epilepsy and Sleep

The activation of 3-Hz SWDs during NREM sleep is supported by the hypothesis of corticoreticular epilepsy of Kostopoulos and Gloor [97] and Gloor [41]. Kostopoulos and Gloor [97] argued that the 3-Hz spike-and-wave discharges of primary generalized corticoreticular or petit mal epilepsy are the result of an excessive response of cortical neurons to those thalamocortical volleys that are responsible for production of normal sleep spindles. In 1942, Morison [87] produced recruiting responses after intralaminar thalamic stimulation. In 1947, Jasper and Droogleever-Fortuyn [98] succeeded in producing 3-Hz spike-and-wave discharges after similar stimulation in the presence of cortical hyperexcitability. Spencer and Brookhart [99] and Spencer and Kandel [100] showed similarities between recruiting responses and cortical sleep spindles in the cat. Both of these waves resulted from summated postsynaptic potentials of cortical neurons due to low-frequency thalamocortical volleys. Gloor [101] confirmed and extended these observations with the feline model of generalized epilepsy induced by intramuscular penicillin and concluded that spike-and-wave discharges resulted from summated postsynaptic potentials of the cortical neurons as a result of the thalamocortical volleys that would normally produce sleep spindles and recruiting responses. Penicillin obviously caused cortical hyperexcitability.

In this connection, it is important to note that Niedermeyer [102] was the first to suggest that generalized synchronous spike-and-wave discharges originated from the physiologic K complex. It was previously suggested that the delta waves are enhanced after deafferentation of the cortex, suggesting that subcortical white matter participates in the production of EEG slow waves [103, 104]. The initial observation of Niedermeyer [17] in 1965 was followed by other reports from the same author and his collaborators and subsequently other authors [105, 106]. Elegant studies by Steriade and colleagues clearly showed the propensity of spike-and-wave discharges to occur during sleep as a result of transformation of the very slow sleep oscillations into paroxysmal discharges [73, 75, 78, 79]. It has been suggested that the depolarizing phase of the very slow oscillations progressively increases in amplitude and decreases in duration, resembling a PDS. The actual mechanism converting the very slow sleep oscillations into rhythmic spike-and-wave discharges is not clearly understood, however, but involves an interaction between neurons, glia, and ions [75]. A good neurophysiologic explanation has been given by Steriade and McCarley for seizures being triggered by K complexes [66]. A synchronous burst-pause firing pattern of the thalamocortical volleys will cause enhancement of the discharges from the potentially epileptogenic neurons, generating spikes or multiple spikes. The interictal spike-and-wave discharges may be triggered by arousal mechanism generating epileptic K complexes and terminating in ictal discharges accompanied by clinical seizures. Thus, all these studies show a close interrelationship among spike-and-wave discharges, K complexes, and sleep spindles, confirming common mechanisms and circuits for transmission shared by the epileptic neurons and normal phasic events of sleep [17, 63, 107, 108]. The spike-and-wave discharges are triggered by the very slow cortical oscillations, which disappear after decortication but survive after thalamectomy [73].

Wyler [109] studied epileptic neurons during sleep and wakefulness in 14 normal and 17 abnormal neurons recorded from alumina gel-induced chronic neocortical epileptic foci in four male *Macaca mulatta* monkeys during transition between sleep and wakefulness. During sleep, the neurons that were mildly epileptic during wakefulness changed their firing pattern drastically and behaved like neurons that were grossly epileptic during wakefulness; normal neurons and those neurons that were grossly epileptic during wakefulness did not change the firing pattern significantly. The author concluded that the neurons may represent the "critical mass" for initiation of seizure activity during synchronized sleep, which is characterized by burst-synchronizing events such as sleep spindles.

Shouse et al. [110] studied the mechanism of seizure suppression during REM sleep in cats. They created two seizure models in 20 cats, systemic penicillin epilepsy and electroconvulsive shock, and produced two types of lesions: bilateral electrolytic lesions in the mediolateral pontine tegmentum producing a syndrome of REM sleep without atonia, and systemic atropine injection producing REM sleep without thalamocortical EEG desynchronization. These authors made the following conclusions based on these experiments:

1. REM sleep retarded the spread of epileptiform discharges in the EEG.
2. The descending brain stem pathways responsible for lower motor neuron inhibition during REM sleep also protected against generalized motor seizure during REM sleep.
3. The mechanism to prevent spread of seizure discharge used a separate pathway in the ascending brain stem structures that caused thalamocortical EEG desynchronization during REM sleep.
4. The data thus suggest a cholinergic mechanism for thalamocortical EEG desynchronization and for retardation of EEG discharges during wakefulness and REM sleep.

They further concluded that for generalized epilepsy, REM sleep was the most potent antiepileptic state in the sleep-wake cycle. It is important to note that Cohen et al. [111] found a lowered convulsive threshold during REM deprivation in cats. REM deprivation thus may exacerbate epilepsy.

It is worth to mention that besides sleep spindles, K complexes, and slow oscillations, another EEG sleep pattern characterized by ultraslow EEG oscillations (with a period of about 20–40 s) also become evident during the build up and consolidation of NREM sleep, both during visual and quantified EEG analysis [112–114]. Ultraslow oscillations are mainly manifested over the frontal regions and are thought to express cyclic changes in cortical and/or subcortical excitability [115, 116]. They often appear as transitional or intermediate states between sleep and wakefulness especially at sleep onset and during the transition toward REM sleep. These features are visually scored and included in the framework of the cyclic alternating pattern (CAP) [112], which is composed of a repetitive, biphasic pattern in which sequences of K complexes, delta bursts, and/or faster activities (phase A) periodically interrupt the tonic theta/delta background activity of sleep (phase B). CAP phases A and B are considered to reflect, respectively, a condition of transient activation and inhibition [112, 115]. These transitional and intermediate states, mainly expressed by the phase A of CAP, act as a gate, facilitating the occurrence of both ictal and interictal epileptic manifestations [112, 117].

Effect of Sleep on Epilepsy

Because of the awareness of an intimate relationship between sleep and epilepsy, various authors have classified seizures according to the time of occurrence of the seizures (clinical and electrical) during certain times in the sleep-wake cycle. Thus, seizures have been classified as waking, sleep, diffuse (both diurnal and nocturnal), circadian, ultradian, and infradian epilepsies. Box 44.1 lists biorhythmic (according to timing) classification of seizures [91]. Diurnal (waking) seizures are mostly primary generalized epilepsies that are mainly genetically determined. Nocturnal (sleep-related) seizures are most often localization-related seizures. Diffuse epilepsies (those occurring randomly during the night and day) show both ictal and interictal discharges during sleep and waking states. These are often associated with diffuse central nervous system dysfunction and are symptomatic generalized seizures. They are often medically refractory.

Box 44.1 Biorhythmic Classification of Seizures

Diurnal (Waking) Epilepsies

- Absence seizures,
- Juvenile myoclonic epilepsy,
- Generalized tonic-clonic seizure on awakening.

Nocturnal (Sleep-Related) Epilepsies

- Nocturnal frontal lobe epilepsy,
- Autosomal dominant nocturnal frontal lobe epilepsy,
- Benign epilepsy of childhood with centrotemporal spikes with or without occipital paroxysms,
- Continuous spike-and-wave discharges during slow-wave sleep,
- Landau–Kleffner syndrome.

Diffuse Epilepsies (Randomly Occurring During Night and Day)

- Lennox–Gastaut syndrome,
- West's syndrome (hypsarrhythmia),
- Progressive myoclonus epilepsies.

As early as 1885, Gowers [4] analyzed 840 institutionalized patients with a variety of seizure disorders and observed that 21 % of seizures occurred exclusively at night; 42 % exclusively in the daytime; and 37 % at random, both during the day and during the night. According to Gowers, the two most susceptible periods were the onset of sleep and the end of sleep. Langdon-Down and Brain [8] and Patry [9] made similar observations. In all three series, the analysis was based on institutionalized patients. Langdon-Down and Brain [8] observed that in a series of 66 patients, 24 % had sleep, 43 % had diurnal, and 33 % had diffuse epilepsies. In a sample size of 31, Patry [9] found 19 % sleep, 45 % diurnal, and 36 % diffuse epilepsies. Using the average of these three groups of institutionalized epileptics, the incidence of each of these three types of seizures in relation to the sleep-wake cycle is 22 % sleep, 44 % diurnal, and 34 % diffuse epilepsies. Thus, the incidence is similar in these three series. Langdon-Down and Brain [8] found the peak incidence of waking epilepsies to be 1–2 h after awakening, approximately 7:00–8:00 AM; smaller peaks were found at approximately 3:00 PM and 6:00–8:00 PM. Sleep epilepsies had two peaks, 10:00–11:00 PM and 4:00–5:00 AM (i.e., early and late at night, similar to that noted by Gowers [4]).

Among the contemporary epileptologists, Janz [13, 118] has contributed most toward classification of seizures based

on the sleep-wake cycle. He analyzed two large series of outpatients with tonic-clonic generalized seizures. In the first series of 2110 patients [13], Janz [118] found 45 % sleep, 34 % diurnal, and 21 % diffuse epilepsies. In the second series of 2825 similar patients, the incidence was 44 % sleep, 33 % diurnal, and 23 % diffuse epilepsies. Therefore, the two series were similar. Janz [13] called diurnal seizures *awakening epilepsies* because of the high prevalence of seizure during awakening from sleep. In a sample size of 314 outpatient seizure patients, Billiard [20] found 15 % sleep, 53 % diurnal, and 32 % diffuse epilepsies. It should be noted that Billiard included a variety of types of epilepsies in his analysis. Earlier, Hopkins [119] analyzed a series of outpatient tonic-clonic generalized seizures and found 51 % sleep, 30 % diurnal, and 19 % diffuse epilepsies. Janz [13, 118] also noted increased frequency at the beginning and end of the night in sleep epilepsies, similar to that observed by Gowers [4]. It is important to note that the earlier classification was based only on clinical studies and no nighttime EEGs were obtained. The contemporary epileptologists and neurologists had the benefit of obtaining the EEG and all-night polysomnographic (PSG) studies using standard sleep scoring criteria. As regards stability of type, Janz [13] reported that 10 % of awakening epilepsies later became sleep epilepsies, whereas only 6 % became diffuse epilepsies. According to Janz [13, 118] and Hopkins [119], sleep and diffuse epilepsies lasting for 2 years rarely become awakening epilepsies. The differences in the incidence of the three types of seizures may be due to the selection of patients (i.e., outpatient, institutionalized, generalized, or partial seizures).

The importance of classification based on sleep-wake cycle is that this classification may shed light on the prognosis and etiology. Patients with diffuse epilepsies often have intractable seizures and structural neurologic deficits, with poor prognosis as compared to patients with awakening or sleep epilepsies [120]. Analyzing the various data, Shouse [120] stated that idiopathic type is generally awakening type, those associated with organic structural lesions are of the diffuse type, and the sleep epilepsies are intermediate in terms of organicity. D'Alessandro et al. [121] analyzed 1200 patients visiting the epilepsy center during a 5-year period (1974–1979). They found that 90 of the 1200 (7.5 %) had sleep epilepsy (i.e., had one or more seizures exclusively during sleep). This frequency is lower than that found by Janz [13] and Kajtor [122] but similar to that noted by Gibberd and Bateson [123]. The authors concluded that pure sleep epilepsies have a good prognosis. They rarely have waking seizures during the first few years after the onset of epilepsy.

A number of investigators have studied the question of whether epilepsy manifests biorhythmicity—specifically, whether there are circadian, ultradian, or infradian epilepsies. Kellaway et al. [21, 124] cited the specific relationship of epileptic phenomena to the sleep-wake cycle as an example of a circadian rhythm. It should be noted, however, that Autret et al. [125] noted an increase in focal discharges during NREM stages 1 and 2 and in generalized discharges during NREM stages 3 and 4, and a reduction or disappearance of the discharges in REM sleep during any time of the day and night. This evidence argues against a circadian rhythmicity. Kellaway et al. [21, 124, 126] suggested that epileptiform activity is linked to two rhythms: circadian and ultradian, related to NREM-REM cycle at 90–100 min. Stevens et al. [127] suggested that focal EEG discharges in adults may at times show an ultradian 90- to 100-min periodicity in phase with prior NREM-REM sleep cycles throughout the day and night. Binnie [128] and Martins da Silva and Binnie [129] also noted periodicities of interictal discharges, both during diurnal waking and during nocturnal sleep EEG recordings. In most of their patients, periodicities were longer or shorter than the typical 90- to 100-minute REM-NREM cycle. However, Kellaway et al. [124] failed to document waking ultradian rhythmicity in petit mal spike-and-wave discharges. In one case of petit mal absence, Broughton et al. [130] provided strong evidence for ultradian daytime variations of spike-and-wave discharges, mainly at the REM cycle rate. However, these observations have been made based only on one case study.

There are clear methodological problems in studying biorhythmicity in epilepsy [128]. The classic methods include temporal isolation to observe the free-running rhythms (entrainment) and shifting the time zone. Such studies in epilepsy, however, have not been performed in detail [128]. Circadian rhythm, sleep, and epilepsy have been studied by Quigg [131] and others [90, 132, 133]. These authors have reported transient dysfunction of normal circadian function during seizures. Transient disruption of hormones under circadian modulation (e.g., an increase in prolactin secretion within 15 min of onset of seizures, particularly generalized seizures) is well known. There is a suggestion that there may be possible damage to suprachiasmatic nuclei as a result of repeated seizures. Quigg [131] noted subtle functional defects in primary circadian regulation in rats, but no gross abnormalities were noted. Quigg et al. [134] demonstrated that electrically induced seizures in rats isolated from time cues and light for 3-week trials induced advances and delays in circadian rhythm of temperature. Based on these findings, the authors suggested that circadian dysregulation might contribute to some of the altered endogenous cycles associated with epilepsy. In a recent prospective pilot study, Hoftsra et al. [133] evaluated seizure timing with respect to the individual's circadian phase as measured by the dim light melatonin onset (DLMO). The authors found that temporal lobe seizures occurred most frequently in the 6 h before DLMO and

frontal lobe seizures mainly in 6–12 h after the DLMO. Quigg [131] suggested that melatonin might have an anticonvulsant effect and may be responsible for limbic seizures not occurring predominantly during sleep. However, the relation between melatonin and seizures remains controversial [135–137]

Several studies show circadian influence on the occurrence and timing of seizures. Of all the epilepsy syndromes, mesial temporal lobe epilepsy (MTLE) appears to be particularly vulnerable to circadian effects, but there is no conclusive evidence for this, as seizure distribution among different syndromes remains confusing because of the complex interrelationship between the circadian effects, the vigilance state, antiepileptic drugs, and possibly unknown pathophysiologic effects of the epilepsy itself. Both animal studies [138, 139] and human studies [137] have provided evidence for circadian influence in MTLE. By comparing the circadian timing of seizures in patients with MTLE with seizures occurring in an animal model of focal limbic epilepsy, Quigg et al. demonstrated that both groups had more seizures between 0700 and 1900 with a nadir of temporal lobe seizure occurrence between 0200 and 0600. Because humans and rats have sleep-wake patterns that are 180° out of phase with each other, Quigg et al. [138] argued that the circadian modulation of limbic seizure occurrence is not likely to be secondary to the vigilance state but influenced by the primary circadian pacemaker or secondary circadian rhythms other than sleep. Using a forced desynchronization protocol in a small group of patients with juvenile myoclonic epilepsy, Pavlova et al. [140] showed that most interictal epileptiform discharges occurred during NREM sleep (ratio of 14:1) and in the two patients who had slept during all circadian phases, there was suggestion of a circadian variation in discharges, independent of any vigilance state. Further studies are needed to confirm these findings in JME and also in other epilepsy syndromes.

Contrary to biorhythmicity, seizure occurrence in relation to the vigilance state has been more extensively documented by recent studies employing scalp or intracranial electrocorticography monitoring to record seizures. These studies have confirmed past clinical observations that seizures from different brain regions have a strong tendency to occur in different diurnal patterns [141, 142]. Using intracranial electrocorticographic monitoring, Hofstra et al. [141] found a prevalence late in the morning and early afternoon for seizures originating from the mesial temporal lobe; frontal seizures occurred preferentially during the night (between 2300 and 0500 h) and parietal seizures between 1700 and 2300 h. In the awake state, larger proportions of clinical seizures were seen from 0500 to 1100 h and from 1700 to 2300 h. During sleep, larger proportions occurred from 1100 to 1700 h and from 2300 to 0500 h [141]. Durrazo et al. [142] analyzed 669 seizures from 131 consecutive adult patients with localized partial epilepsy of different lobar onset. They found that frontal and parietal seizures occurred more frequently at night and had similar unimodal distribution that was 180° out of phase relative to the occipital lobe. Occipital and mesial temporal lobe (MTL) seizures were more frequent in daytime. Finally, it has recently been shown that the clinical evolution of a seizure (from an aura to a clonic, tonic, or generalized attack) also clusters at specific times of day and at specific phases of the sleep-wakefulness cycle [143].

Frontal lobe seizures most commonly arise from NREM sleep [144–147]. In an analysis of 613 seizures in 133 patients, Herman et al. [146] noted that 57 % of frontal lobe seizures occurred during NREM sleep, particularly stage 2, compared with 40 % of mesial temporal lobe, 24 % of neocortical temporal lobe, and about 13 % of occipitoparietal lobe seizures. A study aimed at evaluating the topography of the epileptogenic zone and the etiologic substrate as risk factors for sleep-related focal epilepsy has shown that regardless of its anatomical localization (frontal or extrafrontal), the presence of a type II focal cortical dysplasia (Taylor-type) increases considerably the risk of sleep-related epilepsy [34]. This finding further highlights the complexity of studying seizure occurrence in relation to biorhythmicity or vigilance state in humans as many intrinsic and extrinsic factors, known and possibly unknown, have to be taken into account.

Finally, the question of infradian rhythmicity in epilepsy, as exemplified by catamenial epilepsy (i.e., menstrual related epilepsy), remains controversial. Almqvist [148] found a periodicity in 47 of 146 long-stay patients with epilepsy. The author noted that in some of the patients, the interval of the attacks was equal to the period of the menstrual cycle. However, the concept of catamenial epilepsy, although generally accepted [149], remains questionable and difficult to define as seizure clustering is a common occurrence in many types of epilepsy [150, 151]. Many animal studies have shown a seizure threshold-lowering effect of estrogen and mild antiseizure effect of progesterone [152]. However, a recent transcranial magnetic stimulation study has shown altered variations in cortical excitability during the menstrual cycle in women with epilepsy that cannot be solely explained by hormonal fluctuations across the menstrual cycle [153].

In conclusion, epilepsy in some patients may show a circadian temporal periodicity and an association with sleep periodicity, but it is not known whether this periodicity is "state" linked (sleep vs. wakefulness) or "time" linked (nocturnal vs. diurnal) [154]. Webb [154] considered epileptic events to be "state dependent," whereas Martins da Silva and Binnie [129] considered them to be "time dependent." This understanding may be important for effective control of epilepsy by optimization of the drug regimen. It should also be recognized that there are circadian variations of drug absorption, interaction, and metabolism (e.g.,

valproate absorption is reduced at night because of gastrointestinal physiologic changes at night, and carbamazepine shows circadian variation in autoinduction) complicating management of seizures [155]. In 1985, Binnie [128] raised the question: Can we improve patient care if we learn about biorhythms in epilepsy? Unfortunately, 30 years later, we are still looking for a definite answer [132].

Effect of Sleep on Specific Seizure Types

In this section, we briefly describe the effect of sleep on clinical seizures as well as on the interictal EEG epileptiform discharges in both generalized and partial seizures.

Clinical Seizures

Generalized Epilepsies

Generalized epilepsies commonly include generalized tonic-clonic (grand mal) epilepsy, petit mal (absence epilepsy), juvenile myoclonic epilepsy, infantile spasms (West's syndrome), and Lennox–Gastaut syndrome. Diurnal or *awakening epilepsy*, a term introduced by Janz [156] to differentiate from sleep and diffuse epilepsies, also belongs to the category of generalized epilepsies, which include generalized tonic-clonic, absence, and benign juvenile myoclonic seizure. Some varieties of diffuse epilepsies (e.g., Lennox–Gastaut and West's syndromes and progressive myoclonic epilepsies) also belong to generalized seizures.

Primary Generalized Grand Mal Seizure

Primary generalized grand mal seizure occurs almost exclusively in NREM sleep [157] and is most frequently seen 1–2 h after sleep onset and at 5:00–6:00 AM, as noted originally in 1885 by Gowers [4] and later by others [8, 9, 13]. Grand mal seizure may occur only during sleep or only during the daytime, or be randomly distributed. In a study of 171 patients, Billiard et al. [158] found exclusively nocturnal seizures in only 8 %. This study also confirmed the observations of Passouant et al. [159] and Bessett [157] that primary generalized seizure occurs exclusively in NREM sleep. Passouant et al. [160] called the seizure occurring exclusively during sleep *l'epilepsie morpheique*; this is considered a benign form of epilepsy. These patients rarely go on to develop waking epilepsies, and when they do, it is after the first 2 years from onset [121].

Petit Mal (Absence) Epilepsy

Absence seizures occurring during sleep are difficult to diagnose, and clinical absence seizures are observed in the waking state. According to Niedermeyer [17], there may be fluttering of the eyelids during the spike-and-wave discharges in sleep. Gastaut et al. [161], Gastaut and Broughton [162], and Patry et al. [163] described occasional cases of petit mal status in REM sleep.

Juvenile Myoclonic Epilepsy

Meier-Ewert and Broughton [164] noted increased myoclonic seizures shortly after awakening in the morning, and the duration of the attack is longer on awakening from NREM than from REM sleep. Occasionally, these attacks occur on awakening in the middle of the night or later in the afternoon [9, 13, 165]. Myoclonic seizures can be subtle and misinterpreted as simple clumsiness for many years until the arrival of a generalized seizure. These patients may also have daytime absence seizures with staring spells that can mimic daytime sleep attacks. Patients may be exceedingly sensitive to sleep deprivation and alcohol consumption. Using transcranial magnetic stimulation, Manganotti et al. [71] have shown that cortical excitability is increased early in the morning in patients with JME; this finding may explain the increased seizure susceptibility in these patients at this time of the day.

Lennox–Gastaut Syndrome

In Lennox–Gastaut syndrome, the clinical seizures consist of tonic, myoclonic, generalized tonic-clonic, atonic, and atypical absence [166]. Information regarding the effect of sleep on the clinical seizures in this syndrome is lacking in the literature [167]. Tonic seizures, typically activated by sleep [168], are much more frequent during NREM sleep than during wakefulness and are never seen during REM sleep [169]. They may only be characterized by subtle and frequently undetected brief apneas.

West's Syndrome (Infantile Spasms)

Maximum clinical seizures, often spasms in series, are seen on arousal from sleep or before going to sleep [170]. Less than 3 % of spasms are obtained in sleep.

Partial Epilepsies

Clinical seizures in simple partial seizures and complex partial seizures (CPSs) are more frequent during the day [20, 121]. In Billiard's [20] study of 156 patients, 61.5 % had daytime and 11.5 % had nocturnal seizures only. According to Montplaisir et al. [171–173], Laverdiere and Montplaisir [174], and Rossi et al. [175], REM sleep did not facilitate temporal lobe seizure. However, other authors [159, 176, 177, 178] observed ictal phenomena during both stages of sleep. In fact, Epstein and Hill [178] described a case of temporal lobe seizure with unpleasant dreams during REM sleep associated with increased epileptiform activities in the EEG in the temporal region. Frontal lobe epilepsies occur

more commonly during sleep than during the waking state [146].

Pure sleep epilepsies mostly present as focal seizures with or without secondary generalization [13, 20]. Benign epilepsy of childhood with centrotemporal spikes (BECTSs) and continuous spike-and-wave discharges during slow-wave sleep (CSWS) are also typical examples of sleep epilepsies and are described in the next section.

Interictal Epileptiform Discharges

Primary Generalized Grand Mal Tonic-Clonic Seizures

Interictal EEG discharges (Fig. 44.1) generally increase in NREM sleep and disappear in REM sleep [18, 20, 103, 125, 162, 179–181]. Mostly, the discharges are prominent at sleep onset and during the first part of the night. Sometimes

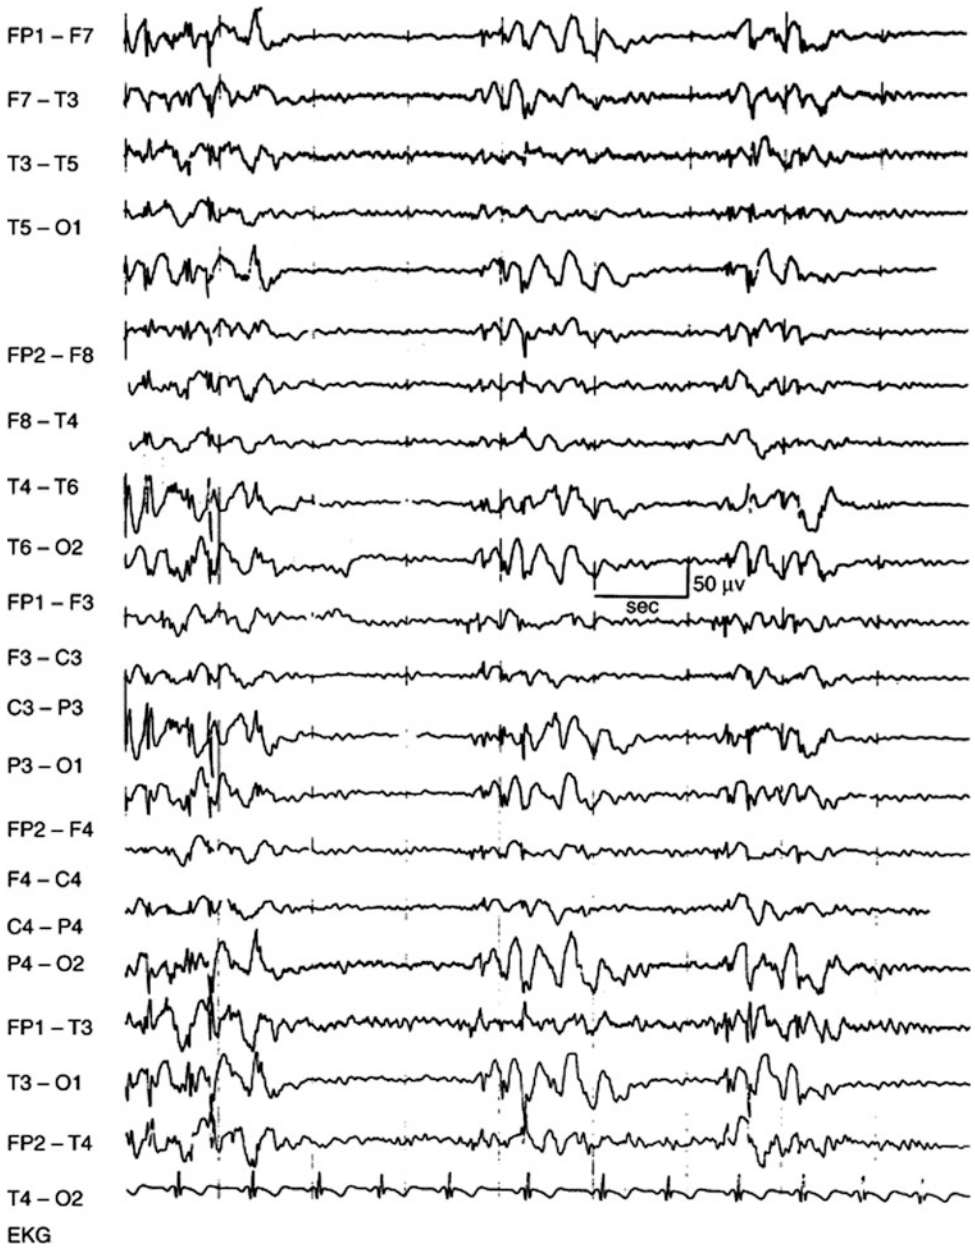

Fig. 44.1 Interictal, primarily generalized epileptiform discharges (4- to 5-Hz spike-and-wave and multiple spike-and-wave discharges) seen synchronously and symmetrically with frontal dominance of amplitude in a patient with generalized tonic-clonic seizures. (EKG, electrocardiography)

the discharges are activated during NREM sleep in the late part of the night, possibly resulting from reduced serum levels of antiepileptic medications [18]. Interictal discharges may be fragmented or may appear as polyspikes or focal spikes during NREM sleep. According to Billiard [20], interictal discharges are more frequent during NREM than during REM sleep (41 % vs. 9 %) in pure sleep epilepsy, but in waking or random epilepsy, interictal discharges are seen throughout the day and night. With nocturnal epilepsies, the daytime EEG remains normal in a high percentage of patients [182].

Petit Mal (Absence Epilepsy)

According to Sato et al. [183], Tassinari et al. [184], and Billiard et al. [158], interictal EEG discharges (Fig. 44.2) in absence attacks are present during all stages of NREM sleep. These are more marked during the first sleep cycle [183] but generally absent in REM sleep. The pattern during REM sleep is similar to that during wakefulness with reduced duration [183, 184]. Sato et al. [183] described alterations of spike-and-wave discharge morphology during different sleep stages: regular or irregular spike-and-wave discharges in NREM stages 1 and 2, and irregular polyspikes

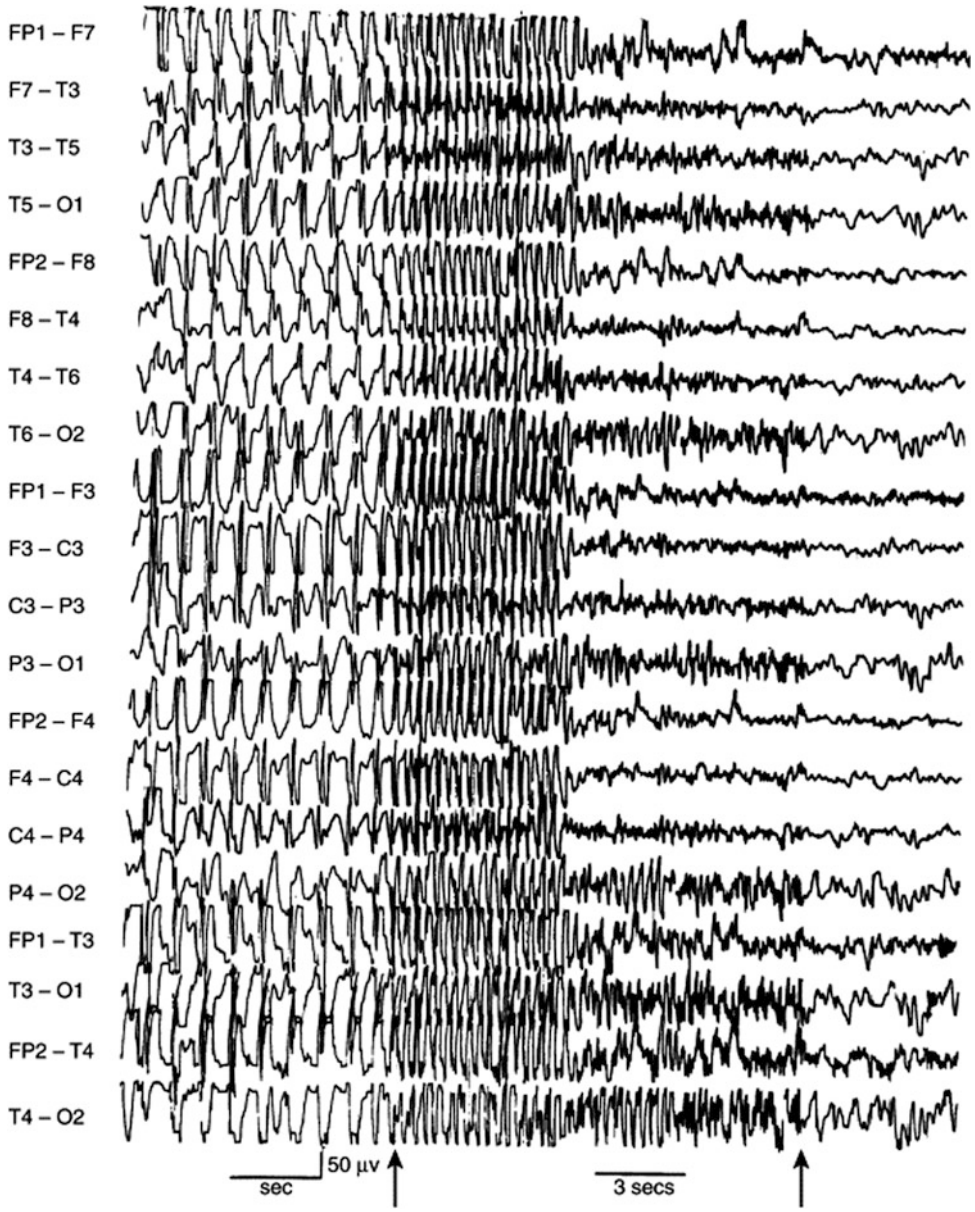

Fig. 44.2 Three-hertz spike-and-wave discharges noted synchronously and symmetrically with dominance of the amplitude anteriorly in a patient with absence spells (petit mal). Note the paper speed on the panel to the *left* at 30 mm/s (*sec*) and to the *right* at 10 mm/s (*3 secs*; between the *arrows*)

and slow waves during NREM stage 3. In addition, fragmentation or focalization of spikes can be seen over the frontal regions during NREM sleep.

Juvenile Myoclonic Epilepsy

Interictal discharges (Fig. 44.3) in these patients are prominent at sleep onset and on awakening [18, 185]. During NREM sleep, IEDs are facilitated by arousal fluctuations, and conversely, they may promote sleep instability and further foster epileptic activity and conceivably seizures [186, 187]. According to Touchon [165], induced awakening is a better facilitator than spontaneous awakening in these patients.

Lennox–Gastaut Syndrome

The typical EEG finding (Fig. 44.4) in Lennox–Gastaut syndrome is slow spike-and-wave discharges (1.5–2.5 Hz). In sleep, these may be intermixed with trains of fast spikes of 10–25 Hz lasting 2–10 s (the so-called grand mal discharges) as interictal abnormalities. The spike-and-wave discharges characteristically increase in NREM sleep [167]. Sometimes bursts of electrodecremental activity alternate

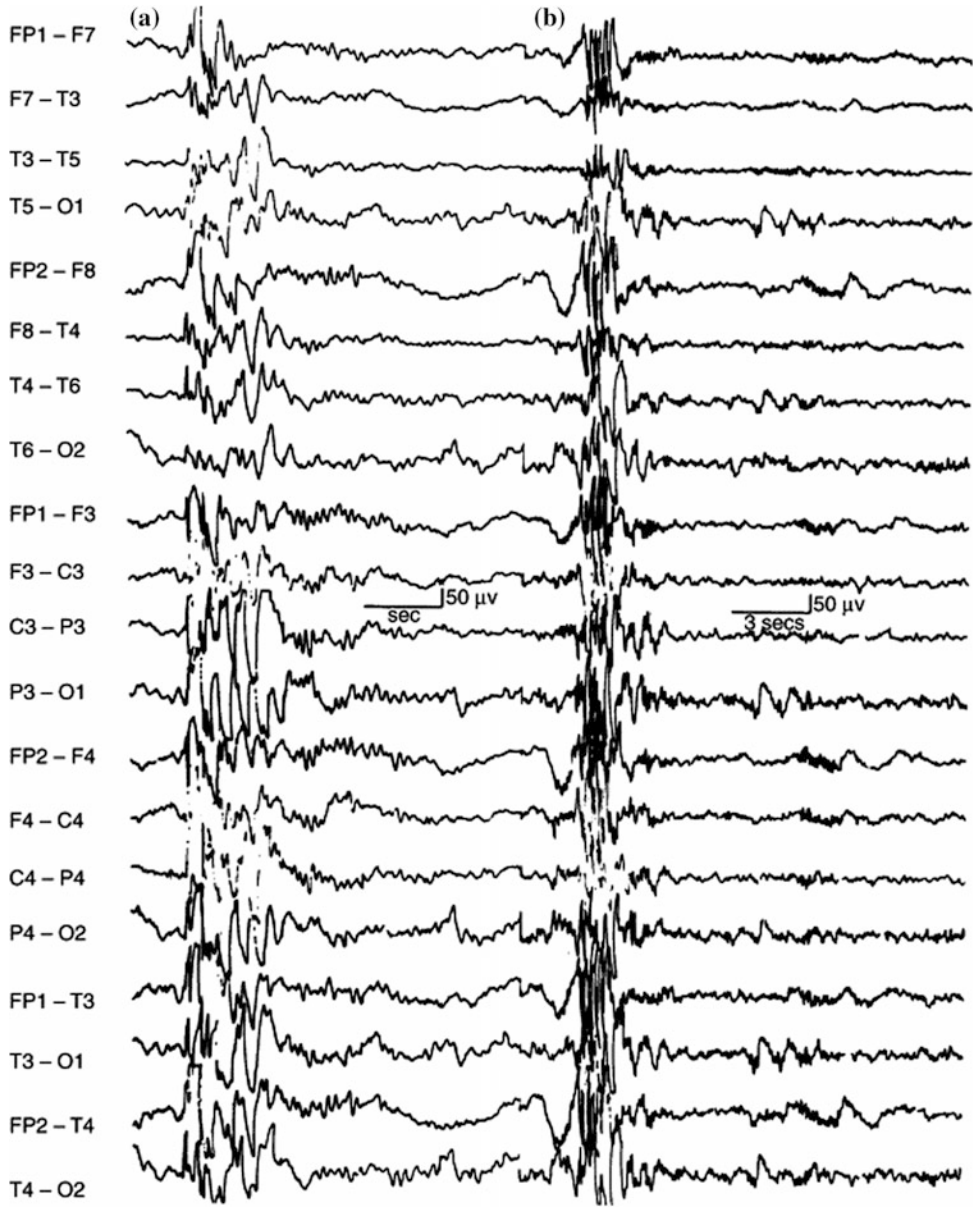

Fig. 44.3 Interictal generalized multiple spike-and-wave discharges in the EEG of a patient with juvenile myoclonic epilepsy. Note the recording at 30 mm/s (*sec*) on the *left* (**a**) and at 10 mm/s (*3 secs*) on the *right* (**b**)

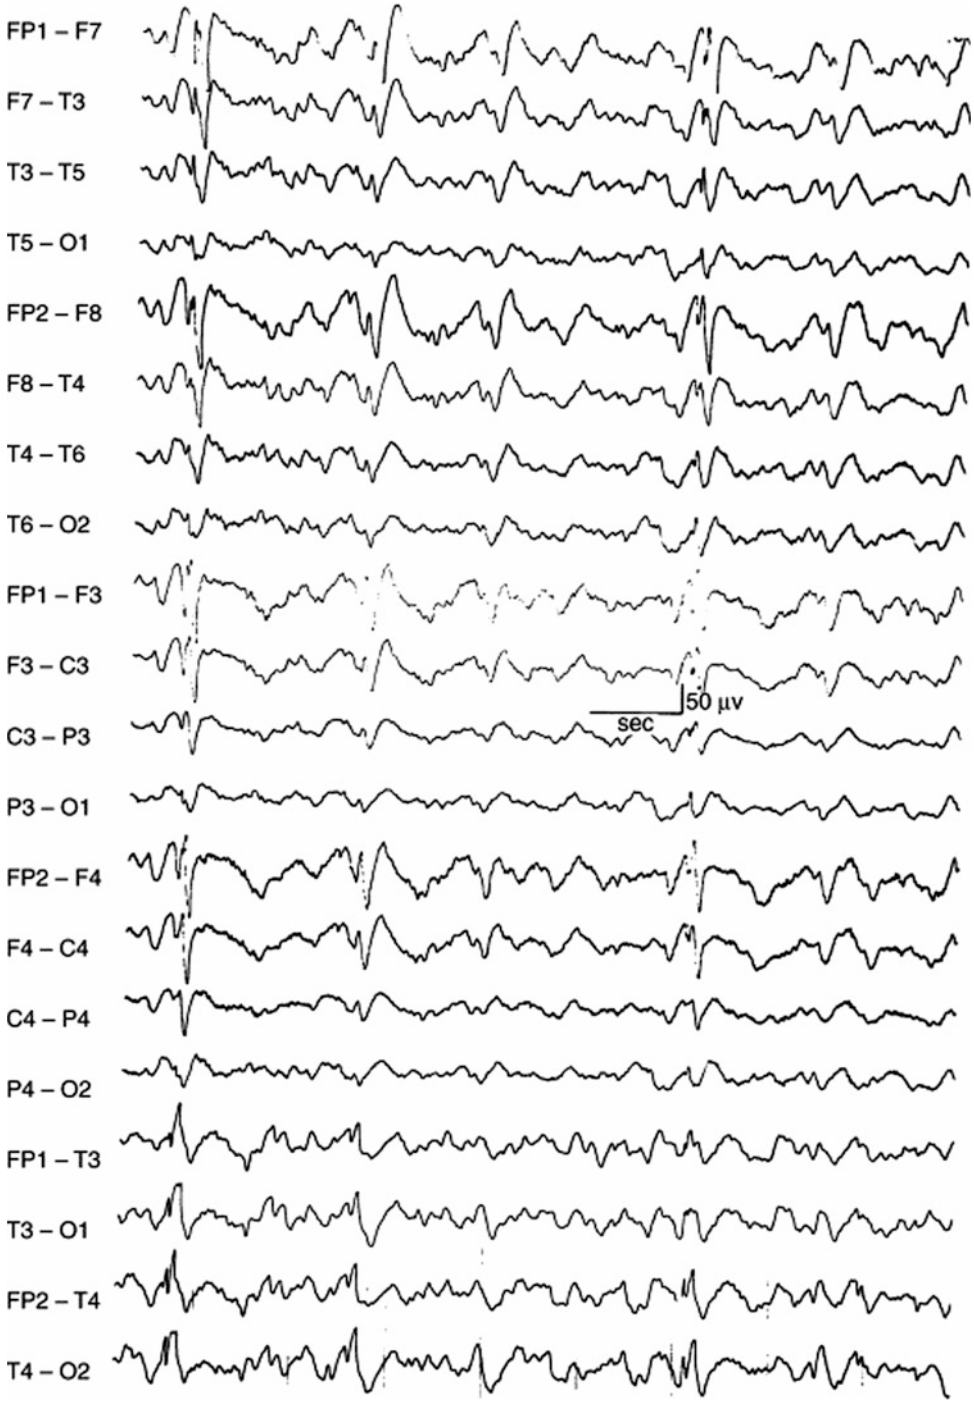

Fig. 44.4 Generalized slow spike-and-wave (2.0- to 2.5-Hz) bursts in a patient with Lennox–Gastaut syndrome

with bursts of polyspikes, giving rise to a burst suppression-like pattern [167]. According to Markand [188], prognosis is better in those patients with significant increase of interictal EEG abnormalities during sleep.

West's Syndrome (Infantile Spasm)

The characteristic EEG finding of West's syndrome (Fig. 44.5) is hypsarrhythmia (high-amplitude slow waves and spikes or sharp waves occurring irregularly), which may show progressive changes during sleep. The characteristic pattern seen during wakefulness may increase in NREM sleep. The hypsarrhythmic EEG of wakefulness may change during NREM sleep into a periodic bilaterally synchronous diffuse pattern interspersed with flattening, resembling "burst suppression," [159] and may even normalize during REM sleep. Occasionally, the waking EEG may be normal, but the NREM sleep EEG may show the irregular high-voltage slow waves and spikes [189].

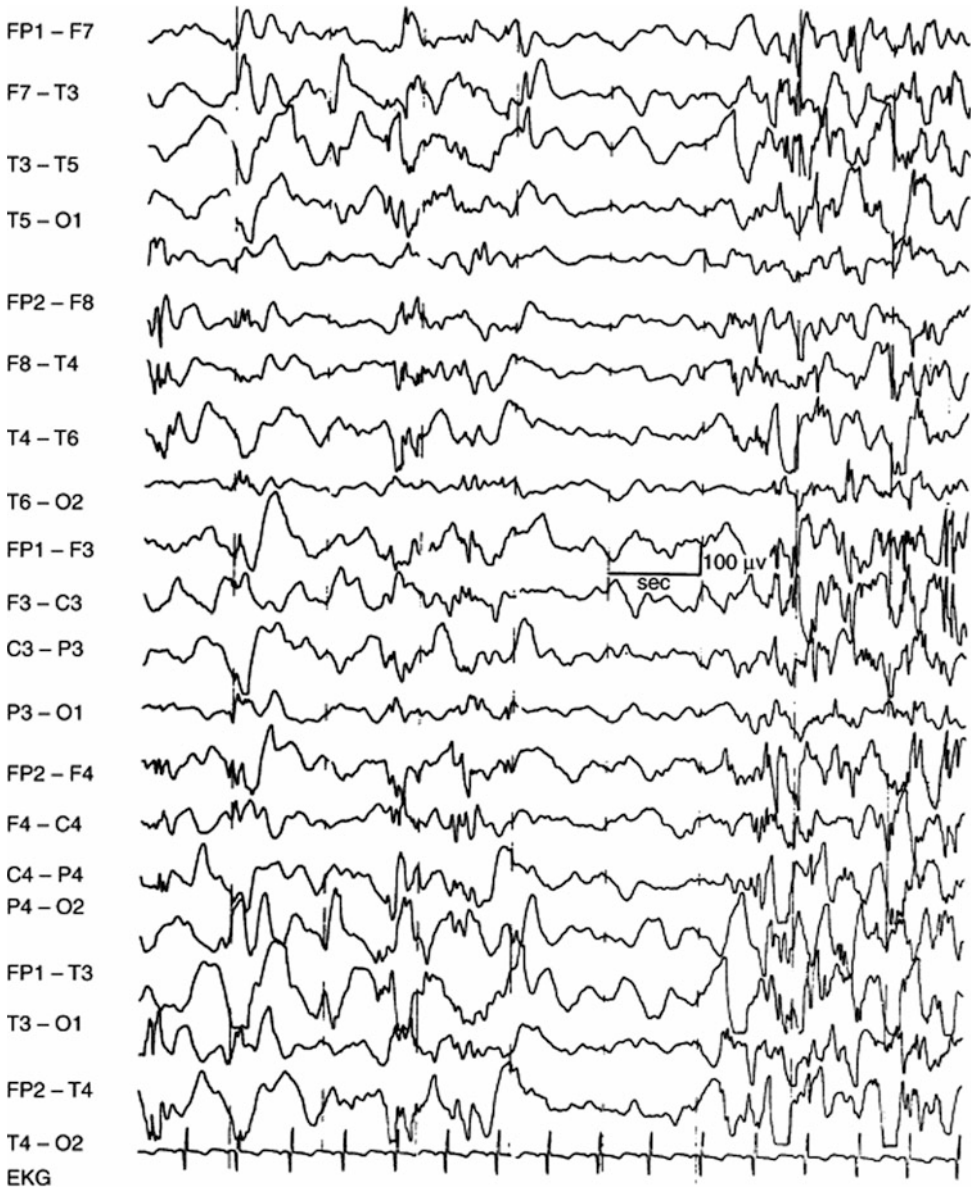

Fig. 44.5 Electroencephalogram showing hypsarrhythmic pattern in a 9-month-old girl with infantile spasms

Partial Epilepsies

An increase of interictal EEG discharges (Fig. 44.6) during NREM and diminution or disappearance during REM sleep have been found both in surface and depth electrode studies and in animal studies [177, 190–195]. Interictal epileptiform discharges increase generally at sleep onset, peak in slow-wave sleep, but then decrease in REM sleep [173, 193, 196, 197]. Malow et al. [197, 198] studied the relationship of spikes to absolute log delta power, a continuous measure of sleep depth, and found that interictal discharge spiking was maximum during slow-wave sleep, particularly on the ascending slope of increasing log delta power. In another study, Malow et al. [199] concluded that temporal interictal epileptiform discharges observed during continuous overnight EEG studies provided important lateralizing information for the presurgical evaluation of temporal lobe epilepsy patients. Although generally observed during NREM sleep, an increase in interictal epileptiform discharges can rarely be observed during REM sleep [165, 178, 200–202]. An important point to note is that during NREM sleep, the discharges spread ipsilaterally and contralaterally from the primary focus, whereas during REM sleep, the discharges seem to focalize maximally [172, 180, 203]. Localizing value of REM sleep in temporal lobe epilepsy has also been shown in other studies [195, 204]. Depth electrode studies in humans by Montplaisir et al. [173] and Lieb et al. [203] showed increased spike discharges during NREM sleep and a reduction of the discharges during REM

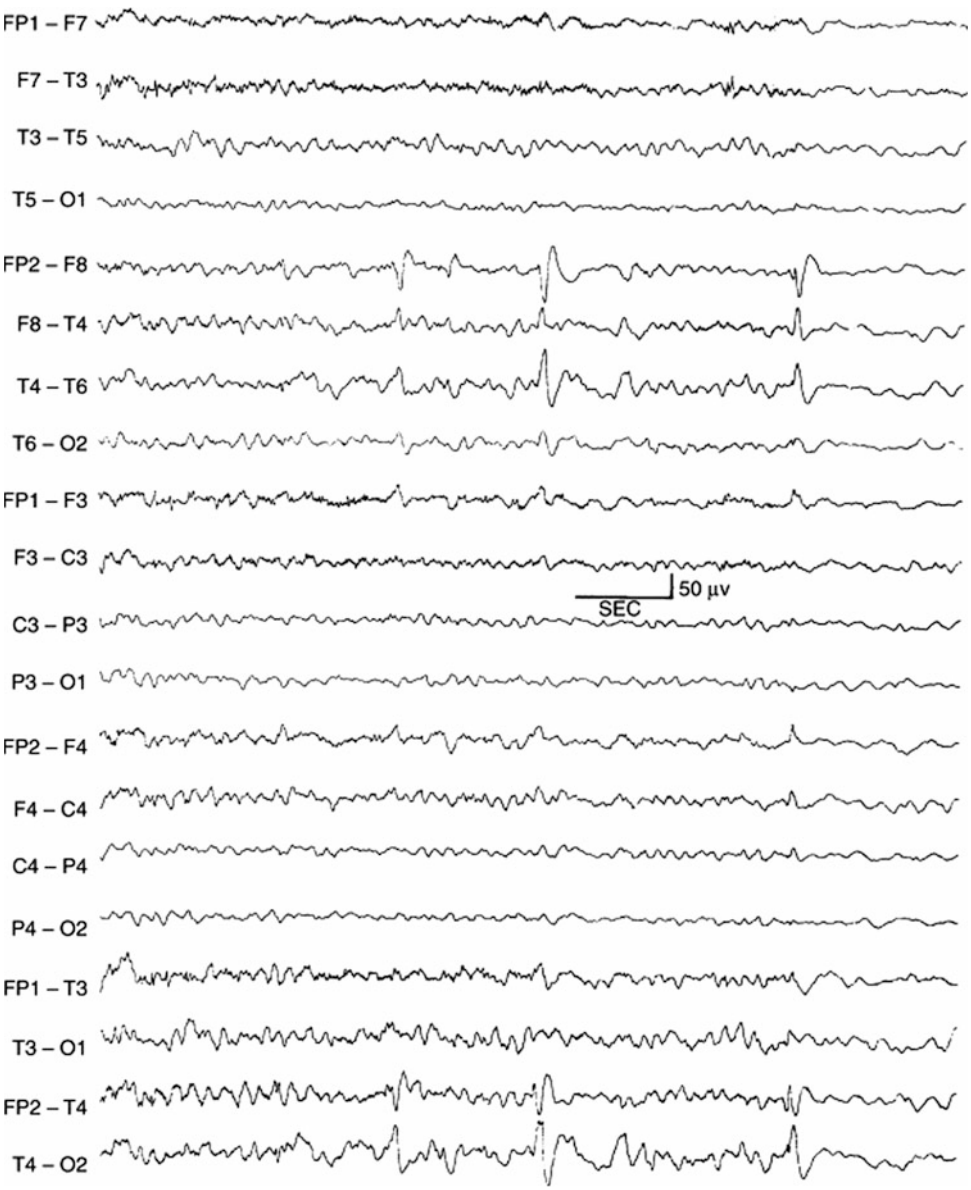

Fig. 44.6 Focal right anterior and mid-temporal sharp and slow waves showing phase reversal at F8-T4 electrodes in a patient with complex partial seizure

sleep. Depth electrode studies also showed that during REM sleep, the spike discharges became maximally focalized [174, 175, 203].

Autret et al. [181] reviewed 236 adult epileptics attending outpatient clinics and classified the seizures in two ways: (1) according to the time of onset of seizures by history (e.g., diurnal, nocturnal, and diffuse epilepsies) and (2) according to the interictal activation during all-night PSG study. They found more frequent myoclonic attacks and increased seizure frequency in patients with diurnal epilepsy. Patients with increased incidence of interictal activities during sleep have less generalized motor seizure, more frequent complex partial seizure (CPS), a higher seizure frequency, and the appearance of new interictal activities during sleep. These authors did not find a significant relationship between the two classifications. It should be noted that these data are at variance with the results of Janz [118].

Lieb et al. [203] performed all-night depth electrode recordings in 10 patients with medically refractory CPS and used a computer spike recognition technique for depth spike activities arising from medial temporal lobe sites. They found the most frequent depth spike activity during deep sleep in six patients and during light sleep in three patients and an equal number during deep and light sleep in one patient. They did not find a strong relationship between temporal lobe epilepsy and sleep pattern. Their findings that the discharge rates are greatest during NREM sleep and are suppressed during REM sleep are in agreement with the previous reports of temporal lobe epileptics. Similar depth electrode findings in temporal lobe epilepsies have been

reported by Montplaisir and coworkers [171, 174, 205] and Passouant [206]. In some previous studies, however [177, 207], maximal spike activity was seen during light sleep. In the study by Lieb et al. [203], the site showing maximal spike activity did not necessarily correspond to the site chosen for temporal lobectomy. This suggests that the interictal spikes and seizure-generating capacity may not bear a close relationship to underlying pathology.

Rossi et al. [175] obtained direct cerebral recordings (stereo-EEG) by stereotactic implantation of stainless steel electrodes on preselected brain sites in 19 patients with medically refractory partial epilepsy who were potential candidates for surgery. They found that interictal spiking increased at the onset of sleep, reaching a maximum level during deep NREM sleep and returning to a lower level during REM sleep. The level in REM sleep was slightly lower as compared with that during wakefulness. They further noted that the spike rate was not influenced by spike location but was affected by the local level of epileptogenicity (i.e., the higher the epileptogenicity, the lower the variation) and that the interictal spiking across sleep and wakefulness showed wide variation in different patients and in the different regions of the same patients.

In conclusion, NREM sleep is the stage of augmentation of interictal focal and generalized EEG discharges. In REM sleep, generalized discharges are usually suppressed, but focal discharges may persist.

To explain the variation in spiking during sleep and wakefulness, three factors may be cited [175]: (1) subcortical-cortical interplay of the mechanisms for sleep and wakefulness as well as EEG synchronization [208], (2) alteration in the cortical excitability during sleep and wakefulness [70, 71, 209], and (3) location of the epileptic lesion [56, 146]. The first factor may play a role in generalized seizures, and the second and the third factors may play a role in the genesis of partial seizures.

Status Epilepticus

The information regarding effect of sleep on status epilepticus is limited, as this is a neurologic emergency and the first priority is treatment of the patient rather than spending time on prolonged recording. Therefore, limited information is available in certain types of status epilepticus. Gastaut [210] defined *status epilepticus* as a condition in which seizure persists for a sufficient length of time or is repeated frequently enough to produce a fixed and enduring epileptic condition. Current guidelines propose a definition of 5 min or more of (1) continuous clinical and/or electrographic seizure activity or (2) recurrent seizure activity without recovery (returning to baseline) between seizures as most seizures lasting longer often do not stop spontaneously [211]. Gastaut [210] classified status epilepticus into three types: (1) generalized status epilepticus consisting of convulsive and nonconvulsive types, (2) simple and complex partial status epilepticus, and (3) unilateral status epilepticus.

Generalized tonic-clonic (grand mal) status epilepticus occurs during the early part of the night [212]. Tonic status as may be seen in patients with Lennox–Gastaut syndrome, in whom it occurs almost exclusively during sleep and is seen mostly during NREM sleep [155]. Myoclonic status epilepticus can arise in two forms [210]: (1) as part of the primary generalized status epilepticus and (2) as the type associated with acute or subacute encephalopathies. In both these conditions, the myoclonic status epilepticus is markedly attenuated during sleep [213]. Petit mal status or absence status epilepticus may be terminated during sleep [213]. Gastaut and Tassinari [214] demonstrated that NREM sleep disrupts the EEG discharges, which are replaced by polyspikes or polyspike-and-wave complexes or even isolated bursts of spikes. According to several authors [14, 215], there may be recurrence of absence status on awakening during the night or in the morning. Occasionally, the spike-and-wave discharges of petit mal status epilepticus may persist during NREM and REM sleep throughout the night [14]. In simple partial status epilepticus, both improvement and activation during sleep have been noted [213]. According to Froscher [213], the role of nocturnal sleep in complex partial status epilepticus remains unknown. Continuous spike and wave discharges during slow wave sleep (CSWS) is discussed in the next section.

Special Seizure Types Related to Sleep-Wake Cycle

In 2010, the International League Against Epilepsy published its revised terminology and concepts for organization of seizures and epilepsies. Generalized and focal are redefined for seizures as occurring in and rapidly engaging bilaterally distributed networks (generalized) and within networks limited to one hemisphere and either discretely localized or more widely distributed (focal). Classification of electroclinical syndromes is now more flexible and can be organized according to a specific purpose, for example age at onset, specific underlying cause or, as in this chapter according to vigilance state (sleep-related epileptic syndrome, Box 43.2) [216]. The second edition of the International Classification of Sleep Disorders [217] listed certain diagnostic criteria for sleep-related epilepsy (Box 44.3).

Box 44.2 Sleep-Related Epilepsies

Generalized Epilepsies and Syndromes

- Juvenile myoclonic epilepsy,
- Generalized tonic-clonic seizures on awakening,

- Tonic seizures (as component of Lennox–Gastaut syndrome).

Focal Epileptic Syndromes

- Benign epilepsy of childhood with centrotemporal spikes with or without occipital paroxysms,
- Nocturnal frontal lobe epilepsy,
- Autosomal dominant nocturnal frontal lobe epilepsy,
- Nocturnal temporal lobe epilepsy.

Undetermined (Focal or Generalized) Epileptic Syndromes

- Epilepsy with continuous spike-and-wave discharges during slow-wave sleep, or electrical status epilepticus,
- Landau–Kleffner syndrome or acquired epileptic aphasia.

Box 44.3 Diagnostic Criteria for Sleep Seizures

- More than 70 % of the episodes occur in sleep.
- Patient complains of one or more of the following:
- Sudden awakening,
- Abnormal sleep-related motor activities,
- Urinary incontinence,
- Tongue biting.
- Patient has two of the following features:
- Generalized tonic-clonic limb movements,
- Focal limb movement,
- Twitching of the face,
- Automatism,
- Postictal confusion and lethargy,
- PSG: ictal or interictal epileptiform discharge in any stage of sleep (an initial EEG may remain normal in many true cases of epilepsy),
- The symptoms do not meet the diagnostic criteria for another primary sleep disorder (e.g., RBD and partial arousal disorder).
- No medical, mental, or substance use disorder or medication use

PSG, polysomnography; RBD, rapid eye movement sleep behavior disorder.

Benign Epilepsy of Childhood with Centrotemporal Spikes

A clear description of BECTS, or benign focal epilepsy of childhood with rolandic spikes, was given by Nayrac and Beaussart in 1958 [218]. Later, Beaussart [219] drew attention to the benign nature of the condition. This is a childhood seizure occurring between 3 and 13 years of age, at an average age of onset of 7, seen mostly during drowsiness and sleep. The clinical seizures are characterized by focal clonic facial seizures often preceded by perioral numbness. In many cases, the patients have generalized tonic-clonic seizures that appear to be secondary generalization. On occasion, there is speech arrest. Consciousness is preserved. The EEG shows centrotemporal or rolandic spikes or sharp waves (Fig. 44.7) with a typical morphology of a triphasic sharp wave of high amplitude localized to the centrotemporal region but sometimes spreading to the contralateral hemisphere. Epileptiform discharges sometimes may occur outside the centrotemporal region and show occipital paroxysms in children exhibiting symptoms similar to those noted in BECTS [53]. The activation of interictal epileptic discharges (IEDs) by NREM sleep is a well-known feature of benign epilepsy of childhood with rolandic spikes. Authors agree in reporting a marked increase of IEDs during NREM sleep and a substantial reduction during REM sleep [220–224]. IEDs tend to be present throughout the night in each consecutive NREM cycles, showing a higher correlation with spindle frequency activity with respect to slow-wave activity time course [224]. The same correlation with spindle frequency activity was found also in other epileptic syndromes of childhood characterized by a marked activation of interictal spikes during sleep as the benign epilepsy with occipital paroxysms, the Landau–Kleffner syndrome, and the continuous spike-and-wave discharges during slow-wave sleep syndrome [225–227]. These findings suggest that the thalamocortical network that plays an important role in pacing sleep spindles in the generalized 3-Hz spike-and-wave discharges may also modulate focal discharges [82].

Indeed, it has been observed that local recurrent oscillatory activity and localized spike-and-wave discharges can be confined within a regional thalamocortical circuitry involving a circumscribed pool of neurons within the cortex [228, 229]. The above data suggest that subtle age-dependent dysfunctions of the thalamocortical system may play an important role in the pathophysiology of epileptic syndromes of childhood characterized by a marked activation of interictal spikes during sleep.

The prognosis of BECTS is generally excellent, with cessation of seizures by the age of approximately 16 years, without any neurologic sequelae and satisfactory response to anticonvulsant therapy. However, in some patients, the marked activation of IEDs during sleep may induce neuropsychological disorders [230]. For these reasons, as proposed in the 2010 Report of the ILAE Commission on Classification and Terminology, it would be better to replace the term “benign” with the term “self-limited” [216].

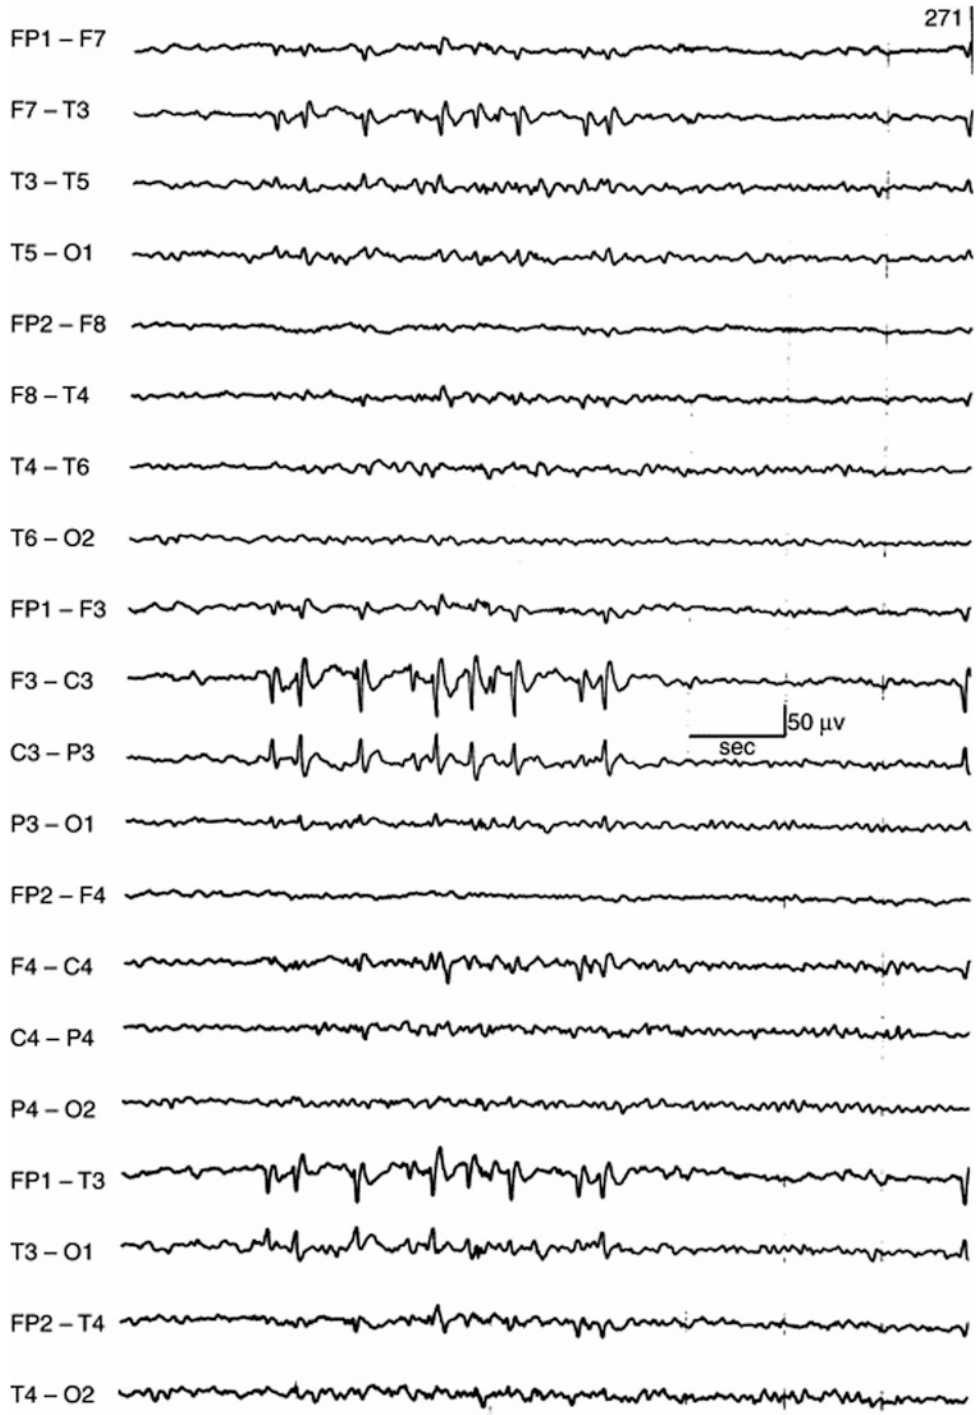

Fig. 44.7 Left centrotemporal spikes and sharp waves in patient with benign focal epilepsy of childhood with rolandic spikes

Juvenile Myoclonic Epilepsy of Janz

JME, an electroclinical syndrome, was described by Janz and Mathes [231] and later published in detail by Janz and Christian [232]. The onset of the syndrome is usually between 13 and 19 years and is manifested by massive bilaterally synchronous myoclonic jerks, which are most commonly seen in the morning shortly after awakening [232, 233]. The EEG is characterized by generalized spike-and-wave and typically multiple spike-and-wave discharges (see Fig. 44.3), seen in a synchronous and symmetric manner. Photosensitivity [234] and the phenomenon

of perioral myoclonia [235] of the lips, tongue, jaw, or throat (precipitated predominantly by talking) may occur in a large number of patients with JME. The excellent response to anticonvulsants makes this condition relatively benign, although not "self-limited" and easily distinguishable from the malignant syndrome of progressive myoclonus epilepsies.

Epileptic Syndrome with Generalized Tonic-Clonic Seizure on Awakening

Epileptic syndrome with generalized tonic-clonic seizure on awakening [233, 236] is manifested by the occurrence in the second decade of generalized tonic-clonic seizures on awakening from sleep. This is a rare syndrome, and clinically, there may be occasional absence or myoclonic manifestations and photosensitivity resembling JME. There is considerable overlap between generalized tonic-clonic seizures on awakening and JME. Patients with generalized tonic-clonic seizures on awakening should have had at least six generalized tonic-clonic seizures, and in JME patients, there are relatively frequent myoclonic jerks and infrequent generalized tonic-clonic seizures [94].

Continuous Spike-and-Wave Discharges During Slow-Wave Sleep

CSWS, formerly known as electrical status epilepticus during sleep (ESES), is a disease of childhood characterized by generalized continuous spike-and-wave EEG discharges during slow-wave sleep. All-night PSG study is necessary for diagnosis. The patients display progressive behavioral disturbances, although the seizures disappear within months or years. This entity is rare and found in children between 5 and 15 years of age. ESES was first described by Patry et al. [163] in 1971 in six children. Later, Tassinari and coworkers reviewed the literature and gave a comprehensive description of the entity [237–239]

Most of the patients had a prior history of epilepsy. The characteristic EEG finding consists of 2.0 to 2.5 cycles/sec generalized spike-and-wave discharges seen during at least 85 % of NREM sleep and suppressed during REM sleep (see Fig. 18.22a–c). Occasional bursts of spike-and-wave discharges or focal frontal spikes were noted during REM sleep. There were a few bursts of generalized spike-and-wave discharges seen in the EEG during wakefulness. These EEG discharges disrupted the stages of NREM sleep. In particular, the vertex sharp waves, K complexes, and spindles could not be well recognized. However, the cyclic pattern of REM-NREM persisted normally. Generally, there were no sleep disturbances, but some children had difficulty awakening in the morning. CSWS is now considered an epileptic encephalopathy of childhood characterized by cognitive and motor impairment and epilepsy [238, 239]. The etiologic heterogeneity of CSWS has been emphasized by Veggiotti et al. [240] and supported by a recent report of its presence in Rett syndrome [241]. The EEG findings of continuous epileptic discharges generally disappear within 3 years of appearance [237–239]. Focal abnormalities, in the EEG, may persist, however. It is not clear whether CSWS is a focal epilepsy or a generalized epilepsy with heterogeneous presentation, and hence, it is classified under the category of undetermined epileptic syndromes. Seizures show a benign course and respond well to antiepileptic medications, with disappearance of seizures by the mid-teens. The psychological impairment, however, persists.

Landau–Kleffner Syndrome

Landau–Kleffner syndrome (LKS) is an acquired aphasic syndrome occurring in a previously normal child and probably is a variant of CSWS [242]. The characteristic language dysfunction in LKS is an apparent "word deafness" or auditory verbal agnosia. There are many similarities between CSWS and LKS, and the type of neuropsychological dysfunction may depend on the location of the discharge (e.g., frontal in CSWS and temporal in LKS). Most CSWS patients have no evidence of language dysfunction. Approximately 70–80 % of children have seizures that are characterized by eyeblinking, head dropping, or minor automatisms with secondary generalization. These patients respond to antiepileptic medications and remain seizure-free by the mid-teens. The EEG pattern is similar to that noted in CSWS.

Nocturnal Temporal Lobe Epilepsy

Nocturnal temporal lobe epilepsy (NTLE) has not been well characterized. It has been described by Bernasconi and coinvestigators [243] in a subgroup of 26 patients with refractory temporal lobe epilepsy without structural lesion, with more than 90 % of seizures occurring during sleep. Focal seizures with transient impairment of consciousness, staring, automatism, and experiential or other sensory components occurring predominantly during sleep characterize the clinical syndrome. These simple partial staring seizures are frequently followed by secondary generalization. The following features differentiate patients with NTLE from the typical nonlesional temporal lobe epilepsy patients with diurnal seizures: a rare family history of epilepsy, low prevalence of childhood febrile seizures, infrequent and nonclustered seizures, and favorable surgical outcome [94, 243].

Nocturnal Frontal Lobe Epilepsy

In the early 1980s, Lugaresi and Cirignotta [244] and Lugaresi et al. [245] reported cases of paroxysmal attacks occurring during NREM sleep characterized by prominent motor behaviors in the form of dystonic posturing, tremors, and ballistic movements of the limbs, lasting 15 s to 2 min and not associated with epileptic abnormalities on the scalp EEG (Box 43.4). The attacks could respond to low doses of carbamazepine, posing the question of whether they represented epileptic seizures or sleep-related movement disorders. These attacks, termed *nocturnal paroxysmal dystonia*, were later demonstrated to represent a form of nocturnal frontal lobe epilepsy (NFLE) [245–248]. Nocturnal frontal lobe epilepsy (NFLE) is a syndrome of heterogeneous etiology as genetic, lesional, and cryptogenetic forms have been described. Although generally considered a benign clinical entity, severe, drug-resistant forms do exist [249].

Box 44.4 Nocturnal Frontal Lobe Epilepsy: Salient Features

- Movements: tonic, clonic, bipedal, bimanual, bicycling, choreoathetoid, ballismic,
- Retropelvic thrust,
- Motor and sexual automatisms,
- Contralateral dystonic posturing,
- Contralateral arm abduction with or without eye deviation,
- Oftentimes exclusively nocturnal,
- Sudden onset and termination in NREM sleep,
- Duration: usually less than a minute,
- Short postictal confusion,
- Often in clusters,
- Mistaken for nonepileptic seizures,
- Ictal EEG may be normal,
- Interictal EEG may or may not show spikes.

The spectrum of frontal lobe epilepsy manifestations include the so-called paroxysmal arousals, characterized by abrupt arousals from NREM sleep often accompanied by asymmetric tonic or dystonic posturing or complex movements such as pelvic thrusting, pedaling, choreoathetoid and ballistic movements of the limbs (Videos 1, 2, 3), lasting less than 20 s [250–252] and the so-called epileptic nocturnal wanderings (Video 4) [253, 254], more complex events lasting 2–4 min and associated with agitated ambulation and jumping about. Notably, paroxysmal arousals, often recurring quasi-periodically every 20–40 s for long stretches during NREM sleep, are often associated with attacks of nocturnal paroxysmal dystonia and epileptic nocturnal wanderings in the same patient and can represent the initial manifestations of the more prolonged attacks [255]. The increasing complexity of NFLE ictal motor behaviors, from minor to major events, reflects a different duration and propagation of the discharge within the frontal lobe [255, 256].

The peculiar features of NFLE thus consist of its nocturnal recurrence, related to NREM sleep stages in over 80 % of the seizures [257], and of the characteristic motor pattern with truncal and bipedal gross and often violent movements with dyskinetic features; the latter have led to the definition of hypermotor or hyperkinetic seizures.

Functional brain imaging in frontal lobe seizures (nocturnal paroxysmal dystonia and paroxysmal arousals) indeed confirms that the peculiar motor patterns are related to involvement of mesial, especially cingulate, motor areas [258, 259]. Studies with intracerebral electrodes (stereo-EEG) conducted in drug-resistant patients with NFLE have shown that the seizure onset in patients with asymmetric tonic or dystonic posturing is generally localized in the posterior portion of the frontal cingulate gyrus and in the posterior mesial frontal cortex with a primary involvement of the supplementary motor area [56, 260]. In patients with seizures characterized by hyperkinetic automatisms and complex motor behaviors, the region of seizure onset may involve the dorsolateral and anterior frontal regions (frontopolar and frontal anteromesial regions) [56, 261, 262]. Seizure characterized by the association between fear and nocturnal wandering seem to involve a cerebral network including the anterior cingulate, orbitopolar, and temporal regions [260, 263–265]. Moreover, it has been shown that "hypermotor seizures" may also be found in seizures originating from the temporal lobe and the insula [263, 266–269]. In such cases, the hyperkinetic features appeared 8–40 s after the beginning of the discharge in the temporal or insular regions, when the discharge spreads to other cortical structures such as the cingulate, frontal, and parietal cortices (Video 5) [266, 269]. Such a possibility of an extra-frontal origin of seizures renders the term NFLE somewhat misleading. Recently, in order to improve the definition of the disorder and establish well-defined diagnostic criteria, a consensus conference was held. It was recommended to change the name into "Sleep related Hypermotor Epilepsy (SHE)," considering that seizures are associated with sleep rather than time of day, seizures may arise outside the frontal lobe and the hypermotor aspects if the attacks are characteristic [270]. The etiology of SHE may be genetics, due to a cortical abnormality or unknown. Diagnostic criteria were developed with three levels of certainty: witnessed (possible) SHE, video-documented (clinical) SHE, and video-EEG-documented (confirmed) SHE. Due to the recurrence of nocturnal motor events, several NFLE patients may complain of non-restorative sleep and of daytime sleepiness [249, 257, 261].

Autosomal Dominant Nocturnal Frontal Lobe Epilepsy

Scheffer et al. [271] described an autosomal dominant form of frontal lobe epilepsy in six families. Brief motor seizures usually occurred in clusters during sleep. The disorder usually started in childhood and persisted through adult life. Patients were of normal intellect and had normal neurologic examination and neuroimaging. Response to carbamazepine was excellent. In most cases, interictal EEGs were normal, although one family with daytime attacks had epileptiform discharges. Video telemetry during the attacks confirmed their epileptic nature. They called this condition autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE). The clinical features of ADNFLE were later confirmed by Thomas et al. [272] in one family with very frequent seizures during infancy, in which carbamazepine therapy again was dramatically effective, and by Oldani et al. [273], who studied 33 patients and found similar results. In 1995, Phillips et al. [274] mapped a gene responsible for ADNFLE in a large Australian kindred to chromosome 20q13.2, and Steinlein et al. [275] demonstrated that epileptic nocturnal frontal lobe (ENFL) type 1 was due to mutations in *CHRNA4*, the gene encoding the A4 subunit of the acetylcholine (ACh) neural receptor. Another linkage site was later reported to chromosome 15q24 accounting for ENFL type [2, 276] and mutations in *CHRNB2*, the gene encoding for the B2 subunit of the ACh neural receptor localized on chromosome 1 as accounting for ENFL type 3 [277]. Another linkage locus to chromosome 8p12.3-8q12.3 and a missense mutation in the gene *CHRNA2* encoding for the neural ACh receptor A2 subunit have been reported in familial seizures characterized by complex and finalized ictal behavior resembling epileptic nocturnal wanderings [264], as well as mutations in the corticotropin-releasing hormone gene [278].

Genetic findings thus implicate the nicotinic ACh receptors in ADNFLE. Mutations responsible for ADNFLE work by increasing the receptor sensitivity to ACh [279], indicating that a gain of function of the mutant receptors underlies the neuronal dysfunction responsible for the epileptic seizures. Mutated nicotinic receptors responsible for ADNFLE were also found to be more sensitive to carbamazepine, which works as a noncompetitive inhibitor of the nicotinic ACh receptors [280]. On the basis of the genetic findings and functional imaging data [281], the pathogenesis of ADNFLE has been attributed to dysfunction in the dorsal cholinergic ascending arousal system, and a common background with the arousal parasomnias has been hypothesized based on epidemiologic and clinical data [282, 283]. In animal models, it has been shown that a mutation of the nicotinic receptors may provoke an unbalanced excitation/inhibition circuitry within the GABAergic reticular thalamic neurons, thus favouring seizures through the synchronizing effect of spontaneous thalamocortical oscillations [96]. On the other hand, other experimental studies have reported an involvement of nAChR in the regulation of arousals, sleep stability, and the activity-rest pattern [95]. The observed genetic alterations in NFLE could create the conditions for both arousal instability and seizure generation [284].

However, ADNFLE is not only related to mutations in the cholinergic system. Since 2005, other genes, not belonging to the nACh receptor subunit family, have been identified. In particular, Combi et al. [278, 285] found mutations of the corticotropin-releasing hormone gene in sporadic and ADNFLE cases. The in vitro functional analysis of both variations demonstrated an altered level of protein expression suggesting an interrelation between CRH concentration and neuronal excitability with a possible effect on thalamocortical loop dysfunctions [278]. Very recently, a further CRH mutation has been found in the protein pro-sequence region of the CRH of two affected siblings of an Italian ADNFLE family [286]. In 2012, a further gene on chromosome 9 encoding the sodium-activated potassium channel subunit 1 (KCNT1) was associated with ADNFLE [287]. In particular, four variants in KCNT1 were identified in three families and in a sporadic ADNFLE case, all showing a severe ADNFLE phenotype with early onset, high prevalence of intellectual disabilities, and psychiatric or behavioral problems, including psychosis, catatonia, and aggression. Very recently, mutations in the DEPDC5 gene were reported as responsible for different types of focal epilepsies, including ADNFLE [288]. However, the prevalence of mutations in this gene remains to be assessed.

In summary, ADNFLE is a heterogeneous genetic syndrome that can be incidental to mutations in different genes. Mutations in these genes, however, account only for a minority of cases [289], and their mean penetrance ranges from 60 to 80 %. Hence, further studies are needed to better characterize this heterogeneous syndrome. Given the high intrafamilial variability and the overlapping features of the clinical manifestations, ADNFLE patients do not show a clear distinction from sporadic NFLE cases, except for certain ADNFLE mutations frequently associated with specific additional neurologic or psychiatric symptoms.

Effect of Sleep Deprivation on Epilepsy

The diagnostic value of sleep-deprived EEG has been well documented [190, 290–293]. What is the mechanism of activation during sleep deprivation? This is probably not a sampling effect and not related to sleep alone [290, 291, 293]. In a study using paired-pulse transcranial magnetic stimulation in 30 patients with untreated newly diagnosed epilepsy (15 idiopathic generalized and 15 focal epilepsies) and 13 healthy control subjects before and after sleep deprivation, Badawy et al. [70] noted an increase in cortical excitability following sleep deprivation at short interstimulus intervals. This change was most

prominent in the patients with idiopathic generalized epilepsy. Manganotti et al. [71] observed similar cortical hyperexcitability following sleep deprivation in a cohort of patients with juvenile myoclonic epilepsy. These findings confirmed the hypothesis that sleep deprivation increases cortical excitability in epilepsy. Sleep deprivation increases the epileptiform discharges mostly in the transition period between waking and light sleep and also has a localizing value [291, 293]. Although the original study by Rodin et al. [294] in 1962 found epileptiform discharges in healthy subjects after sleep deprivation, later studies [293, 295] failed to confirm these observations.

Rowan et al. [291] studied 43 consecutive patients using two types of activation: sleep deprivation (24 h in adults and partial deprivation in children) and sedated sleep (after oral secobarbital). They obtained useful information in 44 % of sleep-deprived as opposed to 14 % of sedated sleep records. The patients were referred because of doubtful diagnosis of epilepsy or because seizure types could not be determined. They also found sleep deprivation superior to sedated sleep for differentiating those with a final diagnosis of seizure. It should be noted that sleep alone does not explain the activating effect of sleep deprivation. The mechanism remains largely unknown. Experimental [65] and human studies [70, 71, 291] suggest an increased cerebral excitability after sleep deprivation. Degen [292] studied 127 waking and sleep EEGs after sleep deprivation in 120 epileptic patients on anticonvulsant medication. He found seizure activity in 63 % of the patients, although in the previous EEG records of these patients, only 19 % had shown seizure activity; thus, sleep deprivation increased the incidence of seizure activity. Approximately 48 % of discharges occurred during slow-wave and 25 % during REM sleep.

It is notable that in 1896, Patrick and Gilbert [296] apparently performed sleep deprivation studies in human beings. The studies by Bennett [297] in 1963 and Mattson et al. [298] in 1965 established the value of sleep deprivation as a diagnostic tool in patients with seizure disorders. Rodin [299] compiled the incidence of activation after sleep deprivation from an analysis of the literature and came up with a figure of approximately 45 %. Later studies by Frucht et al. [300], Roupakiotis et al. [301], and Teraita-Adrados et al. [302] confirmed the value of sleep deprivation in activating EEG epileptiform discharges. Recent studies [303] also supported that sleep deprivation activates ictal and interictal epileptiform discharges. There is, however, a contrasting observation by Malow et al. [304], who failed to note increasing seizure frequency after partial sleep deprivation in inpatient video-EEG monitoring in a group of 84 patients with medically refractory epilepsy.

Phenomena During Sleep that Can Be Mistaken for Epilepsy (Nonepileptiform Disorders)

Certain paroxysmal arousal disorders in NREM sleep may be mistaken for seizures, particularly for CPS. Some examples of these disorders are night terrors (pavor nocturnus), somnambulism (sleepwalking), confusional arousals, tooth grinding (bruxism), rhythmic movement disorder, benign sleep myoclonus of infancy, hypnagogic foot tremor, and nonepileptic seizure (nocturnal pseudo-seizure). Two other parasomnias usually associated with REM sleep, REM sleep behavior disorder (RBD), and nightmares (dream-anxiety attacks) may be mistaken for seizures. These conditions are listed in Box 43.5. Box 43.6 lists some salient features of nonepileptic seizures that may help differentiate this condition from a true seizure [305].

Box 44.5 Conditions That May Mimic Nocturnal Seizures

- Confusional arousals,
- Sleepwalking,
- Sleep terror,
- REM sleep behavior disorder,
- Rhythmic movement disorder,
- Tooth grinding (bruxism),
- Benign sleep myoclonus of infancy,
- Hypnagogic foot tremor,
- Nonepileptic seizure (nocturnal pseudo-seizure).

Box 44.6 Features of Nonepileptic Seizure (Pseudo-Seizure)

- Predominantly diurnal; sometimes nocturnal,
- Gradual onset and gradual termination,
- Prominent pelvic thrusting, mainly forward,
- Asynchronous (out-of-phase) clonic limb movements,
- Eyes usually closed,
- Prominent head movements (horizontal—"no-no"—or rotary),
- Lack of concern about symptoms (*la belle indifference*),
- Urinary incontinence and self-injury: extremely rare[308],
- Video-EEG: normal awake EEG.

Considering the similarities and the possible coexistence of parasomnias in people with NFLE [282], the diagnostic process may be challenging, especially if it is only based on anamnestic investigations. A reliable semeiological description of motor events occurring during the night is often difficult to collect

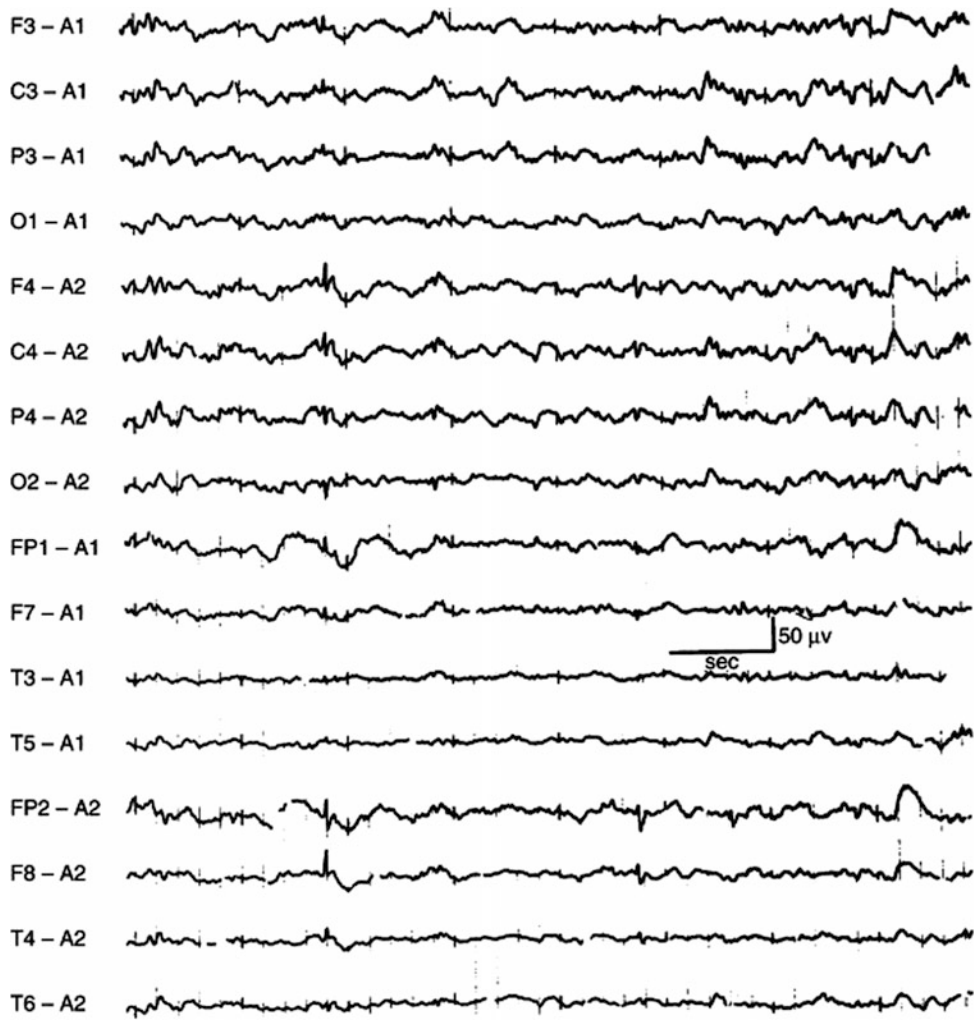

Fig. 44.8 Small sharp spikes (benign epileptiform transients of sleep) seen in channels 5–8 and 13–16 from the *top*

from a witness or sleep partner because observers may be lacking or, if present, not fully reliable or awake when attacks occur. Recent efforts to obtain a systematic assessment of the diagnostic reliability of clinical history have devised two instruments: the Frontal Lobe Epilepsy and Parasomnias Scale [306] and the Structured Interview for NFLE [307]. Albeit clinically useful, these tools are limited by contradictory diagnostic accuracy [249, 308]. Interictal EEGs fail to disclose epileptiform abnormalities in a substantial percentage of NFLE patients [257]. Moreover, small sharp spikes or benign epileptiform transients of sleep, as noted in the EEG (Fig. 44.8) in stages 1 and 2 NREM sleep, may resemble true epileptiform spikes even though the distribution, morphology, and occurrence during particular stages of sleep without any clinical accompaniments differentiate these from true epileptiform spikes [309]. On the other hand, the presence of EEG epileptiform discharges independent of nocturnal attacks may not be proof sine qua non that the attacks are of an epileptic nature [19]. Practical suggestions for differential diagnosis between the arousal parasomnias and NFLE seizures have been proposed [257, 306]: NFLE should be suspected if attacks recur several times during the same night; if they occur in a stereotyped fashion; if tremor, dystonia, or ballism are noted during the attack; if the attacks arise in or persist into adulthood; and if there is a good response to low doses of carbamazepine [310]. Unfortunately, however, these suggestions rely on expert opinion and are not validated against any "gold standard."

Sleep video-polysomnography is considered the "gold standard" diagnostic test; however, it does not always capture the event in a single-night recording. Moreover, even when the nocturnal episode has been recorded, the diagnosis remains doubtful because ictal scalp EEG fails to disclose epileptiform abnormalities, or because the episode captured is a minor motor event, like the so-called paroxysmal arousal (PA), for which the diagnosis is not reliable even among experts [311].

Recently, Derry et al. [312] conducted an accurate and systematic evaluation of parasomnias and NFLE seizures recorded on video-EEG monitoring in order to identify features

that could be used to reliably distinguish parasomnias from nocturnal frontal lobe epilepsy. They noticed that the discrepancy between historical account and recorded events were more prominent in NREM parasomnias than in NFLE; moreover, the clinical features of the initial arousal behaviors (abrupt or slow movements) were often indistinguishable between the two conditions. In contrast, the clinical features of the evolution and the offset of the events could better differentiate NFLE from parasomnias. Indeed, the presence of a coherent speech and a verbal interaction with the neighboring individuals during the episode, the possibility to modify the event by the actions of individuals present, and the absence of a clear and distinct offset of the attack were highly indicative of a NREM parasomnia. Despite the limits of V-PSG, the possibility of analyzing the video of the nocturnal attack remains an important diagnostic tool, making home video recording a useful adjunct when episodes are infrequent, even if the onset of the episode is missed [310, 313].

Effect of Epilepsy on Sleep

An objective evaluation of the states of sleep in epileptic patients reveals that they are altered in a large percentage of patients studied. Although the utility of sleep in the diagnosis of epilepsy is well established, the altered sleep characteristics in epileptics are not well known. One of the difficulties has been that most of the studies have been conducted in patients who have been on anticonvulsants, thus adding the confounding factors of the effect of anticonvulsants on sleep architecture. Furthermore, there have not been good longitudinal studies to determine the effect of epilepsy on sleep in the early versus late stages of the illness. Despite these limitations, there have been several studies from which a general consensus has been reached regarding the effect of epilepsy on sleep and sleep structure. A variety of sleep disturbances have been observed in epileptics and can be summarized as follows [177, 179, 201, 314]: a reduction in REM sleep; an increase in wake after sleep onset (WASO); increased instability of sleep states, such as unclassifiable sleep epochs; an increase in NREM stages 1 and 2; a decrease in NREM sleep stages 3 and 4; a reduction in the density of sleep spindles; and an increase of sleep-onset latency. A recent study conducted in drug-resistant epileptic patients has shown that surgery can improve subjective and objective (PSG-documented) sleep parameters during the early postoperative period with resultant reduction in excessive daytime sleepiness [315].

Box 44.7 lists effects of epilepsy on sleep architecture (macrostructure and microstructure). In patients with absence spells, sleep macrostructure may be normal, but microstructural alterations showing increased cyclic alternating patterns may have relevance to the postulated physiologic mechanism of spike-and-wave generation utilizing the same thalamocorticothalamic pathways that are used for sleep spindles and K complexes. Sleep structural alterations are related to frequency of nocturnal seizures and increased interictal epileptiform discharges during sleep. Severe sleep disruption related to spike-and-wave discharges may be partly responsible for cognitive impairment in epileptics, including patients with CSWS and LKS.

Box 44.7 Effect of Epilepsy on Sleep Architecture

- Increased sleep-onset latency,
- Increased number and duration of awakenings after sleep onset,
- Increased cyclic alternating pattern,
- Reduced sleep efficiency,
- Reduced sleep spindles and K complexes,
- Reduced REM sleep,
- Increased stage shifts,
- Abnormal sleep cycling,
- Sleep state instability (unclassifiable sleep epochs).

Nocturnal seizures may alter sleep architecture by five mechanisms: (1) effects of seizures (ictal discharges); (2) effects of interictal discharges; (3) effects of antiepileptic medications; (4) associated organic brain disorders; and (5) comorbid primary sleep disorders (e.g., sleep apnea, insomnia, and restless legs syndrome/periodic limb movements in sleep). Three questions may be asked regarding the effect of epilepsy on sleep:

1. Is sleep quality related to the duration and type of seizures?
2. Is sleep quality related to repeated episodes of seizures or poorly controlled seizures?
3. Can epilepsy lead to a sleep disorder?

These questions are discussed in the next sections.

Sleep Complaints in Patients with Epilepsy

Patients with epilepsy may complain of excessive daytime sleepiness (EDS), insomnia (inability to fall or maintain sleep and early morning awakening), and adverse daytime consequences related to insomnia and EDS, as well as unusual movements and behaviors intruding into sleep. EDS in epileptics may result from clinical seizures, particularly nocturnal seizures and ictal or interictal EEG epileptiform discharges; comorbid conditions such as obstructive sleep apnea syndrome (OSAS; see later) and polycystic ovary syndrome (PCOS); and effects of antiepileptic medications (see later). Box 44.8 lists causes of EDS in epileptic patients. Maganti et al. [316] reported that EDS and sleep complaints are common among adults with epilepsy, and in some patients, these

may be due to underlying sleep disorders such as sleep apnea. Khatami et al. [317] assessed sleep-wake habits and EDS using a standardized questionnaire in 100 consecutive outpatients with epilepsy and 90 controls. Sleep complaints were more common in epilepsy patients than in controls, and sleep maintenance insomnia and EDS were found frequently; they noted that loud snoring and restless legs symptoms are the only independent predictors of EDS in epilepsy patients. Jenssen et al. [318], based on a questionnaire and chart review of a tertiary referral center, noted subjective somnolence to be related mainly to depression rather than to obstructive sleep apnea (OSA) and other variables. A recent case–control study from Brazil [319] found that patients with epilepsy had more EDS, daytime dysfunction, and sleep disorders compared with a control group. In a systematic review of PubMed-cited articles from 2002 to 2012 (most studies were cross-sectional and questionnaire-based), Giorelli et al. [320] concluded that EDS was related more frequently to undiagnosed sleep disorders than to epilepsy-related factors.

Box 44.8 Causes of Excessive Daytime Sleepiness in Epileptics

- Clinical seizures, particularly nocturnal seizures,
- Frequent ictal and interictal epileptiform EEG discharges,
- Coexisting disorders (e.g., sleep apnea and polycystic ovary syndrome),
- Depression.

Manni and Terzaghi [321] described two elderly men with late-onset sleep-related tonic-clonic seizures and RBD. The authors hypothesized that RBD may facilitate seizure occurrence. In a later study, Manni et al. [322] reported co-occurrence of epileptic seizures and RBD in six cases. The authors cautioned that further investigations of the occurrence of RBD episodes and epilepsy are needed to understand the neurobiological significance of this comorbidity.

Relationship Between Seizure Type, Severity of Seizure, and Extent of Sleep Deficits

The relationship between seizure type, severity of seizure, and extent of sleep deficits remains somewhat controversial, and the reports are contradictory. WASO, sleep stage shifts, and sleep fragmentation are found in all seizure types [157, 314, 323–326]. Reduction of REM sleep and an increase in NREM stages 1 and 2 are in part dependent on the type of epilepsy. Declerck et al. [314] found an increase of NREM stages 1 and 2 and a reduction of REM sleep in 258 patients with primary generalized or partial seizures with secondary generalization as compared with 223 nonepileptic subjects. Seizure occurrence during sleep accentuates sleep deficits, which are more marked in primary generalized and partial seizures with secondary generalization than in other types. In 25 % of epileptics, Declerck et al. [314] could not evaluate PSG recordings because of severe encephalopathies associated with seizures. Similar findings were obtained by Bessett [157]. Baldy-Moulinier [323] noted a decrease of REM sleep in patients with CPS occurring during sleep. However, Baldy-Moulinier found markedly reduced REM sleep in patients having only one attack of secondary generalized seizure during the night. It is interesting to note that Bessett [157] in human epileptics and Baldy-Moulinier [323] in temporal lobe epilepsy models found no rebound REM sleep in subsequent recordings after REM sleep loss, which is contrary to the usual findings of REM rebound after REM deprivation. In summary, WASO and sleep fragmentation are found in all types of epilepsy, and generalized seizures are associated with an increase of NREM stages 1 and 2 and a reduction of REM sleep. In CPS, there is often REM reduction only. Besset [157] could not discriminate NREM stages or REM sleep in the EEG because of disrupted sleep architecture due to the seizures (ictal and interictal).

Hoeppner et al. [327] studied self-reported sleep disorder symptoms in epilepsy. They gave a questionnaire relating to six aspects of sleep: delayed sleep onset, night awakenings, dreams, night terrors, sleepwalking, and fatigue on awakening. They evaluated four groups of subjects: (1) Four patients with simple partial seizures, (2) 18 patients with CPS, (3) Eight patients with generalized seizures, and (4) 23 controls (14 women and 9 men aged 16–53 years). They found significantly more sleep disorder symptoms (particularly frequent awakenings at night) in patients with simple partial seizures and CPS. The generalized group behaved like the control group. Patients with the most frequent seizures, irrespective of type, had the most sleep disturbances.

Roder-Wanner et al. [328] obtained polygraphic sleep recordings in 43 patients with different types of epilepsies. They found that patients with generalized epilepsy had a higher percentage of deeper stages of sleep (NREM 3 and 4) than patients with focal epilepsy. These observations are correlated with the factor of photosensitivity, which was noted in a subgroup of these patients. The authors concluded that there was no real relationship between sleep structure and the type of epilepsy. Thus, there is some controversy regarding the relationship between seizure type and sleep. It can be concluded, however, that the severity of sleep deficits is in part correlated with severity of the seizure disorder. Animal studies support such a conclusion [329, 330]. In

previous studies, sleep structure abnormalities may have been related to clinical or subclinical seizure activity preceding the PSG investigation or to the medication received during the study.

There are contradictory reports regarding REM sleep disturbance [179]. On seizure-free nights, REM sleep is usually normal, but REM decrement is noted when there are primary or secondary generalized seizures during the night. There is no REM suppression during partial seizure without secondary generalization [157, 323]. Bowersox and Drucker-Colin [331] stated that increased cortical neuronal excitability and reduced seizure threshold may result from chronic REM sleep deprivation secondary to repeated and frequent nocturnal generalized seizures. In a recent review, Ng and Pavlova [332] hypothesized that desynchronized EEG with altered connectivity is responsible for seizure suppression in REM sleep. In fact, after reviewing several studies, Jaseja and Jaseja [333] observed a linear relationship between reduction of REM sleep and intractable or refractory epilepsy and postulated REM sleep duration as a biomarker for predicting intractability of seizure. The authors even made a novel suggestion of deep brain stimulation (specifically of pedunculopontine nucleus) as a novel therapeutic approach in intractable epilepsy to increase REM sleep percentage.

In a series of 15 patients with temporal lobe seizure disorders, Touchon et al. [334] found increased WASO, shifting of the sleep stages, and increases in NREM sleep stages 1 and 2. In a study of 23 patients with temporal lobe epilepsy, Kohsaka [335] found significantly decreased sleep efficiency and increased awakenings in both treated and untreated patients. He also noted increased NREM stage 4 in untreated patients compared to healthy controls. The site of the primary focus may determine the type of the sleep disturbances [18]. Foci in the amygdalohippocampal region may lead to increased WASO and decreased sleep efficiency. Frontal lobe epileptics, however, may show a specific reduction in stages 3 and 4 NREM sleep.

In a questionnaire-based study of 40 children with tuberous sclerosis, Hunt and Stores [336] found that concurrent epilepsy was significantly associated with sleep disturbances in these children. This observation was corroborated by Bruni et al. [337], who found a more disrupted sleep architecture in patients with tuberous sclerosis and epilepsy compared with seizure-free children. In large series of children with epilepsy, there was a correlation among seizure frequency, incidence of interictal epileptiform discharges, duration of seizure disorders, behavior problems, poor quality of sleep, and disturbed breathing during sleep [338, 339]. Becker et al. [340] noted that 80 % of 30 children complaining of sleep disturbance had PSG documentation of OSA, abnormal sleep architecture, and fragmentation.

de Weerd et al. [341] reported poor quality of life and sleep disturbances that were more common in adults with focal seizures with or without secondary generalization compared with controls. A variety of PSG-documented sleep abnormalities have been described in patients with JME [136, 342, 343] and focal temporal lobe epilepsy. Bazil et al. [136] documented reduction of REM sleep by seizures in temporal lobe epilepsy. Sleep abnormalities in absence seizures gave conflicting results [180]. In BECTS, no sleep architectural abnormalities are noted [42, 344].

Several authors have noted that sleep abnormalities are more common in patients with primary or secondary generalized seizures than in those with partial focal epilepsies [42, 344, 345], but other studies have shown that patients with severe or medically refractory temporal lobe seizures may have equally severe sleep structural abnormalities [343, 344]. Several investigators have reported severe sleep abnormalities in symptomatic epilepsies associated with neurologic deficits [166, 346–351]. In all of these patients, both sleep dysfunction and seizure disorders must be treated simultaneously to obtain best results.

In several reports, PSG findings and sleep abnormalities have been described in partial seizures, especially frontal lobe [352, 353] and temporal lobe [136, 353] seizures. Tachibana et al. [352] showed an improvement in sleep structure after treatment with appropriate antiepileptic drugs (AEDs) (Fig. 44.9).

Can Epilepsy Lead to a Sleep Disorder?

It is generally thought that sleep deficits in seizure disorders are secondary to the severity of the seizure disorder and are a direct result of seizures during sleep. However, studies by Tanaka and Naquet [354] demonstrated progressive sleep deficits in amygdala kindling models. In addition, the sleep deficits persisted one month after discontinuation of kindling procedures.

Shouse and Sterman [329] produced amygdala kindling in 10 adult cats and studied their sleep and waking patterns chronically. They found a progressive sleep disturbance and retention of the deficit over a prolonged period after termination of amygdala stimulation. These findings suggest the "kindling" of a sleep disturbance in addition to a seizure disorder. The authors further stated that sleep abnormalities cannot be viewed as a simple or temporary side effect of epileptiform activity. It appears that a permanent change in sleep physiology occurs in epilepsy. These observations of Shouse and Sterman [329] partially answer the question posed by Passouant [1]: "Can epilepsy lead to a sleep disorder?" Effective treatment of epilepsy with anticonvulsant

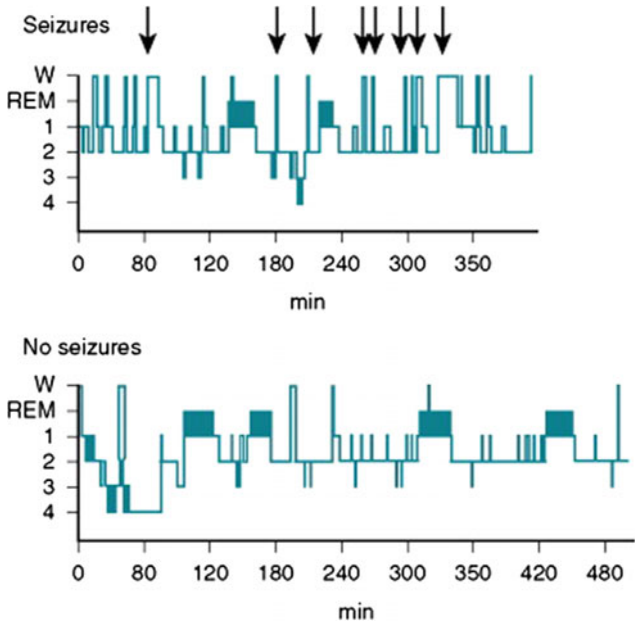

Fig. 44.9 *Top* Polysomnogram showing increased slow-wave and REM sleep along with frequent awakenings during the night with eight nocturnal seizures. *Bottom* Sleep architecture showing remarkable improvement in the same patient following treatment with carbamazepine. Modified from Tachibana et al. [352]

medications or surgical methods normalizes sleep disturbances in human epilepsy [325].

Can a Sleep Disorder Lead to Epilepsy?

In 1995, Silvestri et al. [355] reported six patients who were diagnosed in childhood as having disorders of arousal and later developed epileptic seizures. The sleep disorders consisted of sleepwalking and night terrors, all confirmed by PSG studies. The seizures noted were complex partial in five and generalized tonic-clonic in one. Nocturnal monitoring confirmed the epileptic nature of these events. The authors hypothesized that because both disorders of arousal and epilepsy are related to sleep and share other common factors such as age of onset and precipitating factors, these disorders share common functional substrates, and it is possible that disorders of arousal may later turn into epileptic seizures. It should be noted, however, that sleepwalking and sleep terrors are frequently noted in children, and seizures may simply coexist with these NREM parasomnias. Most sleep specialists and epileptologists simply do not believe that such parasomnias can later turn into epileptic seizures. It should also be remembered that cases of typical disorders of arousal not associated with epileptic discharges in epileptic children have been described [14, 162, 356].

Effect of Anticonvulsants on Sleep and Sleep Architecture in Epileptics

Malow et al. [357] noted increased Epworth Sleepiness Scale scores in 28 % of 158 adult epilepsy patients. Peled and Lavie [250] described bursts of generalized spike-and-wave complexes during stages 2 and 3 of NREM sleep, preceded by K complexes and associated with arousals causing sleep disruption and daytime sleepiness. Some patients with epilepsy may have EDS as a result of sleep apnea (see later) and PCOS, which is more common in women with epilepsy, especially those patients taking valproic acid, than those without epilepsy [358]. Betts et al. [359] reported 30 % of women treated with valproic acid, 6 % with lamotrigine or carbamazepine, and 14 % of age-matched controls with clinical and biochemical evidence of PCOS. PCOS is associated with increased prevalence of OSAS [196, 360].

Some patients with epilepsy may complain of insomnia, which may be difficulty falling asleep or maintaining sleep, or early morning awakening associated with adverse daytime consequences of sleepiness, inability to concentrate and pay attention, and impairment of the quality of life. Insomnia in epileptics may be related to sleep fragmentation and repeated arousal as a result of nocturnal seizures and interictal EEG epileptiform discharges, some AEDs, depression and anxiety, or withdrawal or tapering of AEDs during video-EEG monitoring for presurgical evaluation of refractory seizures or may be due to an associated primary sleep disorder (Box 43.9). Some AEDs (lamotrigine and felbamate) may cause insomnia. Sadler [361] reported a 6.4 % incidence of dose-dependent insomnia among patients taking lamotrigine. In contrast, Foldvary et al. [362] failed to observe any effect of lamotrigine in a PSG study in seven subjects with epilepsy on sleep efficiency, sleep latency, or total sleep time. The other antiepileptic medication that was found to have stimulant-like effects in patients with epilepsy is felbamate [363, 364]; however, because of serious toxicity, felbamate has largely been withdrawn from the market and is rarely used nowadays to treat epilepsy.

Box 44.9 Causes of Insomnia in Epileptics

- Nocturnal seizures and interictal epileptiform discharges causing repeated arousals,
- Some antiepileptic drugs (AEDs; e.g., lamotrigine and felbamate),
- Withdrawal or tapering of AEDs during video-EEG monitoring,
- Depression and anxiety,
- Associated primary sleep disorder.

There is a dearth of well-controlled, careful studies documenting the effects of anticonvulsant medications on sleep architecture that properly take into account the effects of seizures on sleep. Only limited data are available. It is somewhat daunting to study the effects of AEDs in epileptics taking into consideration all the confounding factors. Objectively, the sleep architecture should be studied by PSG recordings before starting the patient on medication—that is, in the drug-free state—and then restudied with the patient on chronic therapy with one rather than multiple drugs. From a practical point of view, this is somewhat difficult because when the patient presents to the physician, he or she must be treated before performing these investigations. Furthermore, the pharmacokinetic and pharmacodynamic effects of AEDs show considerable variation depending on the age and genetic predisposition. There may be a circadian effect of the drugs, and comorbid conditions may also affect sleep. Furthermore, AEDs may have residual effect on sleep architecture even after withdrawal of the medication [365]. Johnson [325] reviewed the literature up to about 1981 showing the effects of acute and chronic exposure to anticonvulsant drugs in relation to the sleep pattern. Acute exposure to anticonvulsants may reduce REM and NREM stages 3 and 4 and increase stage 2 NREM sleep. Acute and chronic drug trials in epileptics suggest that the main effects of anticonvulsants consist of sleep stabilization, however, which includes a reduction in WASO and an increase in NREM stages 2, 3, and 4, along with sleep spindle density. These improvements are concomitant with the reduction of seizures. The bulk of the evidence in the literature points to the fact that effective anticonvulsant treatment and seizure control result in reduction of sleep disturbance. Thus, the effects may be due to the reduction of seizures and not to any specific effect of the anticonvulsants on sleep architecture.

In a survey of experimental epilepsy in animals, Wauquier et al. [366] observed that sleep fragmentation as obtained in epileptic animals and in humans may be the consequence of microarousals. Anticonvulsants may suppress microarousals because of their sedative properties and hence lead to stabilization of sleep fragmentation and normalization of sleep. Anticonvulsants may normalize sleep, however, because of a specific action on particular abnormal EEG patterns. Thus, despite the suggestion that anticonvulsants themselves may be responsible in part for the fragmentation and disruption of sleep architecture, the general consensus is that anticonvulsant medications normalize sleep architecture, most probably by reduction of the seizures.

AEDs have both detrimental and beneficial effects [367]. Most AEDs, however, normalize and stabilize sleep [118, 325, 343, 368] due to the suppression of clinical seizures and interictal discharges or a direct consequence of AEDs. In addition, the AEDs may also have neuromodulatory effects causing sleep disruption [369–371]. Most of the first-generation AEDs may delay REM sleep onset or suppress REM sleep percentages [42, 326, 368]. Some AEDs cause weight gain [372] (e.g., valproic acid, vigabatrin, pregabalin, gabapentin, and probably also carbamazepine) and decrease upper airway muscle tone (e.g., benzodiazepines and phenobarbital), which may have deleterious effects on the upper airway muscles causing sleep apnea in some patients [42] (see later). The effects of AEDs in sleep can be divided into general effects consisting of reduction of REM and slow-wave sleep, reduction of sleep latency, increased percentage of NREM stages 1 and 2, and specific effects depending on the individual AEDs (Table 44.1). In the following paragraphs, effects of the traditional or first generation and some of the newer AEDs are briefly discussed.

Older Antiepileptic Drugs

In most of the studies, phenobarbital is found to increase stage 2 NREM sleep and decrease sleep-onset latency, REM sleep, and WASO without any significant effect on slow-wave sleep [346, 373, 374]. Wolf et al. [373] reviewed the literature to assess the effect of barbiturates, phenytoin, carbamazepine, and valproic acid treatment on sleep. They noted significant reduction of REM sleep, a reduction in total awake time, and an increase in NREM stage 2 sleep as the short-term effects of barbiturates. The long-term effects of barbiturates are similar in general, but in some cases, the sleep pattern returned to the premedication level. Wolf et al. [373] performed a prospective polygraphic study of sleep in epileptic patients before and after medications using a crossover design. They studied phenobarbital, phenytoin, ethosuximide, valproic acid, and carbamazepine. The authors included 40 unmedicated patients to study the effect of phenobarbital and phenytoin. The short-term effects of phenobarbital included reduction of WASO and REM sleep and increase of stage 2 NREM sleep. There was no relationship with the serum drug levels.

Manni et al. [375] performed an objective and subjective assessment of daytime sleepiness using the multiple sleep latency test (MSLT), clinical, and psychometric data on 10 patients with generalized epilepsy treated chronically with phenobarbital, 10 patients with cryptogenic partial epilepsy treated with carbamazepine, and 10 healthy controls. These authors found that patients on phenobarbital had a greater daytime sleep tendency and performed worse on the digit symbol substitution test compared to the other two groups. In a similarly designed study [376], they noted a shorter mean sleep latency in patients on phenobarbital compared with patients on sodium valproate and controls. Psychomotor functioning was also poor in patients on phenobarbital compared to controls, whereas patients on valproate had

Table 44.1 Effects of antiepileptic drugs (AEDs) on sleep architecture*

AEDs	SE	SI. LAT	Stage 1	Stage 2	SWS	REM	WASO

some attentional impairment and a tendency toward longer motor movement time. However, they did not find a correlation between the assessed parameters and serum drug concentrations.

Phenytoin generally causes a reduction of sleep-onset latency, REM sleep, and slow-wave sleep as well as sleep efficiency, but causes increased stages 1 and 2 NREM sleep [351, 371]. Phenytoin also increases daytime sleepiness. The short-term effects of phenytoin included no change in the percentage of WASO, a decrease in NREM sleep stages 1 and 2, and an increase in sleep stages 3 and 4; there was no change in REM sleep and no relationship with the serum drug levels. Wolf et al. [373] studied the long-term effects of phenytoin in 12 patients. The long-term effects were in general a reversal of the short-term effects and consisted of an increase of NREM sleep stages 1 and 2 with a decrease of slow-wave sleep. REM sleep, however, remained unaltered.

Carbamazepine has been studied fairly extensively in various studies. This AED is found to increase sleep efficiency and slow-wave sleep but decrease REM sleep in healthy subjects [374] and transiently decrease REM in epileptics. Baldy-Moulinier [323] reported normalization of disturbed sleep pattern in temporal lobe epileptics after carbamazepine treatment. After acute carbamazepine administration in cats, Gigli et al. [377] reported an increase of NREM stage 1 sleep and total sleep time, a decrease of REM sleep, and reduced duration of awakenings. Some studies examined the effects of carbamazepine in treated versus untreated epileptic patients [334, 342, 343]. Studies in healthy normal subjects showed that carbamazepine can increase slow-wave sleep, decrease REM sleep, and consolidate sleep [378–380]. In some studies, the EEG effects in epileptics have been contradictory. For example, Legros and Bazil [371] failed to find any EEG effects during sleep in 10 epileptics treated with long-term carbamazepine, but Bell et al. [369] found increased slow-wave sleep and decreased stage 2 NREM sleep with carbamazepine monotherapy.

There have been very limited studies to describe effects of primidone on the sleep EEG. In one study using 30 healthy subjects, a single dose of primidone (250 mg) resulted in an increase of slow-wave sleep and a reduction in REM sleep [381]. Treating epileptic patients with 750 mg primidone daily for 3 months resulted in reduced sleep-onset latency and REM density but not percentage [382].

The effects of ethosuximide included disrupted sleep, increased sleep latency, increased stage 1 sleep, decreased slow-wave sleep, and increased REM sleep and awakenings [373, 383].

Valproic acid in general has minimal effects on sleep architecture in patients with epilepsy [368, 373–375, 384]. Findji and Catani [384] reported an improvement of sleep organization and increase of slow-wave sleep in epileptic children after treatment with valproic acid. At higher doses, however, Harding et al. [385] observed a decrease of delta and REM sleep.

The benzodiazepine group of drugs is generally used for status epilepticus (e.g., lorazepam, diazepam, and midazolam), but sometimes clonazepam is used in some

drug-resistant seizures and certain types of seizures (e.g., myoclonic seizures and Lennox–Gastaut syndrome). These drugs generally cause decreased sleep efficiency, sleep-onset latency, stage 1 NREM and slow-wave sleep, and arousals [325, 368, 386].

Newer Antiepileptic Drugs (AEDs)

Most of the traditional AEDs adversely affect nocturnal sleep, sleep architecture, and daytime vigilance, but newer AEDs in limited studies have shown minor and even positive effects [387].

Several newer AEDs have come onto the market to treat patients with seizure disorders; most of them have been indicated to use as add-on drugs, but some are being used as primary AEDs. These drugs have not been studied extensively to determine their effects on sleep architecture.

Felbamate is one of the earlier drugs in the newer generation but has largely been discontinued because of severe hepatotoxicity. This drug has been reported to cause insomnia in epileptic patients [363, 388].

Gabapentin was originally developed to treat seizure disorder, but later was found to be useful in many other conditions, such as neuropathic pain and restless legs syndrome/periodic limb movements in sleep. In healthy subjects, gabapentin increases slow-wave sleep [382, 389, 390]. Placidi et al. [391] studied the effects of long-term gabapentin treatment on nocturnal sleep in drug-resistant epileptics and observed an increase in slow-wave and REM sleep, and a reduction of arousals and stage 1 NREM sleep.

Lamotrigine has minimal effects on sleep in general [351, 371]. Lamotrigine may cause increased REM sleep and decreased slow-wave sleep [374]. Sadler [361] reported insomnia (difficulty initiating and maintaining sleep shortly after administration of the drug) requiring reduction in dosage or discontinuation of the drug in over 6 % of 109 patients treated with lamotrigine. This finding, however, was contradicted by Foldvary et al. [362], who did not find any insomnia in any of 10 adult patients with focal epilepsy on lamotrigine treatment.

Levetiracetam in general has minimal effect on sleep architecture in normal volunteers. Bell et al. [369] studied levetiracetam in normal volunteers and patients with epilepsy in a double-blind, placebo-controlled study. They found increased stage 2 NREM sleep in both epileptics and controls, and increased REM sleep latency only in the healthy subjects and decreased slow-wave sleep in patients. In a double-blind, crossover, placebo-controlled study in 14 healthy volunteers using PSG and the MSLT after oral administration of levetiracetam up to 2000 mg/day or placebo for 3 weeks, Cicolin et al. [392] found increased total sleep time and sleep efficiency and decreased WASO. MSLT findings did not differ between the two groups. The authors concluded that levetiracetam in healthy volunteers consolidated sleep without causing any daytime sleepiness.

Oxcarbazepine has not been adequately studied but has been noted to cause excessive sleepiness [346].

Pregabalin is a more recent AED and has been studied in a limited manner. Hindmarch et al. [393] studied 24 healthy volunteers and measured sleep objectively using PSG and subjectively using a questionnaire. Compared with the placebo, pregabalin significantly increased slow-wave sleep and reduced sleep-onset latency and REM sleep percentage. Subjective evaluation showed significant improvement in sleep quality, but ratings of behavior following awakening were impaired.

Tiagabine, a selective GABA reuptake inhibitor, has been used for partial and secondary generalized seizures. In healthy elderly subjects, tiagabine significantly increased slow-wave sleep and sleep efficiency [394, 395]. In patients with primary insomnia, tiagabine increased slow-wave sleep and reduced WASO in a dose-dependent manner [396, 397].

Topiramate, tiagabine, zonisamide, and vigabatrin, which are used in some partial secondary generalized seizures, especially in those not responding to other AEDs, have not been adequately tested to study the effects of these drugs on sleep architecture in epileptic patients. Bonanni et al. [370], following topiramate monotherapy in an open-label trial with 14 epileptics, found no difference in sleep architecture and daytime sleepiness as measured objectively by multiple sleep latency testing. Bonanni et al. [398] studied the effects of carbamazepine and vigabatrin on daytime sleepiness in patients with partial epilepsy by measuring with MSLT and overnight PSG. The results suggested that vigabatrin did not significantly affect sleep architecture in their patients with epilepsy. Vigabatrin treatment in medically refractory epilepsy, however, causes weight gain, making these patients susceptible to developing OSAS [399].

Lacosamide, a later generation novel AED used as an add-on therapy, has been shown in a small group of drug-resistant epileptics to have no detrimental effects on sleep quality and quantitative EEG characteristics [387]. The other more recently approved AEDs have not been studied to see the effects on sleep architecture.

Nonpharmacologic Treatment

Vagus nerve stimulation has been used with some success in patients with refractory or intractable seizure disorder. However, in addition to improving the seizure state and daytime alertness, vagus nerve stimulation caused sleep disordered breathing in some patients [400–403].

Summary

A survey of the literature thus reveals that we need more studies to understand the interactions among anticonvulsants, sleep, and epilepsy. Based on the literature and their own investigations, Declerck and Wauquier [368] emphasized the importance of the use and development of automatic methods to assess antiepileptic-induced sleep changes in patients with epilepsy. It may be that the anticonvulsants disrupt the circadian distribution of interictal discharges during the night, and this may have practical relevance in terms of treatment.

Sleep, Epilepsy, and Autonomic Dysfunction

There are a number of autonomic nervous system (ANS) changes, particularly involving the respiratory and cardiovascular systems, during sleep [404] (see also Chap. 11). Furthermore, epilepsy itself may cause changes in the ANS, and thus, there is a close interrelationship between sleep, epilepsy, and the ANS.

ANS changes involving the cardiovascular system during sleep consist of reduction of blood pressure and heart rate during NREM sleep and wide fluctuation of these during REM sleep [404]. Respiration shows considerable changes during NREM and in particular during REM sleep (see Chap. 11). Sleep adversely affects breathing, even in normal individuals, and often triggers seizures in epileptic patients. Knowledge of the central autonomic network makes it easy to understand why this relationship between ANS, sleep, circulation, and respiration exists [405, 406]. The nucleus tractus solitarius, a structure in the region of the medulla important for sleep and for cardiovascular and respiratory regulation, is reciprocally connected with the limbic-hypothalamic and other forebrain structures [405, 406] (see also Chap. 11). This connection explains why epileptic seizures triggered by the limbic-hypothalamic or other forebrain structures may interact with the cardiovascular and respiratory regulation during sleep. Respiratory dysrhythmia during generalized seizures, after seizure discharges in the limbic system, and after experimental stimulation of the limbic areas is documented [407]. The coexistence of sleep apnea and epilepsy, once thought to be rare, is increasingly recognized (see later).

It is well known that in generalized tonic-clonic seizures and CPS, transient abnormalities of ANS functions may occur and may consist of alterations in cardiac rhythm, blood pressure, and respiration [408]. In addition, it is well known that epileptiform discharges without any clinical accompaniments may produce a variety of autonomic abnormalities. In patients after electroconvulsive [409] treatment and in animal models after pentylenetetrazol injection [410], there are intense changes in blood pressure and cardiac rhythms. Similar changes have been observed in patients with focal temporal lobe discharges. Furthermore, the phenomenon of unexpected sudden death in patients with epilepsy [411, 412] may account for up to 15 % of deaths in epileptic patients and may be the result of some unexplained autonomic dysfunction affecting the cardiac rhythm (see further on).

Epilepsy and Sleep Apnea

The association between epilepsy and sleep apnea was once thought to be a rare combination; however, in 1981, Wyler and Weymuller [413] described a 26-year-old man with medically intractable CPS and upper airway OSA, whose seizure control improved after treatment of sleep apnea with tracheostomy. Since then, sleep apnea has been increasingly recognized as a comorbid condition of patients with epilepsy. Sleep, epilepsy, and breathing are all interrelated. Both sleep and seizures may adversely affect breathing, and disordered breathing during sleep may in turn adversely affect seizures. Also, while the cause of sudden unexpected death in epilepsy is not definitely known, it has been suggested that the combination of postictal central apnea and neurogenic pulmonary edema may be responsible [414]. There is sufficient theoretical justification for why epilepsy and sleep apnea may coexist. Sleep adversely affects breathing even in normal individuals; for example, sleep is associated with increased upper airway resistance, mild alveolar hypoventilation, mild hypoxemia and hypercapnia, impaired central chemosensitivity with decreased hypoxic and hypercapnic ventilatory responses, and decreased number of functioning medullary respiratory neurons (see Chap. 11). These adverse effects may cause sleep apnea or sleep-disordered breathing (SDB) in susceptible individuals such as patients with seizures. It is well known that sleep and sleep deprivation may trigger seizures in patients at risk.

There is clinical and experimental evidence to suggest that generalized seizures as well as seizure discharges in the limbic-hypothalamic system may cause SDB [405, 407]. Reciprocal connections between central respiratory neurons in the medulla (in the region of nucleus tractus solitarius) and the limbic-hypothalamic and other forebrain structures may explain why epileptic seizures triggered during sleep by the discharges in the limbic-hypothalamic and orbitofrontal regions may interfere with respiratory regulation, causing SDB [405]. Experimental stimulation in animals in the limbic area, including the orbitofrontal cortex, may cause respiratory dysrhythmia [407]. Stimulation of the limbic areas in humans, including that during depth recording, may cause SDB [407]. Furthermore, severe hypoxemia during prolonged seizure or status epilepticus may cause SDB. It

should also be remembered that apnea causing severe hypoxemia may trigger seizures in susceptible individuals during prolonged apnea. Sleep apnea, in most cases, however, does not trigger seizures in those who do not have a propensity toward epilepsy. Recurrent apneas during the night in patients with sleep apnea syndrome cause sleep fragmentation and sleep deprivation, which may trigger seizures in susceptible individuals. Other factors that may trigger seizures associated with sleep apnea include decreased cerebral blood flow in epileptics due to cardiac arrhythmias and decreased cardiac output. Some other factors contributing to sleep apnea in seizure patients include weight gain related to AEDs (e.g., valproate, carbamazepine, gabapentin, pregabalin, and vigabatrin) [374, 399, 415], alteration of upper airway muscle tone by AEDs, or endocrine disorders caused by AEDs.

The frequently quoted figure for the prevalence of sleep apnea from the Wisconsin Cohort Study by Young et al. [416] is 4 % in men and 2 % in women. However, the more recent study from the Wisconsin cohort data listed prevalence figures of moderate-to-severe OSAS (defining by an apnea-hypopnea index of >15 events per hour, all accompanied by excessive daytime sleepiness) at 10 % in men and 3 % in women among 30–49 years but 17 % in men and 9 % in women among 50–70 years [417]. An estimated prevalence of epilepsy in the general population is approximately 1 % [418]. Therefore, by chance association, some patients may have both sleep apnea and epilepsy. A perusal of the literature reveals a few scattered case reports and letters to the editor to document the coexistence of sleep apnea and epilepsy. Wyler and Weymuller [413] were the first to document improvement of both sleep apnea and seizures after tracheostomy treatment for OSAS. Daytime PSG recordings by Chokroverty et al. [419] documented obstructive, mixed, and central apneas in eight patients with partial complex seizures with secondary generalization. In a retrospective survey from a tertiary care sleep medicine division, we reported a prevalence of approximately 6 % of sleep apnea in epileptics [420]. This survey almost certainly underestimated the prevalence of seizure in sleep apnea patients, because the diagnosis was made on the basis of questionnaire only and not by direct interview. Many patients did not answer all relevant questions. Our survey, however, is somewhat similar to the retrospective survey by Sonka et al. [421] that included 480 adult patients with sleep apnea syndrome, 19 of whom (4 %) had a history of seizures. Devinsky et al. [422] reported an improvement in seizure frequency and severity in six of seven patients with refractory partial epilepsy and sleep apnea after treatment. Vaughn et al. [423] identified 10 patients with recurrent seizures and OSA. Following continuous positive airway pressure (CPAP) and positional therapy, there was considerable reduction of seizure frequency. Koh et al. [424] reported improvement of seizure control after treatment of sleep apnea in children with neurodevelopmental disorders and intractable epilepsy. Malow et al. [425] documented OSA in one-third of 39 patients with medically refractory epilepsy undergoing PSG prior to epilepsy surgery. They concluded that sleep apnea is common among men, older subjects, and those with nocturnal seizures.

In a retrospective review of 63 adult epilepsy patients who had PSGs, Malow et al. [426] identified 45 (71 %) with obstructive sleep apnea. Twenty-eight patients with OSA were treated with CPAP, and most reported improvement in seizure control. Subsequent studies by Malow et al. [415, 427] confirmed this improvement of OSA in epileptics after CPAP therapy. Chihorek et al. [415] provided evidence that OSA is a risk factor for epilepsy in older adults and its treatment by CPAP may improve seizure control in this population. The limitation of this study is the small number of patients in each group (11 with late-onset or worsening seizures and 10 seizure-free individuals over the age of 50 years), but this is an important study that should encourage larger prospective studies in the future documenting increasing association of OSA with epilepsy and the effect of treating OSA. In a more recent study, Malow et al. [427] randomized 22 adult subjects with medically refractory epilepsy and coexisting OSA to therapeutic CPAP therapy and 13 similar subjects to sham CPAP. Based on their observations of a significant reduction of the apnea-hypopnea index in the therapeutic group as compared to the sham group, the authors concluded that this pilot study provided valuable information for designing a comprehensive trial to test the hypothesis that treating OSA in epileptics would improve seizure control. Recent results from Cleveland Clinic Group of treating OSA in epileptics with CPAP titration reinforced this conclusion [428]. These authors studied 76 patients with epilepsy and OSA, 43 of which had CPAP titration but 33 were not on CPAP treatment (declined or could not tolerate). The percentage with 50 % or more seizure reduction and the mean percentage of seizure reduction were greater in those on CPAP than in those not on therapy. The literature survey thus gives a high prevalence of sleep apnea in epilepsy and documented improvement of seizure control following effective treatment of sleep apnea [357, 415, 427–433].

SUDEP and Sleep

In epileptic patients, especially in those with pharmacoresistant epilepsy, the risk of sudden unexpected death (SUDEP) is 24–40 times higher with respect to the general population [434, 435]. SUDEP is considered to be the result of a peri-ictal concurrence of a number of predisposing and

precipitating factors [436]; nevertheless, SUDEP is primarily a sleep-related phenomenon, and sleep-related seizures seem to be an independent risk factor for SUDEP [437]. Autonomic factors such as cardiac or respiratory dysfunctions, or both, have been implicated in SUDEP; however, conclusive evidence on their role is still lacking and how they might be related to one another or to an epileptic seizure, eventually leading to sudden death, has not been elucidated yet [438].

Different factors could explain the higher susceptibility to death during sleep-related seizures [436–440]: (a) Seizure-related increase in heart rate is especially evident when seizures occur during sleep and in clusters [439], (b) seizures during sleep could create an extreme autonomic imbalance with a sudden switch from a predominant vagal tone to an extreme sympathetic tone [438], (c) the sympathetic overstimulation due to an abrupt withdrawal of AEDs is especially evident during sleep [440], (d) a comorbidity with obstructive sleep apneas could further increase seizure-related arrhythmias and respiratory complications [439, 441], and (e) the prone position might increase the risk of a mechanical obstruction of the nose and mouth [442].

Utility of Sleep in the Diagnosis of Epilepsy

Utility of sleep in the diagnosis of epilepsy was well established after the landmark paper by Gibbs and Gibbs [12] in 1947 showing activation of epileptiform discharges in the sleep EEG. For the diagnosis of epilepsy, the following sleep recordings are recommended: (1) a standard sleep EEG recording, (2) an EEG recording after sleep deprivation, (3) an all-night PSG study, (4) a video-PSG study, (5) an MSLT, and (6) a 24-h ambulatory EEG and sleep recording. Box 44.10 outlines a suggested protocol for EEG recording in patients suspected to have epilepsy.

Box 44.10 Suggested Protocol for Electroencephalography Recording in Patients Suspected of Epilepsy

1. Routine EEG recording with hyperventilation and photic stimulation.
2. If negative for interictal epileptiform activity (IEA), EEG with sleep (natural or induced) recording.
3. If negative for IEA, EEG study with partial (at least 4 h) or total (24 h) sleep deprivation.
4. If negative for IEA after three to four EEGs, prolonged (4- to 6-h) daytime EEG with sleep recording.
5. If negative for IEA, overnight polysomnographic (PSG) study, preferably video-PSG study for electroclinical correlation. Change the monitor speed to 30 mm/s instead of the usual sleep recording speed of 10 mm/s during interpretation of the recording. Use appropriately devised seizure montage with full complement of electrodes (see Chaps. 17 and 18) or special electrode placements (e.g., T1 and T2 electrodes).
6. If still negative for IEA, ambulatory 24-h EEG recording.
7. If still negative for IEA, long-term video-EEG monitoring for 24–72 h or longer if necessary.
8. Finally, in some patients, invasive intracranial EEG monitoring using subdural grids, strips, or depth electrodes may be necessary for localizing and lateralizing a focus.

Sleep EEG Recording and Sleep Deprivation Study

The usefulness of sleep EEG recording and sleep deprivation is discussed in detail in the previous paragraphs. For such recordings, a full complement of electrodes should be used and various montages have been suggested (see Chap. 18). Broughton [19] listed some of the main indications and objectives of sleep EEG recording as follows: (1) normal EEGs in patients suspected of epilepsy to establish the diagnosis of true epilepsy; (2) normal waking EEGs in patients with known epilepsy to clarify the type of epilepsy; (3) patients with febrile convulsions showing normal waking EEGs; (4) assessment of the familial predisposition to epilepsy in family members; and (5) assessment of the degree of drug control, for example, in patients with hypsarrhythmia.

Interictal EEG findings can help in the confirmation of the diagnosis of epilepsy, in the classification of seizures, and in the identification of specific epileptic syndromes. Epilepsy is a clinical diagnosis, and a single normal EEG in a patient with suspected epilepsy does not exclude the diagnosis of true epilepsy. The reason for a normal EEG in such a patient may be a sampling problem or the fact that the epileptic foci are located in a deeper brain region (e.g., orbitofrontal and medial interhemispheric region). Surface electrodes may not pick up these discharges located in a deeper site. A third reason may be that the EEG recording was obtained without the benefit of sleep or sleep deprivation. In such patients, the protocol suggested in Box 43.10 should be followed. The EEG findings may help in the classification of seizures. Bilateral synchronous spikes or spike-and-wave complexes in the interictal EEGs suggest primary generalized epilepsy. Particular characteristics of generalized epileptiform discharges may help in diagnosing certain epileptic syndromes (e.g., slow spike-and-wave discharges seen synchronously and symmetrically in the Lennox–Gastaut syndrome;

multiple transient spike-and-wave discharges in JME); focal spikes present consistently in one location may correlate with partial epilepsy.

All-Night Polysomnographic Recording

Broughton [19] listed the following important indications to perform all-night PSG study:

1. To differentiate between epileptic and nonepileptic nocturnal events (e.g., pseudo-seizures, syncope due to cardiac arrhythmias, and parasomnias),
2. To clarify the classification in patients with known sleep epilepsies,
3. To diagnose CSWS,
4. To diagnose benign epilepsy of childhood with rolandic spikes,
5. To lateralize or localize the principal focus during REM sleep by the use of stereo-EEG (this may be important before surgical treatment is considered),
6. To unmask the primary focus in a patient with secondary bilateral synchrony during REM sleep by causing suppression of the generalized discharges,
7. To reveal abnormalities in patients with hypsarrhythmia, for whom waking EEGs rarely may be normal but sleep EEGs may, and to clarify focal abnormalities in such patients,
8. To diagnose tonic seizures in patients with Lennox–Gastaut syndrome,
9. To diagnose sleep apnea or other primary sleep disorders, which may be mistaken for or associated with epilepsy,
10. To investigate patients complaining of excessive daytime somnolence that cannot be explained by their anticonvulsant medication.

Two additional indications are (1) to document cardiac arrhythmias that may arise during sleep and may be confused with, or even give rise to, seizures and (2) to document sleep disturbances and sleep architecture in epileptics so that these disturbances may be treated to prevent chronic sleep deprivation, which may in turn have deleterious effects on epilepsy itself. In suspected seizure disorders, all-night PSG recording should include multiple EEG leads and special montages. Figure 44.10 is a representative sample showing upper airway OSA in a patient with CPS and sleep apnea.

Video-Polysomnographic Study

The value of video-PSG for the diagnosis of parasomnias and seizure disorders has been well documented by Aldrich and Jahnke [443] (see also Chap. 26). Figure 44.11 is a PSG showing the onset of a partial seizure recorded at 10 and 30 mm/s paper speed.

Multiple Sleep Latency Test

The MSLT [444, 445] is indicated in patients complaining of EDS that is not explained on the basis of anticonvulsant medication. Seizure during sleep may lead to repeated arousals, causing EDS with further increase of seizure frequency, thus creating a vicious cycle. Sometimes, narcolepsy may be mistaken for epilepsy, and an important diagnostic test for narcolepsy is the MSLT. Finally, as discussed earlier, patients with epilepsy may have sleep apnea, which can be diagnosed by showing reduced sleep-onset latency on the MSLT that is causing EDS.

Ambulatory 24-h EEG Recording and Sleep Scoring

Ambulatory 24-h EEG recording and sleep scoring allow for recording of the EEG discharges throughout the day to understand the circadian and ultradian rhythmicity and the effects of sleep on the interictal discharges. The question of whether epilepsy manifests biorhythmicity was discussed earlier. Technical problems associated with unattended recordings, however, are serious limitations. Ambulatory EEG recording permits 24 h of continuous recording in patient's normal day-to-day environment. This type of recording is valuable in documenting interictal epileptiform discharges in the presence of normal routine EEGs. The presence of movement and muscle artifacts and lack of video documentation of the behavior are distinct disadvantages of ambulatory recording.

Long-Term Video-EEG Monitoring

In some patients, simultaneous video and EEG monitoring in the inpatient unit for several days is necessary to document an ictal epileptiform discharge and its characteristic behavioral correlate, thus providing indisputable evidence of a true

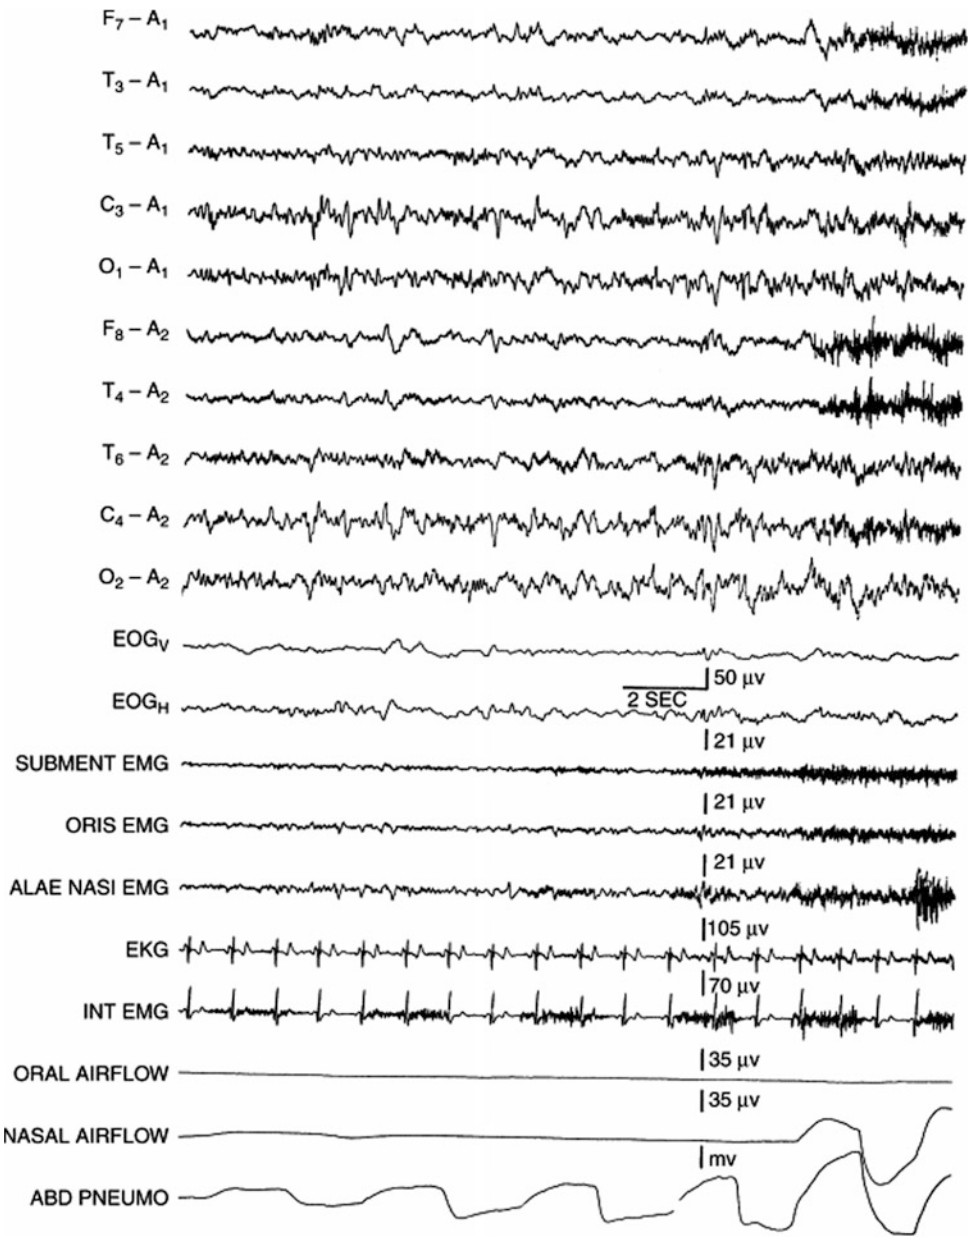

Fig. 44.10 Polysomnographic recording in a patient with partial complex seizure and sleep apnea showing EEG (top 10 channels); vertical (EOG_V) and horizontal (EOG_H) electrooculograms; submental (*SUBMENT*), orbicularis oris (*ORIS*), alae nasi, and intercostal (*INT*) electromyograms (*EMG*); electrocardiogram (*EKG*); oral and nasal airflow; and abdominal pneumogram (*ABD PNEUMO*). Note upper airway obstructive apnea during NREM stage 2 sleep. No epileptiform discharges are seen in the EEG during the episodes. Paper speed is 15 mm/s

seizure episode. Documentation of an ictal epileptiform discharge during long-term video-EEG monitoring permits unambiguous evidence of the presence of true seizure. Persistent normal background EEG activity (alpha rhythm in an adult) and absence of postictal slowing after an apparent seizure episode are inconsistent with a diagnosis of true seizure.

Intracranial Recordings

When the results of EEG, including long-term monitoring and neuroimaging (see later), are discordant in localizing the focus, drug-resistant patients with focal epilepsy should be referred to a specialized epilepsy surgery center for evaluating the possibility of an intracerebral electrophysiologic investigation. Different tools are used to record results of intracranial EEG procedures, depending on a given center's philosophy. The most widely used devices are subdural electrodes arranged in strips or grids according to each patient's needs [446]. They allow an extensive coverage of the cortical surface, but sampling of deep-seated structures is prevented. Intracerebral electrodes are used to record from lesions in deep structures (amygdala, hippocampus, cortex within sulci, and on the mesial portion of the hemispheres) [447], and they provide information from a limited volume of tissue. Other less invasive techniques involve epidural [448] and foramen ovale electrodes [449].

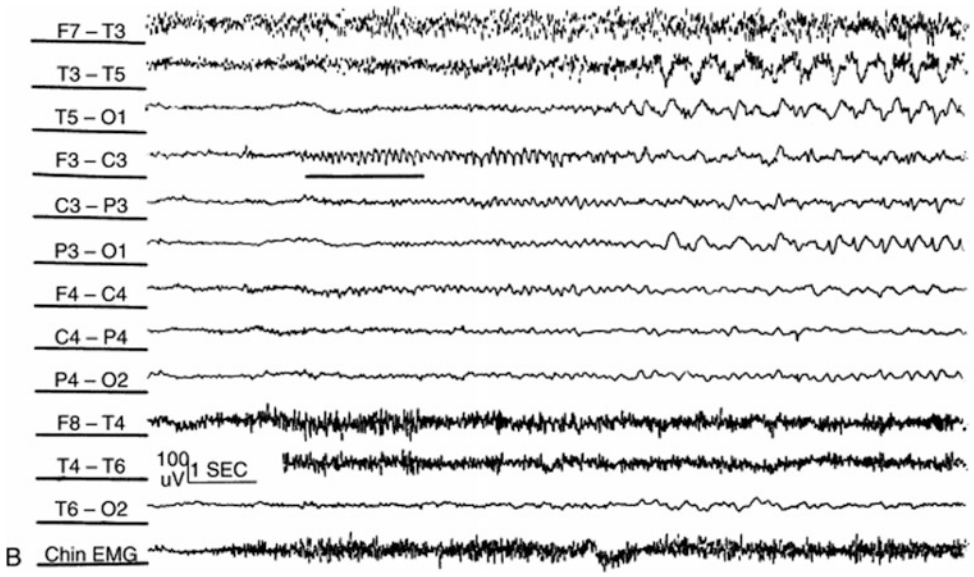

Fig. 44.11 A portion of a PSG recording using 12 channels of EEG showing the onset of a partial seizure recorded at 10 mm/s paper speed. The *underlined* activity represents rhythmic ictal discharges beginning over the left hemisphere (F3-C3) and spreading rapidly to the right hemisphere and is accompanied by clinical seizure. Although at 10 mm/s paper speed (**a**), the *underlined* activity superficially resembles muscle artifacts, at 30 mm/s paper speed (**b**), it becomes obvious that this activity is the beginning of the rhythmic epileptiform discharges in the EEG. Reproduced with the permission from Aldrich and Jahnke [443]

Neuroimaging

Neuroimaging studies are indispensable in investigating the presence of structural lesions that may serve as epileptogenic foci. Anatomic studies (computed tomography and magnetic resonance imaging of the brain) are usually performed in all adults with new-onset seizures and in children without any characteristic epileptic syndromes to identify any structural brain disorders. Specialty magnetic resonance imaging of the brain is more sensitive than computed tomography, and that is the preferred procedure.

Functional or physiologic studies (single-photon-emission computed tomography and positron-emission tomography) may be able to identify seizure foci by revealing areas of cerebral hypermetabolism or hyperperfusion during an ictal episode and areas of hypometabolism during the interictal period.

Practical Relevance to Understanding the Relationship Between Sleep and Epilepsy

An understanding of the relationship between sleep and epilepsy is important for three main purposes:

1. Such an understanding can aid in the diagnosis of seizure and in differential diagnosis between epileptic and nonepileptic events and among different types of seizures.
2. An understanding of this relationship can increase the understanding of the pathogenesis of triggering mechanisms of seizures during sleep and the mechanism and nature of sleep disturbances induced by epilepsy.
3. Therapeutic manipulation can be guided by the knowledge obtained through an understanding of the relationship between epilepsy and sleep. It may be possible to adjust the timing of the drug dose, but this really has not been useful from a practical point of view. An understanding of the biorhythmicity and the relationship between sleep and epilepsy may be important to choosing the type of anticonvulsant, so that one may avoid those with marked hypnotic effects in nocturnal seizure patients and use drugs with less sedative effects (e.g., carbamazepine, valproic acid, and lamotrigine). Finally, one may manipulate sleep stages—that is, give anticonvulsants that may increase REM or NREM stages 3 and 4—to reduce the ictal or interictal discharges.

Finally, as Broughton [19] stated, it may be necessary to put some patients on a strict program of sleep hygiene (see Box 26.17 in Chap. 26) or to treat the sleep disorders with pharmacologic agents because of the deleterious effects the epilepsy has on sleep and sleep on epilepsy. Such patients may be advised to avoid sleep deprivation, alcohol in the evening, and late evening exercise and to maintain regular sleep and waking hours. Broughton [19] suggested that the improvement of nocturnal sleep after such a regimen may be

associated with definite reduction of seizure frequency and overall improvement in general well-being.

Dreaming in Neurological Disorders

45

Mark Solms, Susan Malcolm-Smith, and Danyal Wainstein

Background

Historically, there has been little systematic investigation of changes in dreaming due to neurological damage, despite numerous clinical reports of marked abnormalities. Accordingly, the subject remains poorly understood. This reflects the lack of development in the field of dream research itself: an understanding of the brain mechanisms of dreaming has lagged behind that of other mental functions. There are two main reasons for this. First, unlike most mental functions that were the focus of nineteenth and twentieth century behavioural neuroscience, dreaming is almost entirely subjective. The observable data are retrospective, single-witness qualitative descriptions, only indirectly related to the phenomenon of dreaming itself. This poses special methodological problems.

The second reason for the undeveloped state of this field is closely related to the first. Researchers seeking an objective approach to dreaming eagerly alighted on a physiological state that correlates closely with it—namely rapid-eye-movement (REM) sleep [1–4]. This physiological state was then conflated with dreaming itself, resulting in the development of neuropsychological models of dreaming which were in fact models of REM sleep [5]. This conflation was compounded by the fact that the models were empirically grounded in animal studies (where dream reports are of course precluded) rather than human lesion studies of the kind that informed models of most other mental functions. When the conventional human lesion studies were belatedly performed, it became apparent that dreaming and REM sleep are in fact doubly dissociable states [6].

A traditional neuropsychology or behavioural neurology grounded in the systematic application of clinico-anatomical correlation—which was widely applied to other mental functions since the mid-nineteenth century—is little more than 20 years old in the case of dreaming. Incidental reports of changes in dreaming associated with focal cerebral damage did nevertheless accumulate in the literature over a long period, albeit without any attempt to synthesise the scattered observations into a coherent picture. Systematic clinico-anatomical group studies were first published in the 1980s [7–9]. The available evidence was not comprehensively reviewed before the 1990s [10–12]. The clinico-anatomical studies have since been complemented by a slew of functional brain imaging studies, with strongly convergent findings [13]. Rigorous pharmacological probes of the neurochemistry of dreaming (as opposed to REM sleep) have not yet been conducted [14].

An understanding of the brain mechanisms of dreaming is now beginning to emerge. Systematic observation of abnormalities of dreaming in neurological disease has contributed fundamentally to this emerging picture. The bewildering array of abnormalities may perhaps best be grouped under two headings: (1) deficits of dreaming and (2) excesses of dreaming.

Deficits of Dreaming

The earliest clinical observations of changes in dreaming with neurological disease concerned *cessation* of dreaming (or cessation of aspects of dreaming). The terms 'Charcot–Wilbrand syndrome' and 'anoneira' have been used to describe this abnormality, which is typically (but not exclusively) seen in the acute phase of posterior cortical pathology.

Charcot–Wilbrand Syndrome

The concept of this syndrome, based on two case reports by Charcot [15, 16] and Wilbrand [17, 18] was first articulated by Pötzl [19]. He defined the syndrome as 'mind-blindness with disturbance of optic imagination' (p. 306). Nielsen [20]

M. Solms (✉) · S. Malcolm-Smith · D. Wainstein

e-mail: Mark.solms@uct.ac.za

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_45

defined it as 'visual agnosia plus loss of the ability to revisualise' (p. 74). Critchley's [21] widely cited definition was:

> a patient loses the power to conjure up visual images or memories, and furthermore, ceases to dream during his sleeping hours. (p. 311)

Critchley described prosopagnosia and topographical agnosia or topographical amnesia as associated features. The localisation of the lesion producing this syndrome was never precisely defined, but the occipital cortex was implicated by most early authors (especially area 19)—usually bilaterally. The Charcot–Wilbrand syndrome remained in late twentieth century nosographical usage, although the condition was (until recently) considered rare. A reasonably modern definition of the syndrome reads:

> the association of loss of the ability to conjure up visual images or memories and the loss of dreaming … [indicating] a lesion in an acute phase affecting the posterior regions. (Murri et al. 1984, p. 185) [8]

Deficient revisualisation (called 'irreminiscence' in the nomenclature of Nielsen [20]) was the fundamental deficit in almost all definitions of the syndrome. Cessation of dreaming ('or at least, an alteration in the vivid visual component of the dreaming state'; Critchley [21], p. 311) was seen as a secondary consequence of the visual imagery deficit. The associated visual agnosias, too, were originally considered to be caused by defective revisualisation, since visual agnosia was classically understood as a loss of 'visual memory images' [21, 22].

Subsequent advances in the agnosia concept, and a misreading of the original case reports, have resulted in considerable nosological confusion regarding this syndrome [12, 23]. It is widely assumed that Wilbrand's case—an elderly female patient with bilateral posterior cerebral artery thrombosis—could not *visualise* familiar places [20, 21, 24, 25]. However the original report stated only that she was unable to *recognise* familiar places. This symptom (which we would today call topographical *agnosia*) was conceptualised, in accordance with classical theory, as a disorder of 'topographical *memory*' [17] (Wilbrand 1887, p. 52, emphasis added). This conceptualisation was then misconstrued by secondary authors as a disorder of topographical *revisualisation*. The original report reveals that Wilbrand's case actually lacked the cardinal feature of the so-called Charcot–Wilbrand syndrome. As the patient herself clearly stated: 'With my eyes shut I see my old Hamburg in front of me again' [15, 16] (Wilbrand 1887, p. 56). Charcot's case [15, 16]—also a probable PCA thrombosis (autopsy findings were lacking)—was quite different. He described a striking absence of visual mental imagery. The Charcot–Wilbrand syndrome is therefore misnamed.

It is also misconceived. Charcot's [15, 16] patient ceased to dream in visual images, but he continued to dream in words. Wilbrand's [17, 18] patient, on the other hand, dreamed 'almost not at all anymore' (p. 54). The original report is ambiguous as to whether Wilbrand's patient merely dreamed infrequently or actually lost the capacity to dream completely (and then gradually recovered it), but either way, there is no question of an isolated loss of *visual* dream imagery, which is what Charcot's patient unequivocally described. The 'Charcot–Wilbrand syndrome' therefore appears to be two different (but related) syndromes, one characterised by loss of *visual* dream imagery and the other by *global* cessation or suppression of dreaming. This distinction is supported by a review of the world literature [12].

Charcot's Variant: Isolated Loss of Visual Dream Imagery

At least 10 case reports of isolated loss of visual dream imagery have been published, together with five further reports of patients who experienced deficits of specific *aspects* of visual dream imagery (e.g., colour, movement, faces). Cessation of visual imagery or aspects thereof results from various pathologies, usually of acute onset (thrombosis, haemorrhage, trauma, CO poisoning) but it has also been described in cases of neoplasm, probable Alzheimer's disease, calossal dysgenesis, and Turner's syndrome). The lesion is typically localized to the mesial occipito-temporal or lateral occipito-parietal regions, and is usually bilateral, but precise localising information is often lacking [12, 15, 25–40].

Defective revisualisation (irreminiscence) is a constant feature in these cases, although it is typically restricted to the disordered aspect of vision (e.g. colour, movement, faces) in cases where the loss of visual dream imagery is partial. This strongly suggests a common underlying image-generation deficit causing the same disorder in both waking and dreaming cognition. Various forms of visual agnosia are commonly associated features, but agnosia is definitely absent in some cases and therefore cannot be considered integral to the syndrome [12].

Most published reports of deficits in visual dream imagery derive from retrospective accounts in a clinical setting. However, the reports have been confirmed directly upon REM awakening in at least three cases [21, 32, 34].

Negative Findings

Notably, modality-specific deficits of dream imagery outside the higher visual sphere have never been demonstrated. Thus, although achromatopsic, akinetopsic, prosopagnosic and hemineglect disorders are duplicated in dreams, cortically blind and hemianopic patients invariably report normal vision (full fields) in their dreams. Moreover, hemiplegic patients experience normal somatomotor and somatosensory functions in their dream imagery (as do acute-phase paraplegic and quadriplegic patients). The same applies to the extrapyramidal movement disorders. Similarly, nonfluent aphasics claim to speak normally in their dreams [12].

Of related interest, perhaps, is the fact that the dreams of patients with substantial impairments of executive function due to dorsolateral prefrontal lesions are indistinguishable from the dreams of controls (Badenhorst and Solms, unpublished observation). These findings point to a differentiated network of forebrain structures involved in dream cognition.

Wilbrand's Variant: Global Loss or Suppression of Dreaming

At least 106 cases of global loss or suppression of dreaming have been reported, excluding leucotomy cases which will be discussed separately (see Solms [12] for a full listing of these cases). A larger number of cases in group studies, for which individual case data were lacking, and where 'not dreaming' was defined in variable ways [7–9] have also been reported.

As with Charcot's variant, global anoneira is typically—but not invariably—associated with acute onset, focal cerebral lesions (thrombosis, haemorrhage and trauma are the most commonly reported pathologies). The first systematic attempt to identify the lesion site responsible for global cessation of dreaming pointed to the inferior parietal lobule [12]. Unilateral lesions of either hemisphere were shown to be commonplace, with no lateralising bias. However, at least two cases have since been reported in which the parietal lobe was apparently spared [41, 42], as indeed it appears to have been in Wilbrand's original case [18]. A re-analysis of Solms' data by Yu [43] revealed that the lesions in his 'parietal' cases almost always extended into adjacent occipito-temporal tissues (especially Brodmann areas 22, 19 and 37). It is therefore still not possible to make a more precise localising statement than the one offered by Murri et al. ([8], p. 185): 'a lesion in an acute phase affecting the posterior regions'.

The reference to an *acute phase* is not superfluous. Solms [12] observed that almost all cases of global anoneira recover the capacity to dream within 12 months. This fact, which suggests diaschetic effects, may help explain the imprecise localisation of the causal lesion.

Of particular clinical interest is Solms' [12] observation that hydrocephalus is associated with cessation of dreaming, which recovers after successful VP shunting. Cessation of dreaming might therefore be used as an indicator of shunt malfunction.

Defective revisualisation (irreminiscence) is a relatively common but by no means invariable feature of these cases. It was over-represented in the earlier case reports for the probable reason that patients were only asked about their dreams once irreminiscence had been established. The more recent cases reported by Solms [12] were part of an unselected clinical series and are therefore more likely to be representative. Global cessation of dreaming (unlike visually deficient dreaming) therefore cannot be reduced to irreminiscence.

Not surprisingly, considering the lesion site, global anoneira is frequently associated with disorders of spatial cognition, including visuospatial short term memory [12]. The lack of association between cessation of dreaming and *long term* memory disorder of any kind excludes the possibility that cessation of dreaming is really a memory disorder—failure to remember dreams as opposed to cessation of dreaming per se [44–46]. This applies also to the various language disorders that were previously thought to explain loss of dreaming [10, 47–50]. In his systematic survey, Solms [12] found no relationship between language disorder of any kind and reported cessation of dreaming.

Retrospective reports of absence of dreaming on morning awakening have repeatedly been confirmed by the REM awakening method [41, 42, 51, 52]. This further supports the assumption that this disorder concerns cessation of dreaming per se, as opposed to loss of *memory* for dreams. Even severe amnesiacs with bilateral hippocampal lesions report dreams on awakening from REM sleep and at sleep onset (Ramachandran 2004 [personal communication]) [53, 54].

Cessation or Suppression of Dreaming Following Prefrontal Leucotomy

In a survey of 200 cases of prefrontal leucotomy, Frank [55] observed that a common result of the procedure was 'a poverty or entire lack of dreams' (p. 508). In a later report on the same series of cases, then comprising more than 300 patients, he confirmed this finding [57]. Replication of Frank's observations findings was forthcoming from other authors [24, 57–60] (Slater cited in Humphreys and Zangwill [61]). Moreover, Jus et al. [57] confirmed the absence of dream reports following prefrontal leucotomy by the REM awakening method.

In apparent contradiction to these reports, however, Humphrey and Zangwill [61], Cathala et al. [7], Murri et al. [8, 9] and Doricchi and Violani [10] all observed a relatively *low* incidence of cessation of dreaming with anterior versus posterior cerebral lesions. The same applies to the observation reported above to the effect that the dreams of frontal patients are indistinguishable from those of controls (Badenhorst and Solms, unpublished observations). This apparent contradiction was resolved when Solms [12] reviewed the lesions in the previously reported cases and described nine new cases with cessation of dreaming following naturally occurring bifrontal lesions. His conclusion was that dreaming was entirely spared with *dorsolateral* prefrontal cortical lesions, and affected only with deep *white matter* lesions in the ventromesial quadrant of the frontal lobes (see Figs. 45.1 and 45.2). The lesion site in his nine cases coincided exactly with the area that was targeted by prefrontal leucotomy: 'a circumscribed lesion just anterior to the frontal horns of the ventricle, in the lower medial quadrant of the frontal lobes' [62] (Walsh 1994, p. 177). A re-analysis of the original data in 35 cases from Solms' [12] series with global cessation of dreaming associated with subcortical lesions revealed that the lesion was located in either the deep frontal white matter (areas F09 and F14 in the classification of Damasio and Damasio [63]; see Fig. 45.3), or the head of the caudate nucleus, or both [64]. The lesion is typically bilateral. Of theoretical importance is the fact that the region defined as 'head of the caudate nucleus' in this study included the nucleus accumbens (which is situated immediately beneath it).

It is noteworthy that the psychotropic medications that replaced prefrontal leucotomy as the treatment of choice for psychotic disorders, block dopamine (DA) transmission in a mesial forebrain pathway that projects primarily to the nucleus accumbens. Probably related to this is the observation that both prefrontal leucotomy in general and cessation of dreaming in particular, due to lesions in this general area, are associated with reduced motivational incentive [12] as indeed are most antipsychotic medications [65]. Also of interest in this connection is the observation by Piehler [59] and Schindler [60] to the effect that early recovery of dreaming after prefrontal leucotomy typically coincided with psychiatric relapse, suggesting that absence of dreaming could serve as an index of the clinical success of the operation. Dreaming is, after all, a psychotic state.

Effects of Pontine Brainstem Lesions

Cessation of dreaming following circumscribed pontine lesions—with or without cessation of REM sleep—has never been demonstrated (see Solms [6, 12] for reviews), despite the longstanding assumption that dreaming is caused by—if not identical with—the cyclical, spontaneous activation of cholinergic (ACh) cells in the mesopontine tegmentum during the REM state, together with reciprocal inhibition of serotonergic (5HT) and noradrenergic (NA) cells in the dorsal raphe and locus coeruleus complex [66, 67]. Consciousness in general is of course frequently compromised by pontine lesions, but at least eight cases with cessation or near-cessation of REM sleep have been reported in which patients were capable of communicating meaningfully about their dreams [68–71]. Indeed, one such patient did actually report loss of dreaming [68], but the lesion—caused by ruptured traumatic aneurysm of the basilar artery—almost certainly extended beyond the pontine brainstem and included the visual–spatial cortical areas discussed above. Even this isolated case therefore does not support the old equation of pontine brainstem mechanisms with dream generation. (The relationship between dreaming and REM sleep is discussed further below.)

Neuroimaging and Transcranial Magnetic Stimulation Studies Related to Dreaming

Neuroimaging studies have determined patterns of regional brain activation and deactivation during REM sleep, the stage of sleep during which dream reports are most frequently obtained [72]. These patterns of activity are highly consistent with those areas of the brain linked with dreaming by the clinical lesions studies reviewed above. Significant increases in regional brain activity have been observed in the basal forebrain and other limbic and paralimbic structures, including the hippocampal complex, the anterior cingulate cortex and the pontine tegmentum, during REM sleep [73–75].

Furthermore, Braun et al. [76] reported a dissociated pattern of activity between visual association areas (extrastriate cortices—fusiform, inferotemporal, and ventral lateral occipital) and primary visual areas (striate cortices) during REM sleep compared with slow-wave sleep. Activation within the visual association cortices was also shown to correlate positively with activity within parahippocampal gyri and contiguous portions of the hippocampus, and with deactivation of dorsolateral and orbital prefrontal association areas. Based on these findings, the authors concluded that 'during REM sleep, the extrastriate cortices and paralimbic areas to which they project may be operating as a closed system, functionally disconnected from frontal regions in which the highest order integration of visual information takes place. Such a dissociation could explain many of the experiential features of dreams' (p. 94). This notion of a closed loop between certain medial forebrain and limbic regions and higher order visual association areas is consistent with Solms's [6, 12] suggestion that dreaming is a

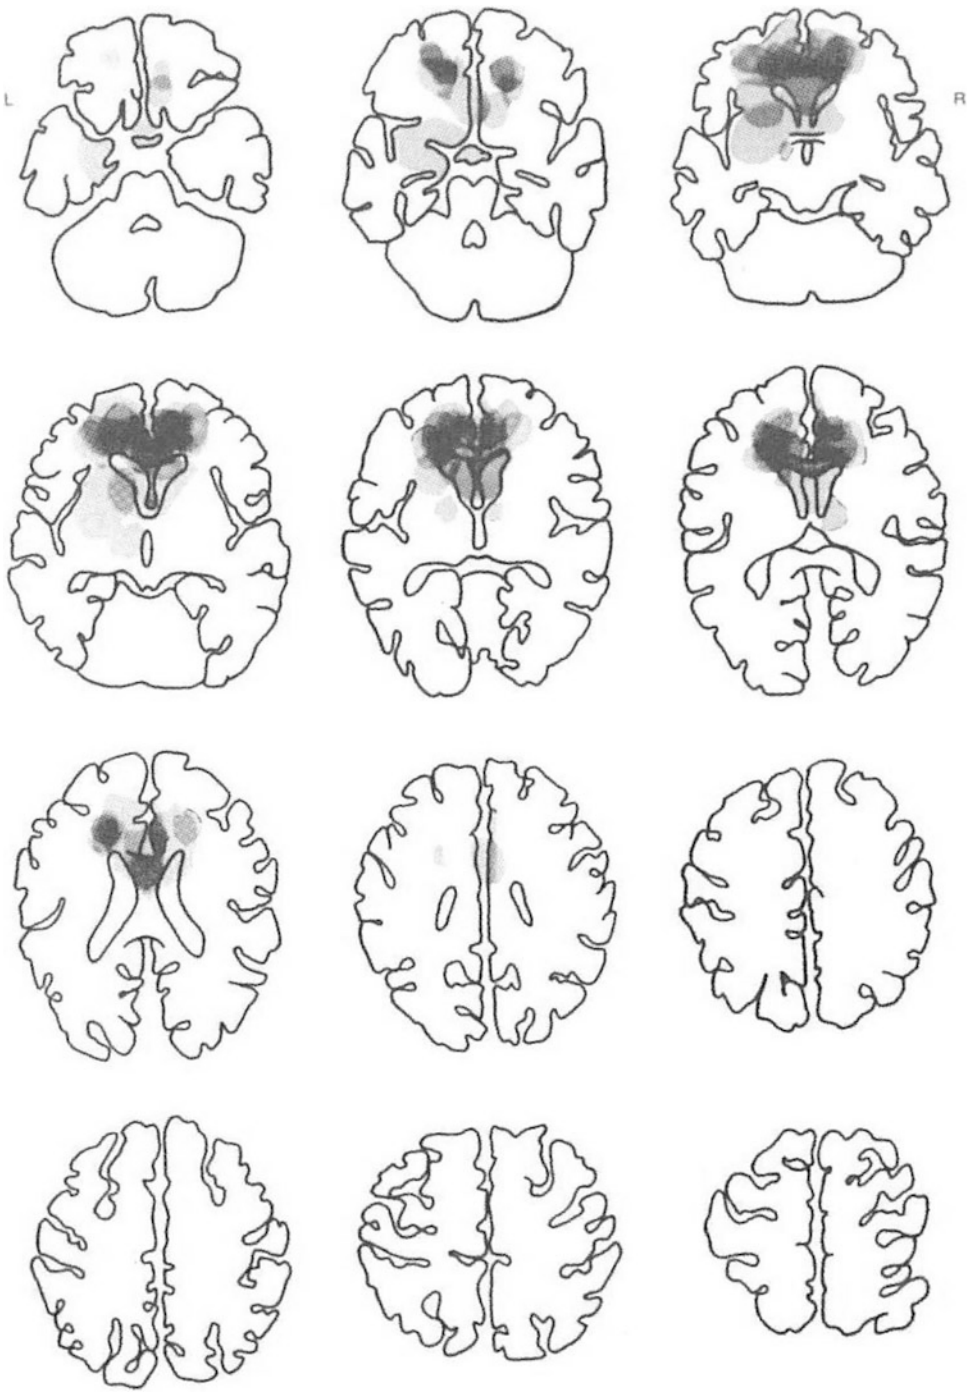

Fig. 45.1 Combined facsimile of scans in nine cases with global cessation of dreaming caused by deep frontal lesions, illustrating the strong involvement of the white matter surrounding the frontal horns of the lateral ventricles [12]

product of deep frontal structures activating higher visual association areas during sleep, instead of the executive and motor areas they activate during waking, thereby generating imaginary (versus real) action.

A recent study, using [15O]H_2O PET in healthy subjects with habitually high and low dream recall frequencies, also showed that high dream recallers—compared with low dream recallers—had greater regional cerebral blood flow in the temporal–parietal junction during slow wave sleep, REM sleep, and waking, as well as greater regional cerebral blood flow in the medial prefrontal cortex during REM sleep and waking [77]. These brain regions are highly consistent with those identified by lesion studies as being critically related to the dream process. As the temporal–parietal junction may facilitate the orientation of attention during sleep to external stimuli, it has been argued that the increase in activation of this region may be responsible for the observed increase in intrasleep wakefulness in high dream recallers. According to

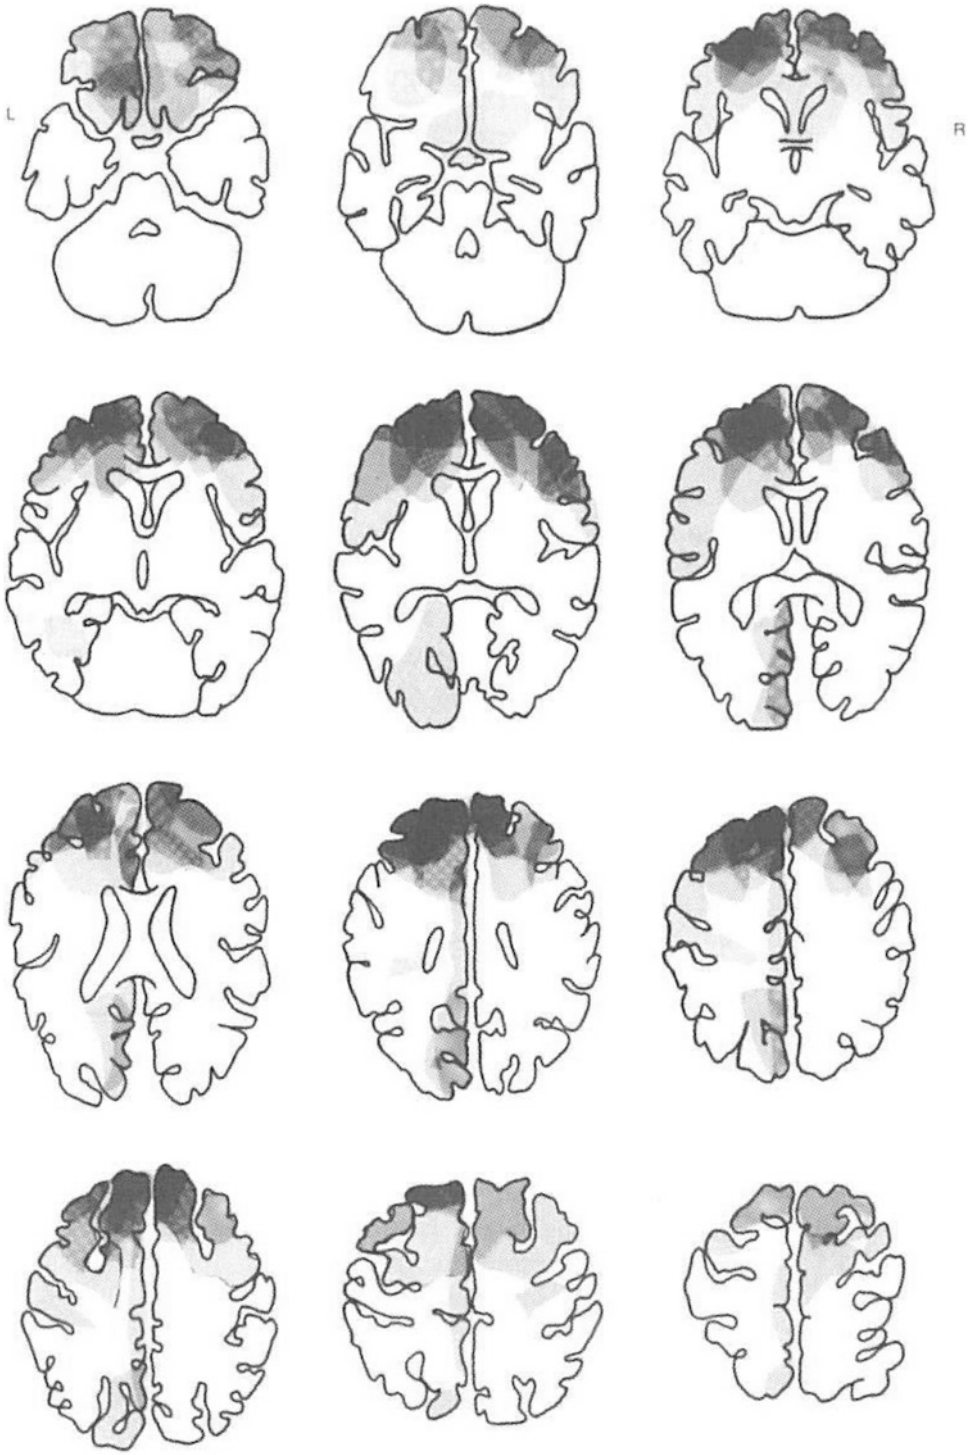

Fig. 45.2 Combined facsimile of scans in 14 cases with preserved dreaming with bifrontal lesions, illustrating the relative preponderance of cortical convexity involvement [12]

the *arousal–retrieval model* of dreaming [78], intrasleep wakefulness may facilitate the encoding of the dream content into long-term memory, consequently facilitating dream recall upon awakening in high dream recallers.

Consistent with this explanation, high dream recallers are more reactive to their external environments during all stages of sleep, as well as during wakefulness, when compared with low dream recallers [79]. (Using a novelty oddball paradigm, high dream recallers were shown to have enhanced P3a and late latency event-related potentials (ERPs) to novel and unexpected auditory stimuli. The P3a and late latency potentials are associated with complex cognitive processes such as familiarity, episodic memory and emotional processing [80–82]. Eichenlaub et al. [79]

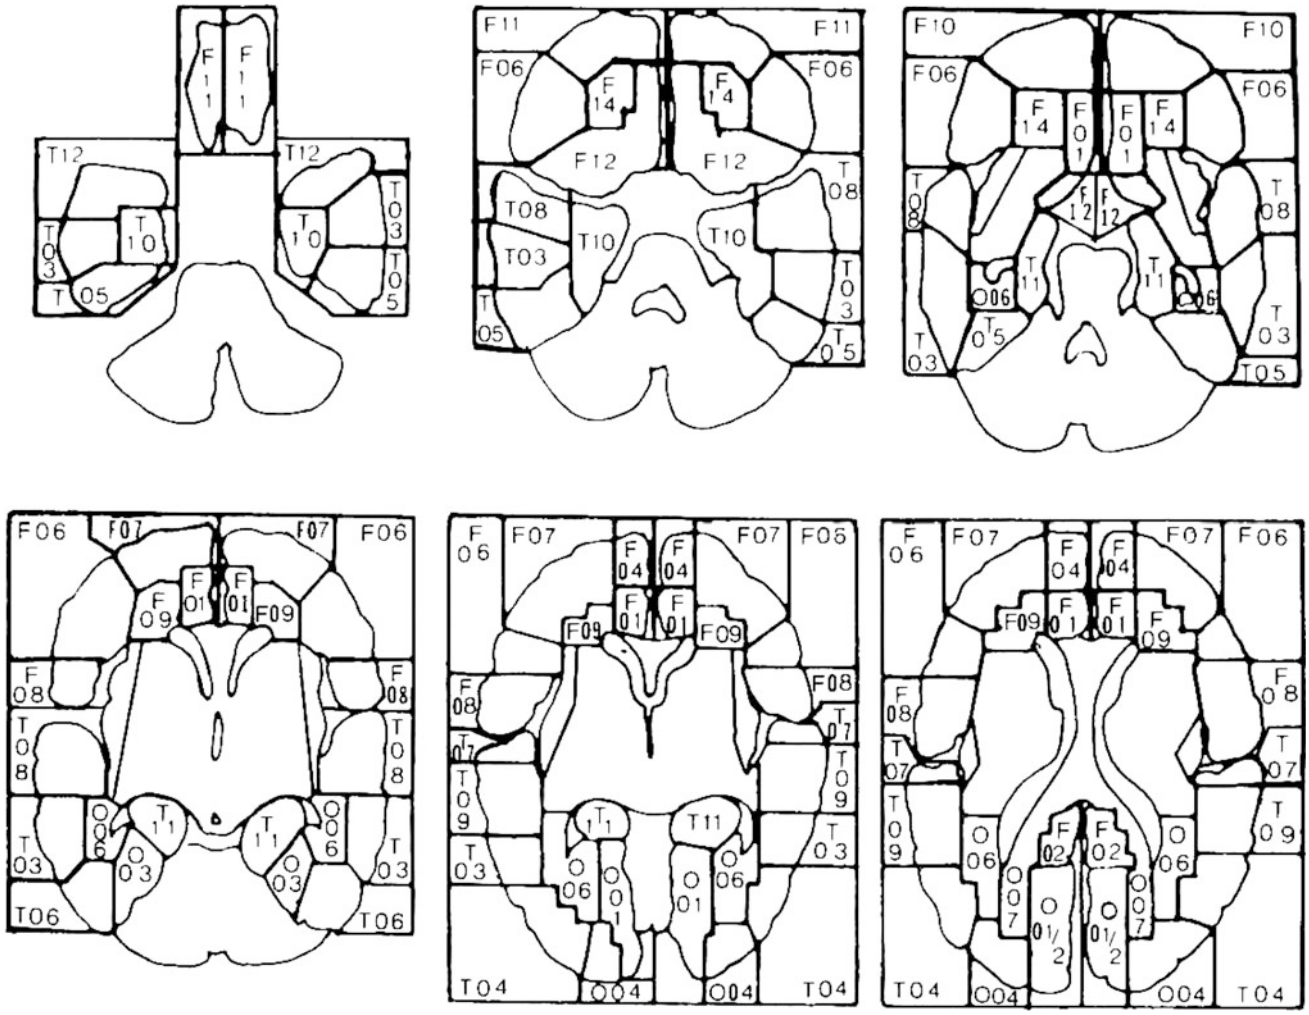

Fig. 45.3 Global cessation of dreaming is associated with subcortical lesions located in the deep frontal white matter (areas F09 and F14 in the classification of Damasio and Damasio [63], shown here)

have argued that these robust differences in brain responsivity show that the cerebral organisation of high recallers is intrinsically different to that of low recallers and that this difference may potentially facilitate either production or encoding of the dream.

This propensity to be more reactive to the external environment is consistent with enhanced activation of the posterior attentional networks in high dream recallers. Whether increased dream recall in habitually high dream recallers is due to more efficient encoding of the memory trace of the dream into long-term memory, or whether activity within these regions indicates a genuine increase in dream activity, remains inconclusive.

However, the latter possibility is supported by a recent set of transcranial magnetic stimulation (TMS) studies which found that visual dream imagery could be enhanced by inhibiting certain frontal regions while stimulating the right posterior parietal cortex, during stage 2 sleep but not during slow-wave sleep [83, 84]. This finding must be understood in relation to the fact that TMS is unable to propagate through connected networks during slow-wave sleep as efficiently as during lighter NREM sleep (Massimini et al. 2005) [85]. It nevertheless corroborates the notion that activity in posterior association cortex is responsible for the perceptual construction of dreams and moreover that activity in these regions during sleep represents an increase in dream activity.

Despite strong evidence that higher visual association cortices are responsible for the perceptual construction of dreams, it has recently been shown that primary visual areas may also be involved. In an innovative combined EEG/*f*MRI study, participants' dream imagery (as verbally reported) was decoded from neural activity measured during sleep onset, by software trained to correlate discrete visual stimuli (i.e. pictures) with brain activity during waking [86]. Horikawa et al. [86] concluded that the 'principle of perceptual

equivalence, which postulates a common neural substrate for perception and imagery, generalizes to spontaneously generated visual experience during sleep' (p. 642). As lesions to primary visual regions do not result in dream loss, or any visual disturbances in dreams [12], the exact contribution of the primary visual regions to dream imagery remains unclear.

Excesses of Dreaming

Dream/Reality Confusion

Solms [12] loosely grouped together 12 case reports in the literature and 10 of his own cases under the heading of dream/reality confusion (or 'anoneirognosis'). These patients reported excesses of dreaming, ranging from increased frequency and/or vivacity of dreams to intrusions of dreaming and dream-like thinking into waking cognition. The principle justification for collecting these cases under a unitary nosological heading was that the focal lesions (representing a wide variety of pathologies) that cause 'anoneirognosis' were typically located in the transitional zone between the anterior diencephalon and basal forebrain. Kindred phenomena are, however, also observed with visual de-afferentation, peduncular hallucinosis, delirium, parkinsonian syndromes, Guillain–Barre syndrome and a variety of toxic and metabolic conditions. The common denominator in these cases may therefore simply be degradation of constraints on consciousness. Certainly, any suggestion at this stage that dream–reality confusion may be considered to be a focal symptom is unjustified.

Dream/reality confusion in parkinsonian syndromes is difficult to interpret. Increased dreaming and hallucinations are frequently seen with Parkinson's disease (PD) but this may be iatrogenic. It is well established that hallucinations and excessive dreaming can be provoked by the administration of L-dopa, both in PD [87] (and in normal subjects, independently of any concomitant changes in REM sleep [88]. Accordingly, it has been shown that reduction of dopaminergic medication, and administration of dopamine blockers, reduces hallucinations and excessive dreaming in PD [89]. However, visual hallucinations in PD may also be an indication of the presence of Lewy body pathology, with involvement of parieto-occipital and limbic regions [90–92]. Excessive dreaming in parkinsonian syndromes may, therefore, have a different mechanism in cases with and without cortical Lewy bodies. In PD, hallucinations occur late in the course of the disorder, whereas they are an early feature of dementia with Lewy bodies (DLB).

Hallucinations and dream/reality confusion are also common in narcolepsy [92]. In these cases, hallucinations may accompany or follow attacks of cataplexy and sleep paralysis. Hallucinations of a presence of someone nearby ('sensed presence') or a pressure on the chest with breathing difficulties ('incubus/succubus'), and floating/flying and 'out of body' experiences, are typical in these cases. Dreams can occur at sleep onset (at night or during daytime naps) as well as on awakening (Rosenthal's syndrome). The retention of elements of normal waking mentation, such as volitional control or environmental awareness, is characteristic of narcoleptic dreams.

Various other rare disorders are associated with dream/reality confusion. Idiopathic hypersomnia manifests in excessive daytime sleepiness, prolonged unrefreshing sleep and 'sleep drunkenness' on attempting to wake up. Habitual dreaming, hypnagogic hallucinations and sleep paralysis are common in these cases [91]. Kleine–Levin syndrome is a rare disorder characterised by recurrent episodes of hypersomnia, compulsive eating behaviour and various psychopathological changes like hypersexuality, irritability or apathy. Hallucinations, delusions and 'dreamy states' are reported in 14–24 % of patients with KLS [93]. In fatal familial insomnia, a variant of Creutzfeldt–Jakob disease (CJD), progressive insomnia is coupled with an oneiric stuporous state in which patients perform complex, jerky movements that correspond to dream content which patients are later able to report [94]. Dream/reality confusion with hallucinations also occurs in sporadic CJD [95].

In populations without neurological disorders, excessive dreaming has been reported as a primary complaint in certain sleep clinics [96]. A study comparing these patients to controls revealed that complaints of excessive dreaming were related to significant microstructural changes, including increased arousals, intrasleep awakenings, period leg movements, alpha–delta sleep and REM density; however, no macrostructural changes were noted, and no differences in REM sleep and sleep onset latencies were apparent. Excessive dreamers were also found to be significantly more stressed, fatigued and anxious than controls, and to have more headaches.

Nightmares

Nocturnal seizures (and complex partial seizures in particular) sometimes present as recurring nightmares [97, 98]. Solms [12] identified 24 cases of this type in the literature and nine in his own series. Of theoretical interest is the fact that such nightmares typically occur during non-REM sleep. The content of the nightmares frequently coincides with that of the patient's typical aura or 'dreamy state' seizures [12, 98, 99]. Penfield was able to artificially generate a waking aura resembling the recurring nightmare in one case by stimulating exposed cortex in the region of the epileptogenic focus [100–102]. Successful pharmacological or

surgical treatment of the seizure disorder invariably results in disappearance of the recurring nightmares. These facts further support the interpretation of the nightmares in these cases as seizure equivalents (and indeed as non-REM phenomena).

As with dream/reality confusion (which frequently co-occurs with nightmares), increased frequency of nightmares is associated with a wide range of toxic and withdrawal states and metabolic abnormalities. The grounds for detaching these two 'excesses of dreaming' from each other are not entirely clear. The common denominator here may therefore, once again, simply be general degradation of constraints on consciousness.

It is important to note that nocturnal panic attacks and sleep terrors are not instances of nightmares. Detailed dream recall is often lacking in such attacks [103, 104], although in certain studies dream content has been reported [105].

REM Behaviour Disorder (RBD)

In this disorder, dreamed behaviours are physically acted out. This is due to disruption of pontomedullary mechanisms that induce REM atonia [106]. The enacted behaviours may be dramatic or even violent, and usually relate to vivid, frightening dreams. A fair proportion of cases injure their bed partners [107]. The disorder is most common in males, and onset is often in the sixth or seventh decade. RBD manifests mainly in the second-half of the sleep cycle (where REM is predominant). Increased slow-wave sleep, and increased periodic limb movements across all sleep stages are also seen [107–111].

Of special interest is the association of RBD with the parkinsonian syndromes. The presence of RBD in PD patients is associated with cognitive deficits and appears to predict dementia [112, 113]. Disorders with Lewy body pathology often involve RBD. The incidence of RBD in PD is 25–50 % and more than 50 % in DLB and MSA. In contrast, disorders without Lewy bodies rarely involve RBD. Notably, idiopathic RBD may present many years prior to the other symptoms of an incipient parkinsonian syndrome [107, 113–118]. The prognostic significance of RBD as a precursor to PD, DLB and MSA is now well established, resulting in the suggestion that the term 'cryptogenic' RBD should replace 'idiopathic' RBD [109, 111, 119, 120].

Pharmacological Findings

The chemical and pharmacological evidence is extremely difficult to interpret. This is due partly to the dynamic interactions that characterise neurotransmitter systems, and the paucity of rigorous pharmacological studies [14]. Mention will only be made here of recent findings which seem particularly relevant to understanding dream generation, and the distinction between dreaming and REM sleep.

The neurochemical signature of the REM state is well established: namely, autochthonous activation of ascending pontine ACh cells—which is thought to produce characteristic pontine–geniculate–occipital (PGO) waves—and reciprocal inhibition of pontine aminergic (5HT and NA) cells—which is thought to demodulate the dreaming forebrain [121]. Equally well established is the fact that non-REM sleep has the opposite pattern. Less widely known is the fact that, unlike other aminergic brainstem cells, the source cells in the ventral tegmental area (VTA) of the mesocortical DA pathway described above in connection with prefrontal leucotomy continue to fire at equal rates during sleeping and waking [121, 122]. These cells also fire with greater interspike variability during REM than non-REM sleep [121]. This has recently been shown to indicate prominent burst activity in the REM state [123], resulting in greater terminal DA release. DA delivery to the nucleus accumbens is in fact maximal during REM sleep when compared with NREM sleep and waking [124].

The REM state is also characterised by minimal prefrontal glutamate release [124], which presumably coincides with the observation reported above to the effect that dorsolateral prefrontal lesions have no obvious effect on dream content (and with the observation that this region is strongly deactivated in PET imaging studies of REM sleep [72]). The chemical signature of the REM state, as regards the neurotransmitter interactions underlying the observed regional patterns of forebrain activation and deactivation, is certainly more complex than was previously assumed [125].

This complexity is underscored by the impenetrable thicket of psychopharmacological evidence. Of particular value is any evidence that could clarify the pathophysiology of dream cessation following deep ventromesial frontal lesions. Since the sleep cycle is unaffected by such lesions [56], it is reasonable to assume that they impair a mechanism which is specific to dream generation (as opposed to REM generation). Two competing hypotheses have been advanced to account for dream cessation following deep ventromesial frontal lesions (and the commensurate hyperactivation of this region in *f*MRI and PET imaging of dreaming sleep and schizophrenic hallucinations [72, 125, 126]). The first hypothesis is that it reflects the activation of ACh cells in the basal forebrain; the second is that it reflects the activation of DA cells in the VTA.

Against the former hypothesis is the observation that ACh antagonists (like scopolamine), rather than suppressing dreaming and dream-like thinking, have the opposite effect: they produce dream/reality confusion [127, 128]. In fact, in this respect, anticholinergic drugs mirror the effects of lesions in cholinergic basal forebrain nuclei [129]. These and

other considerations led Braun [130] to observe that activation of these nuclei during REM sleep may actually reflect *inhibition* of forebrain ACh in dreaming sleep.

In favour of the latter hypothesis is the observation that DA agonists (like L-dopa) increase dream bizarreness, vivacity, complexity and emotionality without having any commensurate effects on REM sleep [87]. DA agonists, of course, also provoke other symptoms of psychotic cognition. Systematic studies of the effects on dreaming of DA antagonists have not yet been performed. However, a preliminary study by Yu (unpublished observation) of the effects on dreaming of antipsychotic medications recently found significant dream-suppressing effects.

Particularly incompatible with the view that dreaming and REM sleep are generated by the same pontine mechanisms is the accumulating evidence to the effect that 5HT agonists (SSRIs), like anticholinergics, have the opposite effect to what the REM-dreaming hypothesis would have predicted. SSRIs suppress REM sleep but produce excesses of dreaming, of both types described above [131–137].

The available pharmacological evidence therefore supports the view that dreaming—like other forms of psychosis—is primarily generated by (demodulated) DA mechanisms rather than ACh ones [138]. It is likely that interactions between the DA system and other neurotransmitter systems also affect dreaming, as enhanced dreaming has been shown in populations receiving noradrenergic beta blockers. However, the neurochemical basis of dreaming is likely to be far more complex than this, the only conclusion that the limited current evidence reasonably allows. Nevertheless, the roles of reward processing and addiction, as they relate to DA activity in the brain, have more recently been used to try and elucidate the dream process.

Reward and Motivational Processes During Sleep and Dreaming

DA circuitry is also central to reward processing. The mesocortical–mesolimbic (MC-ML) DA system is defined as the 'system [that] is formed by dopamine neurons located in the ventral tegmental area … which project to the nucleus accumbens, prefrontal cortex, septum, amygdala, and hippocampus' [123]. This system has been termed the SEEKING system by Panksepp [139] and it is thought to 'drive and energize many mental complexities that humans experience as persistent feelings of interest, curiosity, sensation seeking' (p. 145). It is also involved in reward processing, which refers to 'an instinctual affective and exploratory drive to seek biologically-important stimuli in the external or internal ('intrapsychic') environment' (Perogamvros and Schwartz, p. 1936) [140].

Perogamvros and Schwartz [140] have proposed the *reward activation model* (RAM) of dreaming, which postulates that reward processing during sleep may contribute to the consolidation of memories with a high motivational/emotional relevance, as well as aid in the modulation of REM sleep through projections to REM generating brainstem structures. Due to the strong interconnections between the hippocampus and the ventral tegmental area—which drives DA activity in the MC-ML circuits—RAM proposes that activation of the hippocampus during sleep may stimulate the VTA and lead to reward activation during sleep; in turn, VTA activity can lead to the reactivation of certain memories in the hippocampus. It is thought that during SWS in particular, the reactivation of the ventral striatum and the hippocampal complex allows for the consolidation of 'memory-reward associations' [141]. Therefore—and as originally proposed by Freud [142]—'the fabric of the dream-thoughts is respolved into its raw material' (p. 543).

In support of motivational theories of dreaming are studies of addiction, which has been associated with activity in the MC-ML dopamine system [143]. It is common for abstinent drug addicts to have increased dream content related to finding and taking drugs, a phenomenon that Johnson [144] first termed 'drug dreams'. As many as 80 % of acutely abstinent drug addicts experience drug dreams [145], which is related to drug craving in addicts and previous drug users [146–149]. Drug craving can be triggered by cues related to drug taking, both conscious and unconscious [150]. These types of drug-related cues have also been shown to be associated with the subsequent occurrence of drug dreams [151, 152]. In the absence of these drug-related cues, drug dreams tend to dissipate [145]. Drug dreams persist in drug addicts undergoing pharmacological treatment during abstinence, such as methadone treatment in heroin addicts and nicotine gum in smokers [153], (indicating that drug dreams do not merely result from physical withdrawal, but rather are a type of psychological withdrawal [145]. Furthermore, up-regulation of the MC-ML dopamine system—as measured indirectly by the Limbic System Activity Scale—has been associated with drug dreams [154]. The association between this up-regulation of the MC-ML dopamine system and the presence of drug dreams provides further evidence for this system's role in the motivational aspects of dream genesis [145]. This line of research has been used to argue that not only is the DA system involved in dream genesis, but that the content of drug dreams favours a motivational impetus for dream genesis [144, 155].

Conclusion

Despite the minimal attention that neurologists typically pay to dreams, their assessment can be of diagnostic interest, and have prognostic and management implications. They can also be a major source of distress to patients. There is every reason to expect that systematic studies of clinical dream phenomena will continue to provide valuable new insights into the functions and malfunctions of the human brain and mind. The extension of our understanding of dreams to healthy populations by means of more contemporary research methods has been extremely valuable in furthering our knowledge of the dream process. Consistencies in certain neurophysiological models of dreaming in these two populations are providing the field with sound theoretical departures from which the dream process can be better understood.

Sleep in Psychiatric Disorders

46

Peter L. Franzen and Daniel J. Buysse

Introduction

Numerous studies support a bidirectional relationship between poor sleep and psychiatric symptoms and disorders. The incidence of psychiatric symptoms and disorders is elevated among sleep-disordered patient populations, and sleep disorders are likewise overrepresented in psychiatric patients. This overlap can complicate both the diagnosis and treatment of sleep and psychiatric disorders.

Sleep disturbance has long been considered a manifestation of an underlying psychiatric condition; however, other conditions, including chronic pain [1], medical illnesses, and other sleep disorders, can also lead to insomnia complaints. As an example, Forsell and Winblad [2] investigated the prevalence of psychiatric symptoms in the oldest old. Sleep disturbances were named as the most common psychiatric symptom observed. There are many other plausible reasons, however, that sleep disturbances would be frequently observed in an over-90 population, including age-related neurologic changes and increases in sleep apnea prevalence.

The automatic attribution of insomnia or "sleep difficulties" to psychiatric disorders is problematic for several reasons: (1) Sleep is a physiologically driven process, not simply a state of mind, with mounting evidence that sleep is biologically linked to mood disorders; (2) sleep disturbances can exist independent of psychiatric symptoms or remain after a psychiatric disorder remits; and (3) sleep disturbances have been identified as an important underlying risk factor for psychiatric disorders, as well as in their severity and recurrence. While insomnia may be a frequent consequence of some medical and psychiatric disorders (secondary insomnia), it is now clear that insomnia can be an independent problem that precedes or co-occurs with another condition (comorbid insomnia). In support of this, both ICSD-3 and DSM-5 no longer have separate categories for "primary" or "secondary" insomnia associated with psychiatric and medical conditions. Rather, the clinician is asked to note whether significant comorbidities are present. Thus, it is important to consider other factors in addition to psychopathology that can affect sleep. Such distinctions are important for understanding the pathophysiology of sleep disturbances and may impact treatment.

This chapter reviews the various relationships between sleep and psychiatric disorders, focusing on sleep disturbances and psychiatric symptoms in a broad sense; on psychopathology in individuals with sleep disorders; and on sleep findings in various psychiatric disorders. The chapter concludes with some considerations for approaching sleep disturbances in the treatment of patients with psychiatric disorders.

Sleep Disturbances, Sleep Loss, and Psychiatric Disorders

Insufficient sleep, as a result of sleep loss (e.g., short sleep duration) and/or sleep disturbances (e.g., poor sleep quality, difficulty falling asleep, or staying asleep) can significantly impact mood and psychopathology. Sleep disturbances are frequently observed in psychiatric disorders: 50–80 % of individuals with a primary psychiatric disorder report sleep disturbances at some point during the course of their disorder [3]. Epidemiologic evidence from different countries shows that self-reported habitual sleep duration is associated with increased risk for psychopathology. For instance, large epidemiologic studies from Germany and Korea show that short (≤ 5) and long (>9) sleep times are associated with increased cross-sectional risk for depressive, anxiety, and substance use disorders [4, 5]. Shorter sleep duration (<8 h) and frequent nightmares were significantly associated with increased risk for suicidal ideation and suicide attempts in an epidemiologic sample of 1362 adolescents ages 12–18 from China [6]; the risk for suicide attempts remained significant

after controlling for depressive symptoms. Similar findings for increased suicide risk in adults experiencing frequent nightmares have also been reported [7].

Longitudinal studies further demonstrate that sleep problems in childhood increase the risk for psychiatric problems in adulthood. In a longitudinal sample, 943 children with parent-reported sleep and psychiatric symptoms at ages 5, 7, and 9 were assessed for current anxiety and depression using standardized structured interviews at ages 21 and 26 [8]. Persistent sleep problems in early childhood predicted adulthood anxiety disorders but not adulthood depression in this sample.

Both insomnia and hypersomnia symptoms are associated with increased incidence and severity of psychiatric disorders. A survey of 7954 people in scattered major US cities between 1981 and 1985 as part of the National Institute of Mental Health Epidemiological Catchment Area study [9] revealed that 40 % of those with insomnia and 46.5 % of those with hypersomnia met the criteria for mental illness using criteria from the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised.* Ten percent of the sample complained of insomnia and 3.2 % of hypersomnia [10]. Fourteen percent of the patients with insomnia met criteria for major depression, compared to 9.9 % of those with hypersomnolence. The rate of new psychiatric disorders at one-year follow-up was greater among respondents with persistent sleep complaints. The numbers in this study were thought to be low due to strict criteria for defining insomnia and the omission of generalized anxiety disorder (GAD) and personality disorders from the survey. In a study by Mosko et al. [11], 66.5 % of 206 patients presenting to one sleep disorder center reported one episode of major depression in the previous 5 years, and 25.7 % described themselves as depressed on presentation. Additional studies have established substantial risk of developing major depression and generalized anxiety in patients with sleep disorders [12–14]. Both insomnia and hypersomnia are associated with worsening course of depression [15] and increased suicidal behavior [16].

Sleep loss/deprivation also leads to mood dysregulation. Experimental studies manipulating sleep duration consistently demonstrate a negative impact on self-reported mood [17], although mood can become dysregulated in the opposite direction as well (e.g., mood elevation, giddy laughter). Sleep deprivation has also been shown to increase physiological reactivity to negative emotional images as measured by pupil dilation [18], as well as amygdala activation in response to both negative [19] and positive [20] images. Negative consequences from sleep deprivation are in general more common and can impact functioning. For example, sleep deprivation can impair interpersonal transactions. Average nightly sleep duration was assessed in a sample of medical residents [21]. Reports of treating others badly or feeling belittled/humiliated by colleagues increased as average nightly sleep decreased. Although reported by a smaller percentage of respondents, the incidence of violent behavior (i.e., hitting, kicking, and punching) showed the same inverse relationship with sleep duration.

Sleep deprivation can lead to negative consequences for psychiatric disorders, particularly bipolar disorder. Irregular social rhythms and sleep deprivation can elicit mania in some patients with bipolar disorder [22–25]. Sleep deprivation may also induce bipolar disorder in vulnerable individuals. Lack of sleep has also been associated with the *development* of bipolar disorder [26], as well as pre- and postpartum psychosis [27–29], and greater rates of depression in both new mothers and new fathers have been attributed in part to the sleep disruption that occurs with the arrival of a newborn [30]. A sleep deficit has been found to prospectively predict the development of depressive symptoms in patients with bipolar disorder [31].

Although sleep loss is generally considered to have negative effects with regard to mental health, sleep deprivation can have rapid, albeit usually transient, antidepressant effects. Among patients with major depressive disorder, symptoms can improve following total sleep or selective rapid eye movement (REM) sleep deprivation. The improvement is transient and occurs in 40–60 % of patients with endogenous depression [32–34]. Sleep deprivation can lead to an antidepressant response in patients with bipolar disorder as well [35]. One study [36] in 141 hospitalized, currently depressed, bipolar patients used three total sleep deprivation nights (each separated by one night of recovery sleep) combined with lithium and bright light therapy for two weeks; 70 % had >50 % reductions in Hamilton Rating Scale for Depression, which persisted at one month in 55 %.

Associations Between Sleep Disorders and Psychiatric Symptoms/Disorders

Insomnia

Although insomnia commonly co-occurs with other medical or psychiatric illnesses, insomnia independently places an individual at risk for future medical and psychiatric complications [37]. Not only is psychopathology more severe in people who complain of sleep disturbances, insomnia itself specifically confers an increased risk for the *future* development of a mood or anxiety disorder, even when controlling for baseline mood symptoms [10, 38]. A recent meta-analysis of 21 studies found that insomnia doubles the risk for depression (i.e., odds ratio of 2.10; 95 % CI: 1.86–2.38) [39]. Breslau et al. [13], in a three-year longitudinal study of 979 young adults, found a lifetime prevalence of

16 % for insomnia. Patients with insomnia had a fourfold increase in risk for developing major depression compared to patients without insomnia; notably, sleep disturbance was a stronger predictor of the subsequent development of depression than any other factor.

The timing of chronic insomnia and psychiatric illness was assessed by telephone interview in a population-based sample of 14,915 Western European participants [40]. Of the 19.1 % of the sample with insomnia, about one-quarter had a current psychiatric diagnosis and another quarter had a psychiatric history. For those with mood disorders, insomnia either preceded (40 %) or appeared at the same time (22 %) as mood symptoms. In contrast, insomnia tended to appear at the same time (38 %) or after (34 %) as the development of an anxiety disorder. The strongest predictors of having a psychiatric history were severe insomnia, primary insomnia, or insomnia related to a medical condition, and insomnia persisting more than one year. Studies have shown a relationship between suicide and insomnia in depression [22] and panic disorder [41], as well as higher rates of insomnia [42] and poor sleep quality [16] among suicidal individuals, again illustrating the bidirectional relationship between sleep and psychopathology.

Circadian Rhythm Disorders

Circadian rhythm disorders, such as delayed or advanced sleep phase syndrome, are characterized by abnormal timing of sleep. Difficulty in sleeping at desired, typically socially appropriate times can significantly impact functioning. For example, a severely delayed sleep schedule can significantly impede academic or occupational functioning; such stresses can easily lead to depression, which may in turn hamper the behavioral self-control needed to try to "normalize" the individual's schedule (e.g., taking melatonin at the appropriate time, engaging in a consistent sleep-wake schedule, chronotherapy). As many as three-quarters of individuals with delayed sleep phase syndrome have a past or current history of depression [43], and depression severity correlates with circadian misalignment [44, 45]. Evening circadian chronotype without delayed sleep phase syndrome is also associated with elevated rates of psychopathology, including depression and substance use disorders [46, 47].

Sleep Apnea

Sleep fragmentation and chronic intermittent hypoxemia induced by sleep-disordered breathing (SDB) lead to impairments in cognitive and affective domains (see El Ad and Lavie [48] for review). Patients diagnosed with obstructive sleep apnea often present to sleep disorders centers with concomitant symptoms of depression and other psychopathology. Affective consequences of SDB include elevated rates of depression, anxiety, and hostility symptoms based on self-report questionnaires [49, 50], although inconsistencies have been reported [51]. In a large cohort of Veterans Administration healthcare beneficiaries, those with sleep apnea had significantly greater prevalence of mood disorders, anxiety, post-traumatic stress disorder (PTSD), psychosis, and dementia compared to patients without sleep apnea [52].

The association between SDB and depression has been consistently found, with reports ranging from 24 to 58 % of SDB patients meeting diagnostic criteria for depression [11, 53–55]. In a recent general population study consisting of nearly 19,000 Western Europeans responding to a telephone survey, 0.8 % were found to have both SDB and depression [56]. They found that 17.6 % of individuals with SDB also were diagnosed with depression and 18 % of depressed individuals were diagnosed with SDB. After controlling for obesity and hypertension, an individual with major depression is still at increased risk of also having SDB. Because depression and SDB are both prevalent conditions in the general population, these findings are of particular relevance to both psychiatrists and sleep specialists. That nearly one-fifth of individuals with one of these disorders may have the other underscores the importance of screening for SDB in people diagnosed with depression, and vice versa. By accurately identifying both disorders when present, treatment outcomes for both disorders may be improved (see Schroder and O'Hara [57] for further discussion). Successful treatment of SDB, usually with positive airway pressure therapy but also with surgery, leads to improvements in quality-of-life measures and in anxiety and depression symptoms, although some studies have not found such improvements [50, 58–61]. These inconsistencies may be partly due to overlapping symptoms of depression and OSA, and the possibility that depressive symptoms may be slower to resolve. Long-term use of positive airway pressure therapy (one year or longer) in 300 patients was associated with decreasing depression symptoms; however, depression symptoms remained persistently elevated in 42 % of the sample [62]. Excessive daytime sleepiness was a significant predictor for persistent depression.

Studies in children have tended to not clearly differentiate primary snoring from obstructive sleep apnea; however, cross-sectional evidence suggests a strong increase in behavior problems and neurocognitive abnormalities in children with SDB (see Schechter [63]). Surgical interventions seem to help. Many children who received adenotonsillectomy to treat their SDB have improved academic and behavioral functioning (e.g., aggression, inattention, hyperactivity, alertness) [64–66], although positive results have not always been reported [67].

Restless Legs Syndrome/Periodic Limb Movements

Restless legs syndrome (RLS) is another prevalent sleep disorder that is associated with depression and anxiety [68–70], as well as attention-deficit/hyperactivity disorder (ADHD). An increased association between RLS and depression, and RLS and ADHD, has been reported (see Cortese et al. [71]; Picchietti and Winkelman [69] for reviews). Winkelmann et al. [72] found an increased risk of having 12-month depressive and anxiety disorders based in 130 adult RLS patients who were compared to over 2000 community respondents with other types of physical disorders. Not all studies have found increased depression; one retrospective review of 100 consecutive idiopathic RLS patients failed to find an association between RLS severity and Beck Depression Inventory scores [73]. Whether the increased incidence of psychiatric disorders in RLS patients is due to sleep disruption, or to some shared pathophysiologic process, or is spurious cannot be determined by the epidemiologic associations found to date. Such findings, however, do support assessing psychiatric symptomatology in the diagnosis and treatment of RLS patients.

Narcolepsy

Patients with narcolepsy are at increased risk for psychopathology [74, 75]. In comparison with a general population comparison sample, most depressive and anxiety disorders were more prevalent in a sample of 320 individuals with narcolepsy, especially depression (OR, 2.67) and social anxiety (OR, 2.43) which impacted nearly 20 % [76]. Narcolepsy patients were found to exhibit greater psychosocial impairments than two matched comparison groups (epilepsy patients and normal controls) [77]. Hypnagogic hallucinations, part of the symptom tetrad of narcolepsy, do not occur in all cases of narcolepsy, nor do they typically indicate psychotic symptomatology. There are reports of an increased association between narcolepsy and psychotic disorders, although this association has been disputed [78].

Sleep in Psychiatric Disorders

Studies of REM sleep architecture in various psychopathologic states have been conducted since Dement first evaluated REM sleep in schizophrenic patients in 1955. Subsequently, REM sleep changes were most often examined in relation to affective disorders [79]. Subsequently, numerous studies used measures have examined REM outcomes (i.e., REM sleep latency, REM density, and REM sleep distribution) in various other psychiatric disorders such as schizophrenia, eating disorders, personality disorders, and substance abuse disorders. Others studies examined these same measures as diagnostic measures to distinguish various psychopathologic states from major depression. Unfortunately, a great deal of confusion has resulted from various methodologic issues and diagnostic uncertainties in psychiatric patients. Examples of methodologic differences in studies include the number of consecutive nights patients are studied, determination of the time between sleep onset and REM sleep onset (REM sleep latency), the definition of increased REM density, concurrent use of psychotropic drugs, period of withdrawal from psychotropic medications, sleep schedule, and the severity of the illness [80]. Just as important is the overlap of symptoms among various disorders found in the Research Diagnostic Criteria, the DSM-V, and other classifications for mental disorders. Although in theory, psychiatric diagnoses are categorically distinct from one another, in clinical practice, such distinctions are more difficult to make, and comorbid psychiatric diagnoses are common. All of these factors weaken the ability of sleep measures to serve as sensitive or specific diagnostic markers.

Mood Disorders

Major Depression

Major depression is the psychiatric disorder most studied by sleep researchers, and several theories of the mechanisms involved have been published [81]. In approximately 90 % of cases, major depression results in insomnia. A smaller percentage of patients with major depression complain of excessive sleepiness: Most are adolescents and young adults [82]. Whereas depressed adolescents and young adults may be more prone to be "long sleepers," studies of older depressed patients with the complaint of hypersomnolence have failed to show evidence of pathologic sleepiness [83]. Sleep disturbances can interfere with treatment response in depression. In a sample of depressed women treated with interpersonal psychotherapy, those with higher pretreatment subjective sleep quality ratings showed significant post-treatment improvement in mood symptoms compared to treatment nonresponders [84]. Similar findings of worse subjective sleep quality being associated with worse treatment response have also been reported in patients with depression receiving combined pharmacologic and psychological treatments [85]. Conversely, improvement in subjective sleep quality following depression treatment is associated with lower recurrence rates of depression [86]. Treating insomnia in addition to depression may speed recovery from depression. In a double-blind study, adults with comorbid depression and insomnia who were assigned to fluoxetine and eszopiclone coadministration had improved

sleep and higher rates of responders and remitters compared to those assigned to fluoxetine and placebo [87]. Nonpharmacological interventions for insomnia may also speed recovery from depression. A small randomized control trial of individuals with comorbid insomnia and depression compared patients taking escitalopram and receiving either cognitive behavioral therapy for insomnia (CBT-I) or a control insomnia therapy [88]. Depression remission and insomnia remission rates were higher in those who received CBT-I (61.5 and 50 %, respectively) versus those randomized to a control therapy (33.3 and 7.7 %, respectively). In another study, CBT-I similarly improved insomnia severity index scores (by almost half) in those with low and high levels of depression and both depression symptoms and suicidal ideation significantly improved following treatment [89].

Efforts have been made to distinguish major depression from other psychopathologic states by use of sleep electroencephalography (EEG) and other biological markers. The primary well-documented changes in sleep architecture include shortened REM sleep-onset latency, increased REM density, reduced total sleep time, reduced sleep efficiency, increased awakenings, decreased slow-wave sleep (SWS), and a shift of SWS from the first non-REM (NREM) cycle to the second (Fig. 46.1). More recently, high-amplitude fast-frequency EEG activity has been suggested as a marker for depression [90]. Sleep architecture changes found in depression may serve as a marker for the development of depression in those individuals genetically predisposed to depression.

Changes in sleep architecture, particularly in REM sleep and deep NREM sleep, are more pronounced with age in major depression. Prepubertal depressed children are less likely to show changes in sleep architecture than postpubertal depressives [91, 92]. There has been some conflict in the literature about whether REM sleep latency in depressed children is normal or shortened [93]. Changes in sleep architecture in adolescents appear to depend on the severity of the illness. Inpatient, psychotic, or suicidal adolescents may exhibit the typical adult changes of major depression, whereas the sleep of adolescents who are not as severely depressed may show no changes [93–96].

Aging has a marked influence on sleep, such as REM sleep latency, in depression; elderly depressed patients often have a REM sleep onset of less than 10 min. Older patients with a history of suicide attempts have longer sleep-onset latency, reduced sleep efficiency, and increased REM density than nonattempters [97]. Depressed men have less SWS than depressed women [98], but women may have more and higher amplitude beta activity [99]. Women with past depressive episodes appear to experience more sleep disruption and reduced REM sleep latency [100] in the immediate postpartum months.

Studies of the effects of antidepressant medication on REM sleep measures in patients with major depression have suggested that improved treatment response is associated with immediate and persistent antidepressant-induced prolongation of the REM sleep latency, reduction of total REM sleep time, and REM density [101, 102]. The occurrence of sleep-onset REM sleep episodes and shorter REM sleep duration during maintenance treatment with antidepressants has been associated with increased risk of relapse during treatment [103]. Studies of the effects of electroconvulsive therapy (ECT) on REM sleep architecture suggest that they are not as pronounced as those observed with most antidepressants [104]. As with pharmacotherapy, patients with post-ECT EEG signs of depression are more likely to have recurrence of the illness [105].

Bipolar Disorder

Sleep disturbances are quite common in bipolar disorder and can include insomnia and/or more typically hypersomnia during a depressive episode and reduced need to sleep during a manic episode (for review, see [106]). Sleep disturbances, especially insomnia, are also common during inter-episode periods when individuals are euthymic [107] and are associated with risk for the recurrence of a mood episode [108]. As sleep loss can trigger mania, using behavioral interventions for insomnia (stimulus control instructions and sleep restriction) could be a concern, as they involve some degree of sleep restriction. A case series of 15 individuals with bipolar disorder demonstrated that modified behavioral insomnia interventions can be useful without greatly increased risk of mania [109].

Patients in the manic phase of bipolar disorder have been shown to have reduced total sleep time, which gradually extends as the manic phase passes [110]. There is also a reduction in stages 3 and 4 sleep. No consistent change in REM sleep has been found, probably due to excitability and subsequent reduction of total sleep in these patients, but most studies show the same changes as seen in major depression [111]. It has been suggested that the switch from euthymia or depression into the manic phase occurs during sleep [112]. Lithium, which is the primary drug used to treat the manic phase of bipolar disorder, has been found to increase SWS and reduce REM sleep. Greater REM density during the inter-episode period in bipolar disorder has also been observed [113]. Further, manic symptoms and impairment three months later were associated with increased duration of the first REM period and the amount of SWS, and depressive symptoms and impairment were associated with REM density.

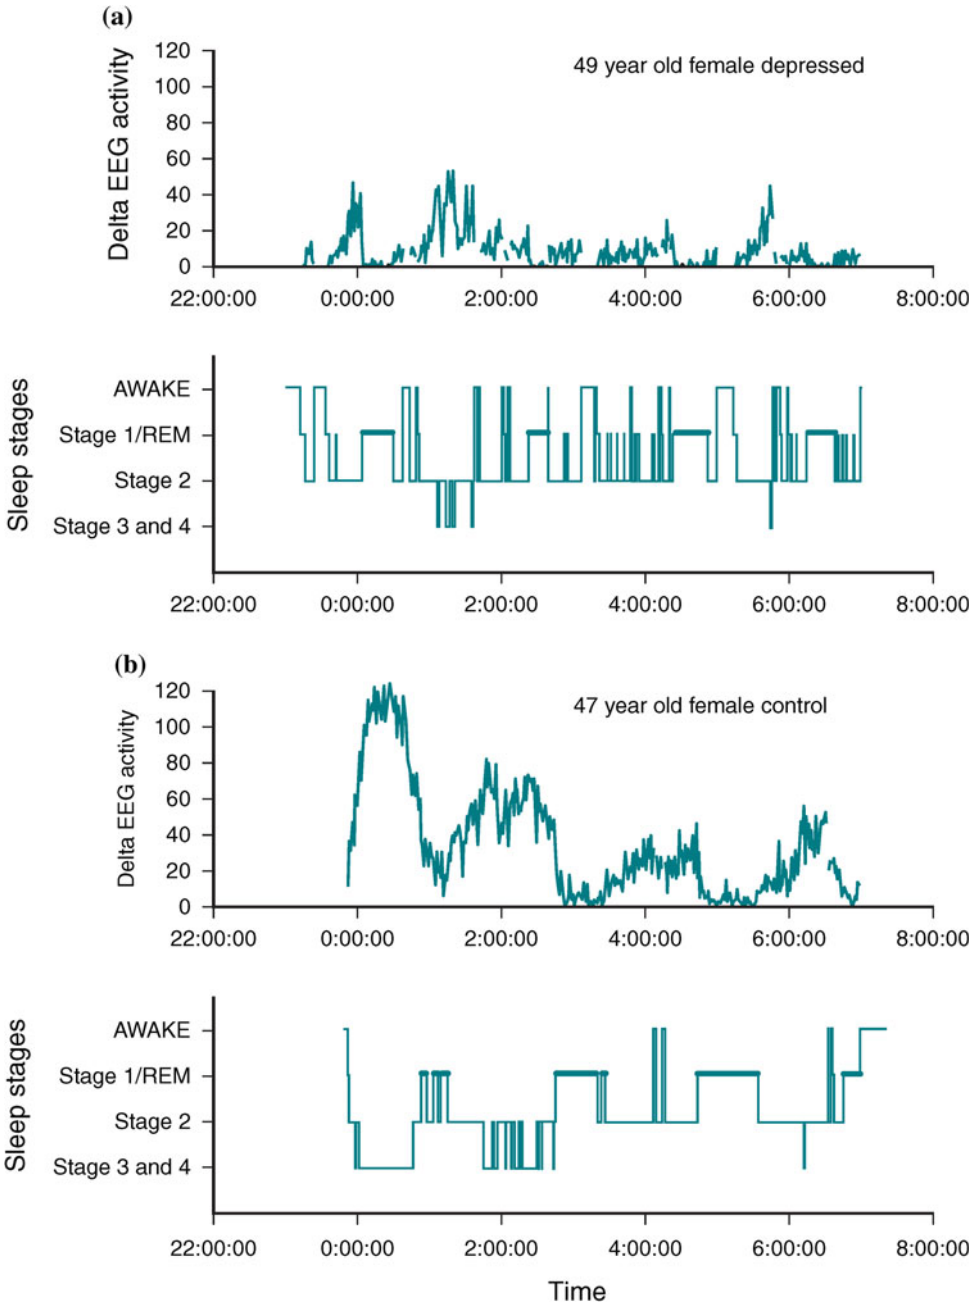

Fig. 46.1 Representative sleep histograms for a patient with major depressive disorder (**a**) and an age- and sex-matched healthy subject (**b**). In each figure, the *top panel* shows EEG delta activity during NREM sleep identified by computer algorithm, and the *bottom panel* shows the sleep histogram from visual sleep stage scoring. Relative to the control subject, the depressed patient has a longer sleep latency, more wakefulness during sleep, less visually scored stage 3/4 sleep and EEG delta activity, and shorter REM sleep latency

Anxiety Disorders

Anxiety disorders are the most prevalent group of psychiatric disorders. Anxiety symptoms and disorders co-occur with many sleep disorders. Anxiety has also long been associated with sleep disturbances, especially insomnia, as a quiet mind is a prerequisite to fall asleep, and anxiety is characterized by heightened worry and rumination. While less research has been done in this area compared to mood disorders, strong cross-sectional associations between sleep and anxiety [114], and significant risk relationships between sleep disturbance and the prospective development of anxiety disorders, have been reported (i.e., panic disorder and GAD [115]. Treating insomnia may reduce anxiety symptoms. A meta-analysis of the impact of CBT-I on anxiety found small to moderate effects on anxiety in individuals with and without a comorbid anxiety disorder [116].

Generalized Anxiety Disorder

While anxiety symptoms are most often associated with sleep initiation difficulties, Belanger et al. [117] found a more varied pattern of sleep difficulties in GAD. They examined self-reported insomnia symptoms both before and after a cognitive behavioral intervention targeting excessive

worry in 44 primary GAD patients. Insomnia subtypes included difficulty initiating sleep (48 %), difficulty maintaining sleep (64 %), and early morning awakenings (57 %); 77 % experienced at least one symptom, 41 % two symptoms, and 26 % all three. Comorbid depression, an important confounding variable, was not discussed and may have influenced study results. In polysomnographic studies, patients with GAD typically have prolonged sleep-onset latency, increased stages 1 and 2 sleep, less SWS, lower REM sleep percentage, and, with the exception of isolated reports, increased or normal REM sleep latency [118, 119]. No difference has been found between patients with GAD alone and those with GAD and depression [120].

Panic Disorder

Panic disorder can present with multiple somatic and emotional symptoms that can resemble symptoms of medical conditions such as mitral valve prolapse syndrome, cardiovascular dysautonomia, and sleep choking syndrome. The diagnosis may depend on the presentation of psychiatric symptoms, as opposed to autonomic and respiratory symptoms. Controversy exists over the roles of increased brain stem carbon dioxide receptor sensitivity and dysautonomia in panic [121–127]. It has been suggested that a number of substances and situations provoke panic attacks, such as caffeine, nicotine, over-the-counter cold remedies, cannabis, cocaine, sleep deprivation, excessive sugar intake, exercise, relaxation, hyperventilation, stress, and even fluorescent lighting [128].

As many as 70 % of patients with panic disorder have difficulty with sleep-onset and maintenance insomnia [129, 130], and often report sleep paralysis [131] and hypnagogic hallucinations [132]. Overbeek et al. [130] compared 70 panic patients and 70 controls on six types of sleep complaints. Panic disorder patients had more sleep complaints, including insomnia and daytime sleepiness, and those panic patients with comorbid depression and panic patients who also had nocturnal panic attacks had the highest frequency of sleep complaints.

Panic attacks can occur in any stage of sleep, but most occur during NREM sleep just before the onset of SWS. Symptoms similar to those associated with nocturnal panic attacks may be observed in patients with arrhythmias, gastroesophageal reflux, sleep apnea [133], sleep terrors, REM sleep behavior disorder, and paroxysmal hypnogenic dystonia [134]. More rarely, panic attacks can occur solely at night. It has been suggested that patients with sleep-only panic attacks experience depression more frequently than panic disorder patients who do not experience sleep-related panic attacks [135]. Of people diagnosed with panic disorder, 44–71 % have a history of nocturnal panic [136], and 30–45 % experience episodes of recurrent episodes of nocturnal panic [137]. Nocturnal panic is typically experienced as more intense than daytime panic. Fear of sleep can develop and lead to restricted sleep, which in turn might facilitate nocturnal panic events [137]. Patients with nocturnal panic attacks tend to experience worse daytime panic attacks, more somatic symptoms [138], and more comorbid psychiatric disorders [139] than daytime-only panic disorder patients.

Polysomnographic studies in nondepressed patients with panic disorder have reported normal sleep-onset latency and modestly reduced total sleep time and delta sleep [140]. However, studies in patients with panic and comorbid major depression have reported features typical of major depression, with substantially prolonged sleep-onset latency, reduced total sleep time, sleep disruption, reduced SWS, and early REM sleep onset [141–144].

Post-traumatic Stress Disorder

PTSD is caused by exposure to events in which a person witnesses or hears of a threat to the integrity (life) of themselves or a loved one, often in natural disasters, combat, torture, physical/sexual assault, or other situations involving physical and psychological abuse. Sleep complaints are nearly universal in individuals diagnosed with PTSD and include nightmares [145], difficulties initiating and/or maintaining sleep (in 70–90 % of individuals with PTSD) [146–148], and sleep paralysis [149]. REM sleep behavior disorder has also been associated with PTSD [150, 151], as has sleep paralysis [149]. Sleep disturbances shortly after trauma exposure predict the development of PTSD at follow-up assessment [152–154]. PTSD patients who report more severe sleep symptoms also report more depression severity, suicidality, anxiety, and substance use [155–157].

Current first-line interventions for PTSD do not directly target the nighttime symptoms in either pharmacotherapeutic (e.g., selective serotonin reuptake inhibitors [SSRIs]) or cognitive behavioral therapy (CBT) approaches; the former has minimal benefits on nightmares and insomnia [158–160], and the latter had minimal benefits for 48 % of PTSD patients who had a reduction in daytime symptoms in one study [148]. Fortunately, behavioral sleep interventions are effective in reducing nighttime symptoms in PTSD. For chronic nightmares, imagery rehearsal therapy has been found to reduce nightmare frequency and severity in both individuals with PTSD and those who have nightmares as a primary sleep disorder [161]. Nightmare reductions have lasted up to 30 months in follow-up studies [162] and are associated with significant reductions in daytime PTSD symptoms, depression, anxiety, and quality of life [163–166]. Effective behavioral interventions for primary insomnia (i.e., stimulus control instructions, sleep restriction) can also effectively reduce PTSD-related insomnia [164, 167, 168]. Prazosin, an α_1-adrenergic receptor antagonist, has emerged as promising treatment of PTSD-related sleep

Table 46.1 Drugs that affect sleep

Drug		Effects on Sleep	Comments
Barbiturates	Acute:	↑TST	Rapid development of tolerance
		↓WASO	Withdrawal insomnia
		↓REM	Daytime sedation
		↑Stage II, ↑spindles	
		↑ or ↓Delta	
	Withdrawal:	↓TST	
Benzodiazepines	Acute:	↓SL (most agents)	Agents vary in onset and duration of action
		↑TST	Daytime sedation (with long-acting agents)
		↓WASO	Tolerance develops (with short-acting agents)
		↓REM	Withdrawal insomnia (with short-acting agents)
		↑Stage II, ↑spindles	
		↓Delta (most agents; some ↑delta)	
	Withdrawal:	↓TST	
Benzodiazepine receptor agents (e.g., zolpidem)	Acute:	↓SL ↑TST	Sleep architecture not typically altered Withdrawal effects inconsistently seen
		→REM	
		→Delta	
	Withdrawal:	or ↑WASO	
Chloral hydrate		↑TST	Little information on tolerance or withdrawal
		→REM	
		→Stage II	
		→Delta	
L-Tryptophan		→ or ↑TST → or ↑REM	Effects are mild and inconsistent and may be delayed
		↑Delta	
Alcohol	Acute:	↑TST 2nd half of night	Acute effects variable
		↑WASO 2nd half of night	
		↓REM 1st half of night	
		↑Delta	
	Chronic:	→TST	
		→REM	
		↓Delta	
	Withdrawal:	↓TST ↑WASO	Degree of REM rebound may correlate with likelihood of withdrawal delirium
		↑REM	
		↓Delta	
Narcotics	Acute:	↑WASO	Effects vary with specific agents
		↓REM	
		↓Delta (total), with ↑delta "bursts"

		→Delta	
Methysergide		→TST	
		→ or ↓REM	
		↑Delta	
γ-Hydroxybutyrate		↑TST	
Steroids		↑WASO	

SL = sleep latency; WASO = wakefulness after sleep onset; TST = total sleep time; MAOIs = monoamine oxidase inhibitors; ↑ = increased; ↓ = decreased; → = unchanged.
Source Adapted from Buysse and Reynolds [249]

disturbance, including both nightmares and insomnia symptoms [169]. Both prazosin and a behavioral sleep intervention that included insomnia and nightmare-related components were found to have similar treatment response rates (~60 % compared to ~25 % in a placebo), which were further associated with improvements in both sleep and daytime PTSD symptoms in a placebo-controlled trial [170].

Much like polysomnographic studies of insomnia, in which sleep variables do not significantly differ from those of controls, reports of polysomnographic abnormalities in PTSD have been inconsistent (see Germain [171]; Kobayashi et al. [172] for meta-analytic review). This disorder has been associated with increased sleep-onset latency, decreased sleep efficiency, increased wakefulness after sleep onset, decreased total sleep time, reduction in stage 2 sleep, and increased stage 1 sleep [173]. There is controversy over the effects on REM sleep: Some authors report normal REM sleep parameters [173], whereas others report reduced REM sleep latency and increased REM density [174–176]. Nightmares have been found to occur during both NREM and REM sleep [177, 178]. Authors have speculated that PTSD may be a disorder of REM sleep mechanisms [179].

Obsessive–Compulsive and Social Phobia Disorders

Less work has been done in obsessive–compulsive disorder or social phobia, although these disorders too are common. Patients with social phobia show increased sleep-onset latency, awakening after sleep onset, and reduced total sleep time [180]. In obsessive–compulsive disorder, sleep can become restricted by repeatedly engaging in compulsive behaviors. Sleep studies in obsessive–compulsive disorder show decreased total sleep time, increased number of awakenings, shortened REM sleep latency, reduced stage 4 sleep, and reduced sleep efficiency [181].

Eating Disorders

Most studies of patients with bulimia show very little change in REM sleep measures compared with controls. REM sleep architecture studies of patients with anorexia nervosa have been more contradictory: Some report no change in REM sleep parameters [182], whereas others suggest that there are changes similar to those seen in major depression [183]. These findings may be due to high rates of comorbidity with affective disorders and frequent family history of affective disorders in anorexia patients. Patients with severe untreated anorexia nervosa often show reduced total sleep time, decreased sleep efficiency, increased wakefulness after sleep onset, increased stage 1 sleep, and decreased SWS. Sleep normalizes after weight is gained [184, 185]. One study suggests that there is initial shortening of the REM sleep latency with severe weight loss but that, with recovery of weight, the REM sleep latency returns to normal [186].

Schizophrenia

Patients with schizophrenia often sleep worse than healthy individuals, with sleep continuity disturbance, reduced SWS, decreased REM latency, and increased REM sleep, although there are contrasting studies showing relatively little change in sleep. Variability in documented sleep architecture changes and sleep quality are most likely due to differences in the age of patients, medications, study techniques, and other variables. In one report, sleep quality was disturbed in all 20 schizophrenia participants, and half showed either marked delayed or free-running circadian rhythms as indicated by urinary melatonin [187]. In comparison with unemployed controls, all the patients had longer sleep onsets and sleep durations based on 6 weeks of actigraphy. Sleep efficiency, stage 2 sleep, sleep continuity, total sleep time, and total REM sleep decrease on withdrawal of neuroleptics [188–190]. In one study [188], patients with tardive dyskinesia had an earlier onset of REM suppression after withdrawal of medication. Mean REM sleep latency was shorter, and total REM sleep time was greater, in patients with tardive dyskinesia than in those without tardive dyskinesia. NREM sleep parameters improved more on withdrawal of medication than REM sleep parameters. All patients had prolonged sleep-onset latencies. SWS was more abundant in patients without tardive dyskinesia. Studies have suggested an inverse relationship between SWS and sleep maintenance and brain ventricle size [191–193]. It has been suggested that reductions in SWS and increases in negative symptoms may be related to reduced anabolism and accelerated aging or atrophy of the brain [194]. SWS also does not rebound after sleep deprivation in patients with schizophrenia [195]. In several more recent and larger studies, reduced sleep spindle activity and EEG power has been observed in individuals with schizophrenia [196–198], suggesting thalamocortical dysfunction. In a further study, reduced density and number of sleep spindles in schizophrenia predicted less overnight improvement in sleep dependent memory consolidation on a finger-tapping motor sequence task [199]. Thus, sleep dysregulation may be a marker or mechanism for the neurocognitive dysfunction central to schizophrenia.

Borderline Personality Disorder

Borderline personality disorder as defined by the DSM-5 encompasses a number of symptoms of other psychiatric disorders, including major depression. In numerous studies of borderline personality disorder, sleep architecture changes are very similar to those observed in patients with major depression [200–203]. Borderline personality disorder patients have less total sleep time, less sleep efficiency, reduced SWS, increased stage 2 sleep, reduced REM sleep latency, and increased REM density. Subjects with borderline personality disorder frequently have symptoms of depression and have been shown to have abnormalities of other biological markers associated with depression [204].

Childhood Psychiatric Disorders

Sleep disturbances are associated with a variety of behavioral and emotional problems in childhood and adolescence: anxiety and depression [205, 206], attention/hyperactivity symptoms [207, 208], and behavioral problems such as acting out [209]. As reported in the adult literature, a number of studies have suggested a bidirectional association between sleep and behavioral/emotional problems in childhood [210, 211].

Sleep and behavioral/emotional problems were longitudinally assessed in 490 children between the ages of 4 and 15 [206]. Sleep problems at age 4 were associated with an increase in behavioral/emotional symptoms in mid-adolescence, although evidence for a reciprocal relationship was inconsistent. Early childhood sleep problems (mother-reported overtiredness and trouble sleeping at age 3–5) were similarly found to predict the early-onset use of alcohol and other drugs during mid-adolescence (age 12–14) in a longitudinal sample of 257 high-risk Caucasian Americans families [212]; sleep problems also predicted elevated attention and anxiety/depression symptoms during adolescence, although these problems did not mediate the relationship between early childhood sleep problems and substance use.

Childhood sleep problems are also associated with increased risk for adult psychopathology. Parent-reported sleep and psychiatric symptoms at ages 5, 7, and 9 were compared with current anxiety and depression using standardized structured interviews at age 21 and 26 in a longitudinal sample of 943 individuals [8]. Persistent sleep problems in early childhood predicted adulthood anxiety disorders (46 %:33 % ratio of adolescents with anxiety who did and did not have persistent childhood sleep problems, respectively), but not adulthood depression, in this sample. Although similar connections between sleep and depression are found in both pediatric and adult populations, polysomnographic differences in clinical populations with depression have been less consistent in the child and adolescent literature (see Ivanenko et al. [213]).

Tourette's syndrome often results in sleep disruption. Increased SWS and decreased REM percentages, and

increased awakenings and motor tics, were observed in a sample of 14 Tourette's syndrome patients less than 23 years old compared to 11 matched controls [214]. Motor tics may disturb sleep, and patients with comorbid ADHD experience the most sleep disturbance [215, 216].

ADHD may be associated with childhood insomnia [215], sleep deprivation, and snoring and obstructive sleep apnea [63], and sleep problems are much more likely to be reported by adults with ADHD. Several polysomnographic studies in children with ADHD have reported relatively normal sleep parameters [217–219]; however, an investigation of 38 school-age boys with ADHD and 64 control school-age boys using sleep diaries and actigraphy found increased instability in sleep onset and sleep duration in the patient group [208]. Objective and subjective sleep was measured in 20 adults with primary ADHD [220]. Compared to matched controls, patients had an increase in polysomnographically measured total sleep time and periodic limb movements in sleep; the latter were inversely related to subjective total sleep time. Subjective sleep quality was lower in patients than the controls. Sleep complaints were also more likely to be reported in a sample of 120 adults with ADHD compared to a control sample, including RLS symptoms and not feeling refreshed in the morning, although complaints of insomnia were related to comorbidity with depression [221].

Rates of sleep disturbances in >75 % in children with autism have been reported [222, 223]. One study compared individuals with autism to their nonaffected siblings [224]. With the autism group, sleep problems such as bedtime resistance, insomnia, and daytime sleepiness were more likely than in the sibling group (respective odds ratios: 2.7, 4.1, and 7.6). Sleep problems were also associated with more behavioral problems such as greater withdrawal, aggression, and total behavioral problems.

Alcohol and Substance Abuse Disorders

Dependence on alcohol or other drugs of abuse almost invariably leads to sleep problems both while on and when trying to get off the substance. Withdrawal effects can often lead to insomnia or hypersomnia symptoms. The impact on sleep can last for years into abstinence, as has been documented in alcohol abuse. Long-term chronic problem drinkers have markedly fragmented and shortened sleep that contains more light and less deep sleep, as well as elevated percentages of REM sleep, after 1–2 years of abstinence [225–227]. Sleep disturbances have been suggested as a pathway for the development of alcohol and substance abuse and are associated with increased risk for relapse following substance abuse treatment. For example, the adolescent who finds she cannot fall asleep unless first smoking marijuana may shift from being an occasional to a habitual user. Alcohol is an oft-used self-medication for difficulty falling asleep; unfortunately, while alcohol is quite effective in hastening sleep onset, the effect wears off after a few hours, leading to sleep fragmentation [228]. Alcohol also has the unexpected effect of interacting with sleep loss, leading to marked daytime sleepiness [229, 230]. Likewise, sleep disruption can be highly frustrating and may be one of the motivating factors driving some back to substance use if disrupted sleep suddenly becomes very prominent during the initial withdrawal and subsequent abstinent period.

Both daytime sleepiness and insomnia symptoms can lead to self-medication with stimulants and to alcohol and marijuana use, which, given the negative effects these substances have on sleep, can lead to an escalating pattern of use and worsening sleep disturbance. Subjective sleep complaints consistently predict relapse in individuals with alcohol dependence, as do objective, polysomnographic markers of sleep disturbance. In the first few weeks of abstinence, elevated REM density was the best predictor of relapse 3 months postdischarge from a 1-month treatment program [231, 232]. At 5 months, REM measures no longer predicted relapse at 1 year; however, objective sleep disturbances consistent with insomnia symptoms, including long sleep latency and poor sleep efficiency, were predictive. Sleep latency measured about 1 month into abstinence was the best predictor of patients who relapsed by the fifth month [233].

Johnson and Breslau [234] reported a positive association between trouble sleeping and nicotine, alcohol, and other drugs of abuse in a large cross-sectional survey of 13,381 adolescents 12–17 years old, suggesting that sleep difficulty, psychiatric symptomatology, and substance use may co-occur within the same individuals. Thus, specific attention to sleep and psychiatric symptoms in people undergoing alcohol and other drug abuse treatment programs may well improve outcomes and decrease relapse rates in these populations.

Medication Effects and Substance Abuse

The reader is referred to Table 46.1 for a review of the acute, chronic, and withdrawal effects on sleep parameters of various medications and substances of abuse.

Treatment of Sleep Problems in Patients with Psychiatric Illness

Patients who present to sleep disorders centers frequently exhibit symptoms of psychopathology, which may or may not be due to psychiatric illness. Because many sleep practitioners do not have extensive psychiatric training, it is often necessary to engage the assistance of a psychiatrist or psychologist to evaluate a patient with suspected or known psychiatric illness. Psychological tests such as the Inventory of Depressive Symptoms, Beck Depression Inventory, and State Trait Anxiety Inventory are useful for screening patients with sleep disorders for psychopathology. These tests alone, however, are somewhat limited. Many patients with untreated organic sleep disorders such as sleep apnea show changes in psychological tests that are suggestive of psychopathology, but the changes may resolve following effective treatment of the disorder; continued assessment is warranted, however, as symptoms may not resolve.

Likewise, may patients with psychiatric illness often have sleep symptoms. The sleep disorder specialist may be called upon to help determine whether there is an underlying organic disorder such as sleep apnea, RLS, or periodic limb movements that may cause or contribute to the symptoms. In addition, the sleep specialist can be especially helpful in assessing and correcting behaviors that contribute to sleep impairment. The sleep disorder specialist may also be in a position to recommend sleep-specific pharmacotherapy, typically involving sedatives and stimulants (i.e., onset of action, duration of action, relative toxicity, drug interactions, drug withdrawal effects, and relative effects on alertness and sleep parameters).

There is mounting objective evidence to support the claim that behavioral/CBT-I interventions are useful in improving insomnia in patients with psychiatric illness (see Smith et al. [235]. for a thorough review of relevant issues and outcome data for CBT-I interventions in the context of other psychiatric and medical disorders). Behavioral interventions include stimulus control instructions [236] and sleep restriction [237]. CBT-I interventions usually include an additional cognitive component, such as correcting dysfunctional beliefs about sleep (e.g., "If I don't get enough sleep tonight, I'll fall apart tomorrow"), although no evidence shows that CBT-I interventions are superior to behavioral interventions alone. In addition, there are data to support the argument that patients with chronic insomnia have sustained benefit with and without adjunctive sedative administration [238, 239]. Most evidence supporting the use of behavioral intervention in psychiatric populations comes from studies in depression and PTSD. Given the links between sleep and psychopathology described earlier, however, such behavioral interventions may prove quite valuable for other disorders such as other anxiety disorders, dementia, or within pediatric populations. Indeed, a pilot study of CBT-I in 15 individuals with persistent persecutory delusions reported large reductions in both insomnia and persecutory delusions (in two-thirds and half the sample, respectively) that persisted at one month [240].

The severity of the insomnia of a psychiatric patient often parallels the severity of the illness. Therefore, the aggressiveness of medication and behavioral management of insomnia in psychiatric patients should parallel the severity of psychiatric symptoms. Patients with severe sleep disturbance due to schizophrenia or affective psychosis often require sedating neuroleptics as well as adjunctive sedative-hypnotics. Patients with schizophrenia and affective disorders with nocturnal hallucinations may need additional neuroleptic medication for better control of their illness to reduce nighttime hallucinations. Chronic psychiatric illnesses with associated insomnia are much more difficult to manage and may require long-term insomnia treatment with medications such as benzodiazepine receptor agonists. Psychiatric illnesses that are intermittent (e.g., major depression) may require hypnotics only during the active phase of the illness.

In some instances, medications used in psychiatric patients aggravate an existing organic sleep problem or insomnia. Antidepressants, antipsychotics, and antihistamines may aggravate RLS. Sometimes, nocturnal akathisia, which has symptoms very similar to RLS, is caused by neuroleptic compounds. Medications such as selective serotonin and serotonin–norepinephrine reuptake inhibitors (SSRI, SNRI), monoamine oxidase inhibitors, bupropion, buspirone, and some tricyclic drugs (protriptyline, desipramine) can have stimulating properties, may aggravate insomnia. Despite studies showing sleep disruption with stimulating antidepressants, however, patients placed on these compounds often report subjective improvement in their sleep, particularly with the SSRIs.

There is little evidence that treatment of insomnia due to depression without other interventions such as psychotherapy, antidepressant therapy, or ECT relieves depression [241]. Combinations of antidepressants and sedatives can improve insomnia without interfering with the antidepressant effectiveness or onset of action [242, 243]. Pharmacotherapy for insomnia in patients with affective disorders can be addressed in one of several ways: The patient can be given an antidepressant alone, a combination of two antidepressants (e.g., SSRI plus low-dose trazodone, doxepin, or mitazapine), or a combination of a benzodiazepine receptor agonist hypnotic plus an antidepressant. Some antidepressants, such as most of the tricyclic antidepressants and trazodone, have the advantage of causing sedation without the addition of another drug but are limited by side effects (e.g., dry mouth, constipation, myoclonus), toxicity, and daytime cognitive and alertness impairment. SSRIs are

sometimes combined with other sedating antidepressants such as trazodone to improve sleep. The potential for drug interaction between some antidepressants [244] and development of the "serotonin syndrome" exists in this scenario. Additionally, there is little empirical evidence to support the use of trazodone in primary insomnia, despite its widespread use to treat insomnia in the USA. There are no studies of long-term use of trazodone for treating insomnia [245], and unfortunately, little treatment outcomes research for secondary insomnia (due to psychiatric or other conditions) exists despite its widespread prevalence.

While there are case reports that tricyclic antidepressant and SSRIs can lead to or exacerbate RLS symptoms, this has not always been supported. Brown et al. [246] did not find an association between antidepressant use and RLS using a retrospective chart review sample of 200 consecutive patients presenting with sleep-onset insomnia. Leutgeb and Martus [247] compared RLS symptoms before and after 6 months of tricyclic or SSRI pharmacotherapy in a sample of 243 mood or anxiety disorders patients. Antidepressant pharmacotherapy was not found to be a significant risk factor for RLS symptoms, although nonopioid analgesics, usually with caffeine, were associated with increased risk of RLS.

The appropriate selection of a sedative-hypnotic for patients with psychiatric illness is often more difficult than for the general population. There is greater potential for adverse drug interactions with multiple psychotropic medications than between most sedatives prescribed along with medications used for other conditions. Particular attention must be paid to the duration of action of sedatives in patients with anxiety. There may be a tendency for increased daytime anxiety in patients taking short- and intermediate-acting sedative-hypnotics [248]. Alternative approaches include using multiple doses of intermediate-acting benzodiazepines (e.g., lorazepam, alprazolam, oxazepam) during the day and using the same medication at bedtime as a hypnotic. Another approach is to use a long-acting antianxiety agent such as diazepam, clonazepam, or chlordiazepoxide less frequently during the day and also as a hypnotic. As some of the intermediate- and long-acting benzodiazepine antianxiety agents have slower absorption, they may need to be given approximately an hour before bedtime for the sedative properties to have enough time to take effect. Patients with nocturnal panic attacks may benefit from benzodiazepines such as alprazolam, estazolam, or clonazepam. In addition, various antidepressants, β-blockers, calcium channel blockers, and α agonists may be useful.

As with all patients, those with chronic psychiatric illness with associated chronic insomnia require careful follow-up to ensure that no long-term adverse effects result from psychotropic drugs and, in cases in which medications with abuse potential are necessary, that the patients do not increase their dose. When any patient presents to the sleep disorders center taking an excessive amount of a sedative with abuse potential, or taking a normal dose of a sedative for a prolonged period, it is very important to determine whether there is a psychiatric illness or any underlying tendency to abuse drugs. Some patients with sleep disorders such as persistent psychophysiologic insomnia and periodic limb movements may not have had the underlying causes of their insomnia identified and therefore resort to long-term use of sleeping medication. These individuals may increase the dose of the sedative to quite large amounts to achieve sleep, yet do not experience the craving or euphoria often associated with substance abuse. For them, it is quite important to identify the underlying causes of the sleep problem. After long-term use of large doses of sedatives, it is very important that the patient be tapered gradually. After treatment of underlying organic sleep disorders and training in sleep hygiene and relaxation skills, these patients may be able to sleep without the help of habituating medication.

Conclusion

Although sleep quality and duration impact affective function, the pathophysiologic processes by which sleep is linked to daytime mood and functioning are poorly understood. Continued research efforts to expand our knowledge of sleep and its functions will improve our understanding of the pathophysiology of disordered sleep generally and its role in the development and maintenance of psychopathology, and pave the way for continued improvements in behavioral and pharmacologic interventions to improve outcome and functioning in individuals with sleep and/or psychiatric disorders.

Sleep Disturbances in General Medical Disorders

47

Sudhansu Chokroverty

Introduction

General medical disorders through metabolic, toxic, or anoxic disturbances may cause a disruption of neuroanatomic substrates for sleep/wakefulness by indirectly affecting the sleep-/wake-promoting neurons. It is therefore incumbent upon the sleep specialist, general internist, and primary care physician to have a high index of suspicion for the presence of sleep disorders so that appropriate steps for assessment and management of these patients can be instituted. This chapter deals with medical disorders—excluding neurologic diseases—associated with sleep dysfunction, which may cause added distress to the existing complaints related to the medical disorders and which may need special attention. For example, if a patient suffering from bronchial asthma or coronary artery disease, complaining of difficulty initiating or maintaining sleep, unrefreshing sleep, and excessive daytime sleepiness, seeks the attention of a physician, these complaints are obviously causing additional distress and need special attention. The latest edition of the International Classification of Sleep Disorders (ICSD-3) [1] does not list a separate category of sleep disturbances associated with medical disorders, in contrast to the first edition. These medical disorders are mentioned within the seven major categories of sleep disorders as well as in Appendix A of the ICSD-3 [1].

Gislason and Almqvist [2] did an epidemiologic study in a random sample of 3201 Swedish men ages 30–69 years. Difficulty initiating or maintaining sleep and too little sleep were the major complaints, followed by excessive daytime somnolence or too much sleep. Sleep maintenance problems became more frequent with increasing age. The following conditions were associated with the sleep complaints: systemic hypertension, bronchitis and bronchial asthma, musculoskeletal disorders, obesity, and diabetes mellitus. The authors suggested that the reported increased mortality among patients with sleep complaints might be related to the intercurrent somatic diseases.

In a questionnaire of 100 adult male medical and surgical patients in a teaching hospital in Melbourne, Australia, Johns and coworkers [3] found that increasing age and ischemic heart disease were mostly associated with long-term sleep disturbances. In a three-year longitudinal study comprising 6800 men and women aged 65 and older, risk factors associated with insomnia included several medical conditions such as heart disease, cancer, diabetes, and stroke as well as hip fractures and use of sedatives [4]. Several other epidemiologic studies [5–8] attest to the frequent association of sleep disturbances with medical disorders. Stroe et al. [7] studied 2612 individuals drawn from an unselected adult population-based sample (18–65 years) to characterize excess daytime sleepiness (EDS) associated with a variety of chronic medical disorders (MD) using Epworth Sleepiness Scale (ESS) as a standardized measure. Sixty-seven percent of the sample reported a MD and the prevalence of 31.4 % in individuals with MD. Among general medical disorders the highest degree of sleepiness associated with significant sleep difficulties (e.g., sleep onset and maintenance problems with frequent awakenings) was found in patients with peptic ulcer diseases. They also noted significant sleep disturbance in those with colitis and that clinically significant EDS increased directly with the number of MD. Using self-reported measures of sleep habits and polysomnographic study (obtained in a subset) in a community-based sample of 3282 men and women aged 18–65 years, Budhiraja et al. [8] documented a prevalence of insomnia of 21.4 % with 2.2 times higher odds ratio for those with any medical disorders than in those without medical disorders. They also noted that prevalence of insomnia increased with increasing number of medical conditions. However, PSG evidence of disturbed sleep was noted in only a small subset of comorbid insomnia population.

When a patient presents to a sleep specialist with sleep disturbance, with the complaint of either insomnia or hypersomnia, the first important step is to obtain a detailed medical history and other histories, followed by physical examination to uncover a cause for the sleep disturbance. Often, the patient presents to an internist or a family practice physician, who may then refer for a consultation to a sleep specialist if there are sleep complaints. Therefore, a comprehensive knowledge of major medical disorders that may present with sleep disturbance is essential. In this chapter, a review of the salient clinical diagnostic points of some important medical disorders presenting with sleep disturbance is offered, along with information on key laboratory investigations.

Medical Disorders that Cause Sleep Disturbances

Several medical disorders are associated with sleep disturbances, as listed here. The mechanisms and general features of sleep disturbances in medical disorders are also briefly described. For further details, readers should consult general textbooks of internal medicine.

- Cardiovascular diseases: cardiac arrhythmia, congestive cardiac failure, ischemic heart disease, and nocturnal angina
- Intrinsic respiratory disorders: chronic obstructive pulmonary disease, asthma (including nocturnal asthma), and restrictive lung disease
- Gastrointestinal diseases: peptic ulcer disease, reflux esophagitis, celiac disease, Whipple's disease, and functional bowel disorder
- Endocrine diseases: hyperthyroidism, hypothyroidism, diabetes mellitus, and growth hormone deficiency and excess
- Renal disorders: chronic renal failure and sleep disturbances associated with renal dialysis
- Hematologic disorders
- Rheumatic disorders, including fibromyalgia syndrome and systemic lupus erythromatosis
- Dermatologic disorders
- Acquired immunodeficiency syndrome
- Lyme disease
- Chronic fatigue syndrome
- Medical and surgical disorders of patients in medical and surgical intensive care units
- African sleeping sickness (trypanosomiasis)
- Cancer
- Medication-related sleep–wake disturbances.

Mechanism of Sleep Disturbances in Medical Disorders

Sleep disturbance may have an adverse effect on the course of a medical illness. Thus, a vicious cycle may result from the effect of sleep disturbance on the medical disease and the effect of the medical illness on sleep architecture.

Sleep may be disturbed in medical disorders by a variety of mechanisms, including

- Indirect effects on the hypnogenic neurons in the diencephalon and brain stem, and respiratory neurons in the brain stem, by metabolic disturbances (e.g., renal, hepatic, or respiratory failure; electrolyte disturbances; hypoglycemia or hyperglycemia; ketosis; and toxic states)
- Adverse effects on sleep organization and sleep structure by drugs used to treat medical illness
- Disturbances of circadian rhythm (i.e., sleep–wake schedule)
- Effects on the peripheral respiratory mechanism (including respiratory muscles) causing respiratory sleep-disordered breathing
- Esophageal reflux, which may be due to prolongation of acid clearance of the lower esophagus, aspiration, and reflex mechanism (see Chap. 11)
- Adverse effect on sleep structure after prolonged immobilization resulting from medical disorders
- Dysfunction of the autonomic nervous system caused by medical disorder (e.g., diabetes mellitus, and amyloidosis).

General Features of Sleep Disturbances in Medical Illness

Sleep architecture, sleep continuity, and sleep organization may be affected in a variety of medical illnesses. Patients may present with either insomnia or hypersomnolence, but the most medical disorders present with insomnia. Some patients may have a mixture of insomnia and hypersomnolence (e.g., those with chronic obstructive pulmonary disease or nocturnal asthma). Other sleep complaints include abnormal motor activity and behavior intruding into sleep (parasomnias), sleep-related breathing problems with sleep fragmentation and snoring during sleep, and disturbances of normal sleep–wake rhythm (circadian rhythm disorders). Table 47.1 lists the medical causes of insomnia. For medical causes of hypersomnolence, see Table 3.1 in Chap. 3.

Patients with insomnia may complain of lack of initiation of sleep, inability to maintain sleep, repeated arousals at

Table 47.1 Medical causes of insomnia

Congestive heart failure
• Ischemic heart disease
• Nocturnal angina
• Chronic obstructive pulmonary disease
• Bronchial asthma, including nocturnal asthma
• Peptic ulcer disease
• Reflux esophagitis
• Rheumatic disorders, including fibromyalgia syndrome
• Lyme disease
• Acquired immunodeficiency syndrome
• Chronic fatigue syndrome

night, and early morning awakening. Daytime symptoms of fatigue, inability to concentrate, irritability, anxiety, and sometimes depression may be related to the sleep deprivation. Polysomnographic (PSG) findings include prolonged sleep latency, reduction of rapid eye movement (REM) sleep and slow-wave sleep (SWS), more than 10 awakenings per night, frequent stage shifts, early morning awakening, increased waking after sleep onset (WASO), and increased percentage of wakefulness and stage 1 non-REM (NREM) sleep.

Patients with hypersomnolence may present with repeated daytime somnolence, fatigue, depression, headache, and intellectual deterioration related to repeated sleep-disordered breathing (SDB) and hypoxemia [9]. PSG findings consist of SDB, repeated arousals with oxygen desaturation at night, sleep fragmentation, sleep stage shifts, reduced SWS, shortened sleep-onset latency on the multiple sleep latency test, and sometimes REM sleep abnormalities [9].

Systemic medical disorders may cause neurologic disturbances, which in turn may cause sleep disturbances either directly by affecting sleep–wake systems in the central nervous system (CNS) or indirectly by affecting breathing. Sleep-related breathing dysfunction and other sleep disturbances which may be seen in neurologic illness are described in Chap. 41.

Specific Medical Disorders and Related Sleep Disturbances

Cardiovascular Disease

It is generally well known that sleep disturbances may occur in cardiovascular diseases, particularly in patients with ischemic heart disease, myocardial infarction, or congestive cardiac failure (CCF). Cardiac arrhythmias and sudden cardiac death at night are also known to occur, although adequate objective tests, including PSG study to document such disturbances, are lacking.

Ischemic Heart Disease

A careful inquiry into history is most important in making the diagnosis. The patient complains of a sense of tightness in the middle of the chest and a band-like feeling around the chest. The pain is often induced by exertion and relieved by rest. Generally, it lasts only a few minutes. When the patient complains of pain on lying supine, it is known as *angina decubitus,* whereas pain that awakens the patient at night is known as *nocturnal angina.* Infrequently, the pain results in coronary artery spasm accompanied by transient ST-segment elevation in the electrocardiogram (ECG), and the entity is then known as *Prinzmetal's* or *variant angina.* The condition is most common in middle-aged men but may affect postmenopausal women. Complications include cardiac arrhythmias; left ventricular failure; acute myocardial infarction; and sudden cardiac, often nocturnal, death.

Sleep disturbances are very common in patients with ischemic heart disease. Pain may awaken the patient, causing frequent awakenings and reduced sleep efficiency. Obstructive sleep apnea syndrome (OSAS) is associated with arterial hypoxemia causing cardiac ischemia. Simultaneous recording of an ECG may show ST-segment depression at least 1 mm below the horizontal, whereas ST-segment elevation occurs in Prinzmetal's or variant angina. Often, the patient complains of discomfort in the arms during the retrosternal pain. Pain may sometimes radiate to the epigastrium or to the neck and the jaw. It may be accompanied by shortness of breath. An ECG is essential for the diagnosis of ischemic heart disease or myocardial infarction. Coronary angiography provides information about the site of coronary artery occlusion.

Treatment consists of avoiding exertion for patients susceptible to angina attacks and administration of drugs such as nitrates, β-blockers, and calcium channel antagonists.

Patients with severe symptoms that persist despite medical treatment may need surgical treatment in the form of coronary artery bypass grafting or stenting.

Factors contributing to myocardial ischemia, infarction, or arrhythmia include increased sympathetic surge during REM sleep, increased platelet aggregability, hypotension associated with SWS and altered balance between fibrinolytic and thrombotic factors, oxygen desaturation, and increased ventricular diastolic pressure and volume associated with supine posture. There is also increased risk of CCF among patients with the onset of myocardial infarction at night [10]. Patients with diabetes, advancing age, and impaired ventricular function are at an increased risk for developing nocturnal myocardial infarction [11, 12].

"Nondippers" (those hypertensive patients whose blood pressure during sleep does not decline or declines less than 10 % from daytime to nighttime readings) have significant risk for developing cardiac arrhythmias, stroke, and death from cardiovascular disease [13]. Newman et al. [14] have shown that daytime sleepiness associated with sleep disturbances in elderly patients, especially women, is a predictor of cardiovascular morbidity and mortality and CCF.

Nocturnal Angina, Myocardial Infarction, and Sleep Disturbance

Nocturnal angina or myocardial infarction may cause frequent arousal, sleep maintenance insomnia, and impaired sleep efficiency. Nocturnal angina is known to occur during both REM and NREM sleep stages. Karacan et al. [15] found increased sleep-onset latency, reduced SWS, decreased sleep efficiency, and very little change in REM sleep on PSG study in 10 patients with a history of nocturnal angina. In several reports, circadian susceptibility to myocardial infarction (attacks are most likely between midnight and 6:00 AM) has been described [16, 17]. Broughton and Baron [18] in an early report found decreased sleep efficiency, increased sleep stage shifts, increased awakenings, and decreased REM sleep in 12 patients with acute myocardial infarction studied in the ICU. Sleep patterns became normal by the ninth day of the illness.

Coronary artery disease (CAD) is one of the most frequent causes of morbidity and mortality [19]. Sleep-disordered breathing (SDB) and CAD have a bidirectional relationship [20]. Impairment of cardiac function by CAD determines the severity of SDB [21]. Fifty percent of patients with CAD have SDB and if the cardiac function is impaired most apneas are of obstructive nature. In contrast, in patients with acute myocardial infarction (MI) causing impaired cardiac function, half of the SDB patients will have obstructive and the other half will have predominantly central apneas [22]. Cross-sectional and case-control studies have documented increased prevalence of calcified and noncalcified coronary artery plaques (subclinical coronary atherosclerosis) in SDB [21, 23, 24].

In several epidemiologic studies, there is a clear relationship between increased cardiovascular morbidity and mortality and sleep disturbances associated with SDB. Patients with CAD and obstructive sleep apnea (OSA) may have an increased cardiac risk due to nocturnal myocardial ischemia triggered by apnea-associated oxygen desaturation. In many case-control studies in the past, an association between sleep apnea and increased risk of myocardial infarction was noted [25–27]. Epidemiologic data from the Sleep Heart Health Study demonstrated a linear relationship between the apnea–hypopnea index (AHI) and risk of CAD, including myocardial infarction [28]. In a population-based prospective study including a postal questionnaire regarding sleep complaints in a random sample of 1870 subjects, Mallon et al. [29] provided evidence at the 12-year follow-up that there was an association between difficulty falling asleep and CAD mortality in men. In a more recent population-based prospective Sleep Heart Health Study, Gottlieb et al. [30] noted that OSA was a significant predictor of incident CAD in men 70 years or less but not in older men or women of any age.

A high prevalence of OSA in patients with CAD has been noted in several other studies [31–43]. An important early observational study was done by Marin et al. [35] recruiting men with OSA or simple snorers from a sleep clinic and a population-based sample of healthy men matched for age and body mass index with untreated severe OSA patients (total $N = 1651$). All had PSGs and were followed up at least once per year for a mean of 10.1 years; compliance with treatment of OSA with continuous positive airway pressure (CPAP) was checked with a built-in meter. Multivariate analysis adjusted for confounders showed that untreated severe OSA increased the risk of fatal and nonfatal myocardial infarction and stroke compared with healthy participants; CPAP treatments reduced this risk. The authors also noted that mild-to-moderate untreated OSA patients had an intermediate risk for these events, indicating a dose–effect relationship. The survival benefit to CPAP therapy in these patients as shown by Marin et al. [35] is also supported by other studies [32, 44, 45]. Prior to the study by Marin et al. [35], long-term beneficial effects of CPAP treatment in patients with OSA and CAD were shown by Milleron et al. [46]. These authors treated 25 of 54 patients with OSA and CAD (29 declined treatment). At a mean follow-up of 87 months, the treatment significantly reduced the risk of occurrence of cardiovascular death, acute coronary syndrome, hospitalization for heart failure, or need for coronary revascularization. Similar results were observed by Doherty et al. [47], who reported that deaths from cardiovascular disease were more common in an untreated group (61 patients who were intolerant to CPAP) than in a CPAP group (107 patients) after follow-up of 7.5 years [47].

There are some more recent studies showing adverse short-term and long-term outcomes in patients with acute MI and SDB. There is evidence that patients with acute MI and SDB have more severe CAD predisposing them to the development of heart failure [21, 37–41]. Recent long-term outcome studies in patients with acute MI and SDB are all observational in nature, precluding from making any definite conclusions [21]. The study by Lee et al. [48] enrolling 120 patients with an acute MI showed that those with comorbid severe OSA had higher incidence of adverse events than those with less severe or no OSA after a follow-up period of 18 months. In another case-control study [40], including MI patients with and without OSA, those who received CPAP treatment for OSA had a lower risk of recurrent MI than untreated OSA patients and similar to those without OSA after a follow-up period of six years. However, long-term effects of CPAP treatment in patients with acute coronary syndrome and OSA in terms of preventing development of heart failure and recurrent MI and mortality cannot be determined definitely without further randomized control studies using larger number of patients and a longer follow-up [21].

In an important study, Kripke et al. [49] noted increased mortality rates among patients with ischemic heart disease, stroke, and cancer who slept 4 h or less, or more than 10 h. Wingard and Berkman [50], in their study of approximately 7000 adults over a period of 9 years, also found excessive mortality from ischemic heart disease in short sleepers (less than 7 h) and long sleepers (more than 9 h). Poor sleep was thus associated with increased risk of future cardiovascular morbidity or mortality. These results, however, were contradicted by a later study by Mallon et al. [29] observing that short or long sleep duration did not influence the risk of CAD mortality or total mortality for either gender. In a later study, Meisinger et al. [51] reported a modest association between short sleep duration and difficulty maintaining sleep, and risk of occurrence of myocardial infarction in middle-aged women, but not men, from a general population sample in Germany. In a more recent study [52], a positive association was noted between short sleep duration and poor sleep quality, and CAD in a selected sample of Indian adults. Therefore, short sleep duration and poor sleep quality can be considered modifiable CAD risk factors, at least in this population.

Heart Failure

Heart failure is the preferred term instead of congestive heart failure as pulmonary congestion, although common, is not a universal feature [53]. There is a strong association between advancing age and HF, and 10 % of the population over the age of 80 has HF. Furthermore, in the USA, HF is the leading cause of hospitalization for those older than 65 years. Chronic HF is a growing public health problem affecting more than 2 % of the adult population, and HF is a leading cause of morbidity and mortality [53, 54]. SDB is the most common comorbidity in HF and newly diagnosed CSA and OSA are independently associated with increased mortality in HF [55–60]. There are two phenotypes: HF with reduced (<50 %) ejection fraction (EF) [HFrEF] or what is known as systolic HF; and HF with preserved (exceeding 50 %) EF (HFpEF) and this is now the preferred term instead of what was known as diastolic HF [60]. About 40–50 % of patients with HF belong to HFpEF. HFpEF is often associated with comorbidities (e.g., hypertension, type 2 diabetes mellitus, and atrial fibrillation) and is commonly seen in older individuals [53, 60, 61]. SDB occurs in 70 % or more of the HF patients (OSA and CSA–CSB, each in about half of these patients). Rostral fluid shift from the lower extremities in the recumbent position at night in HF patients worsens OSA [62, 63]. CSA–CSB relates in part to the instability of the central respiratory controllers in the brain stem [53, 59, 64–67].

Mechanism of Central Apnea and Cheyne–Stokes Breathing in Heart Failure

CSB (see Fig. 41.6b in Chap. 41) is characteristic of heart failure.

The following factors play a role in the complex mechanism of CSA–CSB during sleep in HF [52–66, 68–79].

1. Increased loop gain;
2. Increased arterial circulation time;
3. Decreased functional residual capacity (FRC);
4. Altered apnea threshold;
5. Decreased reactivity of cerebral blood flow; and
6. Physiologic instability of the respiratory control system during transition to sleep, sleep stage shifts, and arousals.

Loop Gain (see also Chap. 25)

This is an engineering term implying a ratio of the ventilatory response to internal or external stimuli (e.g., a disturbance in ventilations such as apnea–hypopnea). In HF, there is an augmented chemosensitivity (i.e., increased loop gain) caused by both a pulmonary congestion and an unstable respiratory controller [59, 60, 64, 78, 79] causing increased ventilation in response to increased partial pressure of arterial carbon dioxide ($PaCO_2$) and also to an extent decreased partial pressure of oxygen (PaO_2) resulting in further instability in the central controller. Recent work has shown that CO_2 plays a key role in the pathophysiology of CSR (see further on) [59, 66, 78]. The increased loop gain in HF results from three major components [59]:

1. Increased chemosensitivity (increased central controller gain);
2. Decreased FRC (i.e., increased plant gain causing a large change in $PaCO_2$ for a given change in ventilation); and
3. Increased circulation time (mixing gain).

Increased Arterial Circulation Time These results from a combination of cardiomegaly, decreased cardiac output, and increased pulmonary blood volume. This delayed circulation time prolongs the time it takes for pulmonary blood $Paco_2$ and Pao_2 to reach the central and peripheral chemoreceptor sites. The longer the delay is, the longer is the cycle of CSB. The circulation delay is very common in HFrEF but the circulation time may be normal in HFpEF.

Decreased Functional Residual Capacity (FRC) It is due to a combination of pleural effusion, enlarged heart, and pulmonary congestion causing decreased pulmonary compliance in patients with heart failure. FRC decreases further in the supine position, promoting CSB. Decreased FRC causes underdamping—that is, for a given change in ventilation (e.g., transient cessation of breathing), there is an increased response to changes in Pao_2 and $Paco_2$ [4, 59, 65].

Altered Apnea Threshold Respiration during NREM sleep depends entirely on the metabolic control system (mainly $Paco_2$ levels) and so a small change in $Paco_2$ level will have intense effect on ventilation [58–60, 80, 81]. The apnea threshold (defined as the level of $Paco_2$ below which breathing stops) is close to the actual level of $Paco_2$ during sleep. This proximity of the two $Paco_2$ levels is called $Paco_2$ reserve which is further narrowed in some HF patients promoting development of CSA in HF. Furthermore, HF patients chronically hyperventilate due to pulmonary congestion resulting from rostral fluid shift in the supine position stimulating pulmonary irritant receptors to stimulate ventilation [59, 64, 66] which lowers the CO_2 crossing the apnea threshold [81]. The resultant apnea promotes increase in CO_2 causing hyperventilation. Thus, a vicious cycle of crescendo–decrescendo (CSR) pattern of breathing is perpetuated.

Decreased Reactivity of Cerebral Blood Flow A change in $Paco_2$ causes alteration in cerebral blood flow (CBF) which is called cerebrovascular reactivity [59, 66]. The physiologic homeostatic regulation of CBF in response to changes in $Paco_2$ protects brain including central chemoreceptors. Patients with HF have decreased cerebrovascular response to $Paco_2$ causing breathing instability during sleep [59, 66, 82].

CSB occurs during sleep and wakefulness, although it is pronounced during sleep. It has been shown that HF patients with CSB during daytime wakefulness have almost a four-fold increased mortality [78]. In many patients with heart failure, there is low $Paco_2$ and a failure of rise of $Paco_2$ during sleep, unlike that which occurs in normal individuals as a result of increased venous return in the supine position, increased respiratory rate, and increased ventilation. Heart failure patients with $Paco_2$ less than 35 mm Hg have a high probability for developing central apnea because the low $Paco_2$ is close to the apnea threshold (i.e., the level of $Paco_2$ at which breathing ceases due to a lack of chemoreceptor stimulation).

Mechanism of Obstructive Apnea in Heart Failure CSB itself may predispose to obstructive apnea by decreasing the tone of the upper airway dilator muscles at the end of the ventilatory cycle (the lowest point or nadir). Other factors for obstructive apnea in heart failure include venous congestion in the oropharyngeal region in right heart failure, especially in the supine position, and comorbid obesity [59, 64]. The presence of periodic breathing (e.g., CSB) in heart failure may increase the morbidity and mortality and so it is important to be aware of this. Treatment with CPAP/bilevel positive airway pressure (BIPAP) with or without low-flow (1–2 L/min) supplemental oxygen inhalation and assisted servo-ventilation (ASV) in selective cases may improve the pattern of breathing (see further on).

Clinical-Pathologic Consequences of Heart Failure and Sleep Apnea

The common symptoms of heart failure in obstructive sleep apnea patients include paroxysmal nocturnal dyspnea, orthopnea, daytime sleepiness and fatigue, and sleep onset and maintenance insomnia. Recurrent episodes of apnea and hypopneas accompanied by repeated arousals, hypoxemia, hypercapnia, and sympathetic activation adversely affect cardiovascular function, particularly in patients with CAD and incipient cardiac dysfunction. Indications for overnight PSG in these patients include witnessed apneas, habitual snoring, nocturnal angina, and unrefreshing restless sleep; overnight PSG is also indicated in patients requiring cardioverters or defibrillators: those requiring cardiac transplantation and those with cardiac arrhythmias. It should be noted that many patients with HF may not present with the classic symptoms of sleep apnea such as snoring, daytime sleepiness, and obesity explaining an underdiagnosis of CSA in HF [58, 59, 78, 83]. Many of these patients may actually have unexplained insomnia and have reduced quality of life and increased mortality [59, 78, 83]. Therefore, a high index of suspicion for possible SRBD in HF patients is needed and many even recommend routine screening for SRBD in these

patients to improve outcome and prevent adverse consequences. The pathophysiological consequences resulting from repeated episodes of apnea, hypoxemia, reoxygenation, and arousals throughout the night consist of increased sympathetic nervous system activation, oxidative stress, systemic inflammation, and endothelial dysfunction. CSA–CSB is associated with malignant nocturnal cardiac arrhythmias (e.g., ventricular tachycardia and premature ventricular contractions) in part due to increased sympathetic activation [59, 66]. Atrial fibrillation is also common in HF patients with CSA. Patients with severe CSB may show reduced heart rate variability suggesting autonomic dysfunction [78, 84, 85] which may be associated with increased mortality in HF patients [86]. Treatment of CSA improves nocturnal cardiac arrhythmias and the associated increased mortality [66, 78, 79, 83].

There is an increased mortality associated with sleep apnea and heart failure [87–89]. He et al. [88] reported for the first time that, among 385 men with OSA, those with an apnea index of more than 20 per hour had an increased mortality when compared to those who had been treated with either CPAP or tracheotomy. This was a retrospective study, but later studies confirmed these earlier observations [32, 34]. In a more recent study, Gami et al. [90] reported occurrence of sudden death from cardiac causes in 46 % of patients with OSA as compared to 21 % without OSA from midnight to 6:00 AM. It should be noted that several factors have been associated with the development and progression of CCF and increased mortality in OSA. The following factors are thought to be responsible for vascular endothelial dysfunction causing CAD, hypertension, and stroke: increased sympathetic activity, repeated hypoxemias, re-oxygenation, hypercapnia, hypercoagulopathy, release of endothelin, abnormal endothelial-dependent vasodilation and vascular growth factor and apoptosis, increased levels of inflammatory mediators, increased concentration of adhesion molecules, and oxidative stress [65, 67, 91–94]. Randomized controlled trials with CPAP in patients with OSA have shown improved cardiac function, sympathetic nervous system activity, quality of life, reduction of blood pressure, and reversal of the various neural, hormonal, and biochemical abnormalities, suggesting a cause-and-effect relationship [95–97].

Most of the more recent studies confirmed an increased mortality with a hazard ratio of 2.1–5.7 for CSB [75, 78, 98–101] excepting two studies [102, 103]. Khayat et al. [55] reported the results of the largest prospective study evaluating the effect of SRBD on post-discharge mortality in 1117 hospitalized inpatients with acute heart failure (AHF) with a median follow-up of three years. They concluded that newly diagnosed CSA and OSA are both independently associated with post-discharge mortality in patients with AHF and reduced EF. An independent relationship between SRBD and mortality in untreated patients with stable chronic HF has been reported in several studies [56, 101, 104]. The effect of treatment, however, of CSA or OSA on survival in HF remains unknown.

Principles of Treatment of Heart Failure and Sleep Apnea
The principles of treatment of HF with sleep apnea (both OSA and CSA–CSB) are outlined in the following five steps:

1. The initial step is optimizing medical therapy for HF;
2. General measures;
3. Treatment of OSA;
4. Treatment of CSA–CSB; and
5. Miscellaneous other measures.

I. **Medical therapy for HF**. It is beyond the scope of this chapter to describe in detail medical therapy and the readers are referred to standard texts for this [54]. Briefly, diuretics (both thiazide and loop diuretics) are used to relieve pulmonary congestion, beta-blockers are used to reduce sympathetic activation, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor blockers (ARBs) a combination of ARBs and neprilysin inhibitor and aldosterone antagonist are used to reduce ventricular afterload and improve cardiac output [59, 60, 64, 66, 78, 105, 106]. It is notable that digitalis glycosides which were a mainstay of treatment for decades had no beneficial effect on mortality in HF in a major clinical trial, and these cardiac glycosides are no longer first-line therapy for HF [105].

II. **General measures**. These include weight loss, avoidance of supine sleep, smoking, alcohol ingestion, and sedative-hypnotic use before bedtime (see Table 47.2).

III. **Treatment of obstructive sleep apnea**. The gold standard for treatment of OSA in heart failure is treatment with CPAP or BIPAP (see Chap. 34). Adequate treatment of OSA in heart failure utilizing the measures outlined in Table 47.2 eliminates excessive daytime somnolence (EDS) and improves sleep of these patients. Such treatment may also decrease blood pressure in hypertensive patients and may help reduce the dose of antihypertensive medications. The treatment of OSA with CPAP increases ventricular ejection fraction significantly even within one month after therapy [58, 59, 107–109]. In a meta-analysis of studies involving both OSA and HF, CPAP treatment improved left ventricular ejection fraction [110]. The most recent addition to OSA treatment is hypoglossal nerve stimulation by an implanted device trial in an observational study in 126

Table 47.2 Principles of treatment of obstructive sleep apnea and heart failure

Adequate treatment of heart failure
General Measures
• Weight reduction if needed
• Follow general sleep hygiene measures
• Avoid alcohol and sedative-hypnotics
• Cessation of smoking
• Avoid supine position in subset of patients with positional OSA
Treatment of OSA
• Treat any nasal abnormalities (e.g., septal deviation)
• Nocturnal CPAP/BIPAP
• Supplemental oxygen through CPAP if needed
• Dental appliances
• Upper airway surgery
• Hypoglossal nerve stimulation
• Tracheostomy

BIPAP Bilevel positive airway pressure; *CPAP* Continuous positive airway pressure; *OSA* Obstructive sleep apnea

individuals (OSA without HF) who could not tolerate or accept CPAP [111]. The data on HFpEF are limited. Arias et al. [112] reported that 15 of 27 consecutive patients with OSA had impaired left ventricular relaxation. The authors performed a double-blind sham-controlled crossover trial of CPAP for 12 weeks and noted an improvement in diastolic function.

IV. **Treatment of CSA–CSF**. Treatment of central sleep apnea in heart failure is more difficult than treating OSA. The general measures for treating central apnea/CSB are listed in Table 47.3. Adequate treatment of heart failure may improve or eliminate periodic breathing and decrease circulation time due to increased stroke volume, decreased pulmonary congestion, increased FRC, and decreased sympathetic activity. Javaheri et al. [75, 79, 113, 114] have clearly shown improvement after aggressive treatment of heart failure with diuretics, ACE inhibitors, ARBs, β-blockers, and positive airway pressure devices. CPAP treatment for central apnea has not produced as dramatic results as in OSA. Javaheri has shown that, in mild-to-moderate central apnea patients, overnight use of CPAP improved central apnea in 43 % of patients with systolic heart failure (HFrEF) [115, 116]. The number of premature ventricular contractions, bigemini, and episodes of ventricular tachycardia also decreased. However, severe central apnea patients with heart failure did not respond to short-term CPAP treatment. Treatment lasting from one-to-three months with nasal CPAP in patients with heart failure showed a reduction in the AHI with desaturation and decrease in plasma and urinary norepinephrine, in addition to an increase in ventricular ejection fraction. There are other reports of quality of life [117] improvement and reduction of mortality in such patients after CPAP treatment [35, 118–121], although a large Canadian CPAP trial for congestive heart failure (CANPAP) contradicted this [113]. However, a later study by Arzt et al. [122] showed suppression of central sleep apnea by CPAP and transplant-free survival in heart failure. Cardiac transplantation will virtually eliminate central apnea, but a large number of such patients develop OSA due to weight gain [123]. Cardiac pacing and cardiac resynchronization therapy have been shown to improve some patients with central apnea in heart failure [124–128]. Atrial pacing was thought to improve patients with obstructive apnea [124, 128], but other studies [129–132] did not support such an improvement. Nocturnal nasal supplemental oxygen therapy improves central apnea in heart failure patients [133–140]. Such treatment decreases muscle sympathetic nerve activity and improves left ventricular ejection fraction and quality of life. Additional studies, however, are needed to determine whether such treatment decreases the morbidity and mortality in patients with HFrEF [65, 140]. Bordier et al. [140] in a recent review analyzed 17 studies to determine the effects of nocturnal oxygen therapy (NOT) as an alternative treatment for sleep apnea in HF patients. They concluded that NOT was effective in approximately 50 % of cases with a 50 % reduction of AHI in CSA–CSB but had no effect on obstructive respiratory events. Furthermore, there were no reports of NOT-related death or other harmful effects on the myocardium.

Since its introduction in 2001, adaptive servo-ventilation (ASV) has been shown to reduce CSA events and improve

Table 47.3 Principles of treatment of central apnea and Cheyne–Stokes breathing in heart failure

Aggressive treatment of heart failure
• CPAP/BIPAP
• Adaptive pressure support servo-ventilation
• Atrial overdrive pacing or biventricular pacing
• Supplemental oxygen
• Cardiac transplantation
Pharmacologic treatment (e.g., acetazolamide, theophylline, and diazepam) in selective cases

BIPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure

cardiac function in patients with CSB and HF [104, 141–148]. In contrast to these findings, the results of the recently published servo-ventilation heart failure (SERVE-HF) trial put the sleep community in turmoil [149]. Cowie et al. [149] included 1325 patients with symptomatic chronic HF (NYHA grades II–IV) with reduced ejection fraction (≤ 45 %) and predominant central apnea (AHI ≥ 15) who were randomized to treatment with a specific ASV device (ResMed Autoset CS) or conventional medical therapy (control group). ASV had no significant benefit on the primary outcomes and no beneficial effect on a broad spectrum of functional measures. In contrast, there was a significant increase in both all-cause and cardiovascular mortality with the ASV group. The increased mortality in this study is unexplained. In an editorial in Sleep Medicine Journal by Randerath [142] and in another editorial in New England Journal of Medicine by Magalang and Pack [140], several questions were raised and possible mechanism (some of which were also suggested by Cowie et al. [149]) were discussed. Until the issue is further clarified, the current recommendation [150] is not to use ASV in HF patients with predominantly CSA.

Miscellaneous Other Measures

1. Nocturnal supplemental carbon dioxide (or added dead space) has been used to increase $PaCO_2$ above the apnea threshold but is currently not recommended to treat CSA–CSB in HF [64, 66, 78].
2. Pharmacotherapy with theophylline (a respiratory and cardiac stimulant) and acetazolamide (a carbonic anhydrase inhibitor causing metabolic acidosis) has been used in small trials to treat CSA–CSB in HF with limited success. These agents are not commonly used in HF patients [55, 66, 78, 151].
3. Device-based therapy and cardiac transplantation. These measures have been described above briefly. The latest addition to device-based therapeutic armamentarium is phrenic nerve stimulation [152]. This is an implantable device-based therapy inserted intravenously into a thoracic vein. The phrenic nerve can be stimulated at a set frequency to prevent central apnea [59]. A multicenter randomized control trial (RCT) is ongoing [153].

Hypertension

A high prevalence (22–48 %) of sleep apnea and related symptoms (e.g., EDS) has been noted in patients with systemic hypertension [154–157]. In contrast, studies by Escourrour et al. [158] found no significant difference between 21 hypertensive and 29 normotensive patients in sleep stage distribution and disorganization, AHI and duration, and arterial oxygen saturation (Sao_2). The prevalence of hypertension in sleep apnea patients is approximately 50–90 % [5, 159–167]. In the Wisconsin Sleep Cohort study, a dose–response relationship between hypertension and the AHI as well as snoring has been described [168, 169]. Furthermore, studies have confirmed that treatment of sleep apnea by nasal CPAP reduces blood pressure [6, 170].

Previously Stradling and Davies and others [7, 171–175] made a persuasive argument based on a critical analysis of the literature, and taking into consideration the confounding variables (e.g., age, sex, smoking, obesity, and alcohol consumption), that there is no convincing evidence yet supporting the contention that OSA is a significant independent risk factor for sustained hypertension in humans. Silverberg and Oksenberg [176, 177], however, contended that, even when the confounding factors are taken into consideration, OSA is an independent risk factor for hypertension and that treatment of OSA reduces daytime as well as nighttime blood pressure.

There is now convincing evidence of an association between hypertension and sleep apnea [178–183]. Epidemiologic studies suggest that approximately 50 % of patients with OSA have hypertension and about 30 % of patients with hypertension develop OSA. Compelling evidence on the association between OSA and hypertension in

humans has been provided by epidemiologic studies [164, 179, 181, 184]. In drug-resistant hypertension, the prevalence of OSA is even higher; one study quoted a figure of 83 % [185]. The Sleep Heart Health Study, in a prospective cross-sectional analysis of more than 6000 subjects, showed an independent association between hypertension and OSA [179]. A subgroup analysis by Bixler et al. [180] failed to show this association in subjects older than 65 years. The Wisconsin Sleep Cohort Study [181] was able to show that OSA is an independent risk factor for high blood pressure during a 4-year follow-up study that also showed a dose–response relationship between OSA and blood pressure independent of confounding factors. A population-based case-control study failed to show an association between OSA and high blood pressure in postmenopausal woman [186]. OSA has been considered to be an important risk factor for hypertension [187]. Several reports including randomized, placebo-controlled studies revealed very significant reduction in mean blood pressure during sleep in the CPAP-treated group [188–193] (see Chap. 34 for a detailed discussion). Several recent studies [194, 195] supported these results. Oral appliances also have shown to improve hypertension. A number of well-designed studies [196–199], however, have failed to show significant improvement in blood pressure after CPAP treatment. In a prospective long-term follow-up study [200] of 83 patients with uncontrolled hypertension, coronary heart disease (CHD), and OSA randomized to control or CPAP groups, 73 patients completed the study. CPAP was used for 4.5 ± 1.1 h/night and the median follow-up period was 36 months (interquartile range = 24–54 months). Systolic blood pressure (SBP) decreased by 8 mm Hg ($P = 0.01$) but diastolic blood pressure (DBP) did not reach statistical significance (81 ± 10 mm Hg vs. 79 ± 8 mm Hg; $P = 0.49$). ESS was significantly reduced ($P < 0.001$) and hypertension control improved in the CPAP group. The same group of authors in another study sought to determine predictors of blood pressure fall with CPAP treatment in hypertensive patients with CHD and OSA [201]. Sixty-six patients with moderate-to-severe OSA had used CPAP for a mean of 4.3 h/night with a mean follow-up of 36 months (range 24–60). There was a reduction in both SBP and DBP as well as improvement of daytime somnolence as measured by ESS. These authors noted that baseline BMI, mean blood pressure, and CPAP compliance are independent predictors of a decrease of BP in these patients.

Thus, OSA is a risk factor for hypertension [202–204] but some studies found a lack of such relationship [205–207]. However, as stated above, several randomized control trials (RCTs) have shown a decrement of BP in OSA patients following CPPA treatment [204, 208–210]. In a meta-analysis covering six studies (observational and randomized control trials), the pooled estimate showed a favorable reduction of BP after CPAP treatment in patients with resistant hypertension and OSA [211]. A recent large meta-analysis including 1000 CPAP-treated patients with OSA from 16 RCTS showed significant but small reduction in BP [212]. Several recent RCTs also showed that the average fall of BP is small [207, 213, 214]. Daytime hypersomnolence [assessed by Epworth Sleepiness Scale (ESS)] has been cited as an important predictive factor for BP reduction after CPAP [201]. It should, however, be noted that CPAP does not cause significant reduction of BP on nonsleepy hypertensive patients with OSA [215, 216]. Huang et al. [201] cited the following factors contributing to hypertension in OSA patients: 1. increased sympathetic activation; 2. systemic inflammation; 3. oxidative stress; 4. endogenous vasoactive factors; 5. endothelial dysfunction; and 6. metabolic regulation.

It has been estimated that a fall of BP of 3.3 mm Hg is associated with a reduction of 20 % risk of stroke and a 15 % risk of coronary arterial disease [201].

Although the results have so far been promising, further studies are needed to confirm the beneficial effect of CPAP therapy on high blood pressure in OSA patients [211, 217, 218].

"Nondippers," those hypertensive patients whose blood pressure during sleep does not decline or declines less than 10 % from daytime to nighttime readings have significant risk for developing cardiac arrhythmias, stroke, and death from cardiovascular disease [13, 219, 220]. In addition, extreme dippers (whose BP during high time sleep falls excessively by 20 % or more) and reverse dippers (those in whom the BP instead of declining increases during sleep above the waking values) are similarly also at increased risk.

In addition to systemic hypertension, OSA may also cause severe pulmonary arterial hypertension, particularly in patients with preexisting cardiopulmonary diseases [65, 187]. Factors for developing pulmonary hypertension include several mechanisms such as repeated hypoxemia causing pulmonary vasoconstriction, left ventricular diastolic dysfunction resulting in increased left ventricular end-diastolic pressure, and possible pulmonary vascular remodeling [65]. It is important to remember that several long-term studies have shown improvement of pulmonary arterial hypertension following treatment of OSA with CPAP.

The recognition of the association of metabolic syndrome with OSA should direct attention to an early diagnosis and treatment with a view to preventing serious consequences such as stroke or myocardial infarction. The metabolic syndrome is a serious risk factor for cardiovascular disease and includes hypertension, hypertriglyceridemia (dyslipidemia), central obesity, glucose intolerance and insulin resistance (syndrome X) or hyperinsulinemia, and low levels of high-density lipoprotein cholesterol [51, 65, 221]. Kaplan

[221] spoke about a deadly quartet: upper body obesity, glucose intolerance, hypertriglyceridemia, and hypertension.

Cardiac Arrhythmias and Sleep

An understanding of the interaction between the autonomic nervous system (ANS), cardiac innervation, and sleep is important to appreciate the effects of sleep on cardiac rhythms. Readers are referred to Chaps. 11 and 41 for such review. It is known that there is an imbalance between sympathetic and parasympathetic tone during REM and NREM sleep. During REM sleep, there is an intermittent increase in sympathetic nerve activity, reaching even higher levels than in wakefulness. This surge causes intermittent increase in the heart rate and blood pressure, although at the same time, vagal tone (parasympathetic activity) is suppressed, causing irregular breathing, oxygen desaturation, and a few periods of apneas. These alterations in the sympathetic and parasympathetic balance can be clinically measured by recording heart rate variability (see also Chap. 11). The high-frequency (HF: 0.15–0.4 Hz) heart rate spectrum reflects parasympathetic tone, the low-frequency (LF: 0.01–0.05 Hz) spectrum reflects sympathetic tone, and the intermediate frequency (0.06–0.14 Hz) spectrum reflects a mixture of both activities. The LF/HF ratio is used in clinical practice to indicate overall sympathetic tone. Sudden cardiac death after myocardial infarction is associated with a decrease of heart rate variability. Based on heart rate variability studies, Bonnet and Arand [222] have clearly shown an increase in HF heart rate spectrum with a decrease of LF in NREM and an increase in LF and a decrease in HF in REM sleep and wakefulness.

A relationship between sleep and atrioventricular arrhythmias has been noted, but reports in the literature are somewhat contradictory. Atrial arrhythmias, such as atrial flutter, atrial fibrillation, paroxysmal atrial tachycardia [223], and first- and second-degree atrioventricular block [224], have been described in normal subjects during REM sleep, but no clear relationship between different sleep stages and atrial arrhythmias has emerged. A prominent sinus arrhythmia has been noted in several studies in normal subjects using Holter monitoring [225]. Brodsky and colleagues [226] monitored 24-h continuous ECGs in 50 male medical students with no apparent heart disease and observed sinus pauses of 1.8–2.0 s' duration in 30 % of them, as well as episodes of second-degree heart block (Mobitz type I) in another 6 %. Guilleminault and associates [227] noted 42 episodes of sinus arrest in four young, healthy adults that lasted 2–9 s during REM sleep. No associated apneas or significant oxygen desaturation was observed. Osuna and Patino [228] observed REM-related sinus arrest in a subject without any associated OSA or oxygen desaturation. The incidence of nocturnal bradyarrhythmias decreases with advancing age [229].

Contradictory results have been noted in human studies of the effects of sleep on ventricular arrhythmia, but the majority shows an antiarrhythmic effect of sleep on ventricular premature beats (VPBs) [230]. This seems to be due to enhanced parasympathetic tone during sleep, conferring protection against ventricular arrhythmia, and sudden cardiac death. Pitzalis et al. [231] evaluated 45 patients with frequent premature ventricular contractions to find out whether the phenomenon of sleep suppression may be a sensitive and specific parameter for predicting the antiarrhythmic effect of β-blockers and premature ventricular contractions. Based on Holter recordings, these authors concluded that sleep suppression of the premature ventricular contractions was a sensitive characteristic for identifying those patients with premature ventricular contractions who are likely to benefit from administration of β-blockers. Ventricular arrhythmias are also noted to occur during arousal from sleep [230]. A classic example was provided by Wellens and colleagues [232], who described a 14-year-old girl awakened from sleep by a loud auditory stimulus who had ventricular tachyarrhythmia. The authors postulated that increased sympathetic activity triggered these episodes, because they could be prevented by the β-blocker propranolol.

Lown's group [233] noted reduction of VPBs by at least 50 % in 22 subjects and 25–35 % in 13 others during sleep. De Silva [234] noted reduction in VPBs in all stages except REM sleep, with stages 3 and 4 NREM sleep showing the most effect. Pickering and colleagues [235] described 12 untreated patients with frequent ventricular extrasystoles who showed a significant decrease in both the heart rate and extrasystoles during sleep. Intravenous propranolol, and to a lesser extent intravenous phenylephrine, produced a similar decrease in the heart rate and ventricular arrhythmias during wakefulness. These changes appear to be mediated by the ANS, the sympathetic system dominating the parasympathetic system. They found that the frequency of ventricular arrhythmias was similar in both REM and NREM sleep. Their findings are similar to those of Lown and colleagues [233].

The observations of Pickering's group [235] also contrast with those of Smith et al. [236], who studied 18 patients in a coronary care unit to document frequency of cardiac arrhythmias in wakefulness and sleep. They found no significant difference in the occurrence of ventricular or atrial premature contractions during sleep and wakefulness. Similarly, Richards et al. [237], in a pilot overnight sleep study on nine patients with cardiovascular disease in the medical ICU, did not find any increase in incidence of dysrhythmias during any sleep stages or during sleep state in these critical

care unit patients. Disturbed sleep in coronary care patients [23] may explain the discrepancies in these data.

Cardiac Arrhythmias, Autonomic Deficits, and Obstructive Sleep Apnea Syndrome

Several investigators [94, 225, 238–242] reported a variety of cardiac arrhythmias in patients with OSAS (Fig. 47.1). These arrhythmias are determined by the changes in the ANS. The most common is bradytachyarrhythmia alternating during apnea and immediately after termination of apnea. The other dysrhythmias consist of the following: sinus bradycardia with less than 30 beats/min; sinus pauses lasting from 2 to 13 s; second-degree heart block; and ventricular ectopic beats, including complex and multifocal ectopic beats, and ventricular tachycardia. There is a clear relationship between the level of Sa_{O_2} and premature ventricular contractions and sleep apnea syndrome. Patients with Sa_{O_2} below 60 % are the most vulnerable. Hoffstein and Mateik [243], using nocturnal PSG, prospectively studied 458 patients with OSAS. They found a prevalence rate of 58 % of cardiac arrhythmias in these patients, and those with arrhythmias had more severe apnea and nocturnal hypoxemia than those without arrhythmias. Earlier studies showed a higher prevalence than more recent epidemiologic studies suggested. Roche et al. [244] performed a prospective study in 147 consecutive patients referred for assessment of OSAS. The authors found OSAS in over 45 % with AHI 10. They found significantly more nocturnal paroxysmal asystole in OSAS patients than in controls (10.6 % vs. 1.2 %). They further noted that the number of episodes of bradycardia and pauses increased with the severity of OSAS. CPAP treatment followed for one year showed amelioration of arrhythmic events in OSAS patients, indicating the usefulness of CPAP treatment. The Sleep Heart Health Study [242] investigated 228 patients with severe sleep apnea (AHI >30/h) and 338 individuals without sleep apnea, and found a significant relationship between nonsustained ventricular tachycardia, bigeminy, trigeminy, or quadrigeminy and severe OSA.

ANS dysfunction was implicated in cardiovascular morbidity and mortality in OSAS (e.g., hypertension, left ventricular failure, increased risk of coronary or cerebral events) [245]. CPAP treatment can prevent the cardiovascular risks associated with ANS dysfunction.

Gami et al. [90], after reviewing the PSGs and death certificates of 112 Minnesota residents who have died suddenly from cardiac causes during the period from July 1987 to July 2003, concluded that OSAS patients had a peak sudden death from cardiac causes during sleeping hours, contrasting with the nadir of sudden death in those without OSAS and in the general population. Peltier et al. [246] recruited 32 patients complaining of EDS and snoring and performed PSG studies and 2-h oral glucose tolerance tests as well as autonomic testing consisting of heart rate response to deep breathing, Valsalva maneuver, head-up tilt, and quantitative sudomotor axon reflex testing (QSART). These authors found that 19 of 24 patients with OSAS had abnormal glucose tolerance, and cardiac autonomic dysfunction was more strongly associated with impaired glucose regulation than OSAS. They concluded that cardiovagal and adrenergic dysfunction are responsible for cardiovascular adverse effects in OSAS, but the question remains whether impaired glucose regulation in such patients may have been responsible for such ANS dysfunction. Further studies using

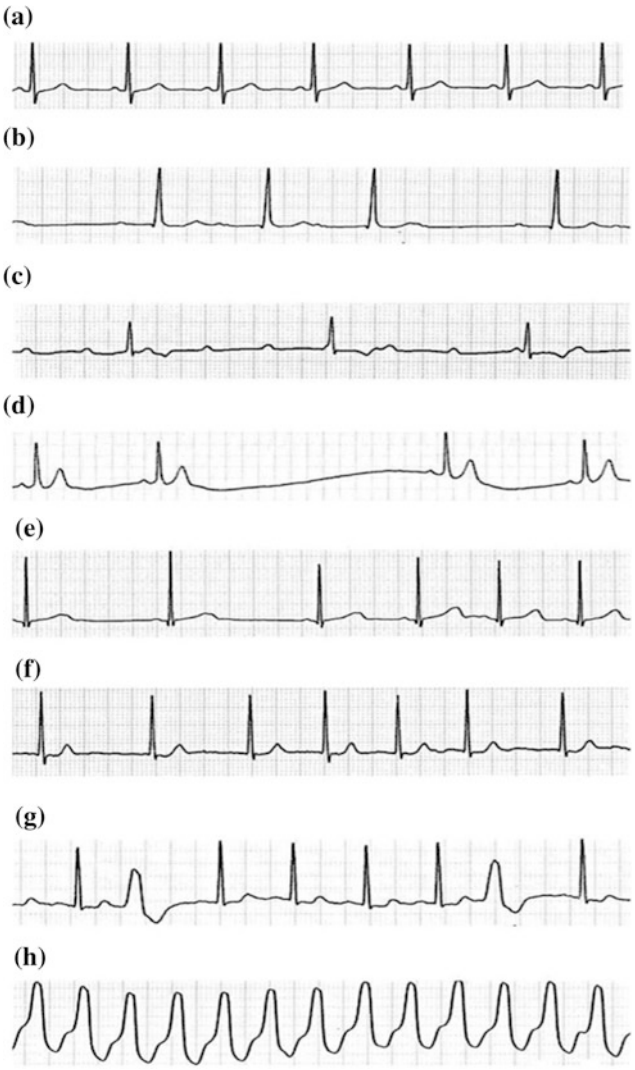

Fig. 47.1 Examples of various ECG rhythms that might be seen during sleep. **a** Normal sinus rhythm. **b**, **c** Atrioventricular conduction block: P wave is not followed by the QRS complex. **d** Sinus pause. **e** Atrial fibrillation: No P waves are visible. **f** Sinus arrhythmia. **g** Isolated extrasystoles. **h** Ventricular tachycardia. Note that the QRS complex is narrow in the supraventricular arrhythmias differentiating them from ventricular arrhythmias (in the absence of preexisting bundle branch block). (Reprinted from Ref. [94]) (Reproduced with permission [94])

larger numbers of patients are needed to resolve this complex relationship between OSAS, autonomic function, and glucose regulation.

Cardiac Arrhythmias and OSA

Recent studies have confirmed a high prevalence of cardiac arrhythmias in OSA patients [247–253] with improvement after effective CPAP therapy [247, 248, 250, 251]. Linz et al. [251] in a systematic literature search noted that the prevalence of OSA in atrial fibrillation (AF) patients is high (about 40–50 %). Effective CPAP therapy of OSA improves catheter ablation success rates in AF patients. Dediu et al. [248] found a favorable response after successful positive pressure therapy in patients with cardiac arrhythmias. Vizzardi et al. [250] conducted a meta-analysis including 1298 articles and observed that arrhythmias are frequent in OSA. Based on this analysis, the authors suggested that treatment with an implantable cardioverter/defibrillator and CPAP should be considered in some of these patients who may show improvement. Figueiras-Rama et al. [251] in a review article concluded that tachy-bradyarrhythmics including AF are highly prevalent in OSA (moderate–severe) which is an indifferent risk factor for such atrial arrhythmias. CPAP therapy has shown a significant effect in preventing or abolishing atrial arrhythmias. Some of the suggested mechanisms in the literature include hypoxia, hypercapnia, autonomic dysfunction, inflammation, negative intrathoracic pressure, and acute atrial stretch. Namveldt et al. [253] in a population-based study from Norway recruited 486 subjects (mean age of 49 with 55 % men) who underwent an overnight PSG study for suspected OSA. They found that 271 out of 486 (55.8 %) had OSA. The prevalence of ventricular premature complexes is increased in middle-aged patients with mild–moderate OSA suggesting an association between OSA and ventricular arrhythmias even in mild OSA patients.

Sudden Cardiac Death

An analysis of the time of sudden cardiac death in 2203 individuals by Muller et al. [254] revealed a low incidence during the night and a high incidence from 7:00 to 11:00 AM. Similarly, nonfatal myocardial infarction and myocardial ischemic episodes are more likely to occur in the morning. It is known that sympathetic activity increases in the morning, causing increased myocardial electrical instability; thus, sudden cardiac death (SCD) may result from a primary fatal arrhythmia.

LaRovere et al. [255] correlated increased cardiovascular mortality among patients with a first myocardial infarction with reduced baroreflex sensitivity. *Reduced baroreflex sensitivity* is defined as less slowing in heart rate for a given rise in arterial blood pressure, which indicates reduced vagal tone.

McWilliams [256] first suggested that ventricular fibrillation is the cause of sudden death and that sympathetic discharges play an important role in causing this fatal arrhythmia. During sleep, cardiovascular hemodynamic activity is decreased, as are heart rate and blood pressure, owing to withdrawal of sympathetic tone and increased vagal tone (see Chap. 11).

Reduced vagal tone, as measured by decreased heart rate variability in 24-h Holter monitoring, was found by Kleiger et al. [257] to be a powerful predictor of increased mortality and SCD after myocardial infarction. Autonomic imbalance (either sympathetic overactivity or parasympathetic underactivity) may trigger ventricular arrhythmias [258].

Besides myocardial infarction, another clinical entity known as *long QT syndrome* may cause syncope or sudden death [259–264]. Based on an evaluation of 54 patients with congenital long QT syndrome (LQTS) and 67 controls, Shamsuzzaman et al. [265] concluded that the presence and severity of OSA in patients with LQTS are associated with increased QT prolongation which is an important biomarker of sudden death. Treatment of OSA may reduce QT prolongation, thus reducing the risk of LQTS-triggered SCD. In long QT syndrome, the ECG shows a prolonged QT interval with abnormal U waves and torsades de pointes (polymorphic ventricular tachycardia). Gami et al. [266] included 10,701 consecutive adults who had PSG study between July 1987 and July 2003 to assess incident resuscitated or fatal SCD. During an average follow-up of 5.3 years, 142 patients had resuscitated or fatal SCD (annual rate of 0.27 %). The authors concluded that in 10,701 adults referred for PSG, OSA predicted incident SCD. The degree of nocturnal hypoxemia strongly predicted SCD. OSA is thus a novel risk factor for SCD. Another cause of sudden death in young adults in the Western literature is the Brugada syndrome, described in 1992 [267–270]. Patients with this syndrome present with life-threatening ventricular tachyarrhythmias without any structural cardiac lesions, and the ECG shows characteristic abnormalities of atypical right bundle branch block and ST-segment elevation over the right precordial leads. An involvement of the ANS is suggested, and abnormal I-MIBG single-photon emission computed tomography (SPECT) uptake in Brugada syndrome indicating presynaptic sympathetic dysfunction of the heart has been reported by Wichter et al. [271]. The Brugada syndrome has a genetic basis and links to mutation in *SCN5A,* the gene encoding the alpha subunit of the sodium channel. The ideal treatment suggested for this syndrome is implantation of a cardioverter/defibrillator. Sudden unexpected nocturnal death syndrome (SUNDS) is another disorder found in Southeast Asia with abnormal ECG findings similar to those noted in Brugada syndrome [272, 273]. It has been

suggested that both SUNDS and Brugada syndrome may have a common genetic and biophysical basis [274].

Intrinsic Respiratory Disorders

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD), the third leading cause of death in the USA and worldwide, is caused largely by cigarette smoking and also combined with a genetic α_1-antitrypsin deficiency. Patil et al. [275] in a retrospective review reported a 2.5 % in-hospital mortality following acute exacerbation of COPD in 70,000 patients. The COPD is defined by the Global Initiative for Chronic Obstructive Lung Disease (GOLD) as an irreversible progressive airflow limitation causing an inflammatory response in the lung parenchyma giving rise to the clinical features of chronic bronchitis and emphysema [276].

The salient clinical features include chronic cough, exertional dyspnea, tightness in the chest, and sometimes wheeze. Physical examination reveals inspiratory and expiratory sonorous wheeze (rhonchi) and crackles (crepitations or rales). Patients with resting hypoxemia and hypercapnia may exhibit cyanosis. Investigations should include radiographic examination of the chest and pulmonary function tests. Complications include polycythemia, pulmonary hypertension, cor pulmonale, and cardiac arrhythmias.

To understand sleep disturbances, it is important to have some knowledge of gas exchange during sleep [277]. In COPD patients, Sao_2 and Pao_2 fall and $Paco_2$ rises during sleep; these values worsen during REM sleep [278–280]. In some patients, SDB (e.g., apnea, hypopnea, or periodic breathing) is associated with reduced Sao_2 saturation, which is generally short lived (less than 1 min) and mild to moderate in intensity [281–283]. Episodes of Sao_2 desaturation during REM sleep last more than 5 min and are more severe than in NREM sleep [281, 284, 285]. Physiologic changes in respiration, respiratory muscles, and control of breathing (see Chap. 11) during sleep adversely affect breathing in these patients. In COPD patients, two basic mechanisms worsen hypoxemia during sleep: alveolar hypoventilation, which is worse during REM sleep, and ventilation–perfusion mismatch [286–289].

Other groups at risk for hypoxemia include the middle-aged and elderly (particularly men), postmenopausal women, and obese individuals [277]. Diminished ventilatory response to hypoxia and hypercapnia in some COPD patients contributes to increasing nocturnal oxygen desaturation [277]. Nocturnal hypoxemia causes repeated disruption and fragmentation of sleep architecture [277].

COPD patients are traditionally divided into two phenotypes, "pink puffers" and "blue bloaters" [290–292]. Pink puffers generally have normal blood gases, hyperinflated lungs, no hypoxemia or hypercapnia, no cardiomegaly, or cor pulmonale, and are cachectic and short of breath [277]. In contrast, blue bloaters are generally hypoxemic and hypercapnic, have cor pulmonale, polycythemia, an enlarged heart, reduced ventilatory response to hypoxemia and hypercapnia, have a stout body habit, and have less dyspnea [277]. In general, blue bloaters have more severe hypoxemia of longer duration than pink puffers [293, 294]. It should be noted that oxygen saturation for both groups is somewhat similar during wakefulness and in the upright position but is markedly different during sleep. The worse value is noted in blue bloaters. There are no absolute criteria for determining which groups of COPD patients have more severe nocturnal hypoxemia. Patients must be monitored at night, which is impractical considering the large number of patients who should be monitored. "Blue bloaters" phenotype is considered emphysema-predominant COPD, whereas "pink puffers" phenotype is considered airway (nonemphysematous)-predominant COPD (based on chest CT scans). "Pink puffers" type is associated with an increased risk of diabetes mellitus. There are contentious issues to be resolved regarding definition and staging and phenotyping of COPD as we know today which may be different from the classic phenotypes of "pink puffers" and "blue bloaters." In some patients, COPD may coexist with OSAS—a condition called *overlap syndrome,* a term introduced by Flenley [295]. In a study [296] of 265 consecutive unselected OSAS patients, COPD was found to be present in 30 (11 %) of these patients. Coexistence of COPD and OSAS results in a higher risk of pulmonary hypertension and CCF than in those with only OSAS [286, 287]. In addition, Bednarek et al. [297] noted that the course of SDB is more severe in subjects with overlap syndrome, but these authors found that COPD in subjects with OSAS was as frequent as in the general population. OSAS has a major impact on quality of life in patients with overlap syndrome [298]. COPD patients who are hypoxemic during wakefulness become more hypoxemic during sleep, which is most severe during REM sleep. Alveolar hypoventilation and ventilation–perfusion mismatching are the two most important factors (alveolar hypoventilation being the predominant factor) for worsening of nocturnal hypoxemia in these patients. Several factors contribute to worsening of hypoxemia during sleep in COPD patients [299]. 1. Diaphragm may be flattened and lengthened due to hyperventilation; 2. COPD patients have increased "dead space" (i.e., does not participate in gas exchange) due to rapid shallow breathing pattern during phasic REM sleep; 3. Many have increased airway resistance during sleep; and 4. Hypoxic and hypercapnic ventilator responses are

more blunted in COPD patients than in normal. Hypoxemia is worse in patients with overlap syndrome [300–302]. The consequences of sleep hypoxemia include pulmonary hypertension due to hypoxic pulmonary vasoconstriction and cardiac arrhythmias [303].

Changes in Sleep Architecture

Disturbances in sleep architecture in COPD patients have been reported by several authors [278, 304–313]. These disturbances may be summarized as follows: a reduction of sleep efficiency, delayed sleep onset, increased WASO, frequent stage shifts, and frequent arousals. Arand et al. [304] correlated these findings with EDS. These patients are more likely to have difficulty with falling and staying asleep as well as EDS [311]. Chronic coughing and nocturnal wheezing in addition to nocturnal oxygen desaturation are mostly responsible for arousals from sleep in these patients.

Nighttime symptoms of COPD patients impacting their sleep quality are often "a forgotten dimension" of COPD [314, 315] in 2011; an expert panel was convened in Barcelona, Spain, to address this gap [314]. It has been suggested that the prevalence of nocturnal symptoms and sleep disturbance may exceed 75 % in COPD patients. The panel concluded that nighttime symptoms are of multifunctional origin and warrant further investigation.

A number of factors cause sleep disturbances in COPD patients, resulting in disturbed electroencephalographic (EEG) sleep patterns, including the use of drugs that have a sleep-reducing effect, such as methylxanthines; increased nocturnal cough resulting from accumulated bronchial secretions; and associated hypoxemia and hypercapnia [286, 316], and comorbid disorders (e.g., OSA, RLS, depression, and cardiovascular diseases) [317, 318]. In a study by Calverley [309], administration of supplemental oxygen at 2 L/min by nasal cannula during sleep improved both oxygen saturation at night and sleep architecture, in terms of decreasing sleep latency and increasing all stages of sleep, including REM and SWS. Other reports did not note improved sleep quality, but the nocturnal hypoxemia did improve after oxygen administration [304, 305].

Aoki et al. [319] noted four patterns of SDB in the desaturation group of COPD patients: hypoventilation, paradoxical movement, periodic breathing, and unclassified pattern. Urbano and Mohsenin [310] listed the following eight mechanisms to explain nonapneic oxygen desaturation during sleep in COPD patients: decreased functional residual capacity, diminished hypoxic and hypercapnic ventilatory responses, impaired respiratory mechanical effectiveness, diminished arousal responses, respiratory muscle fatigue, diminished nonchemical respiratory drive, increased upper airway resistance, and the position of baseline saturation values while awake on the oxyhemoglobin dissociation curve.

Diagnostic Considerations

The most important test to document airflow obstruction and determine severity of COPD is spirometry. An FEV_1/FVC ratio (FEV_1 divided by forced vital capacity [FVC]) of less than 0.70 defines an obstructive defect [317, 320]. The COPD severity is determined by observing FEV_1 percent, predicted as follows: mild, less than 80 %; moderate, 50–80 %; severe, 30–50 %; and very severe, less than 30 % [321]. The spirometric measurements are performed before and after bronchodilator therapy, and other pulmonary function tests may also be important. In addition, pulse oximetry and arterial blood gas determinations, chest radiograph and high-resolution computed tomography chest scan, ECG, and determinations of α_1-antitrypsin levels may be useful. In patients suspected to have an associated OSA (overlap syndrome), an overnight PSG is essential.

Treatment Considerations

The cornerstone of treatment for COPD includes smoking cessation, bronchodilators or inhaled steroids, and pulmonary rehabilitation [320, 322]. The ultimate goal is improvement of sleep quality and quality of life as a result of improvement of lung mechanics and gas exchange. All patients must avoid risk factors by instituting smoking cessation, getting early pneumococcal and influenza vaccinations, and receiving patient education and exercise training. The mainstay of COPD treatment is bronchodilators, which include anticholinergics and β_2-agonists. Metered-dose inhalers and nebulizers both work well. In severe cases, in addition to short- and long-acting bronchodilators (long-acting agents such as salmeterol have largely replaced short-acting agents [albuterol] which may still be used for "rescue" or as-needed basis), inhaled corticosteroids may be needed. In very severe cases, oral corticosteroids (but only on alternate days, using the lowest effective dose) combined with inhaled corticosteroids may have to be used. The role of supplemental oxygen therapy is discussed below. For patients not able to use inhaled medication, oral therapy including sustained-release theophylline in addition to a β_2-agonist or anticholinergic may have to be used. Theophylline can also be useful to control nighttime symptoms; however, nighttime symptoms may cause insomnia that itself needs separate treatment consideration. Insomnia is prevalent in COPD patients and needs to be treated to improve quality of life; however, use of hypnotics in the hypercapnic patient with severe COPD might be dangerous [311, 323]. Benzodiazepines may be dangerous for elderly COPD patients, particularly those with overlap syndrome. Nonbenzodiazepine receptor drugs may be used with some benefit, but even these drugs may promote apnea, thus exacerbating hypoxemia in COPD patients. Ramelteon has been shown to be safe and efficacious in mild-to-moderate COPD and OSA patients; however, further research is needed to determine

the safety in this population [311]. In patients with overlap syndrome, treatment with CPAP or BIPAP therapy may have to be used, but such treatment in these patients may not necessarily lead to an improvement in the coexistent COPD [324]. However, more recent studies have shown that treatment of OSA with CPAP in patients with overlap syndrome improves daytime arterial blood gas abnormalities, nocturnal oxygen saturation, and daytime sleepiness as measured by ESS [325]. Furthermore, in a prospective study of overlap syndrome, it was noted that patients who used CPAP had significantly lower risk of death compared with those who did not use CPAP [326].

In summary, current guidelines for medical therapy in COPD recommend "stepping up" triple therapy (a combination of long-acting beta agonists [e.g., salmeterol], muscarinic antagonists [e.g., triotropim], and glucocorticoids for moderate–severe COPD patients [327]). However, Magnussen et al. [328] have now shown in a recent trial that "stepping down" therapy (discontinuing inhaled glucocorticoids but keeping the other two agents) did not make a significant difference in terms of risks of moderate–severe exacerbations. In very severe cases not responding adequately to medical therapy, lung volume reduction surgery or lung transplantation should be considered [320].

Treatment of Nocturnal Oxygen Desaturation

Investigators have become aware of severe nocturnal hypoxemia in many COPD patients [278–280]. This nocturnal hypoxemia may or may not be accompanied by sleep-related apnea, hypopnea, or periodic breathing and impairment of gas exchange [281–283]. It is clear that repeated or prolonged oxygen desaturation at night may cause cardiac arrhythmias and may lead to pulmonary hypertension and cor pulmonale [329]. In addition, COPD patients show changes in sleep architecture [278, 304–309, 312, 313] that may be related to the poor quality of sleep or may be secondary to nocturnal hypoxemia causing disruption of nocturnal EEG sleep stages. Oxygen desaturation during sleep in COPD patients can be identified only if PSG, using sleep staging or continuous monitoring of oxygenation, is performed. Several studies show episodes of oxygen desaturation during sleep in COPD patients. An important study by Wynne's group [281] showed that oxygen desaturation could be associated with two types of patients: those with OSA (apnea and hypopnea) and those without OSA. In patients with OSA, the desaturation typically lasts less than 1 min and is mild. In the other group, the desaturation lasts 1–30 min and is associated with a profound decrease in oxygen saturation. The maximum episodes, lasting longer than 5 min, occur during REM sleep. Similar episodes of nocturnal oxygen desaturation have been described in patients with kyphoscoliosis [330, 331], in young patients with cystic fibrosis [285, 332, 333] and in patients with interstitial lung disease [334, 335].

Modern treatment of nocturnal hypoxemia is administration of oxygen by nasal cannula at a slow flow rate, usually less than 2 L/min. The multi-center study by the Nocturnal Oxygen Therapy Trial Group [336] and the Medical Research Council Working Party study [337] showed increased longevity for patients who used continuous supplemental oxygen at home. The Thoracic Society of Australia and New Zealand has published a position statement for oxygen therapy in COPD patients [338].

Particular indications for supplemental oxygen can be summarized as follows: daytime Pa_{O_2} below 55 mm Hg (Sa_{O_2} below 88 %) and daytime Pa_{O_2} between 56 and 60 mm Hg (or Sa_{O_2} of 89 %) accompanied by signs of right-side heart failure, unexplained polycythemia, pulmonary hypertension, and cor pulmonale [316, 339, 340], as well as significant nocturnal or exercise-induced oxygen desaturation. Oxygen administration may also improve sleep architecture [309]. O'Reilly and Bailey [341] reviewed the published evidence for and against the use of long-term oxygen treatment in COPD, summarized the problems with current guidelines, and suggested important areas for future research. Earlier, Croxton and Bailey [342] published recommendations for long-term oxygen treatment for COPD for future research based on a National Heart, Lung and Blood Institute Workshop report.

The question of safety of oxygen administration has to be determined [277]. Some patients become more hypercapnic after oxygen administration [278]. Furthermore, Motta and Guilleminault [343] showed the worsening effects of administration of oxygen at night in patients with OSAS. In an earlier study, Chokroverty et al. [344] reported worsening of apnea and prolongation of apnea after administration of 100 % of oxygen in four patients with obesity-hypoventilation syndrome. Many COPD patients may have OSA (overlap syndrome) [278, 295, 296], so physicians must be careful during administration of oxygen. Kearley and colleagues [345] have shown that administration of oxygen at 2 L/min reduces the episodic desaturation. Fleetham et al. [346] confirmed this finding, but Guilleminault et al. [283] contradicted these findings in five patients with excessive sleepiness associated with chronic obstructive airflow disease. The multiple institution studies by the Nocturnal Oxygen Therapy Trial Group [336] showed the relative safety of oxygen therapy, however, including home oxygen. In COPD patients undergoing long-term oxygen therapy, it may be useful to monitor breathing and oxygen saturation by finger pulse oximetry during sleep at night [347]. The role of noninvasive intermittent positive pressure ventilation (NIPPV) to improve hypoxemia in COPD patients remains undetermined [348, 349] in the absence of adequate clinical

trials using a large number of patients. However, in a recent prospective, multicenter, randomized control trial, Kohnlein and coworkers [350] investigated the effect of long-term NIPPV in 195 patients (102 NIPPV groups and 93 control groups) in advanced stable hypercapnic COPD. The authors concluded that addition of long-term NIPPV to standard therapy improved all-cause mortality after 12 months of follow-up of hypercapnic, stable COPD patients. This positive observation was reinforced later by Windisch et al. [351] after summarizing the current literature on NIPPV in COPD. These authors stated that there is now increasing evidence to support the role of NIPPV in hypercapnic COPD patients but how to select such patients needs to be determined.

Bronchial Asthma, Including Nocturnal Asthma

The characteristic clinical trials of asthma are the paroxysm of dyspnea, wheezing, and cough [352]. The paroxysmal attacks of wheezing and breathlessness may occur at any hour of the day or night, and the nocturnal attacks are distributed at random without any relationship to a particular sleep stage. Nocturnal symptoms of wheezing and coughing at least once per week are noted in as many as 75 % of asthmatics [353]. Breathing is characterized by prolonged expiration accompanied by wheezing and unproductive cough. There may be tightness of the chest and palpitation. The attacks typically last for 1–2 h. When the attacks last hours, the disorder is called *acute severe asthma* or *status asthmaticus;* this is a life-threatening condition because of extreme respiratory distress and arterial hypoxemia.

Pulmonary function tests and radiographic examination of the chest are important for confirming the diagnosis of bronchial asthma [352]. Abnormalities of certain pulmonary function tests [i.e., FEV_1, vital capacity (VC), and peak expiratory flow (PEF)] suggest airflow obstruction. An overnight fall in PEF of over 15 % associated with characteristic history is diagnostic of nocturnal asthma [354]. Chest radiography may reveal hyperinflated lungs and emphysema.

Sleep Disturbances in Bronchial Asthma

A variety of sleep disturbances have been noted in patients with asthma [355–364]. Janson et al. [363], using questionnaires and sleep diaries, studied the prevalence of sleep complaints and sleep disturbances prospectively in 98 consecutive adult asthma patients attending an outpatient clinic in Uppsala, Sweden. Compared with 226 age- and sex-matched controls, the authors found a high incidence of sleep disturbances in asthma patients, including early morning awakening, difficulty in maintaining sleep, and EDS. Sleep disturbances in general consist of a combination of insomnia and hypersomnia. Polysomnographic studies may reveal disruption of sleep architecture as well as sleep apnea in some patients. Nocturnal exacerbation of symptoms during sleep is a frequent finding in asthma patients [287, 353, 365].

There is evidence of progressive bronchoconstriction and hypoxemia during sleep in patients with asthma [354, 356]. In an important study by Turner-Warwick [357], 94 % of 7729 asthmatics surveyed woke up at least once a night with symptoms of asthma, 74 % at least one night a week, 64 % at least three nights a week, and 39 % every night. Nocturnal asthma is a potentially serious problem, as there is a high incidence of respiratory arrest and sudden death in adult asthmatics between midnight and 8:00 AM [358, 359].

To understand the relationship between the attacks of asthma and sleep stage and time of night, Kales et al. [360] studied six men and six women aged 20–45 years with PSG, each for 2–3 consecutive nights. They observed a total of 93 asthma attacks in these patients, 73 during NREM sleep, and 18 during REM. They did not find a relationship between asthma attacks and sleep stage or time of night. Sleep pattern showed less total sleep time, frequent WASOs, early final awakenings, and reduced stage 4 sleep. Kales' group [361] observed similar findings in a PSG study of 10 asthmatic children. Montplaisir and colleagues [362] studied 12 asthmatics, eight of whom showed nocturnal attacks on sleep studies (six women and two men aged 20–51 years).

Two questionnaire surveys from the European community [363, 364] found that bronchial asthma was associated with increased daytime sleepiness and impaired subjective quality of sleep (difficulty initiating sleep and early morning awakenings). One survey also noted increased prevalence of snoring and sleep-related apneas during sleep [363]. In the same survey, associated allergic rhinitis may have been a confounding variable. Twenty-six attacks were documented. No attacks occurred in stage 3 or 4 NREM sleep, nor were attacks more frequent during REM than NREM sleep. Thus, stages 3 and 4 sleep was "protective." Sleep efficiency was decreased. The number and duration of apneas were not significantly greater in asthmatics than in controls. Episodes of oxygen desaturation occurred only in the asthmatics. In a retrospective analysis of PSG recordings from children aged 5–17 years with (n = 113) and without (n = 104) asthma from a single pediatric sleep unit in Australia, Jensen et al. [366] reported that female asthmatic children had longer sleep latency but the male asthmatic children had shorter sleep duration, thus underscoring the gender difference in sleep disturbance among asthmatic children. Sleep efficiency and waking time after sleep onset were altered in asthmatics. When there were no attacks, no difference in sleep architecture was noted between the controls and the patients, which suggested that sleep disturbances are characteristic of unstable asthma with nocturnal attacks.

A number of pathogenic mechanisms for sleep disturbances and nocturnal exacerbations of asthma have been suggested [287, 353–355, 367–370]:

- Sleep deprivation [371]
- Impaired ventilatory function in the supine posture [372]
- A decrease in circulating epinephrine at night, with an increase in histamine [373]
- Gastroesophageal reflux [374, 375]
- Marked fluctuation in airway tone during REM sleep [376]
- Theophylline, a commonly used asthma drug that may cause insomnia [377, 378] and increased episodes of gastroesophageal reflux [379, 380] (a study by Hubert's group [381] found no such increase in asthmatics taking theophylline)
- Prolonged administration of corticosteroids in some asthmatics, which may have adverse effects on sleep and daytime functioning because of increased incidence of OSA [381, 382]
- Increased cellular inflammatory response in the bronchopulmonary region at night [369, 383]
- Miscellaneous factors, including allergens (e.g., house dust); increased bronchial secretions combined with suppression of cough, especially during REM sleep; airway cooling at night; increased pulmonary resistance; altered bronchial reactivity; normal propensity for worsening of lung function during sleep; normally increased vagal tone during sleep, which may be a major cause of nocturnal bronchoconstriction as evidenced by circadian desynchronization studies and cholinergic blockade studies [384, 385]; and suppressed arousal response to bronchoconstriction in severe nocturnal asthma [369]
- Certain circadian factors [367–370].

The following evidence supports the claim that circadian factors contribute to nocturnal exacerbation of asthma:

1. PEF typically is highest at 4:00 PM and lowest at 4:00 AM [369]. The variation is ordinarily approximately 5–8 %, but if it reaches 50 %, as it can in some asthmatics, there is the danger of respiratory arrest [369]. This circadian variation in PEF is related to sleep and not to recumbency or the hour [368–370].
2. Airway resistance as measured breath by breath is not increased in normal individuals at night, but asthmatics show a circadian rhythm of increased airway resistance at night that is related to the duration of sleep and not to sleep stages [369, 386].
3. OSA is more prevalent and more severe in severe asthmatics [365, 387–391]. Asthma in turn is more prevalent in OSA [392].
4. Finally, tonsillar hypertrophy has been reported to be more frequent in children with a history of wheezing

Treatment of Bronchial Asthma

Treatment of bronchial asthma, including nocturnal asthma, can be grouped into two main components: [352] 1. Rescue agents (acute relievers) and 2. The controller treatment (agents that modify the airway environment causing less frequent occurrence of airway narrowing).

The rescue treatment includes a rapid-acting β-agonist as inhaler; this is the mainstay of bronchodilator treatment of asthma: a short-acting β2-selective inhaler (e.g., albuterol) on an as-needed basis in patients with mild intermittent asthma (by nebulizer or metered-dose inhaler). The dose consists of two "puffs" from the inhaler with a separation of 3–5 min between the first and the second puffs. The first puff dilates the narrowed airways and then the second puff has a better chance of access to the affected areas of the lungs. This treatment can be repeated every 4–6 h. Another rescue treatment is an anticholinergic agent (e.g., ipratropium bromide, an atropinic agent) which inhibits acetylcholine release promoting bronchodilation. It is given as two puffs every 4–6 h in a metered-dose inhaler.

The controller treatment includes inhaled corticosteroids (e.g., fluticasone, budesonide, and triamcinolone) to improve lung function and prevent exacerbation of asthmatic attacks. One must consider adverse effects of steroids.

Other Modalities of Treatment [352] consist of antileukotrienes (e.g., montelukast, 10 mg tablet once a day), long-acting β-agonists (e.g., salmeterol), one-to-two puffs every 12 h as controller agents, and theophylline bromide for moderate to persistent asthmatics who are also receiving other agents as described above. Systemic corticosteroids may be considered as last resort for moderate-to-severe persistent asthma. Rarely monoclonal antibody treatment (e.g., omalizumab, lebrikizumab, and mepolizumab [not FDA approved in USA]) has been prescribed for severe cases of asthma. Finally in children with tonsillar hypertrophy, adenotonsillectomy is followed by improvement in asthma symptoms [393]. Other measures include treating the reversible factors such as allergens, nasal congestion, or bronchopulmonary infections, and using a humidifier [369].

In a double-blind, placebo-controlled crossover study, Kraft et al. [394] and Wiegand et al. [395] reported that salmeterol, an inhaled β_2-agonist with a prolonged duration of action, improved the number of nocturnal awakenings with nocturnal asthma. Wiegand et al. [395] found that salmeterol was superior to theophylline in maintaining nocturnal FEV_1 levels and in improving morning and evening PEF, and in an improvement in patient perception of sleep but not in PSG measures of sleep architecture. Previously, several studies showed efficacy of salmeterol in

nocturnal asthma, primarily in combination with inhaled corticosteroids [396–400].

Sleep disturbances in asthma caused by nocturnal asthma attacks should not be treated with hypnotic medicines; rather, the best treatment is vigorous treatment of the asthmatic attacks by using oral and preferably inhaled steroids, salmeterol, and anticholinergic medications (e.g., inhaled ipratropium bromide) as stated above [322, 352, 354, 369, 395, 401, 402]. Patients with PSG evidence of OSA should be treated with CPAP, which not only is effective for OSA but also helps nocturnal asthmatic symptoms. Ciftci et al. [389] reported moderate-to-severe OSA based on an AHI of 15 in 16 of 43 asthmatic patients with nocturnal symptoms. CPAP treatment improved nocturnal symptoms but did not correct pulmonary function test abnormalities. Patients with gastroesophageal reflux disease (GERD) often have worse symptoms of the disease at night, which may worsen the nocturnal asthmatic symptoms. Treatment of GERD with proton pump inhibitors (e.g., omeprazole) at bedtime may improve nocturnal asthmatic symptoms and sleep quality [403, 404]. However, the evidence is conflicting; Coughlan et al. [405], after a systematic review, concluded that clear evidence or improvement of nocturnal asthmatic symptoms after treating GERD is lacking.

Restrictive Lung Disease

Restrictive lung disease is characterized functionally by a reduction of total lung capacity, FRC, VC, expiratory reserve volume, and diffusion capacity but preservation of the normal ratio of FEV_1 to FVC [335]. This may be due to intrapulmonary restriction (e.g., interstitial lung disease) or extrapulmonary restriction resulting from diseases of the chest wall (e.g., kyphoscoliosis) or pleura; neuromuscular diseases; obesity; or pregnancy, which may abnormally elevate the diaphragm.

Interstitial Lung Disease

Etiopathogenesis

Interstitial lung disease (ILD) may result from a variety of causes, including idiopathic pulmonary fibrosis, fibrosing alveolitis associated with connective tissue disorders, pulmonary sarcoidosis, occupational dust exposure, pulmonary damage resulting from drugs, or radiotherapy to the thorax [406–410]. The common features of all these conditions include alveolar thickening due to fibrosis, cellular exudates, or edema; increased stiffening of the lungs causing reduced compliance; and ventilation–perfusion mismatch giving rise to hypoxemia, hyperventilation, and hypocapnia.

Clinical Features

Features of interstitial lung disease include progressive exertional dyspnea, a dry cough, clubbing of the fingers, and pulmonary crackles (crepitations) on auscultation of the lungs. The diagnosis is based on a combination of characteristic clinical features, radiographic findings (e.g., diffuse pulmonary fibrosis), and pulmonary function test results.

Sleep Abnormalities

Several authors [334, 408–416] reported on sleep studies in interstitial lung disease. Sleep abnormalities consist of repeated arousals with sleep fragmentation and multiple sleep stage shifts, increased stage 1, and reduced REM sleep accompanied by oxygen desaturation during REM and NREM sleep owing to episodic hypoventilation and ventilation–perfusion mismatch, and occasionally OSA. Mermigkis et al. [412], in a retrospective study, reported OSA in 18 patients with interstitial lung disease. These authors concluded that an increased body mass index and a significant impairment in pulmonary function tests may predict the occurrence of OSA in these patients, and it is important to make the diagnosis and treat comorbid OSA to improve quality of life. Milidi et al. [40] in a review article described fatigue as a disabling symptom of ILD, and the patients show poor sleep quality and SRBD correlating with impaired sleep quality. PSG studies document frequent sleep apnea–hypopnea as well as reduced sleep efficiency, SWS, and REM sleep in addition to REM-related hypoventilation. Treatment of sleep-breathing disorders improves quality of life. Schiza et al. [413] observed an increasing prevalence of OSA in idiopathic pulmonary fibrosis (IPF). The recently published IPF guidelines recognized OSA as an important comorbidity affecting patients' survival.

There is no effective treatment for interstitial lung disease except to treat the comorbid conditions such as OSA. Corticosteroids are found to be effective in some cases. George and Kryger [335] advocated symptomatic treatment with supplemental nocturnal oxygen therapy according to the guidelines developed by the Nocturnal Oxygen Therapy Trial Group [336]. In summary, supportive care, treatment of comorbid conditions, and ultimately lung transplantation are the only therapeutic options available for these conditions.

Kyphoscoliosis

Kyphoscoliosis is a thoracic cage deformity that causes extrapulmonary restriction of the lungs and gives rise to impairment of pulmonary functions, as described earlier for restrictive lung diseases. The condition may be primary (idiopathic) or secondary to neuromuscular disease, spondylitis, or Marfan syndrome [335].

In severe cases of kyphoscoliosis, breathing disorders during sleep (e.g., central, obstructive, and mixed apneas associated with oxygen desaturation) and sleep disturbances (e.g., disrupted night sleep, reduced NREM stages 2 through 4 and REM sleep, and EDS) have been described [330, 331, 335].

The best treatment for patients with chronic respiratory failure secondary to severe kyphoscoliosis is NIPPV. This

has been described in detail in Chap. 41. Long-term NIPPV treatment improves nocturnal and daytime blood gases, respiratory muscle performance, pulmonary function, and hypoventilation-related symptoms in patients with severe kyphoscoliosis [417–419].

Lung Transplant Recipients and Sleep Dysfunction

Lung transplantation has recently become a life-saving modality and a treatment of last resort in many patients with end-stage lung disease (ESLD) (e.g., idiopathic pulmonary fibrosis, chronic obstructive pulmonary disease or COPD, and cystic fibrosis). However, these patients are at increasing risk for poor sleep due to comorbidities and use of immunosuppressants, steroids, and other medications [420, 421]. Insomnia and sleep-disordered breathing (SDB) are the most frequently reported sleep disorders in these patients. Often the sleep disorders are unrecognized and untreated. It is important to screen such patients for sleep disorder before and after transplantation. Sommerwerck et al. [422] polysomnographically studied 77 patients (45 men) and noted a prevalence of SDB of 49.4 % (42.9 % OSA and 6.5 % CSA). The authors concluded that the prevalence of SDB is high in stable lung transplant recipients and COPD is an independent predictor of SDB. High prevalence of SDB was also noted in several other reports [420, 421, 423–425]. Some of the factors cited are weight gain, altered chemosensitivity, and central control of breathing and medication use. Reilly-Spong et al. [420] using Pittsburg Sleep Quality Index and actigraphy in patients with various organs including lung transplant recipients reported poor sleepers in 41 %. Sleeplessness is mostly related to steroids and immunosuppressive medications.

Gastrointestinal Diseases

Peptic Ulcer Disease

A peptic ulcer is an ulcer in the lower esophagus, stomach, or duodenum [426]. The prevalence of peptic ulcer in the general population is fairly high—approximately 10 % of the adult population—and men are most often affected. The most common presentation of peptic ulcer is episodic pain localized to the epigastrium that is relieved by food, antacids, or other acid suppressants. The pain has a characteristic periodicity and extends over many years. The patient generally can localize the pain to the epigastrium. Occasionally, however, it is referred to the interscapular region at the lower chest and is usually described as burning or gnawing. Duodenal pain is often described as "hunger pain" and is relieved by eating. An important feature is that the pain awakens patients 2–3 h after retiring to bed, disturbing sleep. An important physical sign is the so-called pointing sign and localized epigastric tenderness.

The natural history of the disease is episodic occurrence over a course of days or weeks, after which the pain disappears, to recur weeks or months later. Between attacks the patient feels well. Presentation may be secondary to complications of ulcer, such as an acute episode of bleeding or perforation or even an episode of gastric obstruction. The differential diagnosis of ulcer pain should include cholecystitis, angina, gastroesophageal reflux, esophagitis, and pancreatitis. Definitive diagnosis is established by barium examination of the gastroduodenal tract and, if necessary, by endoscopic examination and biopsy.

In the last two decades, it has been clearly established that the most common cause of peptic ulcer disease is *Helicobacter pylori* infection [426–429]. The second most common cause is ingestion of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) [426, 427]. *Helicobacter pylori* infection is responsible for 95 % of duodenal and more than 85 % of gastric ulcers [427].

Sleep, Nocturnal Acid Secretion, and Duodenal Ulcer (See also Chap. 11)

To understand the role of nocturnal gastric acid secretion in duodenal ulcer, Dragstedt [430] studied hourly collections of nocturnal gastric acid from patients with duodenal ulcer and from normal subjects. The study found 3–20 times greater volumes of nocturnal acid secretion in patients than in normal controls (see also Fig. 11.10). Vagotomy abolished this increased secretion and improved healing of ulcers [431]. Studies by Orr et al. [432] have shown that patients with duodenal ulcer exhibit failure of inhibition of gastric acid secretion during the first 2 h after onset of sleep. A study by Watanabe et al. [433] confirmed the findings of Orr et al. [432] and found that the intragastric pH values increased during NREM and REM sleep in healthy controls and gastric ulcer patients, but the intragastric pH of duodenal ulcer patients did not change. Schubert and Peura [434] reviewed the physiology and pathophysiology of acid secretion and its inhibition in the management of acid-related clinical conditions.

Sleep disturbances in duodenal ulcer patients characteristically result from episodes of nocturnal epigastric pain. These symptoms cause arousals and repeated awakenings, thus fragmenting and disturbing sleep considerably in these patients.

Treatment

In light of the evidence about the role of *H. pylori* infection and NSAIDs in the pathogenesis of gastroduodenal ulcers, the theory of hypersecretion of acid in peptic ulcer patients has been relegated to a secondary role [427]. The first step is to find the causes of ulcer based on the history and laboratory tests such as serology, carbon-13 urea breath test, and endoscopic biopsy and histology, particularly in patients with gastric ulcer [426, 427]. The purpose of treatment is to

relieve symptoms; heal the ulcer; and either cure the disease, in the case of *H. pylori* ulcers, or prevent recurrences, in the case of NSAID ulcers [426, 427]. To cure the ulcer, the best approach is a triple combination of antimicrobial therapy as recommended and approved by the Food and Drug Administration as follows [426, 427, 435–437]: esomeprazole, amoxicillin, clarithromycin; lansoprazole, amoxicillin, clarithromycin; omeprazole, amoxicillin, clarithromycin; or rabeprazole, amoxicillin, clarithromycin. Antimicrobial agents effective against *H. pylori* infection include amoxicillin, clarithromycin, tetracycline, and metronidazole. Most commonly a 10- to 14-day regimen may be effective. To accelerate healing, the antimicrobial agent is combined with antisecretory agents [histamine$_2$ (H_2)–receptor antagonists such as cimetidine (Tagamet), ranitidine (Zantac), nizatidine (Axid), or famotidine (Pepcid)]. The most potent antisecretory agents are the proton pump inhibitors (e.g., esomeprazole, lansoprazole, omeprazole, and rabeprazole). Because of emergence of resistant strains of *H. pylori* and failure of eradication in 20–25 % of cases, quadruple [427, 438] and sequential therapy has been suggested for eradication of *H. pylori* infection [426, 435, 436, 439–441]. Sequential therapy includes an initial 5 days of therapy with a proton pump inhibitor and amoxicillin followed by 5 days of a proton pump inhibitor plus clarithromycin and tinidazole. For treatment of NSAID ulcers, NSAID therapy should be stopped and treated with traditional antisecretory agents. Patients who require continued NSAID therapy, however, may be treated with misoprostol, a synthetic prostaglandin E_1 analog (200 mg four times a day) [426, 427]. General measures of treatment of peptic ulcer disease should consist of avoidance of tobacco and alcohol. For detailed management of uncomplicated, complicated, and resistant ulcers, the reader is referred to Feldman [427] and Kuipers et al. [426].

Gastroesophageal Reflux Disease

Clinical Features

Gastroesophageal reflux disease (GERD) is preferable to the term *reflux esophagitis* [442]. GERD frequently occurs in middle-aged and elderly women, and sometimes in younger women during pregnancy. Hiatal hernia is often associated with reflux esophagitis. The characteristic symptom is heartburn, described as retrosternal burning pain exacerbated by lifting or straining or when the patient lies down at night [442, 443]. The nocturnal burning pain causes difficulty in initiating sleep, frequent awakenings, and fragmentation of sleep [431, 444– 447]. The nocturnal pain is characteristically relieved by sitting up or ingesting food or by acid-suppressant agents. An important differential diagnosis would be angina, particularly when the pain radiates to the neck, jaws, and arms, but an important point to remember is that the esophageal pain is usually not related to exertion. Other symptoms include transient or persistent dysphagia if the patient has developed stricture and regurgitation of gastric contents associated with coughing, wheezing, and shortness of breath due to the aspiration of the gastric contents into the bronchopulmonary region [431, 442, 443]. A serious complication of repeated episodes of gastroesophageal reflux and esophagitis is Barrett's esophagus, which may be a precursor to esophageal adenocarcinoma [442, 443, 448, 449]. Another potential complication is exacerbation of nocturnal asthma.

Differential Diagnosis, Pathogenesis, and Diagnostic Tests

Peptic ulcer disease, ischemic heart disease, sleep apnea, abnormal swallowing, and sleep choking syndromes may be mistaken for gastroesophageal reflux [442, 443, 445]. It has been shown that the fundamental mechanism of GERD is the inappropriate, transient, and frequent relaxation of the lower esophageal sphincter, causing episodes of acid reflux [431, 442, 443, 450]. The esophagitis resulting from acid reflux in the esophagus reduces the sphincter pressure and impairs esophageal contractility [431, 442, 450]. An additional mechanism is the presence of a hiatal hernia. Other factors, such as the acid clearance time, frequency of swallowing, and secretion of saliva, play an important role in the pathogenesis. The diagnosis of gastroesophageal reflux and prolonged acid secretion can be made by continuous monitoring of lower esophageal pH [431, 451]. When the pH falls below 4, gastroesophageal reflux occurs [452]. Repeated prolonged episodes of gastroesophageal reflux during sleep at night can cause esophagitis [453]. Physiologic changes during sleep consisting of suppression of saliva, decreased swallowing frequency, and prolonged mucosal contact with the gastric acid all contribute to the development of esophagitis [431, 442, 445, 454, 455]. After repeated prolonged episodes of gastroesophageal reflux at night for many years, patients may develop Barrett's esophagus, which results from replacement of the squamous epithelium of the lower esophagus by the columnar epithelium of the stomach [442, 443, 448, 449]. Documentation of spontaneous gastroesophageal reflux and prolonged acid clearance is important for diagnosis and treatment of esophagitis and of extraesophageal reflux and upper aerodigestive tract diseases resulting from repeated episodes of gastroesophageal reflux [431, 442, 454, 456–459].

Role of Gastroesophageal Reflux in Bronchopulmonary Disease

In some patients with asthma and chronic bronchitis or COPD, spontaneous gastroesophageal reflux at night plays a role in the pathogenesis of symptoms such as nocturnal wheeze, cough, or shortness of breath [431, 442, 443, 460–462]. In such patients, intraesophageal pH monitoring has shown prolonged acid clearance [461]. This is important from a therapeutic point of view, because administration of acid suppressants to such patients improves pulmonary

symptoms [443]. A study by Tan et al. [463], however, casts doubt on the relevance of gastroesophageal reflux to asthma.

The mechanisms of pulmonary symptoms in gastroesophageal reflux include aspiration of the gastric contents in the lungs causing pneumonitis and acid contact with the lower esophagus initiating reflex stimulation of the vagus nerve, causing bronchoconstriction. Actual aspiration of gastric contents into the lungs can be documented with the scintigraphic technique used by Chernow et al. [464]. These authors instilled a radionuclide into the stomach before sleep. A lung scan the next morning showed the radioactive material in the lung, suggesting nocturnal pulmonary aspiration. Children with asthma and bronchopulmonary disease may have sleep apnea, in addition to the other complications of gastroesophageal reflux [465]. Gastroesophageal reflux has been implicated in some cases of sudden infant death syndrome, possibly causing apnea and sudden death, but this has been found in only a small percentage of cases [466, 467]. The relationship between GERD and OSAS remains undetermined, although there is an increased prevalence of GERD in OSAS patients and CPAP treatment in such patients improves GERD symptoms [468–470]. These findings agree with the conclusion of Shepherd et al. [471] that the prevalence of nocturnal reflux symptoms is increased in those with or suspected of having OSA. This conclusion was based on 1116 patients with PSG-diagnosed OSA and 1999 participants of population health survey (2007 Busselton Survey). In a recent report Shepherd and Orr [472] suggested that obesity rather than airway obstruction is responsible for GERD symptoms.

Diagnostic Tests

No single test is diagnostic for GERD, but a combination of tests to assess the potential for reflux damage to the esophagus and actual presence of reflux is necessary to make the diagnosis. The diagnosis is confirmed by barium examination, and, if necessary, by endoscopic examination and biopsy [442, 443]. Measurement of lower esophageal sphincter pressure and a diagnosis of hiatal hernia may detect risk factors for reflux [442, 443]. Damage to the esophagus may be assessed by Bernstein's test (acid perfusion test), esophagography, esophagoscopy, and mucosal biopsy [442]. The actual presence of reflux may be established with the following tests: esophagography, acid reflux test, prolonged esophageal pH monitoring, and gastroesophageal scintigraphy [442]. The importance of 24-h ambulatory esophageal pH monitoring has been emphasized by Triadafilopoulos and Castillo [442].

Treatment

Treatment [442, 450] includes general measures such as avoidance of fatty foods and stooping, weight reduction, and elevation of the head of the bed to reduce reflux at night. Smoking should also be avoided. These simple measures decrease the frequency and length of reflux episodes as demonstrated by 24-h pH monitoring [452, 453]. If the patients fail to improve as a result of these simple measures, H_2-receptor antagonists (cimetidine, ranitidine, famotidine, and nizatidine) in the usual dose range as used for peptic ulcer patients (see earlier) will improve the symptoms of GERD [442, 443, 450]. For patients who are resistant to H_2-receptor antagonists, a proton pump inhibitor may be used [442, 443]. Proton pump inhibitors decrease gastric acid secretion through inhibition of the proton pump (H^+,K^+-ATPase) of the parietal cells (this is the most potent inhibitor of gastric acid secretion) and are in fact the treatment of choice for nighttime symptoms causing sleep dysfunction [442, 471–480]. Several studies have shown improvement of subjective measures of sleep without evidence of objective measurement after pharmacologic treatment for GERD [477, 479]. Other measures found to be useful are prokinetic agents (e.g., metoclopramide, 10 mg qid; cisapride, 10 mg qid; bethanechol, 10 mg qid) [346]. For patients who fail to respond to medical treatment, antireflux surgery (e.g., fundoplication) is indicated [442, 481]. Rarely, a Roux-en-Y near esophagojejunostomy is necessary for those intractable GERD patients who failed prior antireflux surgery [482].

In conclusion, an awareness of the role of sleep in the pathogenesis and treatment of peptic ulcer disease, particularly duodenal ulcer and esophageal reflux, is important for diagnosis and treatment. Facilities for all-night PSG study and 24-h esophageal pH monitoring have contributed to an understanding of the association between sleep and these diseases. These disorders are good examples of diseases that benefit from a multidisciplinary approach to patient management by a gastroenterologist, a pulmonologist, and a sleep specialist. This review also shows that sleep adversely affects patients with GERD by increasing the episodes of reflux and prolonging the acid clearance time. Furthermore, repeated spontaneous reflux episodes adversely affect sleep by causing arousals, frequent awakenings, sleep fragmentation, and excessive daytime sleepiness [444–446, 483].

Sleep in Functional Bowel Disorders

Functional bowel disorders include functional or nonulcer dyspepsia (NUD) and irritable bowel syndrome (IBS). NUD includes functional disorders of the upper gut and presents with upper abdominal pain or discomfort, nausea, gaseous distention, and early satiety [484–488]. A number of patients with functional bowel disorders have symptoms originating from the lower gut consistent with IBS, which is a common medical disorder characterized by symptoms of bowel dysfunction and abdominal pain [488]. In the last two decades, our understanding of IBS has grown considerably [488,

489], beginning with change in the classification and definition, which are the symptom-based Rome III criteria [490]. The basis for IBS symptoms is thought to be dysregulation of the brain–gut (central nervous system–enteric nervous system) relationship. The concept of IBS as a functional bowel disorder with no structural alteration has been dispelled by the functional and structural magnetic resonance imaging (MRI) findings of significant cortical thinning of the anterior cingulate cortex (ACC) and insula [491]. These findings confirm the investigators' previous observation of absent rectal pain-related functional MRI responses in the anterior insula and ACC in IBS [492]. These findings support the earlier abnormal EEG findings in IBS [493]. Davis et al. [491] also noted reduced gray matter in the anterior/medial thalamus and ACC on voxel-based morphometry in the IBS group relative to healthy controls.

Many patients with NUD and IBS have history of sleep complaints (e.g., frequent awakenings with or without pain and nonrestorative sleep) [494–496]. Such functional disorders may be associated with fibromyalgia syndrome (FMS) [489, 497–499]. Patients with FMS complain of a variety of sleep problems (see later). Jarrett et al. [500] and Eisenbruch et al. [501] reported that women with IBS associated with gastrointestinal symptoms complain of poor sleep and nonrestorative sleep more often than women without IBS. In a previous study, Eisenbruch et al. [502] reported poor sleep quality in the absence of objective sleep abnormalities (PSG findings), suggesting an altered sleep perception. In contrast to these findings, Fass et al. [503] prospectively evaluated 505 new patients with functional bowel disorders and 247 healthy controls using validated bowel symptom and sleep questionnaires. They concluded that functional dyspepsia patients, but not IBS patients, reported sleep disturbances more frequently than healthy control subjects. Another important observation is that IBS patients, compared with controls, had greater sympathetic dominance as indicated by increased LF/HF heart rate variability ratio during REM sleep because of vagal withdrawal, suggesting that autonomic functioning during REM sleep may be an useful biological marker to identify IBS patients [504]. However, in a later review of the literature, Mazurak et al. [505] concluded that most studies reported no difference in heart rate variability (HRV) when the IBS population was compared to healthy controls. Treatment of IBS patients includes an integrated pharmacologic and behavioral approach depending on the severity of symptoms and disability [488].

Miscellaneous Gastrointestinal Disorders and Sleep

There is circumstantial evidence that sleep deprivation or sleep disturbance may trigger flare-ups of two chronic autoimmune inflammatory bowel disorders: Crohn's disease or regional ileitis, and ulcerative colitis [506, 507]. Demonstration of exacerbation of colonic inflammation and tissue damage following acute and chronic sleep deprivation in a mouse model of colitis [508] supports such contention. Future research and clinical trials focusing on an improvement in the quantity or quality of sleep in patients with inflammatory bowel disorders are needed to provide definitive evidence.

Hepatic encephalopathy may cause hypersomnia, inversion of the sleep–wake rhythm, and recurrent stupor, which are most likely related to neurotransmitter alterations in the brain. There is an excessive accumulation of endozepines [benzodiazepine-like γ-aminobutyric acid (GABA) type A receptor modulators] in hepatic encephalopathy, explaining the recurrent stupor that is noted in some cases [509]. Prior hepatic encephalopathy may synergize with OSA in worsening sleep architecture and sleep disturbance in cirrhosis of liver [510] (nonrestorative sleep, reduced SWS, and increased stage N2). In a population-based cohort study from Chou et al. [511] observed that the risk of liver disease (particularly cirrhosis of liver and hepatitis c) was more than five times higher and among people with OSA compared with the control group. Previous studies [512–514] have also postulated a high prevalence of OSA in liver disease; however, a prospective study is needed to determine the factors responsible for such a high prevalence and also to evaluate the effect of CPAP therapy on the morbidity and mortality in liver disease.

Sleep disturbances have not been adequately studied in celiac disease (nontropical sprue or gluten-sensitive enteropathy) and Whipple's disease (a chronic multisystem disease due to infection with *Tropheryma whipplei*). Patients with celiac disease may have restless legs syndrome (RLS)—periodic limb movements in sleep (PLMS) [515], and Whipple's disease patients may present with insomnia or sleep–wake cycle changes.

Endocrine Diseases

Thyroid Disorders

It is important to be aware of the association between thyroid disorders, disordered breathing, and sleep disturbances. History and physical examination may direct attention to a thyroid disorder, in which case thyroid function tests should be performed to confirm the clinical diagnosis.

Hypothyroidism

The salient diagnostic features suggestive of myxedema consist of presentation in a middle-aged or elderly individual of fatigue, weight gain, decrease of physical and mental faculties, dryness and coarsening of the skin, pretibial edema, hoarse voice, cold sensitivity (sometimes presenting with hypothermia), constipation, and bradycardia or

evidence of ischemic heart disease in the ECG. Both upper airway obstructive [516] and central sleep apneas [517], which disappeared after thyroxine treatment, have been described in patients with myxedema. Mechanisms include deposition of mucopolysaccharides in the upper airways as well as central respiratory dysfunction as evidenced by impaired hypercapnic and hypoxic ventilatory response [518].

In an important study, Jha et al. [519] evaluated 50 newly diagnosed consecutive patients with primary hypothyroidism using PSG in all patients. Thyroxine replacement therapy was associated with improvement, including the findings in the repeat PSG study. This supports the previous findings of Rajagopal et al. [520]. Grunstein and Sullivan [521] recommended nasal CPAP treatment in patients with hypothyroidism and concomitant OSA while the patient is receiving thyroxine treatment. Routine screening for hypothyroidism in OSAS remains controversial [522–525]. Hashimoto's thyroiditis, an autoimmune disease diagnosed on the basis of high titers of antithyroid antibodies and histologic findings, is associated with higher prevalence of sleep-related breathing problems compared with controls [526]. A recent study [527] of 203 patients documented a total of 12.77 % of subclinical and clinical hypothyroidism in PSG proven OSAS patients.

Hyperthyroidism

Clinical features suggestive of thyrotoxicosis are presentation in a woman (female-to-male ratio, 8:1) of apparent increased energy, weight loss despite increased appetite, staring or bulging of the eyes (exophthalmos), tachycardia or atrial fibrillation, heat intolerance with excessive sweating, feelings of warmth, and a fine tremor of the outstretched fingers.

Few sleep studies have been made in patients with thyrotoxicosis. Dunleavy et al. [528] observed an increased amount of SWS, which returned to normal after treatment. In contrast, Passouant et al. [529] did not find any change in SWS but described an increase in sleep-onset latency in hyperthyroid patients. Johns and Rinsler [530] found no relationship between stages of sleep and alteration of thyroid function.

Ajlouni et al. [531] reported eight cases of patients with new-onset sleepwalking coinciding with the onset of thyrotoxicosis resulting from diffuse toxic goiter. Disappearance of sleepwalking with successful achievement of a euthyroid state supported a cause-and-effect relationship.

Diabetes Mellitus

For a discussion of sleep disturbance and sleep apnea in diabetes, see the section on autonomic neuropathy in Chap. 41.

Growth Hormone Disorders

Growth Hormone Deficiency and Sleep

In eight adults with isolated growth hormone (GH) deficiency (aged 18–28 years), Astrom and Lindholm [532] found a reduction of stage 4 sleep but increases in stages 1 and 2 NREM sleep, with a net result of an increase of total sleep time. In a later paper, Astrom and others [533] studied these patients after daily treatment with GH for 6 months and found a decrease in total sleep time that was due mainly to a reduction in stage 2 sleep, unchanged slow waves, and an increase in REM sleep time. In contrast to these findings, Pavel et al. [534] found no difference in sleep efficiency and daytime sleepiness in 16 GH-deficient adults (7 women and 9 men with a mean age of 36.8) after GH substitution. The subjective sleep parameters improved, however, and the authors suggested that this improvement might be caused by other indices of general well-being in this study with a small sample size. In 30 patients with GH deficiency (pituitary dysfunction in 26 and hypothalamic origin in four), Copinschi et al. [535] reported sleep dysfunction (high Pittsburgh Sleep Quality Index Scores, daytime sleepiness, and reduced QoL) compared with 30 controls. GH efficiency associated with morbid obesity, OSA, and hypogonadism is an important manifestation of Prader–Willi syndrome [536], a rare multi-system paternally inherited disorder of gene expression on chromosome 15q11–q13.

Excessive Growth Hormone Release and Sleep

Sullivan et al. [537] reported sleep apnea in association with GH release from the pituitary in patients with acromegaly. The most common explanation for sleep apnea in these patients is the enlargement of the tongue and pharyngeal wall, which causes narrowing of the upper airway. Sullivan's group [537] studied 40 patients with acromegaly and observed central sleep apnea in 30 %. Increased respiratory drive with increased hypercapnic ventilatory response is present in these patients. Sandostatin, a somatostatin analog, cured central apnea and normalized the ventilatory response.

Grunstein et al. [538] studied 53 patients with acromegaly who were consecutively referred for consultation. Sleep apnea was a reason for referral of 33 patients, whereas 20 patients were referred without any suspicion of apnea. Thirty-one patients of the group of 33 referred for apnea had sleep apnea; 12 of the 20 patients referred without suspected apnea were found to have apnea. Central apnea was predominant in 33 % of patients. The authors concluded that sleep apnea is common in individuals with acromegaly and central sleep apnea is associated with increased disease activity as reflected by biochemical measurement. They speculated that alteration of respiratory control may be a mechanism for sleep apnea in these patients. In a later study of 54 patients with acromegaly, Grunstein et al. [539] found

increased hypercapnic ventilatory responses in those patients with central sleep apnea but not in those with OSA or those without sleep apnea. These authors also found that acromegalic patients with central sleep apnea have increased GH and insulin-like growth factor-I levels compared with their counterparts with OSA. The authors concluded that increased ventilatory responsiveness and elevated hormonal parameters of disease activity contribute to the pathogenesis of central sleep apnea and acromegaly.

In contrast, later investigators found a high prevalence of sleep apnea, predominantly obstructive type and rarely central apnea [540, 541]. Suggested mechanisms for the development of OSA in acromegaly include an anatomic abnormality, especially at the base of the tongue [542]; craniofacial changes (e.g., increased vertical dolichofacial growth) causing narrowing of the posterior airway space, and displacement of the hyoid caudally [543].

Octreotide, a long-acting somatostatin analog, has been found to be an effective noninvasive treatment for sleep apnea in acromegaly [544, 545]. Sze et al. [546] reported a high prevalence of sleep apnea syndrome in acromegaly patients with resolution of SDB symptoms after transsphenoidal adenoidectomy. The relationship between sleep apnea and the GH level in active acromegaly remains unresolved [538, 541, 544]. Nonfunctional pituitary macroadenoma patients ($n = 69$) in long-term remission after trans-sphenoidal surgery on replacement therapy showed impaired sleep quality EDS and altered sleep–wake rhythmicity (decreased daytime and increased nighttime activities in actigraphic recordings) probably due to a dysfunction of the adjacent SCN [547].

Miscellaneous Endocrine Diseases and Sleep

In the only controlled study in patients with Cushing's syndrome (hyperpituitarism with corticosteroid excess), about one-third of the patients were diagnosed with sleep apnea [548]. There is one report of decreased delta sleep and increased stage 1 sleep and sleep fragmentation [549].

Addison's disease (adrenal gland insufficiency) patients may have increased sleep fragmentation and decreased REM sleep [550].

The male hormone testosterone is a risk factor for sleep apnea, as exogenous administration of testosterone induces sleep apnea in both normal and hypogonadal men [551] and worsens sleep apnea in older men [552]. Testosterone treatment transiently worsens severity of OSA [553], and serum testosterone levels are negatively correlated with severity of OSA [554]. However, CPAP therapy has no influence on testosterone level in men with OSA [555].

There is an increased prevalence of OSAS, insulin resistance, and type 2 diabetes mellitus in patients diagnosed with polycystic ovary syndrome, the most common endocrine disorder in reproductive-aged women, characterized by chronic anovulation and hyperandrogenism [556–558].

Renal Disorders

Sleep Disturbances and Chronic Renal Failure

Sleep dysfunction has been well described in cross-sectional studies of patients with chronic renal failure (CRF) on hemodialysis [559–567] and those not on hemodialysis [568–571], and even in patients with renal transplantation [572, 573]. Sleep dysfunction has been noted in up to 80 % of patients with CRF [560]. There is, however, no clear relationship noted between indices of renal failure and sleep disturbance in these studies.

Several studies have used PSG to objectively document the sleep disturbances, which consist of reduced sleep efficiency, increased sleep fragmentation, frequent awakenings with difficulty in maintenance of sleep, decreased SWS, and disorganization of the sleep cycle [559, 560]. Various studies have demonstrated a variety of sleep complaints in CRF patients that include poor-quality and nonrestorative sleep, difficulty in initiating and maintaining sleep, EDS, SDB, and sleep apnea. In a more recent study [574], Ezzat and Mobab sought to assess the prevalence of sleep dysfunction in patients with end-stage renal disease (ESRD) on hemodialysis ($n = 30$), chronic kidney disease (CKD) on conservative management ($n = 30$) comparing these two groups with normal controls ($n = 30$). In addition to standard blood biochemical studies and hemoglobin levels, all had one night of PSG study. They found a high percentage of sleep dysfunction in both patient groups. The types of sleep disorders and percentage were as follows in those on hemodialysis: insomnia (69); OSAS (24); RLS-PLMS (18); nightmares (13); EDS (12); sleepwalking (2); possible RBD (2); and possible narcolepsy (1.4). The figures in the CKD patients not on dialysis were as follows: insomnia (54); RLS (19); PLMS (12); OSAS (16); nightmares (15); EDS (1); sleepwalking (4); possible RBD (3); and possible narcolepsy (1). The authors concluded that sleep dysfunction is common in all kidney disease patients, and treatment of anemia, hyperphosphatemia, and hypoalbuminemia may improve their sleep problems.

In a prospective longitudinal study of 154 consecutive patients with CRF (78 completed the follow-up), Sabbatini et al. [575] determined sleep quality based on the Pittsburgh Sleep Quality Index (PSQI), and the data suggested that the progression of renal disease is accompanied by a progressive worsening of sleep quality. The data showed no correlation with creatinine clearance or with other indices of renal failure, but showed a correlation with age, which served as a

confounding variable. Four patients had high PSQI score at baseline and had further deteriorated at 3-year follow-up.

There are several factors which may contribute to the sleep problems in CRF patients [576]:

1. Disease-related factors (e.g., symptoms related to uremia, anemia, comorbid conditions, metabolic changes, and alterations in neurotransmitters)
2. Treatment-related factors (e.g., rapid changes in fluid, electrolyte, and acid-based balance; alterations in melatonin and thermoregulatory functions; medications; types of dialysis; alterations of cytokine metabolism in patients treated with hemodialysis causing abnormal somnolence [577] and proinflammatory cytokines (interleukin-1β), which might be associated with sleep complaints in hemodialysis patients [578])
3. Demographic factors (e.g., increasing age, male gender, and white race)
4. Psychological factors (e.g., anxiety and depression)
5. Lifestyle factors (e.g., increased intake of coffee, cigarette use, and poor sleep hygiene).

Sleep Apnea in Patients Receiving Dialysis

Sleep apnea is noted in up to 50 % of patients with renal failure [579]. Sleep apnea could be upper airway obstructive or central, but mainly an obstructive type of apnea is noted in most of the patients [577, 580–588]. This sleep apnea improves after nocturnal hemodialysis [488], which may be due to a decrease in chemosensitivity, suggesting also that, in some patients with kidney failure, increased chemoreflex responsiveness may contribute to the pathogenesis of sleep apnea. Beecroft et al. [589] studied 23 patients on hemodialysis and found decreased hypercapnic ventilatory response in sleep apnea patients who showed a significant reduction of the AHI after conversion from conventional to nocturnal hemodialysis. The authors suggested that increased chemosensitivity, by destabilizing respiratory control during sleep, may be responsible for both obstructive [590] and central sleep apnea [79, 591, 592]. An important study from the Sleep Heart Health Study identified an association between conventional hemodialysis and severe sleep apnea with nocturnal hypoxemia [593]. It should be noted that the prevalence of sleep apnea is similar in patients before and after receiving peritoneal dialysis or hemodialysis [594–596]. Although sleep problems may not be as common among transplantation patients as those on dialysis, the problems are still higher than in the general population [572, 573]. There are case reports indicating resolution of sleep apnea after renal transplantation [597]; however, many patients do not improve [584, 586, 598].

The following are the suggested mechanisms for the pathogenesis of sleep apnea in CRF:

- Upper airway edema causing partial airway obstruction coupled with decreased muscle tone during sleep [583].
- CNS depression during sleep resulting from so-called uremic toxins causing excessive reduction of upper airway muscle tone [583] (persistence of sleep apnea after dialysis speaks against this suggestion).
- Disturbance of the ventilatory control of breathing in renal failure and hemodialysis [577, 589, 597] making the respiratory control unstable, causing an imbalance between diaphragmatic and upper airway muscles. Beecroft et al. [599] reported an increased ventilatory sensitivity to hypercapnia in CRF patients with sleep apnea, suggesting an increase in respiratory control system "loop gain," which destabilizes central respiratory control and contributes to upper airway occlusion. Beecroft et al. [589] suggested that decreased chemoreflex sensitivity after conversion from conventional hemodialysis to nocturnal hemodialysis corrected sleep apnea by decreasing respiratory control system "loop gain," thus stabilizing the control of ventilation.
- CCF, which may occur in association with CRF, itself causing sleep apnea.
- Anatomic narrowing of the upper airway [600]. The same investigators also noted that there was an increase in pharyngeal size following conversion from conventional hemodialysis to nocturnal hemodialysis in those patients who previously had decreased pharyngeal cross-sectional area [601].
- Hypertension associated with CRF.
- Metabolic derangement associated with uremia. Soreide et al. [602] reported that an infusion of branched-chain amino acids stimulated nocturnal respiration and resulted in a decreased number of obstructive apneas.

Restless Legs Syndrome in Chronic Renal Failure Patients

There is an increased prevalence of RLS (20–50 % and even higher in patients with ESRD on dialysis [603–617]). Uremic RLS and idiopathic RLS resemble each other and cannot be distinguished clinically [609]. There are no specific biochemical risk factors identified with RLS associated with CKD except for low iron status as a predictor of poor outcome. Serum ferritin less than 70 μg/ml is the best cutoff for identifying possible iron deficiency which is the strongest predictor of RLS in CKD in older hospitalized patients [618]. Reports of disappearance or improvement of RLS symptoms after kidney transplantation suggest that some unknown biochemical or other factors are causing RLS symptoms in ESRD [606, 607]. Winkelmann et al. [607] investigated clinically the long-term course of 11 of 64 hemodialysis patients who underwent kidney transplantation. In all patients, RLS symptoms disappeared within 1–21 days after transplantation, and at follow-up visits up to

9 years, four patients remained free of RLS symptoms. In three other patients, RLS symptoms gradually reappeared. In 3 of 11 patients, transplantation failed and RLS symptoms reoccurred within 10 days to 2 months. In one patient, RLS symptoms reoccurred with transplant failure but disappeared after a second successful transplant. The authors concluded that kidney transplantation has a positive effect on RLS symptoms in hemodialysis patients. In an important cross-sectional study, Molnar et al. [606] assessed the prevalence of RLS in 992 kidney-transplanted patients using an RLS questionnaire. They found a prevalence rate of RLS of 4.8 % and concluded that the prevalence is significantly lower in kidney-transplanted patients than in patients with maintenance dialysis. The increasing prevalence of RLS in their series is associated with declining renal function and iron deficiency. In a preliminary study, Benz et al. [619] treated 10 hemodialysis patients having sleep complaints with recombinant human erythropoietin; in 9 of 10 patients, this therapy corrected the anemia and improved sleep quality. There is one report of MEIS1 and BTBD9 genetic association with RLS in ESRD [620]. Patients with ESRD and RLS showed an increased likelihood of cardiovascular and cerebrovascular events and mortality [621]. But a later report contradicted these findings [622].

Fibromyalgia Syndrome, Rheumatoid Arthritis, and Other Rheumatologic Disorders

All of these conditions are associated with chronic pain, and hence, some knowledge of human pain pathways is essential for understanding the pathophysiology of these disorders [623]. Pain pathways include afferent (ascending) fibers, central pain processing regions, and descending (efferent) fibers modulating these pathways. According to the current consensus, there are two central ascending pain pathways: a lateral sensory discriminative pathway and a medial affective pathway [624]. Impulses from peripheral pain-sensitive receptors are transmitted via thinly myelinated A delta and unmyelinated C fibers to the lateral pain pathway originating in the dorsal horn of the spinal cord in the region of zone of Lissauer, from where the fibers cross within one-to-three spinal segments to the contralateral spinothalamic tracts. The sensory afferent neurons in the spinothalamic tracts terminate in the ventral posterolateral nucleus of the thalamus. The third-order neurons from the thalamus terminate in the somesthetic cortex (SI and SII) for pain perception, discrimination, and central processing. Fibers also project directly both from thalamus and from SII to anterior insular cortex (the cortical pain center) [624]. The medical polysynaptic pain pathway includes spinoreticular and trigeminoreticular tracts projecting to the brain-stem reticular formation and then to the contralateral medial dorsal thalamic nucleus with upward projection to the anterior cingulate cortex which is responsible for the affective component of pain [624–629]. The other emotional pain pathway includes spinomesencephalic fibers to midbrain reticular formation with onward projection to the amygdala which is primarily responsible for the sense of fear [624]. Sensory descending pathways originating from the periaqueductal gray region, locus ceruleus, and hypothalamus [624, 630, 631, 632] modulate pain perception [633, 634]. These anatomic pathways are influenced by several neurotransmitters and neuromodulators [635–638] (e.g., noradrenalin, serotonin, and dopamine) as well as neuropeptides and their receptors. Dysregulation of ascending and descending pathways and alteration of central sensitization may be responsible for chronic pain in articular and nonarticular painful syndromes. Electrophysiologic [639–641] and functional neuroimaging [642–646], as well as SPECT and positron emission tomography (PET) [647, 648], studies have lent support to these hypotheses. This section briefly reviews sleep disturbances in FMS; rheumatoid arthritis (RA), including juvenile rheumatoid arthritis; osteoarthritis; and miscellaneous other painful conditions (e.g., ankylosing spondylitis, systemic lupus erythematosus, Sjögren's syndrome, and scleroderma) causing sleep disturbances.

Fibromyalgia Syndrome

FMS is a common but poorly understood syndrome characterized by chronic diffuse soft tissue pain and tenderness accompanied by a variety of somatic symptoms, including sleep dysfunction, in the absence of any structural lesion and without a single laboratory diagnostic test [649]. The condition has a prevalence rate of 1.3–4.7 % in the general population, with a female-to-male ratio of about 9:1, and onset typically occurs in the middle-aged and older women [650, 651]. The most common symptoms included morning stiffness, fatigue, nonrestorative sleep, pain, low back pain, impaired concentration, and memory "fog." Yunus et al. [652] originally listed specific diagnostic criteria for FMS, and this was followed by a description by Goldenberg [653] of an emerging but controversial condition. The American College of Rheumatology (ACR) in 1990 published the formal diagnostic criteria for FMS [654]. According to these criteria, the diagnosis is based on the presence of widespread diffuse pain affecting both upper and lower extremities lasting for at least 3 months and present in a symmetric fashion accompanied by 11 of 18 "tender points" when applying pressure of about 4 kg/cm^2 by digital palpation using the thumb or two fingers. The original ACR criteria are superseded by the 2010 ACR preliminary diagnostic criteria for FMS in which there was more emphasis on patient's symptoms [655] (Table 47.4). These criteria were later modified based on a self-report questionnaire (Fibromyalgia survey questionnaire [FSQ]) for improved specificity and sensitivity

Table 47.4 Diagnostic criteria for fibromyalgia

• Widespread diffuse pain lasting for at least 3 months
• Tender points in at least 11 of 18 anatomically defined sites (9 pairs of tender spots as listed below) after applying digital pressure of approximately 4 kg of force
– Second rib at the costochondral junctions
– Lateral epicondyle 2-cm distal to the epicondyle
– Suboccipital region
– Midpoint of the upper border of the trapezius
– Low cervical region
– Supraspinatus above the medial border of the scapular spine
– Gluteal region
– Greater trochanteric region posteriorly
– Medial fat pad at the knee joint proximal to the joint line

[656]. Based on a cutoff score ≥ 12, the modified ACR criteria had a sensitivity of 90.2 % and a specificity of 89.5 %; however, the modified ACR 2010 criteria questionnaire had a sensitivity of 97.4 % and a specificity of 85.2 %. Using a score of ≥ 13, the sensitivity was 93.1 % but the specificity increased to 91.7 %. The pathophysiology of the condition remains undetermined. However, based on the evidence that patients with fibromyalgia have dysfunctional pain processing in the CNS and perceive pain differently from the general population (see electrophysiologic, functional neuroimaging, SPECT, and PET studies cited above), suggested mechanisms included central sensitization, alterations in neurotransmitters, blunting of inhibitory pain pathways, genetic factors, neuroinflammation including viral infections, psychological stress, physical trauma, oxidative stress, and associated psychiatric comorbid conditions [623, 657]. A positive family history of fibromyalgia is found in some studies, and this is supported by the findings of a specific polymorphism in the 5-hydroxytryptamine$_{2A}$ receptor gene [658, 659], the serotonin transporter gene [660], and catechol-0-methyltransferese (COMT) gene [661, 662] which may predispose these patients to have psychiatric symptoms. Finally, genome-wide linkage of FMS to chromosome 17p supports a genetic factor in FMS [663].

An important item in the differential diagnosis is polymyalgia rheumatica, which is also characterized by diffuse muscle aches and pains but is often associated with accelerated erythrocyte sedimentation rate and evidence of temporal arteritis. Other differential diagnostic considerations include chronic fatigue syndrome (see later) and other myofascial pain syndromes. Sleep disturbance is very common in FMS [657, 665–671]. The characteristic PSG finding is intermittent alpha activity during NREM sleep giving rise to the characteristic alpha-delta or alpha-NREM sleep pattern in the recording (Fig. 47.2). It should be noted that although alpha-delta sleep is seen in this condition, this variant is not specific for the syndrome. Alpha-NREM sleep has also been reported in other rheumatic disorders [672], febrile illness, post-viral fatigue syndrome [673], psychiatric patients [674], and even normal individuals [675]. Nonrestorative sleep associated with nonspecific PSG abnormalities of sleep fragmentation, increased awakenings, decreased sleep efficiency, and alpha-NREM sleep is the most prominent complaint in these patients [665, 666]. In two retrospective reviews of PSG records and medical charts, there is a high prevalence of sleep apnea and RLS in addition to the other sleep complaints noted previously [669, 670]. Gold et al. [676] reported that, following CPAP treatment in women with FMS and upper airway resistance syndrome, the patients obtained considerable relief from fatigue, pain, and gastrointestinal symptoms. The most prominent feature in all of these studies is the subjective perception of poor sleep, which is out of proportion to objective measures of sleep [665, 666, 677]. Another objective measurement of sleep is actigraphy, which gave inconsistent results in FMS [678–681]. In summary, patients with FMS have a high prevalence of sleep difficulty, with up to 99 % reporting poor sleep quality [665, 666, 682]. The most common sleep difficulties reported are EDS, fatigue, and insomnia [665, 666, 683]. The observation of disassociation of subjective sleep complaints with objective sleep measures is strengthened by a pilot study showing high levels of dysfunctional beliefs and attitudes about sleep and perceived stress associated with poor sleep quality in FMS patients [684].

Treatment of FMS remains unsatisfactory. Treatment options should include both pharmacologic and nonpharmacologic therapies [657, 666, 686–688]. The nonpharmacologic treatment should include an exercise program [689] (more recent studies [690, 691] did not find exercise programs in FMS to be beneficial) good sleep hygiene measures, education and reassurance, and cognitive behavioral therapy [692–695]. Pharmacologic treatment [657, 665–677, 696] found to be useful includes tricyclic antidepressants (e.g., amitriptyline), nonbenzodiazepine hypnotic drugs, selective serotonin reuptake inhibitors (e.g., fluoxetine),

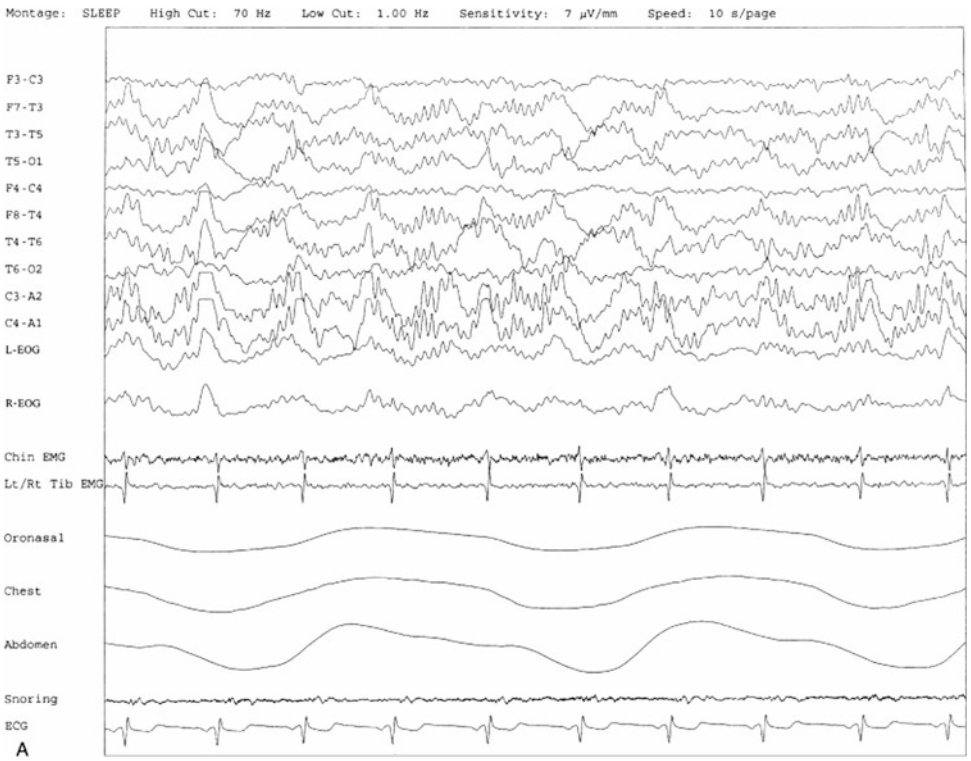

Fig. 47.2 Ten- (a) and 30 s (b) excerpts from a nocturnal PSG showing alpha-delta sleep in a 30-year-old man with history of snoring for many years. He denied any history of joint or muscle aches and pains. The alpha frequency is intermixed with and superimposed on underlying delta activity. Alpha-delta sleep denotes a nonspecific sleep architectural change noted in many patients with complaints of muscle aches and fibromyalgia. It is also seen in other conditions and in many normal individuals. (EEG, top 10 channels; Lt. and Rt. EOG, left and right electro-oculograms; chin EMG, EMG of chin; Lt./Rt. Tib. EMG, left/right tibialis anterior EMG; oronasal thermistor; chest and abdomen effort channels; snore monitor; EKG, electrocardiography) (From Ref. [685])

serotonin/norepinephrine reuptake inhibitors (e.g., venlafaxine, duloxetine, and milnacipran), gabapentin [657, 697], and pregabalin [698–700]. Pregabalin, a centrally acting drug used to treat neuropathic pain and adults with partial epilepsy, is the only drug approved by the Food and Drug Administration for treating and managing fibromyalgia. The recommended dose of pregabalin is 300–400 mg/day in two divided doses beginning with smaller doses of 75 mg twice a day and gradually increasing. Patients should also be treated for comorbid conditions (e.g., depression and sleep apnea). In a meta-analysis of five randomized placebo-controlled trials consisting of 2918 FMS patients (four with pregabalin and one with gabapentin), Hauser et al. [701] reported an improvement of sleep with reduction of pain in the patients. In a later Cochrane review, however, Moore et al. [702] reported that gabapentin 1200 mg or more per day reduced pain by 50 % in only 37 % of patients compared with 21 % on placebo.

Rheumatoid Arthritis and Other Rheumatologic Disorders

Arthritis, including rheumatoid and nonrheumatoid types, is the leading cause of disability in the USA, affecting approximately 70 million individuals. These conditions include RA (including juvenile RA), osteoarthritis, seronegative spondyloarthritis (e.g., ankylosing spondylitis, a reactive arthritis that was formerly known as Reiter's syndrome; and psoriatic arthritis, arthritis associated with ulcerative colitis, Crohn's disease, and Whipple's disease), systemic lupus erythematosis, Sjögen's syndrome, scleroderma, gouty arthritis, and polymyalgia rheumatica. Osteoarthritis is the most common type of arthritis, followed by RA. A systematic approach encompassing history, physical examination, and appropriate laboratory tests will help differentiate these conditions [703]. For appropriate diagnosis and differential diagnosis of these conditions, readers are referred to a standard text in internal medicine. Many of these patients suffer from sleep dysfunction, and in particular insomnia, fatigue, and depression; however, adequate scientific data correlating subjective with objective measures in a large number of such patients are lacking [683, 684].

In limited studies, sleep disturbances in osteoarthritis are commonly noted, consisting of sleep onset and maintenance insomnia (including early morning awakenings), correlating with the severity of joint pain, physical function, and

depression [686, 687]. Polysomnographic findings are not specific but correlate with sleep complaints, showing increased stage 1 sleep and repeated awakenings and arousals [688]. Sleep disturbances in adult RA patients consisting of difficulty in sleep onset and maintenance and fragmentation of sleep associated with EDS and fatigue are noted [689]. In a large percentage of patients [690], PSG studies show normal sleep architecture associated with alpha intrusions and increased PLMS [691, 692]. Studies generally show a positive correlation between sleep complaints and severity of the disease activity [694–696]. There is an increased prevalence of RLS in patients with RA [691, 697, 698]. There is also an increased prevalence of sleep apnea in these patients [691, 699, 700]. Similar sleep disturbances are also noted in juvenile RA [701, 702]. Similar sleep disturbances, particularly insomnia and daytime sleepiness, are also noted in systemic lupus erythematosis, Sjögren's syndrome, and seronegative spondylotic arthritis [411, 667, 703–728]. Comorbid upper airway OSA and PLMS are noted in systemic lupus erythematosis and ankylosing spondylitis. Gastroesophageal reflux, pulmonary fibrosis, and RLS are additional comorbid conditions disrupting sleep in scleroderma patients. Treatment of these conditions includes treatment of the primary diseases and associated sleep dysfunction following the general lines of management for insomnia, hypersomnia, and sleep apnea. Currently, there are no adequate studies describing the prevalence of and appropriate guidelines for treating sleep disturbances in these conditions.

Hematologic Disorders

The hematologic disorders that may cause sleep disturbance or be adversely affected by sleep include paroxysmal nocturnal hemoglobinuria (PNH), sickle cell anemia, hereditary hemorrhagic telangiectasia, and iron-deficiency anemia. Hansen [729] noted increased levels of plasma hemoglobin in five of seven patients with PNH, and the maximum values were found at midnight or at 4:00 AM. However, the author did not record EEGs or electro-oculograms to document any relationship with different sleep stages. Sleep impairment in the form of reduced total sleep time and REM sleep percentage and increased number of awakenings and sleep stage shifts is noted in patients with clinically stable sickle cell anemia, and these findings are probably due to hemoglobin desaturation [730, 731]. OSA and sleep disturbances resulting from reduced Sao_2 can occur in patients with sickle cell anemias and the prevalence of OSA in SCD is higher than in the general pediatric population [732]; when these diagnoses are suspected, overnight PSG recording should be obtained to confirm the diagnosis so that appropriate treatment with CPAP titration can be instituted [733]. Progressive somnolence accompanied by confusion has been described in a patient with hereditary hemorrhagic telangiectasia [734]. Iron-deficiency anemia in infancy is reported to be associated with altered temporal organization of sleep states and stages in childhood [735, 736]. Sleep alterations may persist for years after correction of anemia with iron treatment [736]. Furthermore, iron-deficiency anemia with low ferritin level may be combined with RLS. Zilberman et al. [728, 737] reported an improvement of anemia in congestive heart failure following administration of erythropoietin and intravenous iron, along with an improvement of sleep-related breathing disorder and daytime sleepiness. Finally, sleep deprivation in healthy individuals may cause a hypercoagulable state as evidenced by increased levels of prothrombotic hemostasis factors, which are risk factors for cerebrovascular and cardiovascular diseases [738, 739].

Dermatologic Disorders

Dermatologic disorders may cause sleep disruption because of pruritus and painful skin diseases [740, 741]. Patients may have sleep initiation and maintenance insomnia. In many dermatologic disorders, patients may have recurrent episodes of pruritus, which is most frequently noted during stages 1 and 2 NREM and least frequently noted in SWS; the intensity of symptoms is intermediate in REM sleep [741]. Patel et al. [740] reviewed the question of the high prevalence of nocturnal pruritus in many systemic and dermatologic diseases, causing sleep disturbance and diminished quality of life. Singareddy et al. [742] reported skin picking or pathologic excoriation in nearly 2 % of patients attending the dermatologic clinic in a mid-Western region of the USA. They found a significant correlation between skin picking and poor sleep as well as high anxiety. Nocturnal scratching may occasionally present as a parasomnia not associated with dermatological disorders [743, 744]. Mouzas et al. [745] reported a significantly higher occurrence of sleepwalking, sleep terrors, nightmares, and nocturnal enuresis in 116 patients suffering from vitiligo compared with 52 patients with other dermatologic diseases and 48 healthy controls.

Atopic dermatitis (AD), a common skin disorder beginning in infancy, may also cause disturbance of sleep in children because of nocturnal itching and scratching [746–748]. This can be documented by questionnaire and actigraphic recording [747]. There is a report of patients with OSA especially male younger patients with an increased risk for AD later in life [749]. Lichen simplex chronicus is another common pruritic disorder in which nighttime pruritus is a common feature disturbing sleep. This was documented by overnight PSG

study and the Epworth Sleepiness Scale in 15 patients with lichen simplex chronicus and 15 age-matched controls [750]. Polysomnographic findings in patients demonstrated increased arousals and awakenings associated with scratching bouts during sleep. PSG study and parental report of sleep quality (sleep disturbance scale of children) in 21 children with eczema and 20 healthy controls (ages 6-16 years) documented worse sleep quality on both PSG (increased nocturnal awakening and stage shifts) and parental report in addition to significant neurocognitive deficits [751].

Miscellaneous Disorders

Acquired Immunodeficiency Syndrome

Acquired immunodeficiency syndrome (AIDS) is a multisystem disorder caused by infection with human immunodeficiency virus (HIV). Its manifestations are protean. Neurologic manifestations include both CNS and peripheral neuromuscular dysfunction. Encephalitis, due to either opportunistic infection or direct invasion by the virus, may cause a variety of disorders such as memory impairment, seizures, and pyramidal or extrapyramidal manifestations. Some patients have sleep disturbances, but adequate studies utilizing PSG recordings and validated sleep scales have not been performed in a large number of these patients.

Norman et al. [752–754] found alterations in sleep architecture in groups of asymptomatic HIV-positive men that progressed as the disease became symptomatic in 17 of the initial group of patients followed for 19–63 months. Several other authors [755–758] also reported sleep architectural abnormalities after PSG recordings in asymptomatic HIV-positive patients. Darko et al. [757, 758] also suggested that there is evidence to support a role for the somnogenic immune peptides tumor necrosis factor-α and interleukin-1β in the sleep changes and fatigue commonly seen in HIV infection. These authors [757] stated that these peptides were elevated in the blood of HIV-infected individuals and are somnogenic in clinical use and animal models.

A more recent study utilizing the PSQI and the Medical Outcome Short-Form Health Survey in a sample of 144 HIV-infected African American women recruited from 12 health clinics and AIDS service organizations in three southern states in the USA showed a high prevalence of poor sleep quality associated with an impairment of health-related quality-of-life index in these patients [759]. Moyle et al. [760] also reported sleep disturbances and alterations of sleep architecture following initiation of efavirenz-containing triple antiretroviral therapy in HIV-positive individuals.

HIV infection can cause SDB. Epstein et al. [761] identified three HIV patients with OSA due to adenotonsillar hypertrophy. They also surveyed 134 patients with asymptomatic HIV disease with a self-administered questionnaire designed to detect OSA and EDS. Those patients whose responses suggested possible OSA were studied by overnight PSG recording. Twelve HIV-positive patients with OSA were identified. The consistent risk factor in this young and non-obese population was the presence of adenotonsillar hypertrophy, which was found in 11 of 12 patients with OSA. In a previous paper, these authors [762] reported the first cases of severe OSA in HIV-infected men. Garrigo et al. [763] obtained PSG recording in asymptomatic HIV-positive men and reported an elevated apnea index in 7 of 24 patients who did not have symptoms related to SDB. In a more recent retrospective review of the medical records of consecutively identified HIV-infected subjects, there was a high prevalence of SDB on PSG recordings. The authors suggested that clinicians caring for HIV patients should inquire about risk factors for OSA because overnight PSG study can aid the diagnosis of sleep disturbances in such patients [764]. This is important for treatment and improvement of quality of life.

Whether PSG can document significant and specific abnormalities in asymptomatic individuals or warn of the development of encephalopathy remains to be determined. A systematic study of a large number of cases needs to be done to answer these questions.

There are several recent reports documenting sleep dysfunction and the factors responsible for this in HIV/AIDS patients [765–769]. A recent meta-analysis [770] covering 9246 HIV-positive subjects documented a prevalence of 58 %. Sleep problems may have potential impact on antiretroviral therapy outcome.

Lyme Disease

Lyme disease [771–778] is a multisystem disease caused by the spirochete *Borrelia burgdorferi* and transmitted to humans by tick bite. The clinical manifestations may be divided into three stages:

1. Initially, there is a characteristic skin lesion, erythema migrans, which is followed in the course of time by a febrile illness (acute stage or stage I).
2. In the subacute stage or stage II, which occurs in several weeks to months after the onset of the illness, approximately 12–15 % of patients may develop neurologic manifestations and approximately 4–10 % may have cardiac involvement (conduction disturbance or cardiomyopathy) [771, 776]. Neurologic manifestations may present as axonal polyneuropathy, radiculoneuropathy, cranial neuropathy (particularly affecting the facial nerve), lymphocytic meningitis, encephalitis, or encephalopathy. Encephalitis is rare. Patients with CNS manifestations may have sleep disturbances.
3. In the chronic stage or stage III, which occurs weeks to as long as 2 years after the onset of illness, approximately 60 % of patients develop arthritis [771, 776].

Sleep complaints are common in Lyme disease [771], but no large-scale study using PSG is available to characterize the sleep disturbances in this condition. Greenberg et al. [779] obtained 2 nights of PSG in 11 patients meeting Centers for Disease Control and Prevention (CDC) criteria for late Lyme disease with serologic confirmation and 10 age-matched controls. In addition, the authors performed the Multiple Sleep Latency Test (MSLT) in the Lyme disease patients. All patients had complaints of difficulty initiating sleep, frequent nocturnal awakenings, and EDS; a small percentage had restless legs or nocturnal leg jerking. Polysomnographic findings included decreased sleep efficiency, increased arousal index with sleep fragmentation, and alpha intrusion into NREM sleep. These authors concluded that these sleep abnormalities may have contributed to the sleep complaints and fatigue that are commonly present in this disease.

Because Lyme disease is treatable, every attempt should be made to diagnose it accurately. Diagnosis depends on the serologic detection of antibodies against *B. burgdorferi* in the serum (or, in the case of CNS infection, in cerebrospinal fluid samples) [777]. The usual method of testing is the enzyme-linked immunosorbent assay [777], but antibodies usually are not detectable until 4–6 weeks after the initial infection. Diagnosis may be complicated by false-positive results and lack of a standardized technique to assay for antibodies. Polymerase chain reaction has been shown to be useful in demonstrating *B. burgdorferi* DNA in clinical material [777]. Recently developed serodiagnostic tools, such as the C6 assay, and appropriate use of Western blotting show considerable promise in improving the diagnostic accuracy [780].

In most patients, oral antibiotics are efficient, but in severe cases, 2- to 4-week parenteral therapy is needed. Practice parameters are available for treatment of nervous system Lyme disease developed by the American Academy of Neurology and Clinical Infectious Diseases Society of America [775, 781]. The most effective oral antibiotics include amoxicillin 500 mg three times a day, doxycycline 100 mg twice a day, and cefuroxime 500 mg twice a day given for 2–3 weeks. Treatment of more than 4 weeks' duration is not needed and carries substantial risk but minimal benefit [773, 782, 783].

Chronic Fatigue Syndrome

Chronic fatigue syndrome (CFS) is a complex, ill-defined heterogeneous debilitating condition. Patients complain of profound fatigue, functioning below their usual level of energy, that is not improved by bed rest. CFS affects 836,000 to 2.5 million in the USA and is more common in women than men. The diagnostic criteria for CFS were established from a consensus among international experts [784]. Diagnosis of CFS depends on the patient's history and the information obtained by physical examination as well as exclusion of other causes of the fatigue after extensive laboratory investigations. There is controversy in this case definition as the condition overlaps with many other disorders and because it is based on a consensus of experts without availability of any laboratory diagnostic test [785]. The concept of CFS has evolved over the years and has been modified since the original diagnostic criteria [784] were established. In view of the evidence in later research of widespread inflammation and multisystem involvement, the term myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS) [786] was thought to be appropriate to call this condition. The proposed new evidence-based diagnostic criteria by the Institute of Medicine (IOM) [664] focused on the central symptoms and one of two additional symptoms (Table 47.5). These symptoms should persist for at least six months at a moderate, substantial, or severe intensity at least half of the time. The IOM committee [664] noted that evidence of other manifestations of ME/CFS seen less frequently but these may support the diagnosis (Table 47.6). ME/CFS is thus a chronic multisystem debilitation condition manifested by chronic disability fatigue, post-exertional malaise and unrefreshing sleep associated with cognitive impairment or orthostatic intolerance [664, 787]. There are no diagnostic laboratory tests but all three national agencies [IOM, Agency for Healthcare Research and Quality (AHRQ) and National Institute of Health (NIH)] concluded that there are biological abnormalities [788]. A Positron Emission Tomographic (PET) scan showed evidence of neuroinflammation (activated microglia or astrocytes) [789], functional magnetic resonance imaging (fMRI) studies documented distinctive abnormalities when challenged with working memory tasks, and the NIH report gave evidence of neurotransmitter signaling disruption [788, 789]. There is, however, no conclusive evidence of any biomarker sensitive or specific enough to serve as a diagnostic test [788]. The cause and pathogenesis remain uncertain. Viral causes have been incriminated but no specific virus or other infectious agent has been indentified [787, 790]. There has been a suggestion of an external agent triggering an immune response leading to immune and neuroendocrine dysregulation [790, 791].

The clinical course of CFS follows a randomly cyclical pattern, and studies conducted by the CDC [792, 793] have found that 40–60 % of the people with CFS report partial or total recovery, particularly those who have received early treatment. Certain comorbid conditions with CFS include IBS, fibromyalgia, depression, Gulf War syndrome, and interstitial cystitis. There is some suggestion of increased familial aggregation of CFS because of increased concordance rates in monozygotic compared with dizygotic twins [794]. Several patients with CFS had orthostatic hypotension on tilt-table study, which was thought to be responsible for some of the

Table 47.5 Proposed IOM diagnostic criteria for ME/CFS [664]

Diagnosis requires for the patient to have the following three symptoms (core symptoms)
1. A substantial reduction or impairment in the ability to engage in preillness levels of occupational, educational, social, or personal activities that persists for more than 6 months and is accompanied by fatigue, which is often profound, is of new or definite onset (not lifelong), is not the result of ongoing excessive exertion, and is not substantially alleviated by rest, and
2. Post-exertional malaise, and
3. Unrefreshing sleep
At least one of the two following manifestations is also required
1. Cognitive impairment
2. Orthostatic intolerance

Table 47.6 Additional symptoms of ME/CFS

• Pain which is variable and may manifest as myalgia, arthralgia, or headache
• Evidence of immune dysfunction
• Evidence of infection
• Gastrointestinal or genitourinary symptoms
• Sore throat
• Painful or tender cervical or axillary lymph nodes
• Sensitivity to food, drugs, or other chemical agents

symptoms [795]. It is notable that orthostatic intolerance is listed as one of the five symptoms in the proposed IOM diagnostic criteria [664] (see Table 47.5).

Sleep disturbances (e.g., disturbed unrefreshing and poor quality of nighttime sleep, insomnia, and EDS) are very common in ME/CFS patients, but in many cases these have not been adequately characterized by PSG studies. PSG abnormalities have been found in a few studies [796–801]. Fischler et al. [796], in a PSG study in 49 CFS patients and 20 healthy controls, found more sleep initiation and maintenance disturbances and a significantly lower percentage of stage 4 NREM sleep in the CFS patients than in the control group. However, they did not find any association between sleep disorders and the degree of functional impairment. Similarly, in a population-based study of CFS patients and nonfatigued controls from Wichita, Kansas, utilizing overnight PSG and MSLT tests, Reeves et al. [798] did not provide evidence that altered sleep architecture is a critical factor in CFS. Guilleminault et al. [799] reported that complaints of unrefreshing sleep and chronic fatigue were associated with an abnormal EEG cyclic alternating pattern and an increase in respiratory effort and nasal flow limitation, suggesting subtle undiagnosed SDB. Togo et al. [800] compared PSG findings and subjective scores for sleepiness and fatigue (visual analog scales) in 26 CFS patients (12 with and 14 without coexisting fibromyalgia) with 26 healthy subjects. Compared with controls, CFS patients had reduced total sleep duration and decreased sleep efficiency, which positively correlated with subjective sleepiness and fatigue. The authors suggested that this sleep disruption may explain the overwhelming fatigue and unrefreshing sleep. In conclusion, the entity of ME/CFS remains ill-defined and the treatment, at present, should be symptomatic, using both pharmacologic and nonpharmacological treatment. Nonpharmacologic treatment includes sleep hygiene measures and cognitive behavioral therapy (CBT). Symptomatic treatment for depression using appropriate antidepressants and nonsteroidal medications for pain is suggested. In a meta-analysis evaluating 35 treatment trials, the benefits of therapy remain inconclusive [787]. Limited evidence was seen with the immune modulator, rintatolimod along with counseling behavior therapies and graded exercise therapy (GET) in some patients with ME/CFS [802]. However, the ME Association [803] came out with a report contradicting some of the above conclusions. Their report showed no benefit from CBT and GET but Pacing courses (containing elements of CBT and "learning coping strategies" but not GET) have consistently shown to be the most effective, safe, acceptable, and preferred form of active management for ME/CFS.

Sleep of Intensive Care Unit Patients (Medical and Surgical)

Generally, patients are admitted to the medical ICU because of acute respiratory failure resulting from COPD, bronchial asthma, sleep apnea syndrome, restrictive lung disease, acute cardiovascular disorders (e.g., ischemic heart disease with or without myocardial infarction, cardiac arrhythmias, CCF),

acute neurologic disorders causing respiratory disturbances (e.g., brain-stem lesion, status epilepticus, high cervical cord lesions, neuromuscular disorders), renal failure, or gastroesophageal reflux causing acute respiratory tract symptoms. All of these conditions can be associated with sleep disturbances (insomnia, hypersomnia, and sleep-related respiratory dysrhythmia), which become intense in severely ill patients admitted to the ICU who require life-saving cardiorespiratory support [804–821].

Sleep disruption is very common in ICU patients; a figure of more than 50 % incidence has been quoted [811]. The causes of the sleep disruption include a variety of factors: (1) the ICU environment; (2) comorbid medical or surgical illnesses; (3) effects of many medications used to treat these critically ill patients; (4) individual factors, e.g., anxiety, psychological stress, pain resulting from the surgical procedures, and therapeutic interventions (e.g., use of ventilators, noise generated by the monitors) [804–821]. The ICU environment itself is deleterious to normal sleep and conducive to sleep deprivation with its attendant complications, such as ICU psychosis. In addition to sleep deprivation, physiologic and physical factors contribute to ICU psychosis. Noise, bright light, and constant activity on the part of the ICU personnel for monitoring and drug administration play significant roles in disturbing the sleep of ICU patients.

The ICU syndrome or ICU psychosis describes a cluster of psychiatric symptoms and is a characteristic mental state defined as a reversible confusional state developing 3–7 days after ICU admission secondary to sleep deprivation [812–814, 817, 821]. ICU psychosis is more common in surgical than in medical ICUs, and the prevalence has been estimated to be between 12.5 % and 38.0 % of patients admitted to the ICU [812–814]. Sleep deprivation has been cited as the major cause of the ICU syndrome [795, 822]. In a study by Helton et al. [812], 10 % of patients with moderate sleep deprivation and 33 % with severe sleep deprivation developed the ICU syndrome. There is evidence to suggest that the ICU syndrome is similar to delirium [785]. The question remains whether sleep deprivation is the cause of the delirium [823, 824]. There is evidence that higher morbidity and mortality increases the length of stay and cognitive impairment associated with ICU delirium [825, 826].

An important cause of sleep disruption in the ICU is noise [810, 811, 816, 817, 827–832]. Technological advances in the ICU setting (e.g., monitors and meters, ventilator alarms, television, phones, and beepers) have been cited as the major culprits for contributing to ICU noise and sleep disruption. The role of the noise in contributing to sleep disruption has been documented objectively by continuous sleep monitoring and recording of the environmental peak sound levels [831, 833].

In the surgical ICU, patients are usually admitted in the postoperative period because they are recovering from anesthesia, are beginning to suffer from pain, are experiencing metabolic disturbances, or have an infection related to surgical care. All these factors may cause severe disturbance of sleep and breathing.

Another condition noted in many patients admitted to the ICU is REM sleep behavior disorder. Schenck and Mahowald [834] evaluated over 200 adults with injurious, sleep-related behaviors during 8 years of clinical practice, and 20 of these had ICU admissions. Polysomnography with audio–video recordings documented REM sleep behavior disorder in 17 of these 20 patients.

Several authors have studied ICU patients using PSG to document disruption of sleep structure [827, 835–841]. These disturbances consist of marked diminution of SWS and REM sleep, frequent awakenings, sleep fragmentation, and reduced total night sleep time. The total sleep over a 24-h period appears to remain normal. Because of night sleep disturbances, ICU patients often have EDS [835, 837]. PSG recording in ICU patients has been a challenge. For one thing sleep of ICU patients is severely fragmented, especially those on mechanical ventilators [821, 835], and distributed in short segments throughout 24 h without any consolidated period of sleep containing atypical sleep prompting new scoring guidelines for ICU patients [840, 841].

Some studies have suggested that an impairment of the melatonin rhythm may play a role in explaining sleep disturbances and delirium in ICU patients [818, 819, 840–842]. The questions of ultimate outcome and functional status of patients in the ICU and the impact of improving poor sleep in ICU patients are not clearly known, and further research is needed in this direction [843]. It is stated that, overall, physical recovery is more complete than psychosocial recovery [844]. There have been reports of post-traumatic stress disorder following ICU admission for critical illnesses [845]. Roberts et al. [846] reported experiencing vivid dreams, hallucinations, or delusions associated with a longer ICU stay among 41 participants in three ICUs 24 months of post-discharge. The authors suggested that, because these dreams are disturbing, the patients should have information and counseling about delirium, particularly for those who remain in ICU for longer periods. Another factor known to play a role for sleep disturbance in ICU patients is sepsis which accounts for about 20–40 % of admissions to a medical ICU [817, 847]. Septic encephalopathy may show a characteristic EEG pattern (low-voltage mixed frequency

theta-delta waves) which has been reported to appear before the clinical manifestations of sepsis [827] along with reduced REM sleep and loss of circadian melatonin rhythm [817].

Treatment

The physicians and paramedical personnel who take care of ICU patients must be aware of the various ICU factors contributing to the problem of sleep disturbances, so that correct diagnosis and management of secondary complications (in addition to treatment of the primary disorders) can be effected promptly. The treatment for sleep disturbance in the ICU environment consists of nonpharmacologic and pharmacologic intervention. Nonpharmacologic treatment includes measures to decrease or eliminate many of the factors (noise, light, and others as described previously) causing sleep deprivation in ICU patients. Other nonpharmacologic measures include sleep hygiene rules, cognitive behavioral therapy, counseling the patients after discharge from the ICU, and adjusting ventilator settings to prevent dys-synchronous breathing and central apneas in those using mechanical ventilation [804, 817, 848]. Clinical practice guidelines to improve sleep in critically ill adults have been suggested [849]. These guidelines suggest an integrative approach to improve sleep in these patients, combining pharmacologic and nonpharmacologic measures. The suggested pharmacologic measures include hypnotics and benzodiazepine drugs (short and intermediate acting, such as alprazolam, lorazepam, and temazepam). These drugs should be used with caution because of adverse effects. Nonbenzodiazepine receptor agonists (e.g., zolpidem, eszopiclone, and ramelteon) are preferable to benzodiazepine drugs because of the lesser side effect profiles. The newer antipsychotic drugs (e.g., olanzapine, risperidone, and quetiapine) may be useful to treat delirium, but adequate studies have not been undertaken yet. Opiates and NSAIDs should be used for pain. In a report using a small sample size, significant improvement in postoperative delirium after surgery for esophageal cancer was noted following bright light therapy [850]. There is currently no standardized protocol to improve sleep of ICU patients [817]. Kamdar et al. [851] recently suggested controlling noise and light and increasing daytime activities.

In addition to treating the primary disorder, it is important to treat secondary sleep-related respiratory problems. If a sleep disturbance persists after the patient leaves the ICU, a primary sleep disorder may be suspected and appropriate investigations, such as PSG study and MSLT, should be performed.

African Sleeping Sickness (Trypanosomiasis)

African sleeping sickness is caused by *Trypanosoma gambiense* or *Trypanosoma rhodesiense* and is transmitted to humans by the bite of tsetse flies. The clinical features are characterized by lymphadenopathy, fever, and later (after several months or years) excessive sleepiness due to encephalopathy or encephalitis. In stage 1 of the disease, the parasites proliferate in the hemolymphatic system (hemolymphatic stage). In stage 2, the parasites invade the central nervous system, causing progressive neurologic dysfunction with disruption of sleep–wake patterns (meningoencephalitic stage) [824–856]. The clinical manifestations in the type caused by *T. rhodesiense* (Rhodesian sleeping sickness) are more rapidly progressive, resulting in cardiac failure and acute neurologic manifestations [853, 855]. Gambian sleeping sickness, caused by *T. gambiense,* is a more chronic illness with predominant neurologic manifestations [852]. Within 6 months to several years after the onset of the first symptoms, the Gambian type progresses into a late meningoencephalitic stage. CNS involvement is initially characterized by personality changes followed by delusions, hallucinations, and reversal of sleep–wake rhythm [852, 856]. The patient remains somnolent in the daytime and progresses gradually into the stage of stupor and coma. The cerebrospinal fluid examination shows increased cells and protein.

Several PSG studies lasting for at least 24 h and correlating with several plasma hormone levels have been conducted in patients with human African trypanosomiasis [854–865]. These studies documented disruption of the circadian sleep–wake rhythm, which is proportional to the severity of the illness. In less severely affected patients, the relationship between hormonal pulses (cortisol, prolactin, and plasma renin activity) and specific sleep stages persists. Sleep–wake rhythms are severely disturbed consisting mainly of circadian disruption and occurrence of sleep bouts lasting for 80–90 min throughout 24 h [856]. In addition, sleep-onset REM periods (SOREMP) are noted during many of these episodes which have been proposed to be a diagnostic marker and Buguet et al. [857] confirmed the usefulness of SOREMP in a five-year study of patients in Congo, particularly for diagnosing relapses following treatment. Circadian disruption of plasma cortisol, prolactin, and sleep–wake rhythms is noted in the most advanced patients, but not in patients with less severe illness [861–864]. These findings of circadian disruption suggest selective changes in the suprachiasmatic nucleus (SCN), resulting in circadian rhythm changes in the advanced stage of the illness. The association between SWS and GH secretion persisted in the patients, even in the presence of disrupted circadian rhythms [859]. In one study, circadian periodicity of the sleep–wake cycle was disturbed proportional to the severity of the illness, but the patients' melatonin rhythm was similar to that in normal individuals, suggesting additional control for melatonin beside the SCN [860]. In three advanced patients, the cytokine interferon-γ levels were increased 7- to 12-fold [862]. In an experimental study, rats infected with the

parasite *Trypanosoma brucei brucei* showed selective changes in c-*fos* expression in the SCN, supporting the hypothesis that, in human trypanosomiasis, changes in the SCN are responsible for circadian rhythm dysregulation and changes in the sleep–wake pattern [862]. Lundkvist et al. [866] suggested that the parasites target circumventricular organs in the brain, causing inflammatory responses in hypothalamic structures that may lead to dysfunction of the circadian timing and sleep-regulatory systems in patients with African trypanosomisis.

The possible role of hypothalamic hypocretin was evaluated by measuring cerebrospinal fluid hypocretin 1 levels in 25 untreated patients with human African trypanosomisis [867]. The authors observed that the cerebrospinal fluid hypocretin 1 levels were significantly higher in these patients than in narcoleptic patients but lower than in neurologic controls. The authors observed undetectable hypocretin levels in only one stage 1 patient and intermediate levels in one stage 2 patient. These results do not suggest a unique implication of the hypocretin system in African sleeping sickness, but the authors proposed that a dysfunction of the hypothalamic hypocretin region may participate in sleeping disturbances observed in African trypanosomisis. The diagnosis of trypanosomiasis is based on history as well as confirmation that the organism is in the blood, bone marrow, cerebrospinal fluid, lymph node aspirates, or a scraping from the chancre [852, 856]. The treatment of choice for patients in the meningoencephalitic stage is arsenical melarsoprol [852, 853, 856, 868, 869]. It is divided to have follow-up of these patients every 6 months for 18 months after treatment to diagnose relapse [856]. Actigraphic recording in a pilot study of none of the patients with human African sleeping sickness documented sleep–wake alterations correlating with PSG findings [870]. In a follow-up study, actigraphy showed improvement of sleep dysfunction and could be used for monitoring progress and treatment [870]. Because of growing resistance to melarsoprol, the World Health Organization (WHO) recommended the nifurtimox–eflornithine combination therapy [856, 869, 871]. However, because of adverse effects, lack of adequate synergistic effects, and possible resistance [872], there is ongoing research evaluating two new molecules [873, 874].

Sleep and Cancer

Sleep disturbance, although very common in patients with cancer, has not been systematically studied adequately in such patients as this complaint has been overshadowed by other major problems related to cancer [875]. A prominent complaint in the patient is fatigue [876–878], which may be secondary to insomnia in many of these patients. It is important to differentiate primary fatigue from that secondary to insomnia. Given the opportunity for sleep (e.g., relaxing on a couch or lying in bed during the daytime), a patient whose primary complaint is fatigue will not be able to fall asleep and will not complain of heaviness or drooping of the eyelids or head nodding. These patients remain alert and do not doze off. In contrast, patients with secondary fatigue will doze off under these circumstances. The most common sleep complaints in cancer include sleep initiation or maintenance insomnia, nonrestorative sleep, and impaired daytime function as a result of nighttime sleep dysfunction. Almost two-thirds of cancer patients and survivors have sleep problems [878–884]. Savard and Morin [885] quoted a figure of 30–50 % of patients with insomnia in newly diagnosed or recently treated cancer patients. This figure is much higher in patients with metastasis associated with pain.

The cause of sleep disturbance in cancer patients is multifactorial [878, 882, 886], including severe anxiety and depression related to cancer, cancer chemotherapy (e.g., tamoxifen in breast cancer), corticosteroids given to such patients to alleviate the medication side effects, environmental factors (e.g., hospitalization for surgical intervention), severe pain in patients with bone metastasis or compression of nerves or nerve routes, and radiation therapy. In addition to insomnia [875, 884, 887], which is the most common sleep complaint in cancer patients, some patients may have upper airway OSA after head and neck surgery as a result of edema in the pharyngeal space and reduction of upper airway dilator muscle tone [878, 888]. Sleep dysfunction in cancer patients adds to the burden of impaired quality of life and may also cause EDS in many of these patients. Most of the studies have involved breast and lung cancer patients, but there are scattered reports in patients with cancers in other sites causing sleep disturbances [822, 878, 882, 887, 889].

It is important to diagnose sleep dysfunction in both early and advances stages of cancer to improve the quality of life. The important first step is a history obtained from patients and the caregivers. Laboratory tests are not needed in most of the patients [885], but if upper airway OSAS is suspected (e.g., if the patient complains of snoring and EDS and has witnessed apneas), an overnight PSG study is recommended so that this patient can be adequately treated to improve quality of life in advanced stages of cancer and to prevent long-term adverse consequences of OSAS in early stages of cancer with long-term good prognosis

The relationship between hypnotic medication use and cancer remains contentious. A few studies linked sleep

Table 47.7 Medications causing sleep–wake disorders

Drugs used to treat general medical disorders
• Analgesics, including opioids
• Antiemetics
• Antihistamines
• Cardiovascular medications, including angiotensin-converting enzyme inhibitors and β-blockers
• Bronchodilators
• Appetite suppressants
• Sleeping medications
Drugs used to treat psychiatric disorders
• Antidepressants (e.g., tri- and tetracyclics, MAO inhibitors, SSRIs, trazodone, nefazodone, bupropion, mirtazapine, venlafaxine, duloxetine, and lithium)
• Antipsychotic drugs (e.g., haloperidol, phenothiazines, thioridazine, clozapine, olanzapine, and quetiapine)
Drugs used to treat neurologic disorders
• Antiepileptic agents
• Antiparkinsonian medications
• Drugs used to treat RLS and narcolepsy-cataplexy
Miscellaneous agents (including drugs of abuse and alcohol)
• Amphetamines
• Cocaine
• Marijuana
• Methylenedioxymethamphetamine (MDMA; ecstasy)
• Lysergic acid diethylamide (LSD)
• Phencyclidine (PCP or "angel dust")
• Testosterone
Over-the-counter (OTC) medications
• Nasal Decongestants
• Appetite suppressants
• Caffeine
• Sleeping medications

MAO Monoamine oxidase; *SSRIs* Selective serotonin reuptake inhibitors

medication to an increased risk of cancer [890–892]. A case-control study from Finland [882] observed that sleep medication use (both the yearly dosage and the years of use of hypnotic medications) was associated with increased cancer risk of the respiratory system. These findings should be interpreted with caution as some confounding factors (e.g., smoking and BMI) could not be addressed in this study. Further research is needed to resolve the controversial relationship between cancer and hypnotic medications and the mechanism for such association.

Management of sleep disturbance in cancer patients will follow the same general principles of management of insomnia and sleep apnea as outlined in other chapters of this book. Adequate hypnotic therapy [878, 887], preferably with non-benzodiazepine GABA agonists, should be tried first; for insomnia associated with pain in advanced stages of cancer, stronger hypnotics, including opiates, should be liberally used. Pharmacotherapy should always be combined with nonpharmacologic treatment (e.g., sleep hygiene and cognitive behavioral measures). It is important for physicians to be perceptive of sleep disturbance in cancer patients as treatment will largely improve the quality of life. Another important point to remember is that the patient's caregiver or spouse may also need treatment for insomnia as that individual's sleep is also disturbed as a result of a combination of psychological factors and sleep deprivation [875, 878, 883, 885].

Medication-Related Sleep–Wake Disturbances

Medications causing sleep–wake disturbances can be divided into five groups [893–907] (Table 47.7): (1) drugs used to treat general medical disorders; (2) drugs used to treat psychiatric disorders; (3) drugs used to treat neurologic disorders; (4) miscellaneous agents (drugs of abuse and alcohol); and (5) over-the-counter (OTC) medications. The importance of chronobiology, chronophysiology, and chronopharmacology should be kept in mind when discussing medication effects because biological responses to medications may depend on the circadian timing of administration of the drugs (see also Chap. 2). Responses of antibiotics to bacteria or cancer cells to chemotherapy may depend on the time of administration because pharmacokinetic or pharmacodynamic interactions vary depending on time of day.

Drugs for General Medical Disorders

Antihistamines (histamine$_1$ blockers), used to treat allergies, cause EDS as proven by the MSLT. These agents, however, are not recommended as hypnotics because of inadequate knowledge about their safety and efficacy as well as their daytime sedation and anticholinergic effects.

Narcotics (e.g., morphine, codeine, and other opioids), which are used to relieve severe pain and to induce sleep, can cause CNS sedation and respiratory depression. Other analgesic medications such as anti-inflammatory and antipyretic agents (e.g., acetaminophen and aspirin) have not been adequately studied to understand their effects on sleep, but they may have a mild hypnotic effect. It is shown in healthy individuals that the narcotics may increase wake time and reduce the amount of REM sleep and SWS. Antiemetics (e.g., metoclopramide, domperidone, phenothiazines, and the anticholinergic scopolamine) may produce drowsiness as a common side effect. Scopolamine may increase stage 2 NREM but decrease total REM sleep. Domperidone has the least side effects.

Cardiovascular drugs include ACE inhibitors, β-blockers, and clonidine. ACE inhibitors, used to treat hypertension, may affect sleep adversely, causing impairment of performance and mood. The β-blockers (e.g., propranolol, metoprolol, and pindolol), which are used to treat hypertension, cardiac arrhythmias, and angina pectoris, may cause difficulty initiating and maintaining sleep with frequent nightmares. They may also cause insomnia by suppressing the production of melatonin. Clonidine, a centrally acting α-adrenergic receptor agonist used to treat hypertension, may disrupt the quality of sleep by inducing shift changes to stage 1 or wakefulness and by suppressing REM sleep. Clonidine, like the β-blockers, may increase daytime sleep and sleepiness.

Bronchodilators used to treat COPD and bronchial asthma may cause insomnia. Theophylline may cause sleep fragmentation and increased awakenings during sleep.

Anorectics or appetite suppressants may act as CNS stimulants by increasing catecholaminergic activity, causing insomnia.

Sleeping medications such as benzodiazepine and nonbenzodiazepine (e.g., zolpidem and eszopiclone) receptor agonists may have the opposite effect after prolonged use, and an abrupt withdrawal may disrupt sleep due to severe withdrawal effects. There is individual variation and susceptibility to the withdrawal effects. Transient disruption of sleep after cessation of hypnotic medication is common. All sleeping medications, particularly long-acting ones, may affect daytime functioning. The short-acting drugs may cause rebound insomnia, daytime anxiety, and amnesia. Although benzodiazepines affect cognition and memory, these drugs are relatively safe and have low risk of abuse, and the side effect profiles are predictable. All sleeping medications may have respiratory depressant effect, particularly in COPD patients, bronchial asthma, and OSA. Sleeping medications should be used cautiously in the elderly as these may easily induce side effects because of alterations of metabolism and drug absorption in the elderly. All benzodiazepine agonists improve sleep quality by reducing latency to persistent sleep onset, reducing WASO, and increasing sleep efficiency and total sleep time. Benzodiazepine drugs may suppress SWS, but nonbenzodiazepine agonists do not do so.

Drugs Used to Treat Psychiatric Disorders

Antidepressant medications such as tri- and tetracyclics, monoamine oxidase (MAO) inhibitors, selective serotonin reuptake inhibitors (SSRIs), and others (e.g., trazodone, bupropion, nefazodone, mirtazapine, venlafaxine, duloxetine, and lithium) may disrupt sleep, alter sleep architecture, and suppress REM sleep. Some of the tricyclics and MAO inhibitors are sedating, whereas others are stimulating, but most of the SSRIs are stimulating drugs. These antidepressants suppress REM sleep, may increase latency to REM sleep, and reduce percentage of REM sleep. Sedative antidepressants (e.g., amitriptyline, doxepine, and trazodone) may be used to treat insomnia, especially associated with depression. Most tricyclic antidepressants may cause daytime sedation. MAO inhibitors have alerting properties, so they are best used in the morning or early afternoon. Trazodone, a sedative antidepressant, increases SWS but is a weak REM suppressant. Fluoxetine has an alerting effect and can suppress REM sleep at high doses. Lithium increases

SWS and has a mild REM suppressant effect. Sudden withdrawal of these REM suppressant medications may cause REM rebound. Anxiolytics (e.g., buspirone and alprazolam) may cause sedation.

Antipsychotic drugs such as haloperidol, the phenothiazines, thioridazine, and the newer antipsychotic agents (e.g., clozapine, olanzapine, risperidone, and quetiapine) are used to treat psychotic conditions, including schizophrenia. Some of these drugs, particularly the phenothiazines, may cause drowsiness and impairment of performance. All neuroleptic drugs may produce serious side effects in combination with hypnotics, alcohol, or antihistamines. The newer antipsychotics have a better side effect profile.

Drugs Used to Treat Neurologic Disorders

Antiepileptic drugs (AEDs), especially benzodiazepines and barbiturates, cause sedation. Newer generation of AEDs is in general less sedating. However, well-controlled studies documenting the effects of antiepileptic agents and sleep architecture are lacking (see also Chap. 44). Effective control of seizures following treatment with antiepileptic agents results in the reduction of sleep disturbance due to the reduction of seizures and not due to any specific effect of antiepileptic agents on sleep architecture.

Drugs to treat RLS mainly include dopamine agonists (e.g., Pramipexole, Ropinirole, Rotigotine patch, α-2-delta ligands [Gabapentin, Gabapentin Enacarbil, Pregabalin], and opiates in refractory or intractable cases and those with augmentation). In addition to these short-term adverse effects of daytime sleepiness with these agents, especially α-2-delta ligands, the long-term vexing complication of dopamine agonists in dopamine-induced augmentation (DIA) [908] causing also severe sleep disturbance seen in a large percentage of patients, notably with Pramipexole and Ropinole. A rare side effect with long-term opiate use is opioid-induced hyperalgesia (OIH) resembling DIA [909]. The most serious effect of opiate besides addiction is its adverse effect on breathing causing or aggravating coexisting sleep apnea [898].

Stimulants used in narcolepsy-cataplexy (e.g., Provigil, Nuvigil, methylphenidate, and amphetamines) may adversely affect night sleep if taken late in the afternoon with reduction of SWS and REM sleep [898, 907]. Sodium oxybate, indicated mainly for cataplexy but also for consolidating night time sleep, is a CNS sedative and has an increased risk of sleep apnea [903–905].

Antiparkinsonian medications such as L-dopa may cause nocturnal hallucinations and agitated confusion during sleep at night. Some of the dopaminergic agonists (e.g., pergolide, pramipexole, ropinirole, and cabergoline) may cause nightmares.

Miscellaneous Agents

Drugs of abuse and alcohol (although not a drug, alcohol can be considered a social drug) have potentially deleterious effects on sleep. Stimulant drugs of abuse (e.g., amphetamines and cocaine) may cause insomnia. Amphetamines increase wakefulness, suppress REM sleep, and delay sleep onset. Cocaine reduces REM sleep and increases sleep latency and REM latency. On cessation, these may cause REM rebound. Hallucinogens such as lysergic acid diethylamide (LSD) and mescaline may cause a state resembling dreaming. Marijuana, through its active ingredient tetrahydrocannabinol (THC), may cause sedation at lower doses and hallucinations at higher doses. THC increases SWS and reduces REM sleep. Drugs of abuse mostly alter the amount and timing of REM sleep and produce REM rebound on discontinuation.

Alcohol has profound effects on sleep/wakefulness. Acute alcohol administration, by acting as a CNS sedative, will cause shortening of sleep onset, increase SWS, and reduce REM sleep. However, after the initial sedative effects lessen and as the blood alcohol level falls, the patient will have repeated awakenings causing sleep fragmentation and REM rebound. REM rebound is also noted on discontinuation after several nights of alcohol consumption. The sedative action of alcohol may be due to facilitation of GABA function and inhibition of glutamate. Alcohol, barbiturates, tricyclic antidepressants, and SSRIs may produce REM sleep behavior disorder and other complex phenomena such as status dissociatus.

Testosterone levels in men with sleep apnea have been reported to be low which improved after CPAP therapy, but testosterone administration may worsen sleep apnea by adversely affecting neuromuscular control of upper airway potency [898].

Over-the-Counter Medications

OTC medications include nasal decongestants and anorectics, which are stimulants (e.g., pseudoephedrine and phenylpropanolamine) and will cause insomnia. Caffeine, which is present in coffee, tea, colas, and chocolates, also is a stimulant and may promote wakefulness by blocking adenosine A_{2a} receptors. As little as 150 mg of caffeine, which is the equivalent of 1–2 cups of coffee, may disturb sleep quality by increasing sleep latency and reducing total sleep time. During sleep deprivation, high doses of caffeine reduce total sleep time, increase stage 1 NREM sleep, and reduce SWS but do not affect neurocognitive functions.

OTC sleeping medications are widely used for the induction of sleep. The active ingredients in these agents are antihistamines (diphenhydramine and doxylamine), and

these drugs represent the most common use of antihistamines in OTC preparations. These histamine$_1$ blockers have undesirable anticholinergic effects (e.g., dryness of the mouth, palpitations, dilation of pupils, tachycardia, and difficulty in urination) and cause daytime sedation.

Summary and Conclusions

There has been explosive growth in sleep medicine and increasing awareness about the importance of sleep in everyday life. It is therefore important for sleep specialists, general internists, and family physicians to have adequate knowledge about sleep dysfunction in general medical disorders to practice their trade effectively. This chapter attempts to summarize in a comprehensive manner general medical disorders that may account for a variety of sleep complaints (e.g., insomnia, hypersomnia, parasomnias, sleep-related breathing disorders, and circadian rhythm sleep–wake dysfunction) or may be comorbid with sleep disorders. General medical disorders may affect sleep–wake neurons by indirect mechanisms through metabolic, toxic, or anoxic disturbances. The possibility of medically induced sleep disturbance should always be kept in mind because the natural history of medical illness may be altered by this comorbidity. It is unfortunate that the ICSD-2 eliminated medical disorders as a separate category of classification and introduced these conditions in a scattered manner throughout the eight major categories and appendices.

All major categories of general medical disorders were addressed in this chapter, and some conditions were addressed in greater details than others because of the importance of sleep complaints affecting quality of life and because of long-term adverse consequences of sleep-related breathing disorders in many of these medical conditions. In the final section, a brief description was also given of a variety of medications used to treat general medical, neurologic, and psychiatric illnesses that may affect sleep and breathing, causing acute and emergent events during the course of the practice of sleep medicine.

Evaluation and Management of Circadian Rhythm Sleep Disorders

48

Sabra M. Abbott and Phyllis C. Zee

Introduction

Circadian rhythms are the near 24-h oscillations in physiology and behavior that persist in the absence of external time cues. The sleep–wake cycle is one of the most apparent of these behaviors, the timing of which is regulated by a combination of a homeostatic drive for sleep, which builds up the longer one is awake, and the circadian clock which regulates the appropriate timing of sleep [1].

In mammals, the primary circadian pacemaker is located in the suprachiasmatic nucleus (SCN), a set of paired nuclei located in the hypothalamus, lying on either side of the third ventricle, directly above the optic chiasm [2]. In the absence of external time cues, the SCN is able to maintain a near 24-h period through a complex transcription/translation feedback loop, but is also capable of being reset by various signals within the environment. The most well studied and presumably strongest of these signals is light. Light exposure during the evening and before the core body temperature minimum delays the circadian clock, while light in the early morning, after the core body temperature minimum advances the circadian clock [3–5]. In addition to light, melatonin also has resetting effects on the circadian clock. Endogenous melatonin levels normally rise 2–3 h before sleep onset, peaking in the middle of the night [6]. Opposite to the effects of light, exogenous melatonin given during the early evening causes advances, while melatonin in the morning causes delays [7, 8]. Other factors, including exercise [9] and restricted feeding [10], are also known to affect the circadian clock, though are not as well studied, and are not believed to be as strong a signal as light. The ability of these signals to reset the circadian clock can be used for treatment of the circadian rhythms sleep–wake disorders (CRSDs) which will be detailed below.

The CRSDs result when either an individual's internal clock is unable to maintain appropriate alignment with the external environment, or social/work obligations force an individual to follow a schedule that is misaligned with their internal clock. The principles of circadian physiology can be used to understand and diagnose these disorders, as well as provide treatment options for these individuals.

Circadian Rhythm Sleep Disorders

Delayed Sleep Phase Disorder

Delayed sleep phase disorder (DSPD) results in a stable sleep–wake cycle that is delayed by around 3 h with respect to the general population [11], with patients generally reporting being unable to fall asleep before 2–6 am. When allowed to sleep during their preferred schedule, sleep duration and quality are normal for age. DSPD has an estimated prevalence of 0.7–8 % depending on the population studied, with the highest prevalence among adolescents [12], and affects up to 5–10 % of chronic insomnia patients [13].

There does appear to be a familial component to DSPD. Certain haplotypes of hPER3 appear to occur with increased frequency in DPSD [14, 15] and may result in altered timing of the degradation of hPER3, prolonging the overall period. Polymorphisms in the Clock gene have also been associated with morningness–eveningness preference, though not specifically with DSPD, and this also has not been consistent across ethnic groups [16, 17].

DSPD has also been associated with traumatic brain injury (TBI). There are several case reports of individuals developing DSPD following TBI [18–20], and in a large case series of 42 individuals with TBI, 15 developed a CRSD, either DSPD or irregular sleep–wake rhythm [21]. This may

be due to disruption of the melatonin signaling pathway, which normally projects from the hypothalamus, through the intermediolateral cell column in the cervical spine then back through the sympathetic chain to the pineal. Injuries to the cervical spine could potentially disrupt this pathway, resulting in alterations in melatonin secretion, with concomitant effects on circadian rhythms [22].

Advanced Sleep Phase Disorder

Individuals with advanced sleep phase disorder (ASPD) have a stable sleep–wake cycle that is several hours earlier than the conventional time [11]. Bed times are generally reported to be between 6 and 9 pm and wake times range from 2 to 5 am. ASPD is thought to be less prevalent than DSPD; however, this may simply be due to under-reporting, as individuals with ASPD and extreme morning types generally have fewer work and social disruptions resulting from their sleep patterns.

There is a strong heritable component to ASPD, with several cohorts of families with ASPD identified. The common feature to all of these families is a mutation either in CK1e or the binding site on hPER2 for this kinase [23–25]. CK1e normally phosphorylates and stabilizes hPER2 and slows the translocation back into the nucleus [26]. In the absence of this phosphorylation, the transcription–translation feedback loop progresses more quickly, resulting in an overall shortened period [27–29].

Irregular Sleep–Wake Rhythm

The hallmark of irregular sleep–wake rhythm (ISWR) is an absence of a clear major sleep and wake period, with at least 3 distinct sleep periods occurring with a 24-h window. While irregularly distributed, the total sleep obtained during a 24-h period is normal for age. Symptoms include complaints of both insomnia and excessive sleepiness related to the abnormal timing of sleep [11]. ISWR is most commonly seen in individuals with neurodevelopmental disabilities and elderly institutionalized individuals [30]. Symptoms are believed to result from a combination of dysfunction or degeneration of the SCN, in conjunction with either decreased exposure or decreased sensitivity to entraining time cues [31].

Non-24-h Sleep–Wake Disorder

Non-24-h sleep–wake disorder (N24SD) results when an individual's intrinsic pacemaker is unable to entrain to the 24-h environment. Symptoms include both insomnia and excessive daytime sleepiness as the circadian drive for sleep moves progressively later each day, moving out of phase with the surrounding environment [11]. N24SD is most commonly seen in blind individuals, who are unable to receive the daily signals of light to maintain entrainment with the surrounding environment. However, more rarely, this disorder can also be seen in sighted individuals. The etiology remains unclear at this point; however, there is some evidence that these individuals have a longer intrinsic period, which may make it more difficult for them to entrain to a 24-h environment [32].

Shift Work Disorder

Shift work disorder (SWD) consists of symptoms of insomnia or excessive sleepiness associated with a recurring work schedule that overlaps with the usual sleep time. To account for adaptation to a change in schedule, symptoms should be present for at least one month [11]. SWD is most commonly seen among individuals who work either night or rotating shifts, however, can also be seen in individuals working early morning or late evening shifts, if this work period is not aligned with their preferred sleep and wake times [33]. SWD is more common in individuals who are morning types, those who require longer sleep times, and those with significant daytime family or social responsibilities [34].

Jet Lag Disorder

Jet lag disorder consists of symptoms of insomnia or excessive daytime sleepiness secondary to travel over two or more time zones. In addition to sleep complaints, there are often symptoms of generalized malaise, cognitive impairment or somatic symptoms including gastrointestinal distress [11]. The severity of symptoms depends on many factors, including the distance and direction of travel. Eastward travel is generally more difficult to adapt to than westward travel, as eastward travel requires a phase advance of the circadian clock, which is generally more difficult to achieve than a phase delay of the circadian clock. In addition, older adults tend to have more difficulty adapting to time zone changes when compared to younger adults [35].

Evaluation of Circadian Rhythm Sleep Disorders

The diagnosis of the CRSDs depends primarily on taking a careful history; however, additional diagnostic testing can also be used. Clinical history should focus on getting a sense of when the individual's preferred sleep and wake times are. Both DSPD and ASPD can often be mistaken for insomnia, with individuals with DSPD complaining of inability to fall asleep, and individuals with ASPD complaining of early morning awakenings. The key distinguishing feature, however, is that when allowed to sleep at their preferred time, sleep will be of normal quality and duration. Irregular sleep–wake disorder may be more difficult to

distinguish with history alone, however, should be suspected, particularly in individuals with developmental delay, or dementia in whom caregivers note frequent prolonged napping throughout the day, with difficulty staying asleep at night. All non-sighted individuals should be questioned regarding possible symptoms of N24, with complaints of going through periods where they are unable to sleep at night, but feel tired during the day. In sighted individuals, N24 often presents in individuals who initially had extreme DSPD, but eventually are unable to maintain a 24-h pattern of rest and activity. SWD should be readily apparent from the history; however, it is important to question all individuals with a sleep complaint regarding their daily schedule.

Sleep Logs

Sleep logs provide useful adjunctive information for the clinical history, particularly for individuals who may have difficulty recalling their daily schedules, and are considered a guideline for the diagnosis of CRSD by the American Academy of Sleep Medicine (AASM). A variety of sleep logs are available but at a minimum should collect information regarding bedtime, wake time, and any naps. In individuals where there is a concern for insomnia, information regarding the timing of caffeine, alcohol, and medication intake is also useful. General recommendations are to obtain sleep log data for at least 2 weeks; however, particularly in individuals with suspected N24SD, collecting this information for at least 3–4 weeks may be useful [36].

Actigraphy

Actigraphy consists of an accelerometer that is usually worn on the non-dominant wrist to provide objective measurements of activity and rest periods. Actigraphy has been validated as a means of measuring sleep and wake [37] and recently was demonstrated to be approximately 80 % accurate in determining sleep and wake when compared to polysomnography (PSG) [38]. Newer devices also are capable of measuring both the intensity and wavelength of light exposure, which can provide additional data that can aid in diagnosis and management. The use of actigraphy is considered a guideline in the diagnosis of CRSDs and can also be used to evaluate the response to treatment [36]. Actigraphy should generally be performed for at least 2 weeks, preferably longer, particularly if evaluating for N24SD (Fig. 48.1a–c).

Circadian Phase Markers

Measurement of circadian phase markers can potentially be useful in demonstrating the presence of a circadian rhythm disorder and is considered an option under the AASM guidelines [36]. Melatonin release peaks in the middle of the night, and the onset of melatonin secretion in dim light (DLMO) generally occurs 2–3 h prior to the habitual sleep time [39]. Melatonin can be measured in the plasma; however, this is often impractical in the outpatient setting, as samples need to be collected every 30–60 min through an indwelling venous catheter. As an alternative, melatonin can also be collected in the saliva and has been validated as a comparable measure to plasma [40]. Samples should be collected every 30 min starting 5–7 h prior to expected sleep time, either under dimly lit conditions or while wearing light-blocking goggles. The timing of DLMO can be used both as a marker of circadian phase, but can also be used to assess response to treatment [41].

Core body temperature is another marker of circadian timing; however, the standard method of collection, using an indwelling rectal thermometer, is often impractical or undesirable in the clinical setting. Newer techniques are being developed, using a wrist mounted thermometer to measure the daily fluctuations in temperature. Core body temperature normally falls as an individual is falling asleep, reaching a nadir, and then beginning to rise $\sim$2 h prior to waking. Skin temperature, on the other hand, begins to increase prior to bedtime and drops just after awakening [42]. Validation studies have shown good correlation between the evening temperature increase measured at the wrist and DLMO suggesting that this may be another, less invasive means of measuring circadian timing [43].

Questionnaires

The Horne-Ostberg Questionnaire (MEQ) is a 19-item questionnaire that evaluates an individual's subjective sense of morningness–eveningness [44]. However, there has been some criticism of the MEQ, as it primarily assesses subjective sleep preferences, without evaluating the actual timing of sleep. More recently, the Munich Chronotype Questionnaire (MCTQ) was developed, which determines sleep times on work and non-work days and can also be modified to account for shift work [45]. Using this assessment, chronotype has been found to strongly correlate with morningness–eveningness preferences [45]. Based on current AASM guidelines, while questionnaires are an option for obtaining additional information, they are not required for the diagnosis of CRSDs [36].

Polysomnography

Unless there are concerns for other comorbid sleep disorders, polysomnography (PSG) is generally not indicated in individuals in whom a primary CRSD is suspected, as the disorder is primarily one of abnormal timing, rather than quality of sleep [36]. Patients should be carefully screened for potential symptoms of obstructive sleep apnea (OSA) and restless legs syndrome (RLS). In addition, PSG should be considered if individuals are still complaining of significant fatigue, despite being allowed to sleep during their preferred sleep window.

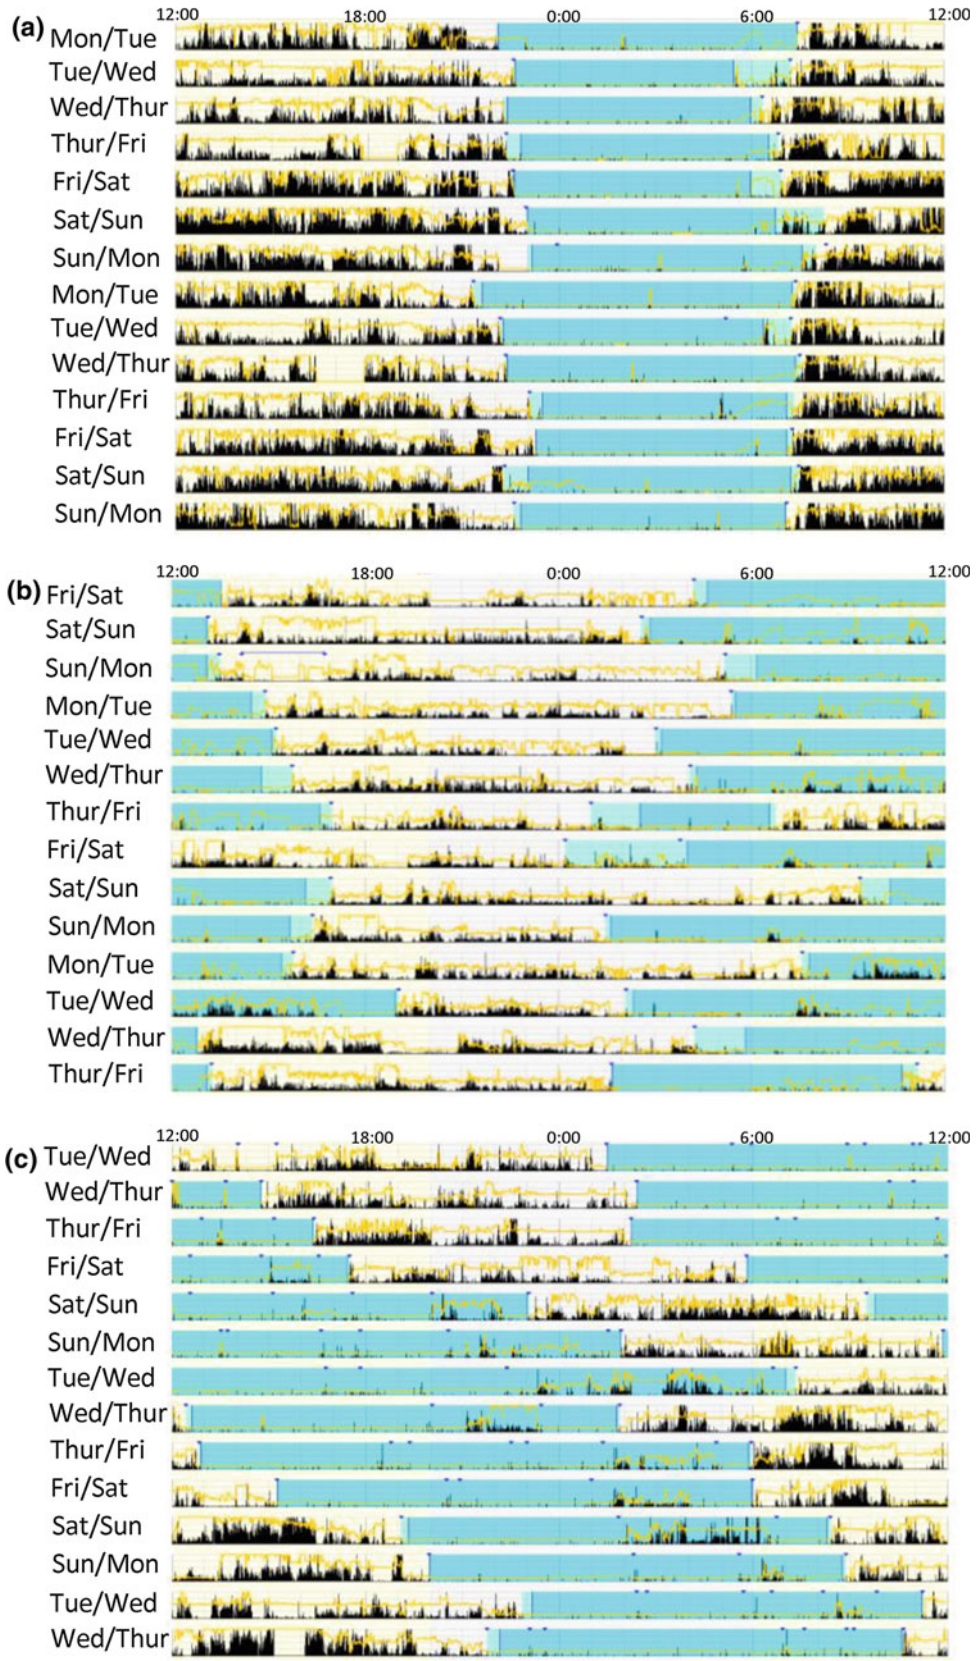

Fig. 48.1 Representative 2 week actigraphy data from an individual with normal sleep timing (**a**), delayed sleep phase disorder (**b**), and non-24-h sleep disorder (**c**). Each *horizontal line* represents 24 h. *Black vertical lines* indicate periods of activity, *blue shaded* areas represent reported self-reported sleep periods, and *yellow line* indicates light exposure

Treatment of Circadian Rhythm Sleep Disorders

Delayed Sleep Phase Disorder

Successful treatment of DSPD relies primarily on a combination of bright light and melatonin to advance the circadian clock. Bright light, given either immediately after or shortly before the habitual wake time (after the core body temperature minimum) can successfully advance the circadian clock. In addition, low doses of evening melatonin (0.5–3 mg) can provide additional advancing signals. A recent randomized controlled trial with bright light and melatonin showed improved subjective daytime sleepiness, fatigue, and cognitive function. Subjects were instructed to use the bright light for 30–45 min on awakening, take melatonin (3 mg) 12 h after the light exposure, and progressively advance their wake time by 1 h each day until the desired sleep window was reached [46].

While chronotherapy, consisting of progressively delaying the sleep time until the desired sleep window is reached, can sometimes be effective, caution should be exercised, as there have been case reports of this technique actually inducing N24SD in individuals with DSPD [47]. Hypnotics are generally not recommended for treatment of DSPD [36], as this is a disorder of sleep timing, rather than a primary insomnia, so the focus should be on adjusting the timing of sleep, rather than using medications to induce sleep at a time when the circadian system is not in a permissive state for sleep.

Advanced Sleep Phase Disorder

Perhaps due to the lower prevalence or fewer complaints associated with ASPD, there are fewer treatment trials for this disorder. There are case reports of progressively advancing the sleep period until the desired sleep time is reached [48]. In addition, there are a few small studies supporting the use of bright light in the evening, from 7 to 9 pm to delay the circadian clock, with results showing a delay on average of 1–2 h, as well as increase in total sleep time [49, 50]. In addition to light, exercising in the early evening has been demonstrated to delay the circadian clock [51] so may be a useful intervention in this population, though trials have not been performed looking specifically at individuals with ASPD. Theoretically, melatonin taken in the early morning should also delay the circadian clock [52]; however, there are no trials to date looking at its use in individuals with ASPD.

Irregular Sleep–Wake Rhythm

In treating ISWR, a focus on overall sleep hygiene is very important, as this often affects institutionalized individuals who are living in environments with few time cues and frequent nocturnal disruptions. A multi-modality approach is often most effective. Daytime bright light exposure can improve activity during the day and consolidate sleep at night [53–55]. Melatonin administered prior to bedtime has been shown to improve sleep in children with ISWR [56–58]; however, similar results have not been observed in elderly patients [59]. In elderly patients, a combination of daily light exposure, physical activity during the day, and a structured bedtime routine has been shown to be most effective [60].

Non-24-h Sleep–Wake Disorder

N24SD affects two distinct populations, sighted and non-sighted individuals, and treatment differs depending on the individual. In blind individuals, there is strong evidence that regularly scheduled melatonin, given one hour prior to the desired bedtime can serve as an effective entraining signal. Study doses have ranged from 0.5 to 10 mg, though generally lower doses are preferred [61, 62]. More recently tasimelteon, a synthetic melatonin agonist has been FDA approved for treatment of N24SD in non-sighted individuals [63].

In sighted individuals with N24SD, treatment is more complicated and is often multifaceted. There is a focus on enforcing strong social cues, with regular sleep–wake schedules, meal times, and exercise. In addition, the use of bright light upon awakening [64, 65], and melatonin prior to bedtime can also be beneficial [66, 67].

Shift Work Disorder

The treatment of SWD relies on multiple strategies. There is strong evidence that planned napping prior to the beginning of the shift can improve alertness and decrease accidents during the work shift [68]. During the work shift and commute home, close attention should be paid to the lighting conditions. During the work shift, increased exposure to bright light toward the beginning of the shift can improve alertness and mood. However, to avoid significant circadian phase shifting, which could impair work time performance, care should be taken to avoid bright light exposure during the commute home [69]. Shift workers often complain of insomnia related to difficulty sleeping during the day. Simple measures to improve sleep include making the bedroom as conducive for sleep as possible. Interventions include adding black out curtains to minimize light exposure, white noise machines to limit external noise, and instructing family members to minimize disrupting the individual during their sleep time. If this alone is not effective, studies have shown benefits from taking either a low dose of melatonin [70, 71] or hypnotic prior to sleep [72–74]. Particularly with hypnotic use, patients must allow enough time for sleep after taking the hypnotic to minimize any carryover of sedative effects into the next work period. While often attempts to improve daytime sleep are enough to minimize fatigue during work, if

Table 48.1 Clinical features and recommended treatment strategies for the circadian rhythm sleep disorders

Disorder	Clinical features	Diagnosis	Treatment
Advanced sleep–wake phase disorder (ASPD)	Stable advance of the major sleep period, resulting in early morning awakenings and difficulty staying awake in the evening	Sleep logs and when possible actigraphy for at least 7 days demonstrating a stable advance	Bright light therapy for 2 h in the evening
Delayed sleep–wake phase disorder (DSPD)	Stable delay of the major sleep period, resulting in difficulty falling asleep at night, and difficulty waking up in the morning	Sleep logs and when possible actigraphy for at least 7 days demonstrating a stable delay	Bright light therapy for 2 h on awakening, and melatonin (0.5–3 mg) 5–7 h before bedtime
Non-24-h sleep–wake rhythm disorder (N24SD)	Sleep period does not follow a 24-h pattern, instead usually delaying by 1–2 h every day	Sleep logs and actigraphy for at least 14 days demonstrating a pattern of sleep and wake times that delay each day	Blind: 0.5 mg of melatonin 1 h before bedtime Sighted: Bright light therapy for 2 h on awakening and melatonin (0.5–3 mg) 1 h before bedtime
Irregular sleep–wake rhythm disorder (ISWR)	Chronic disorganized pattern of sleep and wake with insomnia during the usual sleep period and hypersomnia during the usual wake period	Sleep logs and when possible actigraphy for at least 7 days demonstrating at least 3 irregular sleep bouts in a 24-h period	Mixed modality treatment, including increased daytime light and social activity, with decreased evening light and noise. Evening melatonin may also be helpful
Shift work sleep disorder	Insomnia or excessive sleepiness associated with a work schedule that overlaps the usual time for sleep	Sleep log and actigraphy, with measurement of light exposure if possible, for at least 14 days demonstrating a disturbed sleep–wake pattern	Sleep hygiene, scheduled naps, modafinil/armodafinil, and timed light exposure at the beginning of the work shift, melatonin at bedtime
Jet lag	Insomnia or excessive sleepiness associated with travel across at least 2 time zones	Clinical history	Timed melatonin (0.5–5 mg) 3 to 5 days prior to and after travel. Gradually change the sleep/wake time by 1 h each day

sleepiness during the work period remains a problem, modafinil [75] and more recently armodafinil [76] have been demonstrated to improve alertness and work performance in shift workers.

In addition to the above strategies for work days, one must also pay close attention to behaviors on non-work days as well. While ideally one would have a patient follow the same schedule on both work and non-work days, family and social responsibilities on non-work days often make this difficult. To accommodate for this, a compromise phase position has been proposed, where individuals sleep from 8 am to 4 pm on work days and from 3 am to noon on non-work days, allowing for daytime activity on days off, without completely losing entrainment to the night shift schedule [77, 78]. While following this schedule, it is important to also take advantage of the other strategies described above, including bright light exposure during the beginning of the work shift.

Jet Lag Disorder

The treatment of JLD depends on the direction, distance, and duration of travel. For short trips (<48 h), it is generally easier just to maintain the home time rather than trying to reset the clock multiple times during such a short time window [79]. For longer trips, options are to either gradually start resetting the clock before departure or adapt once arriving at the new destination. In either case, appropriately timed light and melatonin are the mainstays of treatment. Along with resetting strategies, the addition of hypnotics may be beneficial for some individuals; however, there is somewhat mixed data regarding their overall efficacy [80–82].

When traveling eastward, it is necessary to advance the circadian clock, which is generally more difficult to adapt to. Prior to departure, one option is to move the sleep schedule earlier by one hour each day, combined with morning bright light exposure, so that the clock is already advanced to the new time zone by the day of travel. Alternatively, if waiting to reset until the time of travel, once arriving at the destination the goal should be to avoid bright light during the morning (before the core body temperature minimum) when it can further delay the clock, but seek out light in the afternoon (after the core body temperature minimum) to help advance the clock. In addition, a low dose of melatonin (0.5 mg) at bedtime can be beneficial. Along with the above strategies, the addition of armodafinil during the daytime has been shown to increase alertness in individuals traveling >6 time zones east [83].

Westward travel is generally easier to adapt to, as it involves delaying the circadian clock. If attempting to transition prior to departure, the recommendation is to use bright light in the evening and gradually delay the bedtime

by one hour each day. On the other hand, if the preference is to wait until arriving at the destination, bright light exposure during the afternoon and a low dose of melatonin in the evening should both help to facilitate delays.

For travel in either direction, close attention to the timing of meals can also be beneficial. There is evidence in rat models of jet lag that scheduled food exposure can increase the speed of entrainment to the new time zone [84].

Conclusion

The CRSDs encompass a variety of disorders of the timing of sleep. Diagnosis depends on a complete clinical history, with adjunctive information obtained from sleep logs, actigraphy, and circadian phase markers. Treatment relies primarily on the resetting effects of light and melatonin on the circadian clock, with appropriate timing depending on the nature of the disorder, summarized in Table 48.1.

Rapid Eye Movement Sleep Behavior Disorder 49

Stuart J. McCarter, Erik K. St. Louis, and Bradley F. Boeve

Introduction

REM sleep behavior disorder (RBD) was first described in humans in 1986 after a series of patients reported curious nocturnal behaviors that resulted in injury to patients or their bedpartners [1]. Due to the loss of normal REM sleep muscle atonia, RBD patients often "act out their dreams," most commonly expressing violent complex movements that often mirror dream content [1–10]. RBD patients are primarily divided into two groups: idiopathic RBD, with no obvious cause, and symptomatic RBD, which is primarily associated with synucleinopathy neurodegenerative disorders, including Parkinson's disease (PD), Lewy body dementia (DLB), and multiple system atrophy (MSA) [3–12]. However, RBD is also common in patients with narcolepsy and in patients receiving antidepressant treatment and may be seen rarely in those with brainstem lesions in dorsal pons and medulla [10, 13–26]. In addition, RBD has also been associated with the use or withdrawal of drugs or alcohol, high chocolate intake [27], and migraine headaches [27–31]. However, because up to 82 % of idiopathic RBD patients develop parkinsonism or dementia over longitudinal follow-up, growing evidence suggests that idiopathic RBD may be a prodromal feature of a neurodegenerative disease, often preceding other characteristic more overt neurological manifestations by several years to decades [3, 5, 7, 8, 12, 32–37]. In addition, recent neuropathology data suggest that up to 94 % of patients with RBD, and 98 % of RBD patients confirmed by polysomnography (PSG), have synucleinopathy neurodegeneration at autopsy, furthering the presumption that RBD may represent the *forme fruste of* neurodegeneration in many patients [37].

Diagnosis and Classification of RBD

The minimal diagnostic criteria according to the International Classification of Sleep Disorders (ICSD) 2 include: (A) presence of REM sleep without atonia on PSG; (B) sleep-related injurious or potentially injurious disruptive behaviors by history, and/or abnormal REM sleep behaviors during PSG; (C) absence of epileptiform activity during REM sleep (unless RBD can be clearly distinguished from any concurrent REM sleep-related seizure disorder); and (D) sleep disturbance is not better explained by another disorder [38]. However, an evolving diagnostic standard for probable RBD (pRBD) for patients having dream enactment behaviors but who lack PSG evidence for RSWA (due to either unavailability of PSG or failure to record REM sleep) is included in ICSD 3, given the resource intensive nature of confirmatory PSG (38a).

The core clinical feature of RBD is a history of witnessed dream enactment by the patient's bed partner, with or without recall of dream mentation by the patient himself or herself [1, 5, 11, 34, 39]. Patients are often able to vividly recall their dreams for weeks or longer, and when enacted dreams are recalled, patients typically report that their dream mentation contains a theme of being chased, or defense against an attack by animals or people [11, 40]. However, less aggressive themes such as playing sports or performing household chores are also common [41, 42]. Collateral history obtained from the patient's bed partner is crucial in diagnosing RBD patients, since NREM parasomnias like sleep walking or sleep terrors also often report frightening dream content. However, dreams of patients with sleep walking or sleep terrors more often involve natural disasters with a "flight" response, as opposed to the "fight" response reported by patients with RBD [5, 11, 39, 42, 43].

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_49

RBD patients often have coherent vocalizations such as shouting, screaming, laughing, crying, and swearing, most often matching recalled dream content described by the patient [4–6, 11]. Excessive, repetitive phasic muscle jerking during REM sleep is the most frequent RBD clinical phenomena captured during PSG; however, complex motor behaviors such as punching, kicking, and running can lead the patient to leave the bed, potentially resulting in injuries [5, 11, 44]. Due to the violent nature of dreams, injuries prior to treatment are frequent and have been reported in approximately 55 % of patients [41]. While most often minor injuries such as bruises occur, more serious injuries such as fractures, lacerations requiring suturing, and subdural hematomas occur in as many as 12 % of patients [1, 5, 11, 41].

While PSG is required for a formal diagnosis of RBD, PSG is expensive and requires expertise for accurate interpretation, and is not readily accessible in many locations. Given the resource intensive nature of PSG, several validated screening measures for pRBD are available [39, 43, 45–49]. The RBD-HK consists of 13 questions regarding frequency and severity of dream enactment behavior. Out of 100 possible points, a cutoff score of 18 yields positive and negative predictive values of over 80 % [43]. The REM Sleep Behavior Disorder Screening Questionnaire (RBDSQ), a 10-item patient self-rating questionnaire (maximum total score of 13 points) covering core clinical features of RBD, demonstrated that RBD patients scored an average of 9.5, compared to 4.6 in controls [45]. This survey has been adapted for use in Japanese patients, with a score of 5 yielding a sensitive, specific, and reliable diagnosis of RBD [47]. The Mayo Sleep Questionnaire (MSQ) is another validated diagnostic questionnaire tool for RBD screening in older patients with or without cognitive impairment and/or parkinsonism [39, 48]. While other surveys utilize patient-reported symptoms, one of the main strengths of the MSQ is completion by bed partners, providing valuable collateral history verifying dream enactment symptoms, which may be more reliable for patients who are cognitively impaired and in those who have little recall of their dreams. In addition, the MSQ is 100 % sensitive and 95 % specific for diagnosis of RBD, indicating its utility for screening for RBD when PSG is unavailable [48]. The RBD1Q is a multicenter validated screening questionnaire consisting of a yes or no answer to a single question about dream enactment (which is almost identical to the core RBD question on the MSQ), with a sensitivity of 93.8 % and specificity of 87.2 % for a diagnosis of RBD in patients with Parkinson's disease [46]. These questionnaires may be valuable for future epidemiological studies given their brevity, efficiency, and accuracy for diagnosis of RBD.

While surveys have been shown to be useful measures for RBD screening, exclusion of RBD-mimics such as nightmares, sleep walking, sleep terrors, nocturnal seizures, obstructive sleep apnea with atypical arousals from REM sleep, post-traumatic stress disorder, nocturnal panic disorder, psychogenic dissociative states, and delirium may be difficult by reliance on questionnaire instruments alone [5, 6, 42, 50, 51]. Given that violent behaviors during sleep in the general population are often associated with vivid dreams in sleep terrors and sleepwalking, the "gold standard" for clinical RBD diagnosis should remain a combination of clinical diagnostic interview with a thorough history, neurological examination, and PSG to confidently diagnose and differentiate RBD from other sleep disorders and parasomnias, and to confirm the necessary diagnostic feature of REM sleep without atonia [1, 5, 11, 38].

Diagnosis of RSWA

PSG diagnosis of RSWA requires the presence of abnormally elevated muscle tone during REM sleep, most often observed in the mentalis and tibialis muscles, but also in arm EMG leads [9, 38, 52, 53]. While most clinical laboratories primarily use mentalis, anterior tibialis, and forearm muscles to identify RSWA, some studies have suggested that an expanded EMG montage including the biceps brachii, flexor digitorum superficialis, and abductor pollicis brevis muscles is the most sensitive for RSWA determination [52, 53]. RSWA is classified as short phasic bursts, with muscle tone reaching at least two to four times larger than the amplitude of the lowest background EMG during REM or NREM sleep, or tonic segments with twice the background amplitude, usually lasting longer than 10–15 s in duration [52–54]. RSWA may also be found incidentally on PSG recording without dream enactment behavior. However, the significance of incidental RSWA for future development of dream enactment or neurodegeneration remains to be elucidated [5, 55]. In addition, RSWA without dream enactment is not uncommon in PD, suggesting that lesions in separate specific structures may be necessary to cause RSWA and DEB [55]. Since a small amount of phasic or tonic muscle activity can also be found during REM sleep in normal individuals [56], the AASM has established a standard for abnormal or potentially clinically relevant RSWA, defined as at least 5 mini-epochs of 3-s duration containing abnormally excessive phasic muscle activity within a single 30-s epoch of REM sleep, or excessive tonic muscle activity in the chin EMG channel lasting over 15 s in duration [38].

Quantitative Methods of RSWA Analysis

In addition to AASM criteria, several manual and automated methods of RSWA quantification have been developed, resulting in definitive cutoff values for a RBD diagnosis [9, 51–53, 57–60]. Many of the manual methods employ variations of the AASM standard, including the percentage of 3-s mini-epochs containing phasic muscle activity, as well as the percentage of 30-s epochs containing tonic activity [53]. In addition, 3-s mini-epochs containing the presence of either scorable phasic or tonic activity have been defined as "any" muscle activity, resulting in percentage of "any" muscle activity [61]. Various phasic, tonic, and "any" percent muscle activity cutoff values have been established for a diagnosis of RBD with 100 % specificity. For the common montage of mentalis and muscles in the submentalis region combined with anterior tibialis muscles, cutoffs of 46.4 % and 44.2 % have been reported for "any" and phasic percent muscle activity. In addition, a submentalis tonic percent muscle activity cutoff of 9.6 % has been reported [61].

Recently, similar methods have been extended to define appropriate density cutoffs for RBD patients with comorbid obstructive sleep apnea, as is commonly seen in clinical populations. Diagnostic RSWA percent muscle activity (phasic, "any") cutoffs were as follows: submentalis (SM) (15.5, 21.6 %); anterior tibialis (AT) (30.2, 30.2 %); and combined SM/AT (37.9, 43.4 %) [54]. A tonic percent muscle activity cutoff of 1.2 % was 100 % sensitive and specific, while an automated chin REM atonia index of 0.88 is appropriate in this patient population [54]. This manual methods also showed that in addition to standardly determined RSWA percent muscle activity measures, RBD patients have longer phasic muscle burst duration when compared with controls, and that measurement and consideration of phasic muscle burst durations further increases the specificity and sensitivity for diagnosis of RBD when combined with cutoff values for phasic and "any" percent muscle activity [54]. However, whether phasic muscle burst duration measurement may identify which patients with "incidental" RSWA are at greater risk for the development of RBD and future synucleinopathy is yet to be determined [54].

In addition to manual scoring methods, automated methods of chin RSWA analysis have been developed. The REM atonia index (RAI) is a computer generated value from 0 to 1, with a score of 0 indicating absolute absence of REM muscle atonia, and a score of 1 indicating completely preserved REM muscle atonia [58, 62, 63]. RAI of <0.9 has been found to be highly sensitive and specific for a diagnosis of RBD [54, 62]. Another automated method of chin tone analysis found that the number of both short duration (<0.2 s) and long duration (>0.2 s) muscle bursts was significantly greater in RBD patients than controls [60].

While both automated and manual methods of RSWA analysis have been shown to be accurate in the diagnosis of RBD, both have serious limitations. Manual methods are extremely time intensive, and many clinical sleep laboratories do not use expanded recording montages used to determine RSWA cutoff values for RBD diagnosis in some studies. Automated methods, while less time and labor intensive, have yet to be developed for limb muscles, limiting application toward RBD diagnosis in patients with RSWA primarily limited to the limb muscles [64].

Epidemiology

RBD most commonly presents after the age of 50, with 70–90 % of RBD cases occurring in men [34, 37, 65–68]. The prevalence of RBD has traditionally been estimated to be between 0.38 and 0.5 % in large population-based studies, [4, 11] but RBD patients represent up to 4.8 % of patients presenting to sleep disorders clinics, with the most common complaint being self or bedpartner injury due to dream enactment behaviors [67, 69]. More recent data suggest that pRBD (based on the MSQ) may be more common than previously believed, occurring in over 6 % in a community-dwelling subjects aged 70–89 years [70], and a very recent study from a large Korean cohort demonstrated a frequency of RBD of 4.8 % [71]. In addition, data on over 19,000 individuals found that violent behaviors during sleep are present in 1.6 % of the general population and occur more often in male individuals [11]. However, violent behaviors were also associated with NREM parasomnias such as sleep terrors, sleep walking, and confusional arousals, so not all violent behaviors during sleep can be attributed to RBD [11]. While the majority of RBD patients are older men, DEB can begin at any age, and may, in fact, occur as commonly in women as men, although RBD may be under diagnosed in women due to less violent dream enactment behaviors [72–74]. In patients with RBD diagnosed before the age of 50, and in those with comorbid narcolepsy, prevalence is nearly equal between genders [28, 75]. In younger patients with RBD, the most frequent causes are antidepressant use, drug or alcohol withdrawal, underlying narcolepsy, brainstem lesions, or congenital or neurodevelopmental disorders [28–30, 72–74]. In addition, evidence for coexistent autoimmunity is found in 20 % of women with RBD [28, 29]. Psychiatric diagnosis and antidepressant usage have also been reported to increase the likelihood of RBD as much as 10-fold [30]. In addition, limited evidence suggests that there may be a genetic association of RBD with human leukocyte antigen DQw1 [76]. However, this link has not been fully explored. RBD has

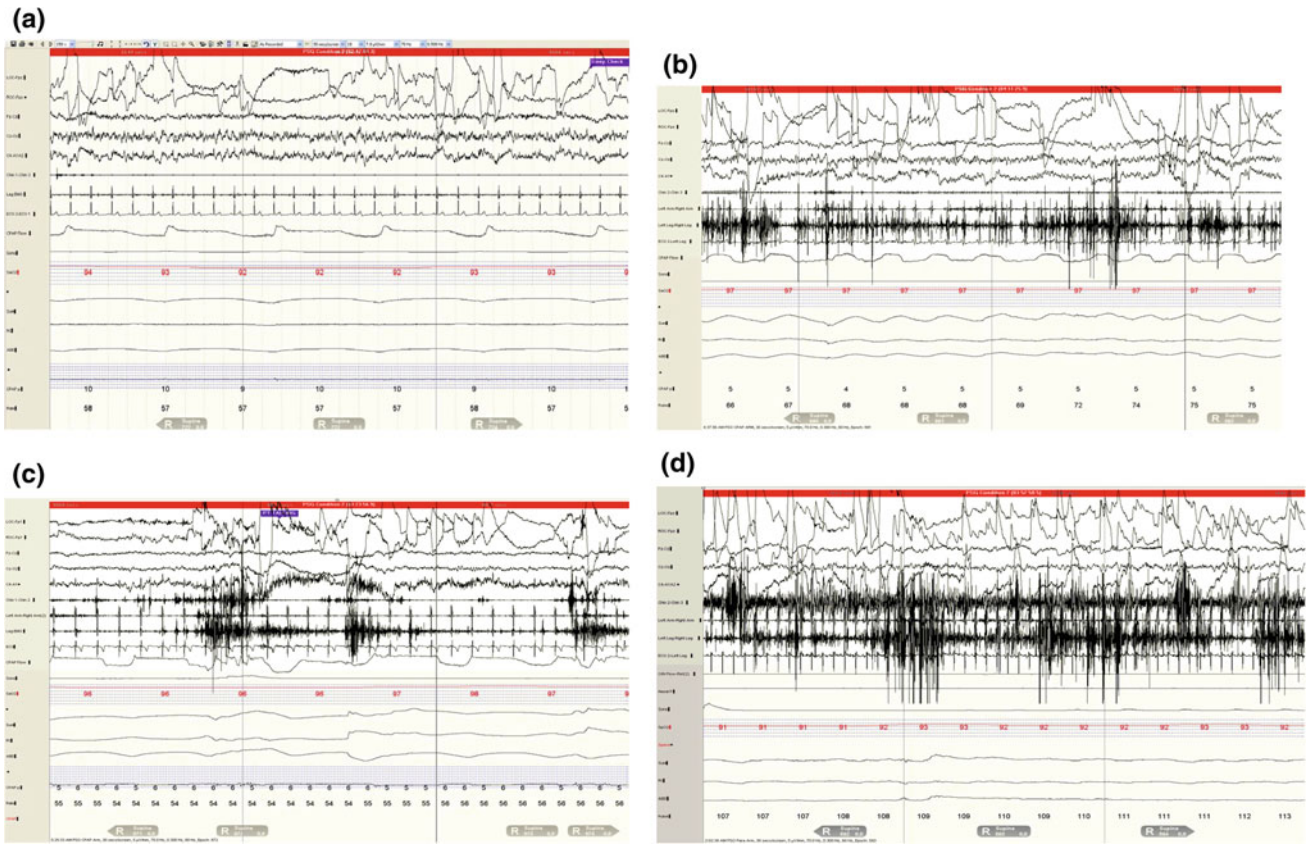

Fig. 49.1 Muscle tone during REM sleep in a normal subject, and in patients with REM sleep behavior disorder. The figure shows representative examples of 30 s polysomnogram epochs recorded during REM sleep. Muscle tone in the chin (submentalis), legs (linked tibialis), and arms (linked extensor digitorum communis) are shown in the sixth, seventh, and eighth channels of each example epoch, respectively. **a** demonstrates a normal level of REM sleep muscle atonia, while **b**–**d** demonstrate clear excessive phasic and tonic muscle tone, **b** shows predominantly excessive phasic muscle activity, especially in the leg, where there is also subtly increased tonic muscle activity. **c** demonstrates predominate excess phasic burst activity in the chin, arm, and leg muscle channels, accompanied by probable dream enactment manifested by vocalization; **d** shows excessive phasic and tonic muscle activity in the chin and leg muscle channels. Each of the examples seen in **b**–**d** is consistent with REM sleep without atonia, the neurophysiologic substrate of REM sleep behavior disorder

also recently been shown to be four times more likely in primary relatives (i.e., parents or siblings) of patients with iRBD when compared to primary relatives of individuals without RBD suggesting that there may be familial link in RBD [65]. In addition, history of head injury, smoking, pesticide exposure, lower level of education, and occupation as a farmer have been reported as potential risk factors for RBD. However, further research in this area is needed [77] (Fig. 49.1).

The Association of RBD with Neurodegenerative Synucleinopathy Disorders

RBD can result from several synucleinopathy phenotypes, as shown in Table 49.1. Both idiopathic and symptomatic RBD have been shown to be especially strongly associated with the synucleinopathies, a group of neurodegenerative disorders of unknown etiology related to intracellular accumulation of the protein alpha-synuclein, including Parkinson disease (PD), Lewy body dementia (DLB), multiple system atrophy (MSA), and pure autonomic failure (PAF) [5, 8, 12, 33, 37, 38, 67, 78]. Mild cognitive impairment (MCI), especially the non-amnestic subtype, has also been associated with RBD [5]. RBD is strongly associated with parkinsonism and/or cognitive impairment, which affects more than 82 % of RBD patients [36, 79]. Idiopathic RBD patients have an approximate 12–45 % risk of developing parkinsonism or dementia within five years of RBD symptom onset, which rises to 60 % within fifteen years, and to approximately 84 % risk 20 years after RBD symptom onset [5, 8, 79, 80].

There is growing evidence in iRBD patients of frequent presence of "soft," subtle neurological and neuropsychologic abnormalities (also known as non motor signs) consistent with the early stages of a developing synucleinopathy [5, 81–83]. Patients with iRBD show abnormalities in smell and

color vision, similar to that seen in patients with PD [81–84]. Some useful batteries for assessment of vision and olfactory function include the Farnsworth-Munsell-100-Hue test (FM 100) for color vision, and the University of Pennsylvania Smell Identification test (UPSIT) and Brief University of Pennsylvania Smell Identification test (B-SIT) to test olfaction [81, 83]. These clinical assessments may help clinicians clarify which RBD patients are most likely to develop parkinsonism, and poor performance on the FM-100 and UPSIT tests appears to be good predictors for the development of impending neurodegenerative disease in patients with iRBD [81, 82, 84]. RBD patients without impaired olfaction have an 86 % chance of remaining disease free for 5 years, contrasting with a 35.4 % chance in those with abnormal olfaction [12]. Abnormal olfaction in RBD appears similar to olfactory deficits in previously diagnosed PD patients, indicating that progressive neurodegeneration in RBD leads to PD [81, 83]. In addition, RBD patients with impaired color vision have an 18–26 % chance of 5-year disease-free survival [12, 83].

Patients with idiopathic RBD and PD with RBD have difficulties with object identification compared to controls and patients with PD lacking RBD [82]. Neuropsychological performance can also be used as a potential predictor of progressive neurodegeneration in iRBD patients [78, 85]. Impairments in attention, executive function, decision-making abilities, verbal memory, and verbal learning are most common in RBD patients, similar to deficits seen in synucleinopathies [86, 87]. Because iRBD is likely an early manifestation of synucleinopathy, serial neuropsychometric testing may help determine the timeline and progression of neurodegeneration in iRBD patients. Similarly, quantitative electroencephalography (EEG) has demonstrated temporo-occipital slowing in patients with iRBD, with higher theta power similar to that seen in patients with DLB and PDD [86, 88]. Of note, mild cognitive impairment appears to be the driver of EEG slowing in iRBD patients and likely heralds impending MCI [89, 90].

Cognitive impairment in iRBD likely varies due to the time point at which patients are sampled. Patients with iRBD are a heterogeneous group and are considered "idiopathic" because they do not yet express clinical symptoms of neurodegenerative disease, but that does not mean patients in the reported studies are at the same point in the disease progression. Because we do not sample patients at a uniform time point in their supposed disease process, and we do not fully understand why patients progress at different rates, it is difficult to draw conclusions about accompanying cognitive, motor, and autonomic dysfunction that would apply to all iRBD patients [91]. RBD patients that have progressed further toward overt clinical manifestations of neurodegenerative disease would very likely have greater impairments in cognition; therefore, differences seen between controls and iRBD patients may be driven by those patients closer to the clinical expressions of synucleinopathies. To our knowledge, no studies have yet examined cognition in the very early stages of dream enactment behavior with subsequent longitudinal, serial follow-up to determine whether or not there is a discernible common pattern of temporal progression of cognitive decline in iRBD. Future studies examining early RBD are of significant importance in the hopes of better understanding the underlying neurodegenerative process in iRBD.

Autonomic dysfunction may be the earliest predictor of impending neurodegeneration in iRBD. Orthostatic blood pressure drop may present as early as 20 years prior to development of overt neurological signs of synucleinopathy [92]. Urinary incontinence (13 years), constipation (15 years), and erectile dysfunction (11.5 years) also begin long before other neurological symptoms [92]. In addition, there is increased cardiac denervation in patients with iRBD and PD, further indicating that RBD may be an early expression of PD in many cases. However, the amount of cardiac denervation does not appear predictive of neurodegenerative disease development [84, 93, 94]. Reduced ^{123}I-MIBG uptake may begin as early as Braak Stage 1, indicating that cardiac

scintigraphy may be useful in early identification of PD development. Since cardiac denervation is present in the earliest stages of PD and RBD, but the amount of denervation does not predict neurodegeneration, RBD may represent early PD in a subset of patients [94]. Notably, while ^{123}I-MIBG scintigraphy may be significantly decreased in RBD and PD, iRBD patients have been shown to have even greater reduction of MIBG uptake when compared to PD patients without RBD and neurologically normal controls, possibly indicating that PD-RBD may be a specific PD phenotype [95, 96]. Recently, plasma urate levels have also been shown to be a possible predictive factor of synucleinopathy neurodegeneration, with higher uric acid levels reportedly associated with a decreased risk for PD development [97] and a longer duration of RBD without conversion to PD, suggesting that plasma urate may modulate the progression of neurodegeneration in RBD. However, significantly more research is required to draw definitive conclusions [97].

Imaging in RBD

Similarly, advances in objective neuroimaging tests have begun to allow the non-invasive identification of patients at risk of development of a neurodegenerative disorder [5, 7, 98]. These tests include dopamine transporter uptake ^{123}I-FP-CIT SPECT (DaTscan) and transcranial sonography (TCS), which have shown to be effective in detecting subclinical changes in the substantia nigra that may reflect evolving synucleinopathy; and ^{99}mTc–ethylene cysteinate dimer SPECT (ECD-SPECT), a measure of regional cerberal blood flow (rCBF) which has been shown to predict future development of PD and DLB [98]. These tests may be useful in the identification of patients who could participate in future clinical trials of neuroprotective therapies designed to slow progression or arrest neurodegeneration in patients with iRBD [7]. Abnormalities on TCS (i.e., substantia nigra hyperechogenicity) and DaTscan (i.e., ^{123}I-FP-CIT binding deficiencies in the striatum) in iRBD patients appear predictive of those who subsequently develop more classic features of a synucleinopathy, whereas patients with no abnormalities on neuroimaging remained disease free during follow-up [7]. The sensitivity of combined TCS and DaTscan scans was 100 % for predicting development of neurodegenerative disease within 2.5 years, so DaTscan and TCS may be useful in diagnosing neurodegenerative disease before clinical symptoms of parkinsonism, cognitive decline, or dysautonomia appear [7].

ECD-SPECT scan showed increased hippocampal rCBF in all iRBD patients who developed PD or DLB when compared to iRBD patients who remained disease free [98]. Notably, patients who developed PD displayed increased perfusion in the hippocampus, pons, and anterior cingulate cortex, while patients who developed DLB had increased rCBF confined to the hippocampus. Increased rCBF was also associated with several clinical markers of neurodegeneration. UPDRS-III was positively correlated with rCBF in the right hippocampus, and olfaction was correlated with increased rCBF in the medial frontal gyrus, while impairments in color vision were correlated with increased perfusion in the pons and left hippocampus [98].

Cortical afferent inhibition during transcranial magnetic stimulation (TMS) study was shown to be decreased in iRBD patients when compared to controls and correlates strongly with poor performance in episodic verbal memory and executive function tasks, suggesting that cholinergic dysfunction may underlie cognitive impairment in iRBD [99]. In addition, voxel-based MRI morphometry (VBM) has recently shown gray matter loss in the left and right anterior cerebellum, pontine tegmentum, and left parahippocampal gyrus in iRBD patients, a pattern similar to neurodegeneration in DLB and MSA [100]. These findings indicate the utility of SPECT, TCS, TMS, and MRI scans to predict future neurodegeneration, and possibly synucleinopathy subtype in patients with iRBD, which may enable more accurate prognostication and individualized diagnostic and therapeutic approaches.

Finally, the degree of RSWA appears predictive for future PD development. Patients with a more significant degree of elevation in baseline mentalis tonic density were more likely to develop PD in one study [33]. RSWA increases over time in patients with iRBD, suggesting a progressive neurodegenerative process leading to the destruction of brainstem regions responsible for the control of REM sleep toward clinical manifestations of parkinsonism and dementia [101, 102]. However, RBD symptom duration may not be the correct measure to determine group comparability, and patients with higher RSWA densities may have been studied further along in their disease course toward the eventual expression of PD, so additional prospective studies are necessary to determine whether the degree of RSWA is a marker for progression to PD.

RBD and RSWA Association with Specific Synucleinopathy Disorders: Parkinson Disease, Lewy Body Dementia, and Multiple System Atrophy

RBD and Parkinson Disease

RBD is common in Parkinson disease (PD) with as many as 55 % of PD patients reporting RBD symptoms [12, 32, 103–105]. RBD symptoms can develop prior to the development

of clinical PD symptoms or during any of the six stages of PD [67]. Depression has been shown to be a risk factor for future development of PD [106]. In addition, depression and antidepressant use have also been associated with RBD [28, 30, 51, 107]. PD patients with RBD are more likely to have a comorbid psychiatric disorder compared to PD patients without RBD, and iRBD patients with comorbid depression have an increased risk for development of PD compared to RBD patients without comorbid depression [96, 108].

There is some evidence that PD-RBD may be a specific PD subtype. PD patients with RBD are less likely to be of the tremor predominant phenotype, less levodopa responsive, have higher Hoehn–Yahr scores, more frequent hallucinations, a greater degree of autonomic dysfunction, and most important, an increased risk for dementia [95, 96, 105, 109]. PD-RBD patients have a 45 % risk of development of dementia within four years compared to a 0 % risk in PD patients without RBD [95]. Of note, only PD patients with clinical RBD symptoms were at an increased risk for future development of dementia, when compared with PD patients with RSWA on PSG but no history of dream enactment and PD patients with normal REM sleep [109]. This suggests that PD-RBD may be a more widespread disease process compared to PD patients without RBD.

PD-RBD patients may have a gender disparity for the type of dream enactment behaviors similar to that seen in iRBD [110]. Men with PD-RBD report more aggressive and violent dreams with a higher percentage of violent movements during sleep. However, women with PD-RBD report more disturbed sleep with less violent movements during sleep [110]. Clinical RBD symptoms may remit in PD patients and appear less injurious when compared with iRBD patients [41, 111, 112], possibly due to decreased functionality as PD progresses. However, motor activity appears improved during dream enactment behavior compared with awake motor activty, so decreased functioning may not be fully responsible for clinical RBD remission and the lesser injury potential due to RBD behaviors in PD patients [113, 114]. The smoothing of movements during dream enactment represents sleep-related intact corticofugal and corticospinal neural circuitry that bypasses the basal ganglia, where functioning is impaired by synucleinopathy during wakefulness [114].

RBD and Lewy Body Dementia

Cognitive impairment is frequent in RBD and many patients develop dementia, primarily DLB or PDD [67, 84, 115–117]. While DLB and PDD are similar, important differences exist in the time course for the development of cognitive symptoms relative to development of motor symptoms. If motor symptoms are present for >1 year before cognitive decline, patients are considered to have PDD. If motor symptoms are present for <1 year prior to cognitive decline, or if they develop anytime after the onset of cognitive decline, patients have DLB [118]. Dream enactment is common in DLB, and PSG-confirmed RBD is present in as many as 83 % of DLB patients [119]. In fact, DLB and RBD are so closely associated that including RBD as a core feature of DLB increases the likelihood of DLB diagnosis sixfold [117]. Visuospatial impairment is one of the hallmarks of DLB, but can also be present in PDD. In addition, executive functioning is also affected in patients with DLB and PDD [84, 115, 116]. Idiopathic RBD patients show visuospatial and visuoconstructive dysfunction similar to patients with DLB, indicating that RBD may be a predictor for the development of dementia [82, 84]. In addition, many RBD patients eventually express clinical and/or pathologic features of Lewy body dementia/disease [5, 78, 107, 116, 117, 120, 121]. DLB patients with RBD have a shorter duration of dementia, earlier onset of parkinsonism and visual hallucinations, and lower neuritic plaque scores than DLB patients without RBD, indicating that DLB-RBD is a specific subtype of DLB which may have more widespread neurodegeneration than DLB without RBD [121]. Further insights clarifying the association between dementia and RBD, especially determining which patients are at highest risk for deteriorating cognitive functioning, are needed.

RBD and Multiple System Atrophy

Of the synucleinopathies, multiple system atrophy (MSA) appears to be the most strongly associated with RBD, with 68–100 % of patients having RBD or RSWA [85, 122, 113, 123]. Why MSA is more strongly associated with RBD than PD or DLB remains unclear. RBD symptoms in MSA appear to be less severe, even though RSWA is increased, when compared with PD-RBD and iRBD patients, a possible consequence of the more widespread neurodegeneration in MSA and its impact on functionality [124]. A diagnosis of RBD may help differentiate MSA from pure autonomic failure (PAF); in one case series, four patients with MSA had dream enactment behaviors, while all six patients diagnosed with PAF had no sleep disturbances [123]. However, other studies have shown RBD also occurs in PAF, indicating that further research is required on the association of PAF with RBD [122]. RBD has been found to be equally common in both MSA-P and MSA-C subtypes, suggesting that RBD is not a reliable finding to differentiate between subtypes of MSA [125].

RBD and Tauopathies

There have been reported cases of RBD in Alzheimer's disease, but the pervading theory is that concomitant Lewy body pathology instead may more likely explain the RBD symptoms [126]. REM sleep without atonia and RBD have been variably reported in patients with progressive supranuclear palsy (PSP) and rarely in patients with corticobasal degeneration [127–130]. Evidence is contradictory on whether the amount of RSWA in PSP is similar to the amount seen in Parkinson disease [128, 130, 131]. Regardless, RBD rarely presents years in advance of PSP features, instead tending to occur concurrently with the motor dysfunction [5, 126, 130]. RBD has not been found in other primary tauopathies. Yet rare examples of autopsy-proven Alzheimer's disease and PSP with RBD have been documented [5]. While it is possible that RBD can occur with a variety of the neurodegenerative proteinopathies, the frequency of RBD associated with synucleinopathies is far greater than in non-synucleinopathy disorders [5].

Narcolepsy and RBD

Since narcolepsy is a boundary state disorder, RSWA and RBD frequently co-occur in up to 60 % of cases [57]. Unlike RBD associated with synucleinopathy neurodegenerative disorders, RBD occurs equally in female as in male narcolepsy patients and has less complex and violent dream enactment behaviors which begin at an earlier age [57, 132]. RSWA without dream enactment occurs more frequently in patients with narcolepsy–cataplexy compared to both idiopathic hypersomnia patients and neurologically normal controls, correlating with the degree of hypocretin cell loss [57]. RSWA may be a useful diagnostic marker when unsure of a diagnosis between narcolepsy and idiopathic hypersomnia [133]. Antidepressants or stimulants may induce clinical RBD symptoms in narcolepsy patients, so sleep neurology clinicians must regularly inquire about dream enactment symptom occurrence and frequency in narcolepsy patients during follow-up care.

RBD Associated with Brainstem Lesions and Autoimmunity

Lesions of the brain stem caused by tumors, paraneoplastic, and autoimmune neurological disorders such as anti-Ma2-associated encephalitis or Morvan syndrome have been associated with clinical RBD symptoms and RSWA [13, 15, 16, 18, 19, 22–25, 128, 134, 135]. In addition, autoimmune disorders have been reported to occur in up to 20 % of women with RBD [29]. Brain stem lesions in patients with subsequent development of RBD symptoms have been helpful in localizing the structures responsible for control of REM sleep muscle tone in humans. One recent case identified RBD due to a discrete lesion in the right dorsomedial pons, the presumed location of the human sublateral dorsal nucleus/subcoeruleus that is believed to play a major role in generation of REM sleep muscle atonia [136]. Other lesional cases of RBD have also impugned the dorsal pontine tegmentum [26, 135]. Further case reports of brain stem lesions may allow insights into RBD pathophysiology. RBD or RSWA has also been found in up to 13 % of patients following traumatic brain injuries, indicating damage to brainstem structures responsible for REM sleep muscle control [137].

RBD Associated with Psychiatric Disorders and Antidepressants

There is growing evidence that RBD is common in psychiatric populations [28, 30, 51, 138]. Depression and antidepressant use are common, with as many as 60 % of RBD patients using antidepressant medications [30, 66]. In addition, RBD patients report significantly greater feelings of anxiety and depression when compared with matched control patients [107]. However, it remains unclear whether psychiatric RBD is a specific RBD subtype with a different pathophysiologic mechanism or simply an early manifestation of synucleinopathy neurodegeneration unveiled by antidepressant medications. A recent longitudinal study comparing iRBD patients taking antidepressant medications compared with antidepressant naïve iRBD patients showed a decreased rate of conversion to symptomatic RBD in the antidepressant users [139]. These findings, along with similar RSWA profiles between iRBD patients taking antidepressants and those not taking antidepressants, support the contention that psychiatric RBD is not a distinct RBD subtype, but simply iRBD that has been unveiled by antidepressant medication use [107, 139]. Notably, patients with depression have shown to be at an increased risk for developing PD, indicating that depression may be an early maker of PD [140, 141]. In addition, iRBD patients with depression appear to be at a significantly greater risk of future development of PD when compared to iRBD patients without depression [108]. PD patients with depression have been shown to have decreased norepinephrine binding in the locus coeruleus compared to PD patients without depression, providing evidence for a possible link between RBD and depression [142]. However, while there appears to be some relationship between psychiatric disease, RBD, and PD, idiopathic and symptomatic RBD patients have significantly

greater tonic RSWA elevation when compared to patients with psychiatric RBD on antidepressant medications, indicating that there may be mechanistic differences between these RBD types [107]. Further research in this area is needed to understand these relationships.

Selective serotonin reuptake inhibitors (SSRI) and tricyclic antidepressants have been shown to exacerbate RBD symptoms and increase REM sleep muscle tone in patients without clinical dream enactment [29, 30, 138]. However, it remains unclear whether neurochemical effects mediated by antidepressants cause a reversible state of RSWA and RBD, or these drugs simply unveil RSWA and RBD in predisposed individuals [6, 29, 30]. Patients without a history of dream enactment on antidepressant medications have been reported to have increased RSWA when compared to normal volunteers not on antidepressants [107, 143]. In addition, limited evidence suggests that patients who previously received antidepressant medication use but who were not using antidepressants at the time of polysomnography had normal RSWA indices, suggesting that antidepressant medications do not cause a permanent alteration in REM sleep muscle tone [107]. Clinically, it is important to consider the impact of antidepressant effects in patients with RBD. Gradual cessation of SSRI medications or changing to an alternate antidepressant medication such as bupropion, which may have lesser propensity to aggravate RBD, may help decrease the frequency of dream enactment behaviors [144].

Pathophysiology of RBD

The mechanisms for RSWA and RBD remain poorly understood. Animal studies involving the rat and cat have informed much of our understanding of REM sleep atonia control. RBD-type behaviors were first demonstrated by selective lesioning of the cat locus coeruleus in 1965 [145]. Further study of sleep in the cat and rat has shown that the regulation of REM sleep is complex, and primarily located within the pons and medulla, especially the noradrenergic locus coeruleus (LC) and the cholinergic pedunculopontine nucleus (PPN) and laterodorsal tegmental nucleus (LDTN). Glutamatergic projections from the medullary magnocellular reticular formation (MCRF) also play a role in motor inhibition. In addition, the glycinergic/GABAeric nucleus raphe magnus, and the ventral and alpha gigantocellular nuclei have been implicated in the suppression of REM sleep muscle tone [146]. The hypothalamus, thalamus, substantia nigra, basal forebrain, and frontal cortex also participate in REM sleep regulation [145, 147].

Brainstem regions thought to be involved in the pathophysiology of RSWA and RBD are the MCRF, locus coeruleus/subcoeruleus (LC/SC) complex, PPN, LDTN, and the substantia nigra [145, 148]. Lesions in the LC/SC cause RSWA, and the site and severity of the lesion determines whether simple or complex behaviors result [3]. However, the rat sublateral dorsal nucleus (SLD), analogous to the cat SC, appears to have a vital role in the regulation of normal REM atonia, and when lesioned, mediating the pathophysiology of RSWA and RBD [149–153]. The SLD is located in the dorsal pontine tegmentum [152]. Lesions in the SLD result in RSWA in rats. The SLD contains primarily excitatory glutamatergic neurons with both caudal and rostral projections [153]. Rostral projections excite thalamocortical neurons, the basal forebrain, and lateral hypothalamus to generate REM sleep (EEG) [153]. Caudal projections to the ventromedial medulla (VMM), the premotor glycinergic/GABAergic neurons of the nucleus raphe magnus, and the ventral and lateral gigantocellular nuclei are responsible for activating hyperpolarization within spinal motorneurons and subsequent generation of REM sleep muscle atonia [153]. Rats also possess a "REM-on" and "REM-off" region [154]. The REM-on region is inhibited by GABAergic and galaninergic projections from the forebrain ventrolateral preoptic nucleus (VLPO), in addition to cholinergic projections from the PPN/LDTN which are active during wakefulness and non-REM sleep [153, 155]. The REM-off nuclei are activated by projections from the noradrenergic LC, serotonergic raphe nucleus (RN) and by hypocretinergic pathways from the lateral hypothalamus [3]. The REM-on nuclei in the SLD and the precoeruleus (PC) also interact with REM-off nuclei and are mutually inhibitory [154].

Recent research from a RBD transgenic mouse model has illustrated the importance of ionotropic glycine/$GABA_A$, and metabotropic $GABA_B$ receptors for generation and maintenance of REM sleep muscle atonia [151]. Only simultaneous inhibition of both ionotropic and metabotropic receptors results in heightened REM sleep muscle tone similar to that of wakefulness [151]. Inhibition of only single neurotransmitter receptors results in incomplete muscle activation, and it is very likely that the large degree of variation of RSWA seen between different patients, and within the same patients on repeated studies over different nights, is a direct result of how many receptors are inhibited [151, 156]. While large lesions to the SLD result in RSWA, they also cause a large decrease in total REM sleep time [153, 154]. Therefore, because RBD patients often have a normal amount of REM sleep, it is unlikely that RBD and RSWA in iRBD result from lesions directly to the SLD [150, 153]. Two populations of SLD/SC neurons have been found in the cat brain; ascending glutamatergic projections responsible for generation of REM sleep EEG activity, and descending glutamatergic projections inducing REM sleep muscle atonia [153]. Possibly only the descending projections are disrupted in iRBD, resulting in RSWA and dream enactment, while

the ascending projections are relatively spared [153]. Another possible hypothesis is that the selective degeneration of premotor REM-on GABA/glycinergic neurons of the nucleus raphe magnus and the ventral and alpha gigantocellular reticular nuclei occur in RBD as a result of alpha-synuclein aggregation, which is also in accordance with the Braak hypothesis [157]. Both noradrenergic and serotonergic influences also play a role in REM sleep muscle tone. Decreased serotonin and noradrenaline concentrations have been found in the nuclei of hypoglossal motor neurons, with a subsequent increase in REM muscle tone with direct injection of serotonin into these nuclei [153, 158]. On the other hand, noradrenaline does not appear to directly increase muscle tone, but instead amplifies glutamatergic driven muscle excitation [159]. Dream enactment behavior and phasic muscle twitches during REM sleep are hypothesized to result from direct or indirect glutamatergic inputs from the motor cortex projecting to spinal motor neurons [153]. The fact that movements during DEBs in patients with PD appear faster and less stereotyped than movements during wakefulness argues for direct activation of spinal motor neurons resulting from corticospinal and corticofugal projections bypassing the smoothing contributions of the basal ganglia during REM sleep [153, 160]. Ultimately, REM sleep muscle atonia likely results from a powerful combined glycinergic/GABAergic drive stimulated by glutamatergic projections from the SLD, with additional mediation by seratonergic and noradrengergic influences [153].

Since most of our understanding of REM sleep comes from animal models, there are very likely interspecies differences between humans and animals. However, lesional cases of RBD in humans also propose that human dorsomedial pontine structures analogous to the SLD and MCRF play similar roles to the animal models. Discrete dorsomedial pontine lesions in SLD-analogous structure lead to decreased motor inhibition, as well as decreased excitation of the MCRF, thereby potentially causing RBD symptoms [136]. It remains unclear whether lesions causing RBD in humans may involve the MCRF alone, or whether lesions must have additional involvement of the REM-off regions [154].

Because patients with narcolepsy frequently have RBD, the relationship between orexin-A and orexin-B (hypocretin-1 and hypocretin-2) and REM sleep muscle tone has also been examined. Decreased levels of CSF hypocretin-1 from damage to the lateral hypothalamus have been associated with a greater amount of muscle activation during REM and non-REM sleep in patients with narcolepsy with and without cataplexy [161]. Hypocretin has also been shown to play a role in REM sleep muscle activation by directly acting on LC neurons, in addition to REM sleep muscle tone suppression by action on the pontine inhibitory area [162, 163], suggesting that hypocretin likely plays a large role in the stabilization of REM sleep muscle control, and that disruptions in hypocretin expression, whether deficient or excessive, could result in RSWA [161, 162, 163]. Decreased hypocretin levels have been associated with RSWA in narcolepsy, while increased hypocretin levels have been associated with RSWA in PD [161, 164]. In addition, in a small case study of patients with idiopathic RBD, hypocretin levels were normal, so further research on the role of hypocretin in mediating RSWA and RBD is needed [165]. Dopamine may also play a stabilizing role in the control of REM sleep muscle tone, with both dopamine deficiency and excessive levels of dopamine resulting in increased REM muscle tone [166, 167]. Because RSWA is occasionally seen in PD patients without RBD, it is possible that dopaminergic dysfunction in these patients contributes to the RSWA without DEB [55]. Further exploration of this relationship is needed.

The Braak Staging Hypothesis and RBD

Because of the strong association of RBD with PD, the Braak staging hypothesis of PD may provide a possible explanation for the occurrence of RSWA and RBD symptoms in PD and perhaps also in DLB [3, 5]. Braak has postulated six stages of progressive and selective Lewy body deposition and Lewy neurite accumulation based on the clinical phenotype of PD, corroborated by pathologic examination [157]. Each successive stage has increased Lewy bodies and Lewy neurites compared to the previous stage. In addition, some structures are almost never affected in the six stages, while others are affected in most, indicating a selective vulnerability in the synucleinopathy neurodegeneration [168]. In stage 1, Lewy bodies and neurites begin to accumulate in the dorsal motor nucleus of the vagus in the medulla, while in stage 2, Lewy bodies and neurite progress rostrally through the magnocellularis reticular nucleus, subceruleus–ceruleus complex, olfactory bulb, and anterior olfactory nucleus. RBD symptoms are also considered to be part of stage 2, given common impairments in olfaction and cardiac denervation reported in idiopathic RBD patients [83]. Stages 1 and 2 are considered the "preclinical" phase of parkinsonism, preceding the evolution of motor or cognitive symptoms, in which RBD is the most distinguishing feature [168]. The parkinsonian stage is encompassed by stages 3 and 4 with the progression of Lewy deposits to the substantia nigra, the pedunculopontine nucleus, and the amygdala occurring in stage 3, while stage 4 results from progression of Lewy deposits into the temporal mesocortex. Widespread neurodegeneration occurs in stages 5 and 6, with Lewy deposits affecting the neocortex, causing cognitive

impairment [157]. Further evidence for the relationship between RBD and Braak staging stems from reportedly impaired olfaction and dysautonomia in patients with idiopathic RBD, indicating that RBD may be a precursor of PD [81–83, 94, 103]. As PD progresses from stage 1 to stage 6, there is an increasing loss of hypocretin cells, possibly supporting the hypothesis that hypocretin deficiency either plays a role in RBD pathology, or occurs concurrently and causes other PD-associated features [169]. However, a recent small case series reported increased levels of RSWA associated with increased hypocretin, so this relationship remains incompletely understood [164]. In addition, Braak staging does not well explain why some Lewy body disease patients never display RBD symptomatology, nor why some RBD patients never develop PD.

Treatment of RBD

Suppression of nightmares and prevention of patient and bed partner from injuries are the main goals of RBD treatment. Prediction of injury occurrence in RBD is very difficult. Patients with idiopathic RBD and those who remember their dreams have been recently found to be at significantly greater risk of injury [41]. However, frequency of dream enactment behaviors has not been shown to be predictive of possible injury, highlighting the importance of RBD treatment, even in patients with infrequent episodes of dream enactment [41]. All dangerous objects should be removed from the bedroom. Moving furniture away from the bed, padding the corners of bedside tables, and placing a mattress next to the bed may help prevent injury if the patient falls or leaves the bed during dream enactment [44]. If injury to the bed partner occurs, sleeping in separate beds or separate rooms minimizes risk of injury. Bed rails or barriers between the patient and bed partner may also be utilized, and bed alarms may be useful if the bedpartner has had to move to another room. A novel bed alarm designed to provide RBD patients with a calming instruction to return to sleep has been effective in reducing DEB in medication refractory patients [170]. The alarm system includes a pressure sensitive pad underneath the shoulders of the patient, as well as a clothing tether that is attached magnetically to the alarm system that detaches from the alarm system, activating the alarm and waking the patient from sleep, thereby averting the RBD episode [170]. The device is most effective in patients with a history of leaving the bed during dream enactment behavior. Confusional arousals resulting from obstructive sleep apnea, a common comorbidity in RBD patients, may mimic RBD episodes [171]. Treatment of apnea with continuous positive airway pressure may result in improvement in the frequency and severity of these episodes; however, treatment of OSA has not been shown to decrease RSWA, indicating there may be no direct effect of treatment of comorbid OSA on the pathophysiology of RBD [54].

Clonazepam and Other GABA Agonists

Melatonin and clonazepam are considered to be the two mainstays of pharmacologic treatment for RBD [32, 66, 68, 172, 173]. Melatonin and clonazepam appear to be equally effective in reducing frequency and severity of DEB, but only melatonin has been reported to significantly reduce injuries, with fewer side effects than clonazepam [66]. The $GABA_A$ receptor modulator clonazepam was the initial treatment reported as effective for decreasing RBD symptoms, with a median effective dose of 0.5 mg and a range of 0.25–2.0 mg given approximately 30 min before bedtime [8, 28, 59, 66–68, 75, 108]. Of note, while patients on clonazepam have decreased motor activity during REM, REM sleep muscle atonia is not restored, indicating that clonazepam may act on the motor cortex to inhibit glutamate induced phasic muscle bursts, but not on regions responsible for control of REM sleep muscle atonia [153, 174–176]. While clonazepam effectively reduces RBD symptoms, it can also increase the severity of obstructive sleep apnea and cognitive impairment. Additional side effects include sleepiness, dizziness, unsteadiness, and sexual dysfunction [32, 66, 176]. Therefore, patients with cognitive impairment, dementia, and sleep apnea must be monitored carefully when treated with clonazepam. While most patients with RBD associated with neurodegenerative disorders tolerate clonazepam well and benefit from its use, melatonin has been shown to be more effective in treating this population with fewer side effects [66]. Other GABA receptor modulators may also be useful in treating RBD; however, very little research on the effectiveness of these drugs on RBD symptoms exists [177]. Zopiclone has been reported to be effective in reducing RBD symptoms in a small number of patients [35, 177]. Zopiclone is a selective GABA α-1 and α-5 agonist with a short half-life and may impact the pathophysiology of RBD and reduce REM muscle tone by selectively acting on $GABA_A$ receptors [35]. However, further research is needed to validate this hypothesis.

Melatonin

Melatonin has recently been shown to be equally effective for RBD treatment, with fewer side effects than clonazepam [32, 66, 172, 173]. Adverse effects are dose related and primarily include daytime sleepiness; however, headache and hallucinations have been reported [32, 66, 178]. Melatonin may be a more efficacious treatment for patients with symptomatic RBD due to its more tolerable side effect

Table 49.2 Treatments for RBD

Drug	Mechanism	Dose (mg)	Adverse effects
Clonazepam	$GABA_A$ receptor modulator	0.25–2.0	Sedation, sexual dysfunction, and cognitive respiratory depression
Melatonin	Unknown	3–12	Sedation
Pramipexole	Dopamine agonist	0.125–0.5	Sedation, nausea, impulse control disorders

profile [66]. The median effective dose of melatonin has been reported to be 6 mg at bedtime [66]. However, ranges of 3–25 mg have also been reported as tolerable and effective [66]. Melatonin has been shown to increase REM sleep atonia during treatment; however, the mechanism by which this occurs remains unknown [35, 172, 173].

Other Potential Treatments of RBD

Other treatments of RBD have been limited to case reports and small case series. The association between RBD and PD has prompted interest in the role of dopamine in the pathophysiology of RBD. While levodopa decreases the amount of REM sleep time, possibly providing less opportunity for dream enactment behaviors, high doses of levodopa have been shown to increase both REM muscle tone and hallucinations which may be mistaken for RBD [166, 179]. Pramipexole has shown mixed results, varying from little or no effect, to reduction of RBD episodes [180–182]. In a recent large series, 62 % of patients treated with pramipexole monotherapy reported improvement in RBD symptoms, compared to 88 % improvement reported by patients treated with clonazepam, suggesting that pramipexole is likely not a suitable first-line therapy for RBD [183]. In this study, pramipexole was more effective in treating patients with lower amounts of RSWA compared to patients with significant amounts of RSWA, indicating that dopaminergic agents may help stabilize control of REM muscle tone early in the early course of PD [183]. Zonisamide, which is used to treat motor symptoms of PD, has been reported to decrease DEB in one PD patient [184]. Zonisamide has been shown to increase GABA-ergic neurotransmission and decrease glutamate in the rat brain, indicating that zonisamide could influence RBD symptoms both by inhibition of glutamatergic phasic muscle bursts as well as through GABA induced hyperpolarization of motor neurons [185, 186]. Given the high frequency of RBD in PD, further research on the effects of zonisamide on RBD symptoms is warranted. If efficacious in treatment of RBD symptoms, zonisamide may allow for the use of one treatment for both motor dysfunction and RBD symptoms, eliminating the need for polytherapy in a cognitively vulnerable patient population that may be impacted more severely by polypharmacy. Donepezil has also rarely been reported to reduce motor events related to RBD [187, 188]. Agomelatine is a novel antidepressant with a melatoninergic mechanism that has been reported to effectively decrease RBD symptoms with minimal side effects [189]. In addition, RSWA decreased in patients taking agomelatine, suggesting a relatively potent melatoninergic effect [189]. Because agomelatine has also shown similar efficacy to other antidepressant medications with fewer side effects, agomelatine may be considered a very useful medication in RBD patients with depression [190]. In addition, the herbal supplement Yi-Gan San has been shown to suppress RBD symptoms in three patients, possibly by acting on serotonergic and GABAergic systems [191]. While clonazepam and melatonin are effective in reducing RBD symptoms, only rarely do these or other treatments completely eliminate potentially injurious dream enactment behaviors. Therefore, future large, prospective comparative treatment trials are needed to develop better and more tolerable treatments that completely eliminate injury potential (Table 49.2).

Conclusions

RBD is a potentially injurious parasomnia that can reflect an early manifestation of synucleinopathy neurodegenerative disorders in many individuals, especially Parkinson disease, Lewy body dementia, and multiple system atrophy. Injuries are frequent to both patients and bedpartners, occurring in at least 50 % of cases, and not infrequently, injuries are serious enough to require medical intervention [1, 66, 67]. Currently, addressing bedroom safety in addition to pharmacologic treatment is the most effective form of therapy. A 6 mg bedtime dose of melatonin, with its relatively benign side effect profile and comparable efficacy to clonazepam, may be considered the first-line treatment of RBD, especially in patients with neurodegenerative disorders. Unfortunately, no neuroprotective therapies to prevent the progression of RBD to other clinical manifestations of neurodegenerative disorders exist at this time.

Early identification of patients with RBD could enable entry of individuals vulnerable to developing future synucleinopathy neurodegenerative disorders into clinical trials of neuroprotective therapies, with the goal of preventing

further neurodegeneration and arresting its course at a time point before clinically significant motor or cognitive sequelae unfold, or at least delaying the onset of these features [192]. Symptomatic treatment of RBD is focused on injury prevention by advising environmental measures to assure bedroom safety, and reduction of the frequency and severity of RBD episodes through administration of pharmacotherapy with clonazepam or melatonin. Future research of RSWA and RBD is necessary to determine sensitivity and specificity as biomarkers for conversion to overt synucleinopathy, to more effectively manage dream enactment so as to prevent injury, and to better understand the time course and causes of progressive neurodegeneration to inform design of future neuroprotective treatment trials.

Parasomnias

50

Jacques Montplaisir, Antonio Zadra, Tore Nielsen, and Dominique Petit

Introduction

The fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) defines parasomnias as "disorders characterized by abnormal behavioral, experiential, or physiological events occurring in association with sleep, specific sleep stages, or sleep-wake transitions" [1]. Parasomnias can sometimes be considered benign sleep phenomena, especially when occurring during childhood, and do not necessarily have serious impacts on sleep quality or quantity, or on daytime functioning. In some cases, however, injuries, psychological distress, and/or sleep disruption can ensue and seriously disturb the individual and his or her spouse or family.

True parasomnias are classified by the second edition of the International Classification of Sleep Disorders (ICSD-II) [2] into (1) disorders of arousal, or nonrapid eye movement (NREM) parasomnias; (2) parasomnias associated with rapid eye movement (REM) sleep; and (3) other parasomnias. Disorders of arousal (from NREM sleep) comprise somnambulism (or sleepwalking) and sleep terrors. Parasomnias associated with REM sleep consist of nightmare disorder, recurrent isolated sleep paralysis, and REM sleep behavior disorder (RBD). Other parasomnias include sleep enuresis and sleep-related groaning, among other conditions. The classification is slightly modified in the ICSD-3 published in 2014 (see Chap. 27). Sleep-related bruxism, sleep-related rhythmic movement disorder, and somniloquy (or sleep talking) were classified under parasomnias in the first edition of the ICSD but not in the second (see Chap. 27). We have, however, included these topics in this chapter.

The clinical presentation, polysomnographic (PSG) characteristics, prevalence, associated factors, pathophysiology, and treatment of the diverse conditions forming this heterogeneous group are reviewed in this chapter. Secondary parasomnias (disorders of specific organ systems that manifest preferentially during sleep) are not discussed here.

Disorders of Arousal (From NREM Sleep)

The symptoms and manifestations of the disorders of arousal can be considered along a spectrum. The patient's emotional expression can range from calm to extremely agitated while the actual behavioral manifestations can range from simple and isolated actions (e.g., sitting up in bed, mumbling, fingering bed sheets) to complex organized behaviors (e.g., rearranging furniture, inappropriate sexual activity, playing a musical instrument, driving a vehicle). Moreover, an episode can be composed of two overlapping disorders such as a sleep terror followed by sleepwalking.

The two disorders of arousal share many characteristics. Generally, episodes develop from sudden but incomplete arousals from slow-wave sleep (SWS: NREM sleep stage N3) [3–5] and sometimes from stage 2 sleep [5–7]. As a consequence, these parasomnias tend to take place in the first third of the night when SWS is predominant. In all disorders of arousal, episodes are typically characterized by misperception and relative unresponsiveness to external stimuli, mental confusion, automatic behaviors, and variable retrograde amnesia. Conditions that intensify sleep, such as sleep deprivation [6, 8, 9], intense physical activity [10], hyperthyroidism [11], fever [12–14], neuroleptics [15, 16], or medications with depressive central nervous system effects [17], can precipitate disorders of arousal in predisposed individuals. Finally, a common genetic component is suspected. People with an arousal disorder often have a positive family history for one of the two disorders [18–21].

Somnambulism

Clinical Presentation

Somnambulism (or sleepwalking) is characterized by complex behaviors usually initiated during arousals from SWS; it may begin with simple movements (e.g., sitting up in bed) and culminate in walking, bolting from the room, or worse [2]. Table 50.1 presents the diagnostic criteria established by the American Academy of Sleep Medicine [2]. Although usually considered a benign condition in children, sleepwalking in adults is potentially injurious. Episodes of surprising complexity have been reported: cooking or eating [22], driving a car [23], even homicide [24–28]. Accordingly, the duration of episodes may vary from a few seconds to several minutes [22]. The number of legal cases of sleep-related violence is on the rise [29–33] and raises fundamental questions as to the medicoforensic implications of these acts [23, 24, 34–39]. Associated mental activity includes instances of confusion, perceived threat, dreaming, and even pseudohallucination.

Experimental sleep deprivation can be used to trigger episodes of somnambulism in the sleep laboratory, since these rarely occur spontaneously in laboratory conditions. In fact, 25–38 h of sleep deprivation can significantly increase the number of actual somnambulistic events recorded in the laboratory by a factor of 2.5–5 when compared to baseline [6, 40, 41]. The fact that none of the control subjects investigated in these studies experienced nocturnal behavioral manifestations in the laboratory demonstrates that sleep deprivation alone does not lead to somnambulistic episodes, but rather that it increases the probability of somnambulistic behaviors in predisposed individuals. Experimentally triggered arousals using auditory stimulation during slow-wave sleep can also be used to successfully induce episodes during sleepwalkers' normal sleep and even more so during recovery sleep [40]. Diagnosis may thus be substantially aided by such techniques.

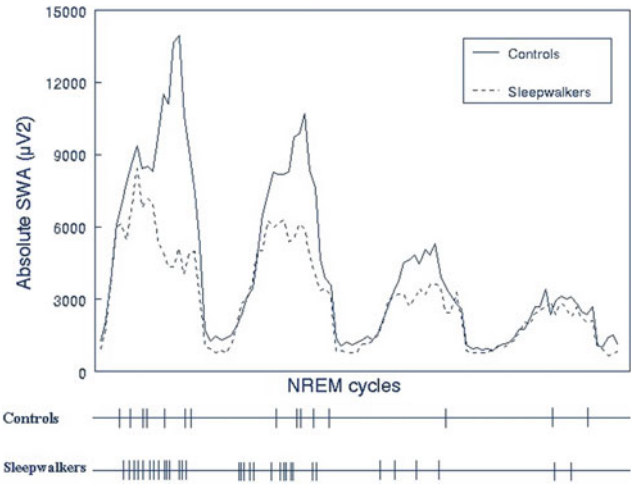

Fig. 50.1 Slow-wave activity (SWA) over 4 consecutive NREM-REM cycles in 15 sleepwalkers and 15 healthy paired controls. Power is significantly reduced in the second half of the first NREM period. Awakenings from SWS are indicated on the two *horizontal lines* below the graph (reproduced with permission from Gaudreau et al. [44])

Analyses of sleep architecture reveal no significant differences between adult somnambulistic patients and control subjects [42–47], except for a greater number of arousals selectively out of SWS in sleepwalkers, even for nights without sleepwalking episodes [3, 42, 44]. On quantitative analysis of their electroencephalograms (EEGs), sleepwalkers were found to have lower power in slow-wave activity (0.75–4.5 Hz) during the first NREM cycle [44]. They also had a higher number of awakenings during SWS than control subjects (Fig. 50.1) [44].

Several studies have documented the presence in the EEG of high-amplitude delta waves, termed *hypersynchronous*

Table 50.1 ICSD-2 diagnostic criteria for somnambulism and sleep terrors

Somnambulism	Sleep terrors
(A) Ambulation occurs during sleep (B) Persistence of sleep, an altered state of consciousness or impaired judgment during ambulation demonstrated by at least one of the following: i. Difficulty in arousing the person ii. Mental confusion when awakened from an episode iii. Amnesia (complete or partial) for the episode iv. Routine behaviors that occur at inappropriate times v. Inappropriate or nonsensical behaviors vi. Dangerous or potentially dangerous behaviors (C) The disturbance is not better explained by another sleep disorder, medical or neurologic disorder, mental disorder, medication use, or substance use disorder	(A) A sudden episode of terror occurs during sleep, usually initiated by a cry or loud scream that is accompanied by autonomic nervous system and behavioral manifestations of intense fear (B) At least one of the following associated features is present: i. Difficulty in arousing the person ii. Mental confusion when awakened from an episode iii. Amnesia (complete or partial) for the episode iv. Dangerous or potentially dangerous behaviors (C) The disturbance is not better explained by another sleep disorder, medical or neurologic disorder, mental disorder, medication use, or substance use disorder

delta (HSD) activity, occurring during SWS or immediately prior to somnambulistic episodes [4, 42, 45, 48]. However, more comprehensive studies have shown that HSD has a low specificity for the diagnosis of somnambulism [47, 49, 50] and that actual episode onset is often not preceded by a gradual accumulation of HSD waves [49]. However, episodes may be preceded by an abrupt change in high-amplitude slow oscillations (<1 Hz) [51], a process that may reflect cortical reactions to brain activation.

With regard to postarousal EEG, Schenck et al. [47] described three patterns that characterized the first 10 s of most SWS arousals in adults with sleepwalking/sleep terrors: pattern I, diffuse rhythmic, and synchronous delta activity (0–4 Hz), most prominent in bilateral anterior regions; pattern II, diffuse and irregular moderate- to high-voltage delta and theta activity intermixed with, or superimposed by, alpha- and beta-activity; and pattern III, prominent alpha- and beta-activity, at times intermixed with moderate-voltage theta activity. A follow-up investigation [52] of adult sleepwalkers showed that patterns II and III were the two more frequently observed forms of postarousal activity and that these patterns were also the only two that occurred during stage 2 episodes.

There is a strong genetic component to somnambulism [18]. About 80 % of somnambulistic patients have at least one family member affected by this parasomnia, and the prevalence of somnambulism is higher in children of parents with a history of sleepwalking [53–55]. A population-based twin study [18] showed a considerable genetic effect in adulthood sleepwalking (proband-wise concordance five times higher in monozygotic than dizygotic pairs), although the effect in childhood sleepwalking was not as pronounced (1.5 times higher in monozygotic than dizygotic pairs). In fact, this parasomnia was recently found to be linked to excessive transmission of the human leukocyte antigen DQB1*05 and *04 alleles [56]. However, the functional significance of this finding remains unclear. More recently, a genomewide scan conducted on a single family composed of 22 members found evidence for a significant linkage at chromosome 20q12-q13.12 [21]. Of particular interest is the fact that the candidate interval includes the adenosine deaminase gene which is believed to play a role in slow-wave sleep [57].

Although daytime somnolence or impairment in daytime functioning has never been part of the clinical portrayal of sleepwalking, there is increasing evidence showing that adult sleepwalkers often complain of excessive daytime somnolence. The association between somnambulism and daytime sleepiness has been found in a large population-based survey [58], in laboratory-based studies based on sleepwalkers' mean sleep latencies on the Multiple Sleep Latency Test [59] as well as on their scores on the Epworth Sleepiness Scale [60, 61], The EDS reported by adult sleepwalkers does not appear to be explained by the presence of concomitant sleep disorders or PSG signs of nocturnal sleep disruption and may thus be part of the sleepwalking phenotype and linked to its underlying pathophysiology [60].

Associated Factors and Pathophysiology

Although considerable progress has been made in the conceptualization of sleepwalking and its correlates [62], the exact pathophysiologic mechanisms of somnambulism remain unclear. Several factors have been proposed, including psychopathology, genetics, and deregulation of serotonergic systems.

Traditionally, the presence of somnambulism in adulthood has been viewed as a sign of major psychopathology [52, 63, 64]. However, several studies have shown that most adult patients do not have a *Diagnostic and Statistical Manual of Mental Disorders*-based [1, 65] Axis I psychiatric disorder, nor do they necessarily present with highly disturbed personality traits [46, 66–69]. However, anxiety may increase its occurrence in both children and adults [70, 71]. Based on clinical and research experience, Rosen and colleagues [70] proposed that somnambulism and sleep terrors may be nocturnal expressions of repressed anger concerning major life events such as separation, divorce, marital conflict, or family relocation.

Serotonin has also been hypothesized to be involved in the pathophysiology of sleepwalking on the basis that certain factors implicating the serotonergic system (e.g., certain drugs, fever) can precipitate sleepwalking [72]. In addition, sleepwalking episodes are four to nine times more common in conditions associated with abnormalities in the metabolism of serotonin, such as Tourette's syndrome or migraine headaches [73–75].

Finally, one single-photon emission computed tomography study was performed during sleepwalking in a 16-year-old boy with a history of somnambulism [76]. It showed that sleepwalking arose from the selective activation of thalamocingulate circuits and the persisting inhibition of other thalamocortical arousal systems. During the episode, the EEG showed diffuse, high-voltage rhythmic delta activity. This supports the notion that sleepwalking is a dissociated state consisting of motor arousal and persisting mind sleep.

Prevalence

The peak incidence of somnambulism (approximately 17 %) is around age 12 years [77]. For adults, a suggested prevalence of 2–2.5 % [78, 79] is probably an underestimate. Although many studies report no gender difference in older children, adolescents, or adults [77, 80], a study of two large cohorts of young children (2.5–6 and 4–9 years old) found it to be more common in boys than in girls [81, 82].

Treatment

Treatment is often unnecessary when the episodes are benign and not associated with potential injury. In this case, reassuring the patient/family about the benign nature of the episodes and demystifying the events is often sufficient. However, identifying and avoiding the potential precipitating factors, such as sleep deprivation, stress, and environmental disturbances, is effective in preventing episodes. Precautions should also be taken to ensure a safe sleep environment.

In children, the preferred treatment for somnambulism consists of a behavioral technique called anticipatory or scheduled awakening [83]. The parents keep a diary of their child's episodes and determine an average time at which the episodes take place. They then awaken their child about 15–20 min before the typical time of occurrence of the episode for a period of 1 month. It has been reported that the episodes cease as soon as this intervention is started, and the benefit is maintained on long-term follow-up [84, 85]. Hypnosis (including self-hypnosis) has been found to be effective in both children and adults with sleepwalking or sleep terrors [84, 86–91].

Pharmacologic treatment should be considered only if the behaviors are hazardous or extremely disruptive to the bed partner or other household members. Benzodiazepines (clonazepam or diazepam) and tricyclic antidepressants (imipramine) can be effective [92–97]. However, pharmacotherapy does not always result in adequate control of sleepwalking [68]. Treatment should always include instructions on sleep hygiene and stress management.

Sleep Terrors

Clinical Presentation

Sleep terrors (also known as night terrors or *pavor nocturnus*) are "arousals from SWS accompanied by a cry or piercing scream and autonomic nervous system and behavioral manifestations of intense fear" [2]. The American Academy of Sleep Medicine [2] diagnostic criteria for sleep terrors are presented in Table 50.1. Historically, sleep terrors have been confused with nightmares, a distinct REM sleep parasomnia. In 1965, Gastaut and Broughton [98] first observed by PSG that sleep terrors were not associated with REM sleep but rather occurred suddenly during SWS. Typically, within 90 min after sleep onset, the individual will scream loudly and sit up in bed with a panic-stricken expression. There is usually intense autonomic activity (sweating, flushing of the skin, mydriasis, tachycardia, rapid breathing) and, less often, complex behavioral manifestations such as leaving the bed, fleeing the room, or thrashing around. Injuries may result in such cases. The distinction between sleep terrors and somnambulism is ambiguous, although the activity displayed during sleep terrors is usually more rapid and abrupt than it is during somnambulism [95]. Inconsolability is a key feature of sleep terrors; attempting to console or awaken an individual during an episode will only unduly prolong or intensify it. As is the case for somnambulism (and contrary to a nightmare), the individual usually does not fully wake up and remains amnesic for the event the next day.

As for somnambulism, sudden awakenings from SWS (even without an actual episode starting) are typical of this condition, especially in the second half of the first two SWS sleep episodes. Instability of the NREM EEG pattern was also demonstrated [99]. However, a normal PSG does not rule out a diagnosis of sleep terrors. Time spent in SWS preceding an episode appears to be positively correlated with severity of the episode [95]. Rarely, sleep terrors may arise from stage 2 sleep.

Associated Factors and Pathophysiology

Sleep terrors that occur in childhood are usually not associated with a neurologic condition, whereas onset in adulthood could indicate a neurologic disease. Sleep terrors in adulthood have been described in relation to various psychopathologies, but many studies have shown that such parasomnias can occur in otherwise mentally healthy individuals [3, 46, 100]. As is true for somnambulism, genetic factors play a major role. Monozygotic twins are more concordant than dizygotic twins for sleep terrors [101]. A model-fitting analysis showed that sleep terrors were explained by a two-component model at 18 and at 30 months (about 42–44 % of additive genetic effects and 56–58 % of nonshared environment) [102]. Sleep terrors are twice as frequent in children for whom one or both parents have a sleepwalking history than in children with nonaffected parents [103]. These data and the clinical similarities between these two parasomnias suggest a common genetic predisposition and similar pathophysiologic mechanisms.

As for somnambulism, the incidence of sleep terrors in the sleep laboratory is lower than in the patient's normal environment [95, 104]. However, sleep terrors can be induced in predisposed individuals by auditory stimulation during SWS [46, 95]. Indeed, in individuals with sleep terrors, the orienting response to auditory stimuli has been reported to be more intense and persistent than in normal subjects, suggesting a hyperexcitability of the nervous system in these individuals [105]. In the sleep laboratory, the severity of the sleep terror, as assessed by heart rate increase and maximum heart rate after arousal, has been found to be proportional to the duration of the preceding SWS episode [106]. The prearousal delta power was also proportional to the sleep terror's intensity [107]; the EEG preceding sleep terrors contained significantly more delta power in central and frontal regions than control EEG (no event) sections.

This was confirmed by Espa et al. [3], who showed that sleep terrors were preceded by an increase of slow-wave activity with the main increase occurring immediately prior to the episode. During the sleep terror itself, the EEG activity demonstrated that the subject was neither fully asleep nor fully awake [95].

Prevalence

Reported incidence estimates are wide ranging [80, 108–110]. For childhood sleep terrors, the estimate is influenced by the age range studied, the sampling method, and definition used. Further, some parents may fail to differentiate between nightmares and sleep terrors. When an operational definition was supplied to parents, a high overall prevalence (40 %) was found for preschool period [82]. More specifically, the prevalence of sleep terrors was found to be 36.9 % at 18 months and 19.7 % at 30 months [102]. As for somnambulism, sleep terrors tend to resolve during adolescence and do not display a gender difference [80, 82]. The prevalence in the general adult population is about 2.2 % and declines gradually with age to attain about 1 % at 65 years of age and older [79]. In adults, there is a high degree of overlap among the two principal disorders of arousal.

Treatment

The scheduled awakening technique was shown to be effective to treat sleep terrors in children [83, 111]. Results of a randomized study in children with sleep terrors indicate satisfactory treatment with L-5-hydroxytryptophan [112]. In adults, when the episodes are not associated with injury potential, treatment is often unnecessary. If a treatment is needed, the same pharmacologic and nonpharmacologic approaches as for somnambulism can be tried.

Parasomnias Associated with REM Sleep

Nightmare Disorder

Clinical Presentation

Nightmare disorder consists of persistent disturbing dreams that arise primarily from REM sleep (and more rarely from stage 2 NREM sleep) and that usually awaken the sleeper [2, 113]. Nightmares are often distinguished from bad dreams precisely because the nightmare triggers an awakening. These awakenings are usually abrupt, not confused, and accompanied by detailed recall of disturbing content. However, there is typically a much lower level of autonomic activation during nightmares than during sleep terrors. Dream-enacting behaviors are not frequent but can occur during transitions to wakefulness [114], e.g., racing heart, perspiration, limb contraction, or bodily start. Nightmares are associated with varying levels of heart rate and respiratory activation during REM sleep, but often the autonomic arousal appears much less than might be expected from the emotions or thematic content of the disturbing dream [115].

Associated Factors and Pathophysiology

Bad dreams among 29-month-old preschoolers are predicted by material ratings of difficult temperament as early as 6 months of age and by parental ratings of child anxiety as early as 17 months [116]. Among adults, nightmares are also associated with demographic factors (e.g., low income) [117], psychopathologic traits [118–120], and personality variables such as physical and emotional reactivity [118, 121, 122], fantasy proneness [123, 124], and thin boundaries [125–128]. Nightmares are more frequent and prevalent in psychiatric populations [129–134] and are associated with pathologic symptoms such as anxiety, neuroticism, post-traumatic stress disorder, borderline symptoms, schizophrenia spectrum symptoms, dissociative phenomena, problematic health behaviors, and sleep disorders (see review by Levin and Nielsen [113]). Several studies converge on the finding that frequent nightmares signal an elevated risk for suicidal and self-harm behaviors [135–138].

Nightmares are also reactive to stressful life events [118, 122, 139–143]. This general pattern of comorbidity among nightmares, pathologic symptoms, and stress has been explained as due to an underlying distress-prone personality style [113]. More frequent nightmares are also associated with the eveningness chronotype [144, 145]. Finally, genetic contributions to nightmares have been suggested by population studies. The estimated proportion of genetic effects to the phenotypic variance in childhood was 44 % for males and 45 % for females in one study [146] and 51 % for all adults combined in another [147].

The few available PSG studies of frequent nightmare sufferers provide inconsistent findings but nonetheless all suggest disruption of REM and NREM sleep regulation. For REM sleep, there is more frequent skipping of early REM periods, longer REM latency and REM/NREM cycle length, lower REM%, and altered REM density across the night—all changes consistent with a possible disruption in REM/NREM cycle timing and duration and low REM sleep propensity in nightmare sufferers [148]. Another study found none of these differences, but did find an increase in REM% [149]. For NREM sleep, reduced NREM sleep duration, more NREM sleep awakenings, increased WASO [149], and anomalies in cyclic alternating pattern (CAP) subtypes (reduced A1, increased A2 and A3) also suggest a disruption of the regulation of sleep-promoting and arousing mechanisms during sleep [150].

A neurocognitive model has been proposed to explain nightmares [151]. The affect network dysfunction model of nightmare production is based on a combination of findings in brain imaging, sleep physiology, post-traumatic stress disorder, fear memory, and anxiety disorders. It complements a neurophysiologic description of nightmare formation, the AMPHAC model, which describes key roles for amygdala, medial prefrontal cortex, hippocampus, and anterior cingulate cortex [113]. Accordingly, nightmares result from dysfunction in a network of affective processes that, during normal dreaming, serves the function of fear memory extinction. Evidence for the involvement of prefrontal and limbic areas in nightmares has been reported [152]; frequent nightmare sufferers have impaired reaction times on Emotional Go/NoGo and Stroop tasks and more perseveration and word generation disturbance on a verbal fluency task.

Prevalence

Prevalence of nightmare disorder is difficult to assess precisely because of different operational definitions, response scales, age ranges, and study samples used (see reviews by Levin and Nielsen [113] and Spoormaker et al. [153]). In addition, prevalence studies usually evaluate nightmares as an isolated symptom but rarely as a disorder per se. The prevalence of nightmare symptoms is estimated in tandem with their temporal frequency. Accordingly, nightmares as a symptom occur occasionally in over 85 % of the general population, at least once a month in 8–29 %, and at least once a week in 2–6 % [78, 121, 129, 154, 155]. There is a consensus (e.g., DSM-5) that a frequency of one nightmare per week reflects clinical pathology.

Surprisingly, bad dreams are not frequent among preschoolers (1.5–3.9 % report them *often* or *always*). They can appear as early as 29 months, and the prevalence remains stable until age 6 years [116]. An Internet survey of 23,839 respondents found that the typical monthly recall of nightmares peaks between the ages of 20 and 29 and declines steadily thereafter. There is a gender difference in prevalence favoring girls that appears in adolescence [156, 157] and continues throughout the life span (Fig. 50.2) [158].

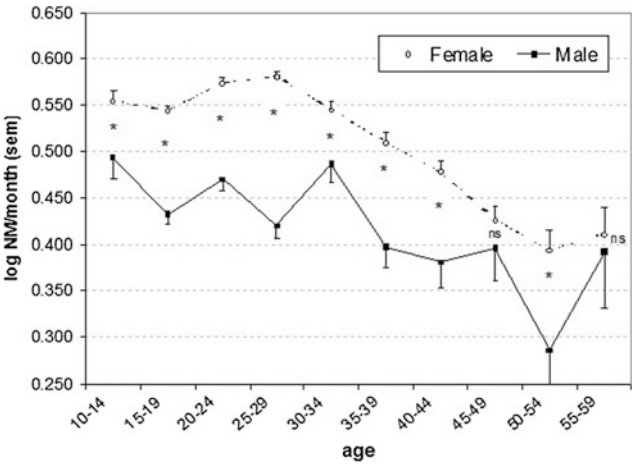

Fig. 50.2 Retrospective estimates of monthly nightmare frequency by 5-year age strata in an Internet sample of 23,839 respondents. *Asterisk* significant difference between female and male subjects at that stratum ($p < 0.05$) (reproduced from Nielsen and Petit [158])

Treatment

Treatments for nightmares include psychotherapy, systematic desensitization and relaxation, eye movement desensitization, imagery rehearsal, hypnosis, and pharmacological approaches [159–164]. A best practices guide to treatment of nightmares recently proposed by the Standards of Practice Committee of the American Academy of Sleep Medicine recommends only a single Level A drug treatment for nightmares—prazosin—and this only for PTSD nightmares [165]. The same committee also recommends only a single Level A nondrug treatment, Imagery Rehearsal Therapy, for Nightmare Disorder. However, more recent meta-analyses suggest that the recommendations for psychological therapies may need updating. One meta-analysis [166] found empirical support for both psychological and pharmacological (prazosin) treatments. Effect sizes for the psychological treatments (0.47–0.48) were higher than those for drug treatments (0.15–0.29), but equal to the effect size for prazosin alone (0.50). Further, studies of individual therapies had higher effect sizes than did those of self-help therapies. The second meta-analysis [167], examining only nondrug treatments, found that methods of *imagery rescripting and rehearsal*, which includes IRT, had lower effect sizes than did methods of *imaginal confrontation with nightmare contents*, such as self-exposure therapy [168].

Recurrent Isolated Sleep Paralysis

Male sex, poor mental health, drinking alcohol, taking a long daytime nap, early or late bedtime, difficulty initiating sleep, low subjective sleep assessment, presence of excessive daytime sleepiness, and presence of nightmares had higher odds ratios than other factors for sleep paralysis [133].

Clinical Presentation

Previously known as isolated sleep paralysis or simply sleep paralysis, recurrent isolated sleep paralysis is a common, generally benign, parasomnia characterized by brief episodes of motor or vocal paralysis combined with a waking state of consciousness [2]. Its benign status is perhaps responsible for its removal from the DSM-5 list of sleep disorders; it is now considered a subcategory of nightmare disorder. During

sleep paralysis episodes, fear-provoking dreamlike hallucinations often intrude and produce considerable distress. Episodes occur primarily at sleep onset (hypnagogic) and upon awakening (hypnopompic). Feelings of fear and terror are accompanying sleep paralysis experiences [169], and they are often linked to a feeling of presence (i.e., a vivid impression that a sentient being is nearby, but without a clear visual image of it) [170, 171].

Sleep paralysis episodes usually arise from sleep-onset REM periods [172, 173], suggesting that they are periods of state dissociation in which some REM sleep characteristics, muscle atonia and dreaming, intrude upon wakefulness [174, 175].

Associated Factors

Stress, shift work, and irregular sleep–wake schedules are factors associated with sleep paralysis episodes [173, 176–178]. Several studies link sleep paralysis to various neurologic and psychiatric disorders. It is predicted by bipolar disorder, automatic behavior, and use of anxiolytic medications [79]. It is also comorbid with post-traumatic stress disorder [179–181], depression symptoms [182, 183], anxiety disorder with agoraphobia [184], panic disorder [181, 185–188], generalized anxiety disorder, anxiety sensitivity [189], social anxiety [190, 191], excessive daytime sleepiness, and poor sleep [192]. This wide comorbidity has been attributed to mediation by an affect distress personality style ("sleep paralysis distress" [171]) in a manner analogous to that proposed for nightmare disorder ("nightmare distress" [113]).

Associations of sleep paralysis with psychiatric conditions vary among ethnic groups [193, 194]. Some of these differences may stem from cultural interpretations of sleep paralysis hallucinations, sensed presence in particular, as a form of spiritual entity, such as "ghost oppression" in China [178], "Old Hag" in Newfoundland [195], "kanashibari" in Japan [176], and "the ghost that pushes you down" in Cambodia [179]. Finally, a genetic component has also been reported: About 36 % of respondents in a Japanese sample had family members who experienced sleep paralysis [196].

Prevalence

Variations in prevalence estimates (5–40 %) depend upon differences in operational definitions, age of subjects, ethnicity, and other sociocultural factors [79, 176, 177]. One meta-analysis [197] of 35 studies (total N = 36,533) found lifetime prevalence rate to be 7.6 % of the general population, 28.3 % of students, and 31.9 % of psychiatric patients, with a slightly higher value for females (18.8 %) than for males (15.7 %). A study, which queried over 90,000 Japanese junior and senior high school students (90 % response rate) about whether or not they had experienced sleep paralysis ("kanashibari") in the last month, found a prevalence of 8.3 % with prevalence increasing monotonically with age (Fig. 50.3) [133]. Age of onset for sleep paralysis is typically 14–17 years. Accompanying vivid dreams are common (e.g., intruders, vestibulo-motor sensations); sensed presence hallucinations are particularly characteristic, occurring in 60–69 % of cases [170, 171, 198, 199].

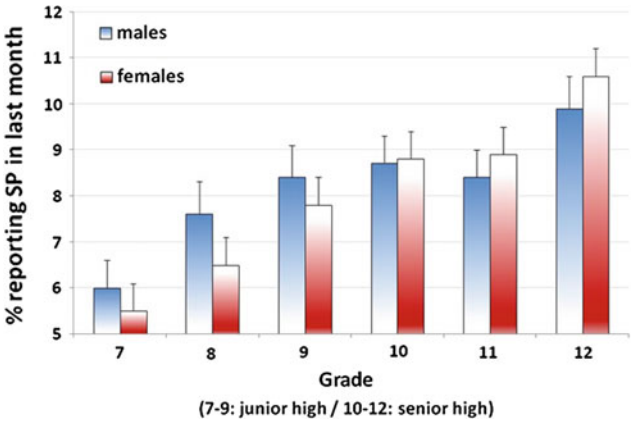

Fig. 50.3 Percent of 43,380 male and 44,769 female students reporting any occurrence of sleep paralysis in the last month by grade. Age may be approximated by adding 6 to grade (adapted from Munezawa et al. [133]. Table 50.1)

Treatment

Snyder and Hams [200] report three cases of isolated sleep paralysis controlled by L-tryptophan.

REM Sleep Behavior Disorder

Clinical Presentation

RBD was first described as a clinical entity in 1986 [201]. It is characterized by the loss of skeletal muscle atonia normally present during REM sleep and accompanied by complex dream-enacting motor activity. Behaviors can range from simple motor activities such as laughing, talking, shouting, or excessive body and limb jerking to complex, seemingly purposeful and goal-directed behavior, such as gesturing, punching, kicking, sitting up, leaping from bed, and running [2]. The close relationship between the dream content and the observed RBD behaviors has been demonstrated in a PSG video study with blind judges [202]. Too often, these sleep behaviors produce injuries to the patient or the bed partner such as ecchymoses, lacerations, fractures, and subdural hematomas. Injuries are a main reason for consultation, being reported by 79–96 % of consulting cases [203]. RBD episodes may also cause severe sleep disruption for the bed partner and lead to major marital discord, mood changes, and even suicide attempts [204]. In addition, the dream process and its content appear altered. Most patients

(87 %) report that their dreams became more vivid, intense, action filled, and violent with the onset of RBD [203]. Dream themes associated with behaviors are largely stereotyped in structure and emotional content. The most frequent pattern is that of vigorous defense against attacks by people (58.8 %) and animals (23.5 %) (see review by Nielsen [205]).

It has been observed that the aggressiveness displayed during nocturnal behaviors stands out against the good-natured daytime personality [203]. Indeed, a controlled study using content analyses of recently remembered dreams revealed an elevated proportion of aggressive content, yet normal levels of daytime aggressiveness [206]. The mechanism by which dream content is changed is unclear. However, it has been proposed that hyperactivity (disinhibition through degeneration) at the brain stem level activating motor, perceptual, and affective pathways may be responsible for both REM sleep behaviors and altered dreams [206]. The fact that clonazepam reduces both behavioral manifestations and disturbed dreaming [203, 207] supports the notion that the two phenomena share a common neurophysiologic substrate.

Clinical diagnostic criteria include (1) complaints of violent or injurious behaviors during sleep, (2) limb or body movements associated with dream mentation, and (3) one of the following: harmful or potentially harmful sleep behaviors, dreams that appear to be acted out, and sleep behaviors that disrupt sleep continuity. Polysomnographic recordings reveal an intermittent or complete loss of REM sleep muscle atonia and an excessive phasic electromyographic (EMG) activity during REM sleep [92]. This excessive tonic and phasic EMG activity during REM sleep worsens over time [208]. Diagnostic criteria are listed in Table 50.2. Early studies reported a substantial loss of REM sleep muscle atonia in patients with RBD. For example, three large series reported that 92–100 % of patients had some loss of REM sleep muscle atonia [209–211]. Changes in REM sleep in patients with RBD seem to be restricted to the excessive tonic and phasic motor activity. All other features of REM sleep, including REM latency, REM percentage, REM density, number of REM periods, and REM/NREM cycling, are usually preserved [46, 212].

Table 50.2 ICSD-2 diagnostic criteria for RBD

1. Presence of REM sleep without atonia: electromyographic finding of excessive amounts of sustained or intermittent elevation of submental electromyographic tone or excessive phasic submental or (upper or lower) limb electromyographic twitching
2. At least one the following is present:
   - Sleep-related injurious, potentially injurious, or disruptive behaviors by history
   - Abnormal REM sleep behaviors documented during polysomnographic monitoring
3. Absence of electroencephalographic epileptiform activity during REM sleep unless RBD can be clearly distinguished from any concurrent REM-related seizure disorder
4. The sleep disturbance is not better explained by another sleep disorder, medical or neurologic disorder, mental disorder, medication use or substance use disorder

In contrast, Schenck et al. [210] originally reported an increase in the proportion of SWS in patients with RBD. In one series, 80 % of patients over the age of 50 years had more than 15 % of sleep time spent in SWS. This was not associated with prior sleep deprivation. In the Mayo Clinic series, 33 % of patients over the age of 58 years had more than 15 % SWS [209]. These observations were confirmed in a comparison with age-matched controls: RBD patients demonstrated a higher percentage of SWS and more delta power in NREM sleep [213]. Patients with RBD also showed lower occipital beta power during REM sleep [214], as well as markedly higher theta power in frontal, temporal, and occipital regions, lower occipital beta power, and lower dominant occipital frequency during wakefulness [214].

Another polygraphic characteristic of RBD is the presence of periodic leg movements in sleep (PLMS). In a study of RBD and restless legs syndrome (RLS) patients, RBD patients showed a mean PLMS index of 39.5 per hour of sleep, a value not significantly different from the mean PLMS index found in patients with RLS [215]. In this study, 70 % of RBD patients had a PLMS index greater than 10. This percentage is similar to the prevalence of PLMS previously reported in RLS patients and significantly higher than the prevalence rate found in healthy subjects of the same age [216]. One difference between RLS and RBD patients, however, is that the periodicity of leg movements was shown to be lower in RBD patients compared to that of patients with RLS [217]. Another more important difference is that, in RBD patients, PLMS occurred mainly during REM sleep [215]. This is most likely due to the lack of motor inhibition during REM sleep in this condition, and this suggests that PLMS have a different pathophysiologic basis in RBD. Also, PLMS were significantly less likely to be associated with microarousals in RBD compared to RLS patients [216], and a markedly reduced amplitude of cardiac response was found in patients with RBD [215]. These findings suggest the presence of dysautonomia and/or reduced cortical reactivity in RBD.

Until recently, the diagnosis of RBD was based on clinical manifestations; PSG recordings of patients were not necessary for diagnosis. However, there are some limitations in using clinical criteria only. RBD-like features can occur with other sleep conditions, such as obstructive sleep apnea syndrome, sleepwalking, night terrors, and sleep-related seizures. Therefore, it is important to ensure that behavioral manifestations occur exclusively during REM sleep. In addition, PSG allows the detection of subclinical forms of RBD, such as REM sleep without atonia, which can be

observed in the absence of behavioral manifestations. In the ICSD-2 and ICSD-3, PSG features are essential (see also Chap. 27) to the RBD diagnosis [2]. The first essential criterion is the presence of REM sleep without atonia, that is, the EMG finding of excessive amounts of either sustained or intermittent elevation of submental EMG activity or excessive phasic submental or limb EMG twitching. The second criterion is the presence of either sleep-related injurious or disruptive behaviors by history, or abnormal REM sleep behaviors documented during PSG recording. Time-synchronized video recording is essential for helping to establish the diagnosis of RBD during PSG. The last two criteria are the absence of epileptiform activity during REM sleep and the absence of other sleep disorders or medical or neurologic disorders that could better explain the sleep disturbance.

One limitation of these new criteria was the absence of a validated and universally accepted method for scoring REM sleep in RBD. Assessing REM sleep without atonia by using standard criteria is impossible—muscle atonia is an essential defining criterion for REM sleep [218]. Montplaisir et al. [212] developed a scoring method for REM sleep based on the EEG and electro-oculography only (Table 50.3). In this method, the occurrence of the first REM is used to determine the onset of the REM sleep period. The termination of the REM sleep period is identified either by the occurrence of specific EEG features of a different sleep stage (K complexes, sleep spindles, EEG signs of arousals), or by the absence of REMs for 3 consecutive minutes. Then, tonic and phasic components of REM sleep are scored separately. Each epoch is scored as tonic or atonic depending on whether tonic chin EMG activity is present for more or less than 50 % of the epoch duration. Phasic EMG density is also scored from the submental EMG recording and is expressed as the percentage of mini-epochs (2 or 3 s depending on epoch duration of 20 or 30 s) containing phasic EMG events. Using this method, the following criteria have been proposed to diagnose RBD patients: chin EMG tonic density ≥ 30 % or phasic chin EMG density ≥ 15 %. Although some night-to-night variability in REM atonia has been shown [219], these cutoffs show a high degree of sensitivity and specificity. A study investigating 11 different muscles showed that upper limb muscles provided the highest discriminative power for RBD diagnosis, even higher than that of the chin EMG [220]. Computer-assisted scoring methods have also been developed (see [221] for a review of the various EMG scoring methods for RBD).

Finally, validated questionnaires have also been put forth to either help screen patients [222, 223] or diagnose RBD [224, 225] and assess its severity for large-scale epidemiological studies.

Associated Factors (Idiopathic and Secondary RBD) and Pathophysiology

RBD may be associated with a great variety of medical conditions or with the use of various psychotropic medications. Therefore, RBD has been divided into primary and secondary forms [1]. Primary or idiopathic RBD is diagnosed when none of the conditions listed for secondary RBD is present. Potential risk factors for idiopathic RBD have nonetheless been identified; they include smoking, head injury, pesticide exposure, and farming [226].

Secondary RBD has been classified into acute and chronic subtypes depending on the time course of clinical manifestations [2]. Acute RBD is usually associated with intoxication or withdrawal from psychotropic substances. Abuse of caffeine, tricyclics antidepressants, biperiden, and monoamine oxidase inhibitors have been reported to trigger episodes of acute RBD as well as withdrawal from alcohol or from medications such as meprobamate, pentazocine, barbiturates, and nitrazepam (for review, see [92]). Chronic secondary RBD may occur during long-term use of several medications: cholinesterase inhibitors, monoamine oxidase inhibitors, tricyclic antidepressants, or newer serotonergic agents such as fluoxetine, paroxetine, citalopram, sertraline, and venlafaxine (for review, see [227]). RBD has been reported in patients with psychiatric disorders, and several

Table 50.3 Polysomnographic scoring criteria for RBD

REM sleep onset	Occurrence of the first REM
REM sleep termination	Occurrence of a specific EEG feature of another sleep stage (K complex, sleep spindle, EEG sign of arousal) *or* absence of REMs for 3 consecutive minutes
Muscle atonia	Each 30-s epoch is scored as tonic or atonic depending on whether chin EMG activity is present for more or less than 50 % of the epoch duration. Presence of EMG activity is defined by chin EMG amplitude at least twice that of the background or greater than 10 μV
Phasic EMG activity	Percentage of 3-s mini-epochs containing chin EMG events. EMG events are defined by any burst of EMG activity lasting 0.1–5 s, with amplitude exceeding 4 times the amplitude of background EMG activity
REM density	Percentage of 3-s mini-epochs of REM sleep containing at least one REM

Modified from Montplaisir et al. [212]
EEG electroencephalogram; *EMG* electromyographic; RBD REM sleep behavior disorder; *REM* rapid eye movement

indices suggest that use of psychotropic drugs might not be the only cause of the RBD symptoms in this population [228]. Secondary RBD can occur in association with narcolepsy [229, 230], especially narcolepsy with cataplexy and hypocretin deficiency [231], and other neurologic disorders, such as olivopontocerebellar degeneration, ischemic cerebrovascular disease, multiple sclerosis, Guillain–Barré syndrome, Shy–Drager syndrome, and Arnold–Chiari malformation [92]. Finally, RBD is strongly associated with neurodegenerative diseases, especially the synucleinopathy subtype [232–236], which includes Parkinson's disease (PD), dementia with Lewy bodies (DLB), and multiple system atrophy (MSA). In a sleep laboratory study, one-third of patients with PD (11/33) had RBD based on PSG criteria [232]. Of note, a video-monitored PSG study revealed that patients with PD show a striking improvement of their movements during their RBD episodes (compared to wakefulness) almost as if they were disease-free [237]. RBD has been shown to coexist, albeit to a lesser extent, with Alzheimer's disease [238] and progressive supranuclear palsy [239], two tauopathies.

Patients with primary (or idiopathic) RBD are, conversely, at high risk of developing a neurodegenerative disease. As more patients with so-called idiopathic RBD are studied in a longitudinal manner, it is becoming increasingly clear that most patients will eventually develop neurodegenerative disorders, especially PD or DLB. Initially, Schenck et al. [233] had found that a parkinsonian syndrome developed in 38 % of 29 patients with idiopathic RBD after 5 years of follow-up. Seven years later, 65 % of patients from the same cohort had developed a parkinsonian syndrome [240]. Now, two prospective studies have estimated that up to 82 % of the patients with iRBD will eventually develop a neurodegenerative disease at a 10 to 16-year follow-up [241, 242]. It was shown that symptoms of RBD can precede the initial manifestation of synucleinopathies by up to 50 years [243]. Since RBD patients are at risk of developing PD, studies have looked at a variety of potential early markers of PD in patients with idiopathic RBD who were free of parkinsonism. Multiple dysfunctions have been described in the last 10 years for idiopathic RBD patients (Fig. 50.4), such as olfactory and color identification deficits [244], decreased motor speed [245], EEG slowing [214], mild dysautonomia [215, 246–250], subtle neuropsychological dysfunctions [214, 251–255], and brain perfusion anomalies [256–258]. These abnormalities are similar to those found in early stages of PD [259] and many are good predictors of conversion to PD with different prodromal period lengths and variable sensitivity and specificity (for review, see [260]). Finally, fluorodeoxyglucose positron emission tomography brain imaging of cognitively normal patients with dream-enacting behaviors revealed lower metabolic activity in several brain regions known to be affected in DLB [261]. In this respect, idiopathic RBD is considered a prodrome of neurodegenerative disease and, consequently, a form of neurodegeneration itself as the following paragraphs on pathophysiology demonstrate.

Due to the close association between RBD and PD, the striatal dopaminergic system was investigated as a possible candidate in the pathophysiology of RBD. Single-photon emission computed tomography showed a reduction in striatal dopamine transporters in patients with idiopathic RBD [262]. A reduced density of striatal dopaminergic terminals has also been shown with positron emission tomography [263]. In addition, there appeared to be a continuum of reduction in striatal dopamine transporters on single-photon emission computed tomography from patients with subclinical RBD to clinical RBD and finally to PD [264]. Moreover, a significant correlation was found between the percentage of REM sleep muscle atonia and striatal dopaminergic transmission [264], but not with thalamic cholinergic transmission [265]. However, the dysfunction of the nigrostriatal dopaminergic system is not likely the primary cause of RBD.

Animal studies using various methodological approaches (electrophysiology, lesions, and neuropharmacology) have shown that REM sleep muscle atonia results from the interaction of several neuronal systems located in the brain stem. Bilateral tegmentopontine lesions in animals can produce both a loss of muscle atonia and the presence of motor behaviors during REM sleep [266, 267], a model for human RBD. To produce RBD in animals, two different systems must be involved: the atonia system and the locomotor system. Lesions to the atonia system will produce only REM sleep without atonia, a phenomenon frequently encountered in neurodegenerative diseases and thought to be a form of incomplete RBD. To produce RBD in animals, the lesions should also involve the system that normally suppresses the brain stem motor generators during REM sleep. Therefore, RBD may result from a dysfunction in these two systems: either a loss of REM sleep atonia, excessive locomotor drive, or both [268]. Two different reviews of a large amount of animal physiological data recently proposed that the degeneration of the glutamatergic sublaterodorsal nucleus and of the GABA/glycinergic neurons located in the raphe magnus and gigantocellular reticular nuclei is at the heart of REM sleep without atonia in RBD patients [269, 270].

Neuropathologic and imaging studies of patients with RBD, associated with or without neurodegenerative disorder, also provide answers which are consistent with this hypothesis. Autopsied cases of RBD [66, 235, 241, 271, 272] revealed histopathologic anomalies (i.e., Lewy bodies, neuronal loss, or gliosis) in the locus coeruleus–subcoeruleus complex (the structure homologous to the sublaterodorsal nucleus in humans) and the substantia nigra for all patients and anomalies in the raphe, dorsal vagus, gigantocellular reticular, and pedunculopontine nuclei in

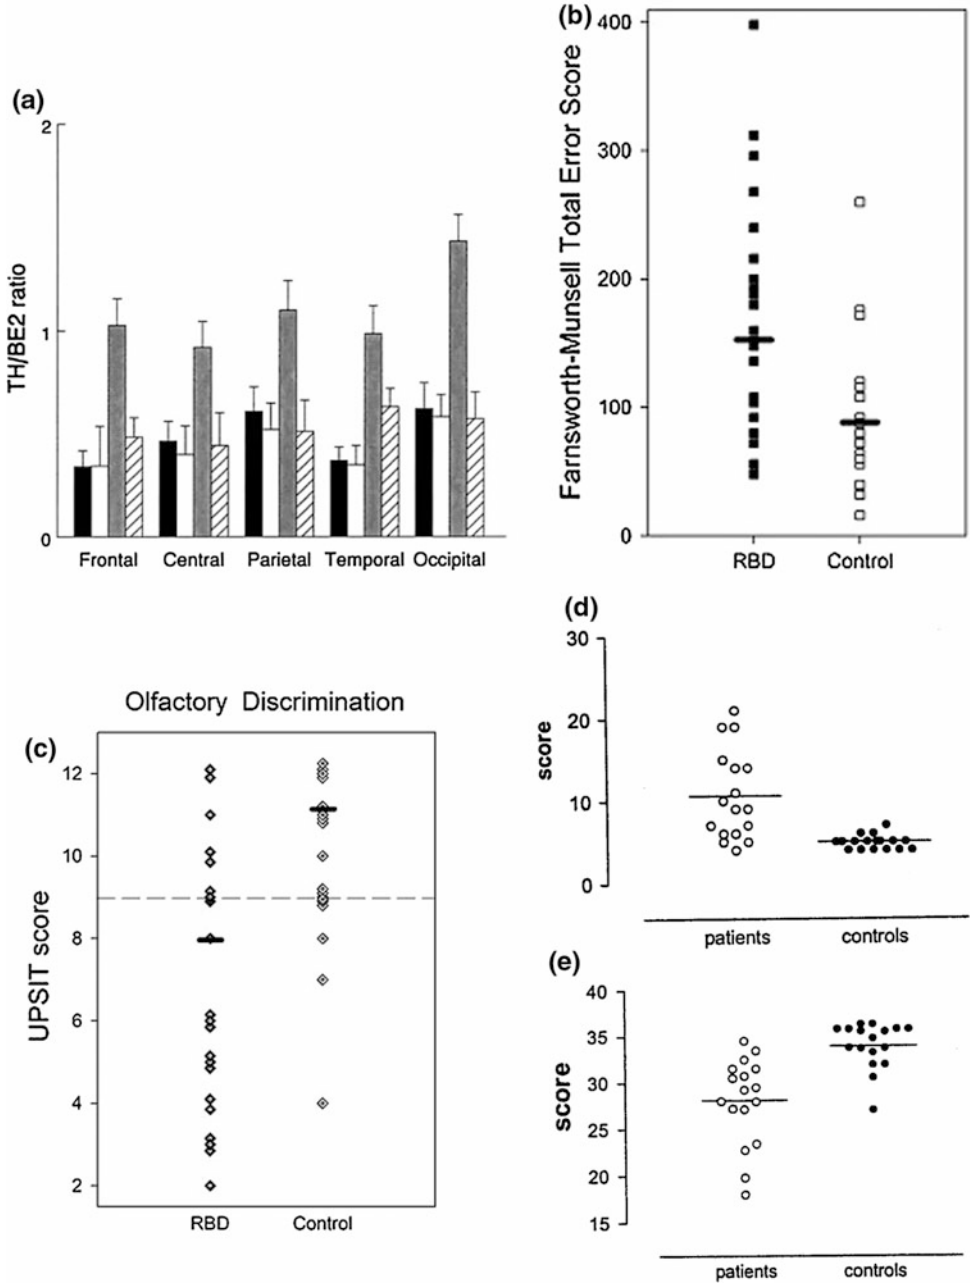

Fig. 50.4 Electroencephalographic changes and sensory and neuropsychological deficits associated with REM sleep behavior disorder (RBD). **a** Electroencephalographic slowing during wakefulness is indicated by a generalized increase in the theta/beta2 ratio in male RBD patients (*dark blue bars*) relative to male controls (*black bars*), female controls (*light blue bars*), and female RBD patients (*hatched bars*). **b** Visual discrimination deficits are apparent as higher error scores on the Farnsworth-Munsell 100-Hue Test for RBD patients. **c** Olfactory discrimination deficits are apparent as lower average scores on the University of Pennsylvania Brief Smell Identification Test. **d** and **e** Neuropsychological deficits are shown by higher error scores on the Corsi Supraspan Learning Test (**d**) and lower scores on the Rey-Osterrieth Complex Figure Design (**e**) (**a** reproduced with permission from Fantini et al. [214]. **b** and **c** reproduced with permission from Postuma et al. [403]. **d** and **e** reproduced with permission from Ferini-Strambi et al. [253])

most patients. Magnetic resonance imaging revealed ischemic lesions in pontomesencephalic regions in three patients with RBD [273]. Other studies have also demonstrated that tumor, ischemic infarct, or surgery in the pontine region are sufficient to trigger RBD [274–277].

In conclusion, in humans there are probably different anatomical and neurochemical (GABAergic, dopaminergic, cholinergic) dysfunctions that, alone or in combination, could lead to RBD. This could account for the efficacy of various families of medications.

Prevalence

The overall prevalence of RBD remains largely unknown. A large telephone survey assessing violent behaviors during sleep in the general population (15–100 years of age) suggested a prevalence of about 0.5 % [278]. Another study of 1034 individuals (70+ years of age) in the Hong Kong area found a prevalence of PSG-confirmed RBD of 0.4 % [279]. However, these studies screened only for people who suffered sleep injury inclusion of those without injury [280] would likely result in a higher prevalence rate [281]. To that effect, a sleep laboratory study in a population-based sample of 348 individuals 60 years and older found a prevalence of PSG-confirmed RBD of 2.01 % [282]. There is a male predominance (87 %) with primarily men over the age of 50 being affected [174]. When RBD is triggered by antidepressant medications, demographics include younger patients and more women [283]. A certain degree of familial aggregation was recently revealed for RBD by a multicenter study. A positive family history of dream enactment behaviors was found in 13.8 % of iRBD patients compared to only 4.8 % for controls (odds ratio = 3.9, 95 % confidence interval 2.0–7.7) [284].

Treatment

Since 2010, a best practice guide for the treatment of RBD is available [165]. This guide is based on numerous reports of case series of RBD treated with a variety of medications; there are no large randomized double-blind clinical trials. In addition, many of these reports have important methodological limitations and few have included PSG assessments.

Clonazepam, a sedating benzodiazepine, is considered the treatment of choice for RBD. Two large case series have reported substantial improvement in a majority of patients treated with clonazepam [209, 210]. In most cases, a suppression of problematic sleep behaviors and nightmares was reported during the first week of treatment. Sustained efficacy was reported during long-term administration of up to 17 years [92], although some degree of tolerance did occur. Polysomnographic recordings revealed that clonazepam suppresses behavioral manifestations and decreases phasic EMG activity without restoring REM sleep muscle atonia [212]. Clonazepam was also shown to decrease NREM sleep instability in RBD patients [285]. The mechanism of action of clonazepam is unclear but likely results from its serotonergic properties [286]. This hypothesis is based on observations made in animals where selective destruction of brainstem serotonergic neurons produced a disinhibition of REM sleep phasic activity and triggered hallucinatory behaviors, whereas the administration of serotonin inhibited motor activity in several experimental designs [287, 288]. However, clonazepam is ineffective in approximately 10 % of patients [209, 210]. In addition, some patients experience serious side effects, such as an increased risk of confusion and falls in elderly individuals [289] and a worsening of sleep-related respiratory disturbances in patients with obstructive sleep apnea syndrome [290]. Therefore, alternative treatments must be considered.

A 6-week open-label trial of 3 mg of melatonin given 30 min before bedtime demonstrated a dramatic clinical improvement in five of six RBD patients [291]. A PSG recording showed a significant restoration of REM sleep muscle atonia without any significant reduction of phasic motor activity. This initial observation was confirmed in a study of 15 idiopathic RBD patients treated with melatonin 3–9 mg [292]. These authors noted a nearly threefold suppression of REM sleep tonic activity after melatonin therapy. More recently, Boeve et al. [293] looked at the efficacy of melatonin (3–12 mg) in 14 patients with RBD associated with neurologic conditions. RBD was controlled in six patients, significantly improved in four, and initially improved but subsequently returned in two. No improvement occurred in one patient and increased RBD frequency/severity occurred in one patient. Melatonin and clonazepam were recently compared in a clinical practice setting, and it was concluded that both treatments were comparably effective in reducing RBD behaviors and injuries. However, adverse effects were reported less frequently with melatonin than with clonazepam [294]. In summary, melatonin can be considered as an alternative therapy in both idiopathic and secondary RBD, but long-term, controlled trials are needed to ascertain the efficacy of melatonin in this condition. The mechanism of action of melatonin in RBD is still unknown; it appears that melatonin restores REM sleep muscle atonia, whereas clonazepam exerts its therapeutic effect by suppressing phasic motor activity.

Another drug family was shown to produce therapeutic benefit in RBD. Indeed, some studies of acetylcholinesterase inhibitors (donepezil and rivastigmine) demonstrated increased sleep quality and reduced motor events in patients with idiopathic RBD [295] and in patients with RBD associated with DLB [296–298]. However, neither of these studies used PSG recordings to confirm treatment efficacy. Other studies of patients with RBD associated with DLB did not find any change in the frequency or the severity of RBD symptoms with donepezil [293, 298].

Based on the strong association between RBD and PD, dopaminergic agents have been considered as a treatment of RBD. Pramipexole, a dopamine D_2 receptor agonist with a high affinity for D_3 receptors, was shown to reduce the intensity and the frequency of clinical motor events reported by patients and to decrease the number of simple motor manifestations seen on PSG video recordings [299, 300]. In neither of those studies was REM without atonia reduced. The second study postulated that the improvement in symptoms could rather be due to changes in dream content or dream frequency since the improvement observed

correlated with the reduction of REM density. A third study on 98 patients concluded that pramipexole was more effective for mild iRBD cases with a lower rate of REM sleep without atonia [301]. The therapeutic effect of pramipexole was not found in RBD associated with PD [302].

Finally, since injury to the patient or to the bed partner is the most common reason that brings patients to consultation, the treatment program should start with a discussion on risk of accidents, indication of sleeping in different beds and safety measures such as removal of dangerous objects in the room, protection of the windows, and placement of cushions around the bed or the mattress on the floor. These recommendations are important even in treated patients since cases of injuries were reported in patients apparently successfully treated for RBD.

Other Parasomnias

Sleep Enuresis

Clinical Presentation

Sleep enuresis is characterized by recurrent involuntary voiding during sleep at least twice a week among individuals who are at least 5 years of age [2]. If the child has never been constantly dry during sleep, it is considered primary. Sleep enuresis is secondary when the child (or adult) had been previously dry for at least 6 consecutive months and started wetting at least twice a week for at least 3 months.

A common belief among parents is that sleep enuresis is the result of sleeping too deeply. However, changes in sleep depth and sleep architecture have not been consistently demonstrated [303]. For most enuretic children, voiding occurs in the first half of the night and is not associated with a specific sleep stage [303]. Conversely, a PSG study has demonstrated that enuretic boys are more difficult to arouse from sleep than are age-matched controls [304].

Associated Factors and Pathophysiology

A three-system model has been proposed to explain enuresis, which has wide clinical appeal [305]. It identifies three processes that alone or in combination can engender nocturnal enuresis: (1) increased nocturnal urine production due to lack of arginine vasopressin release during sleep; (2) overactivity of the bladder (uninhibited bladder contractions) or low functional bladder capacity; and (3) decreased perception of full bladder sensations during sleep [306]. Tachycardia and short EEG arousals are often present prior to enuretic events [303].

Some evidence indicates that bed-wetting may reflect delayed development of the central nervous system. It has been shown that premature and/or low-birth-weight children were bed-wetting more often than normal-birth-weight children [307, 308]. Moreover, several studies or clinical observations have suggested an association between bed-wetting and developmental delays in motricity, [309, 310] language [310–313], physical growth [311], and skeletal maturation [314, 315]. Microstructure abnormalities were found in the thalamus, medial frontal gyrus, anterior cingulate cortex, and insula of enuretic children [316]. The authors propose that, since these regions are involved in micturition control, a developmental delay in these areas may be the cause of nocturnal enuresis. The full intelligence quotient (IQ), the verbal IQ, and the performance IQ appear to be normal in older enuretic children, but impairments in memory and attention were reported, together with some structural abnormalities of the right dorsolateral prefrontal cortex and left cerebellum [317].

Children with nocturnal enuresis show a higher prevalence of sleep problems, such as disorders of initiating and maintaining sleep, excessive daytime somnolence, sleep-disordered breathing, disorders of arousals, and disorders of the sleep–wake transition [318]. Obesity is a risk factor for nocturnal enuresis in children and adolescents [319]. Enuresis is not linked with anxiety in preschoolers [82] but is in older children [320, 321]. However, anxiety is more likely a consequence than a cause of enuresis, brought about by perplexity or a sense of immaturity, humiliation, social embarrassment, or fear of detection. Similarly, lower scores on self-esteem and higher scores on depression were found in adolescents and adults with nocturnal enuresis [322].

Finally, hereditary factors have been recognized; it is inherited via an autosomal-dominant mode of transmission (for a review, see von Gontard et al. [323]). The odds ratios for severe child nocturnal enuresis were found to be 3.63 times higher in maternal and 1.85 times higher in paternal nocturnal enuresis [324].

Prevalence

In 5-year-old children, population-based studies [82, 312, 325] found a prevalence between 20 and 33 %. A male predominance in childhood prevalence is well established [80, 82, 312, 325]. Prevalence is 77 % when both parents were enuretic as children and 44 % when one parent was enuretic [326]. A Korean population-based study on the prevalence of enuresis in adolescents and adults found that 2.6 % of individuals had at least one episode in the last 6 months and 4.5 % had one in the last 12 months [322]. The percentage of people with at least one episode in the last 6 months was about the same for both genders (men = 2.1 %, women = 3.0 %) and for the different age groups: 16–20 years = 2.8 %, 21–25 years = 2.5 %, 26–30 years = 3.2 %, 31–35 years = 1.8 % and 36–40 = 2.6 %. Enuresis occurs in about 3 % of elderly women (65 years and older) and in 1 % of elderly men living at home [327].

Treatment

Practical guidelines and checklists for the diagnosis and management of enuresis now exist [328, 329]. Most cases of nocturnal enuresis can be treated with bedwetting alarms (devices that alert and sensitize the child to respond quickly to a full bladder by waking up) and by specific treatment programs integrating cognitive-behavioral elements [328, 329]. Concomitant counseling is always recommended. When bed-wetting is caused by lack of arginine vasopressin release during sleep, a pharmacologic intervention using desmopressin, a synthetic analog of vasopressin, can be indicated. The anticholinergic agent oxybutynin is preferred in cases in which the cause is bladder overactivity. Oxybutynin is a smooth muscle relaxant with specific effects on the bladder. Combining treatments is also possible when mixed causes are present (for review, see Butler [330]). In a meta-analysis of randomized trials for the treatment for enuresis (other than with desmopressin or tricyclics), bedwetting alarms were found to be more effective than amphetamine, oxybutynin, and oxybutynin plus holding exercises [331]. The treatment of nonmonosymptomatic nocturnal enuresis is more problematic (for review, see the standardization document from the International Children's Continence Society [332].

Sleep-related Bruxism

Clinical Presentation

An international consensus [333] was recently reached for the definition and grading of bruxism. The adopted definition is as follows "Bruxism is a repetitive jaw-muscle activity characterized by clenching or grinding of the teeth and/or by bracing or thrusting of the mandible. Bruxism has two distinct circadian manifestations: it can occur during sleep (indicated as sleep bruxism) or during wakefulness (indicated as awake bruxism)." This activity results in tooth wear, headaches, jaw dysfunction, and pain. However, it does not seem to affect occlusal and functional parameters [334].

The international group of experts proposes the following diagnostic grading system for both sleep and awake bruxism: possible (self-report), probable (self-report and clinical examination), and definite (self-report + clinical examination + PSG findings preferably with audio/video monitoring). The definitive diagnosis therefore rests on the presence of rhythmic masticatory muscle activity and grinding sounds during all-night PSG recording. Bruxism episodes most frequently occur in stages 1 and 2 but can occur in all stages [335, 336]. Surprisingly, bruxers have a normal sleep architecture and high sleep efficiency (>90 %) [335]. However, rhythmic masticatory muscle activity is associated with blood pressure surges during sleep [337].

Associated Factors and Pathophysiology

Various hypotheses have been put forward to explain sleep bruxism. The first one was changes in dental occlusion, but no strong evidence-based data support this hypothesis [338]. Orofacial morphology and temporomandibular disorders were shown not to be causal factors [339, 340]. Anxiety has been reported as a strongly associated factor in children [80, 341, 342], adolescents, and adults [343, 344]. Smoking also exacerbates bruxism [345]. A deficiency of the dopaminergic system has been implicated, but that remains to be confirmed since most randomized trials with dopaminergic medications have only marginally reduced sleep bruxism episodes [346, 347]. Finally, a 2013 meta-analysis revealed that bruxism can be triggered by esophageal acidification [348]. It also confirmed that bruxism has an important dose-dependent relationship with smoking and that disturbances in the central dopaminergic system are involved in the etiology of bruxism.

A clear sequence of cortical to cardiac activation preceding jaw motor activity in bruxism patients [349] suggests that sleep bruxism is secondary to microarousals. In fact, both microarousals and rhythmic masticatory muscle activity/sleep bruxism episodes were shown to increase concomitantly just before each REM sleep period [350]. Periodic limb movements during sleep, microarousals, and bruxism often occur concomitantly during sleep and in a time-linked manner [351]. It has been suggested that the sudden apparition of sleep bruxism is under the influence of brief and transient activity of the brainstem arousal–reticular ascending system contributing to the increase of activity in autonomic cardiac and motor modulatory networks (Fig. 50.5) [352].

Finally, as it is the case for many parasomnias, there is a strong genetic influence on bruxism in both childhood and adulthood [353]. Children of sleep bruxers are more likely to be affected than those of individuals who never had the problem or who suffer from daytime bruxism only [354]. Twin studies in bruxism have suggested that genetic factors account for half of the phenotypic variance [355] and are important to both the genesis and pattern of bruxism [356].

Prevalence

Sleep bruxism is common in childhood. However, prevalence estimates reported are variable between the studies due to the different age groups studied (for review on prevalence, see [357]). A longitudinal, population-based study found that the prevalence increases from 2.5 years to reach 33 % at 6 years of age [82]. Another population-based study found prevalence of 36.8 % for preschoolers and 49.6 % for first graders for a frequency of more than once a week [358]. Another longitudinal study reported a progressive decrease from age 10 to 13, attaining 9 % at age 13 [80]. A nationwide Japanese study of adolescents reported a low

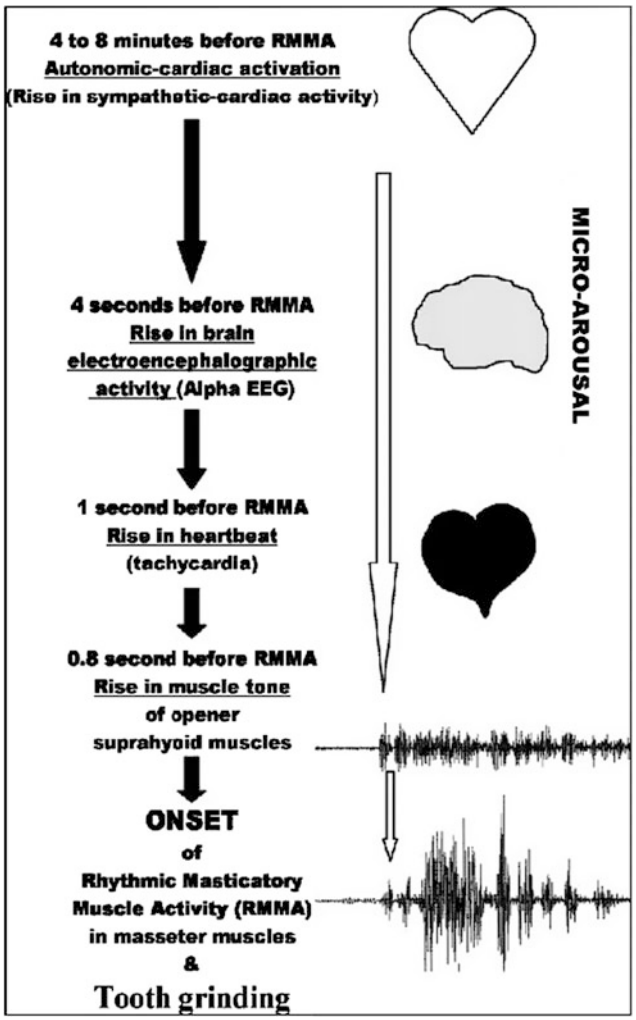

Fig. 50.5 Sequence of physiological events preceding rhythmic masticatory muscle activity (RMMA) associated with sleep bruxism (reproduced with permission from Lavigne et al. [352])

prevalence of 2.3 % in boys and 3.0 % in girls [359]. A self-reported adult prevalence around 8 % had been found in Canadian [360], European (UK, Italy [361]), Finnish [355], and Japanese [362] populations. Using a representative population of 1042 adults, the overall prevalence in Brazil was found to be 12.5 % if using questionnaires alone, 7.4 % when only PSG was used as diagnosis and 5.5 % when using both questionnaires and confirmation by PSG [363]. Usually, no striking gender difference is found for either children [80, 357] or adults [360]. The presence of sleep bruxism in childhood is highly predictive of bruxism in adulthood [353].

Treatment

A meta-analysis study evaluated randomized controlled studies of seven pharmacologic treatments and three oral devices [364]. The mandibular advancement device and clonidine are the most promising experimental treatments, although both are associated with adverse effects (discomfort for the device; REM suppression and morning hypotension for clonidine). Clonazepam appears to be an acceptable short-term alternative. Occlusal appliances (soft mouth guard, occlusal stabilization splint, splint with vibration) can protect orofacial structures. A PSG study comparing the efficacy of a stabilization splint and gabapentin showed significant reductions in the total duration of bruxism episodes per night and in the number of episodes per hour and per night with both treatments [365]. A recent randomized, double-blind, placebo-controlled, clinical trial reported that hydroxyzine was effective and well tolerated for treating bruxism in children [366]. Finally, the use of biofeedback technology as treatment for bruxism was reviewed and it was concluded that there is no strong evidence of efficacy [367].

Sleep-related Rhythmic Movement Disorder

Clinical Presentation

Sleep-related rhythmic movement disorder is characterized by the repetitive, stereotyped, and rhythmic activity of large muscle groups that occurs predominantly during drowsiness (sleep onset) or sleep [2]. It is largely a parasomnia of infancy and early childhood and usually disappears around age 10 [2]. The most frequent rhythmic movements are body rocking, head rolling, and head banging, although it can involve any body part. Body rocking may be difficult to distinguish from head banging because the former sometimes includes banging of the head into a solid object. The frequency of movements is more typically around 1 Hz (one per second) but can range from 0.5 to 2.0 Hz [368]. Episodes of rhythmic movement can last from a few seconds to more than an hour [368]. In most sufferers, they will occur nightly or almost every night [369]. The majority of episodes (around 80 %), at least for head banging, occur at sleep onset [369]. When appearing at sleep onset, rhythmic movements are considered to be a self-soothing or tension-releasing behavior linked with pleasurable sensations that have hypnotic properties. However, more violent movements, usually in cases of mental retardation, have been reported to cause head or eye injuries [370, 371].

Polysomnographic recordings show that rhythmic movement disorder can arise from REM sleep, NREM sleep, or sleep onset with persisting activity in light sleep [372]. Longer movements are usually observed at sleep onset and during stage 1 sleep, whereas shorter movements are seen in stages 2, 3, and 4 NREM sleep and in REM sleep [368]. Rhythmic movements are not preceded by EEG changes, as are nocturnal seizures, and do not provoke arousals or interrupt SWS even in older children [369, 373].

Associated Factors and Pathophysiology

There are reports of rhythmic movement disorder in association with other sleep-related problems such as RLS, which is associated with body rocking [374, 375], insomnia [376], and RBD [377, 378]. Familial forms are rare but have been reported [372, 376, 379]. Adult cases of rhythmic movement disorder are not usually associated with severe psychiatric disorders as previously believed [372], but a relationship with ADHD has been documented [368, 380]. Finally, some studies have reported daytime complaints such as attentional difficulties, sleepiness, morning headaches, fatigue, and poor concentration—and even more serious problems such as anxiety, depression, hyperactivity, and irritability [368, 372, 381]. Whether or not the daytime symptoms result from poor sleep caused by the rhythmic movements remains to be determined.

The etiology of rhythmic movement disorder is still unknown. The involvement of the central motor pattern generator in the genesis of motor phenomena during sleep has been suggested [382]. This network is involved in the control of early locomotor function [383] and is thought to be under the inhibitory control of the cortex. Immaturity of the inhibitory cortical system in early infancy might account for rhythmic movements occurring during sleep, coinciding with the acquisition of motor milestones.

Prevalence

This parasomnia is quite common in infancy but decreases rapidly in prevalence with increasing age. Incidences of 66 % at 9 months, 26 % at 2 years, and 6 % at 5 years had been reported using a sample of children [384], but an epidemiologic study reported lower incidences of about 6 % at 2.5 years, 3 % at 4 and 5 years, and 2 % at 6 years [82]. Body rocking was found to be present in 3 % of children ages 11–13 years [80]. Rhythmic movement disorder can persist into adulthood [372]. No gender difference has been demonstrated for childhood cases, but there is a male preponderance in adult cases [372].

Treatment

There are no systematic pharmacologic studies or behavioral trials for rhythmic movement disorder; it generally has a benign course and is not usually associated with a severe clinical picture. Benzodiazepines, especially clonazepam, or tricyclic antidepressants can be effective [379, 381, 385]. For rhythmic movement disorder associated with RLS in adulthood, pramipexole seems to be effective in alleviating both conditions simultaneously [375].

Somniloquy

Clinical Presentation

Somniloquy, also known as sleep talking, is defined as talking during sleep "with varying degrees of comprehensibility" [2]. Somniloquy is such a prevalent phenomenon that it is considered to be a normal sleep behavior, especially in childhood.

Somniloquy can arise from all sleep stages [386]. Since there are few systematic PSG studies, no clear profiles have been identified. However, EMG-induced artifact is common and may begin several seconds prior to, and continue several seconds following, verbalizations [387]. Temporary suspension of eye movements and occurrence of sustained alpha-EEG trains during REM sleep somniloquy episodes have also been noted [387], as has suppression of theta- and alpha-activity prior to utterances [388]. Episodes frequently occur in parallel with sleep mentation, but concordance between verbal utterances and ongoing dreamed speech may vary from isomorphic to completely absent [389].

Associated Factors and Pathophysiology

The pathophysiology is unknown. In addition, since somniloquy is so prevalent, it is virtually impossible to isolate predisposing factors. Nonetheless, a clear genetic influence has been demonstrated [390]. Somniloquy is also the parasomnia that most often co-occurs with other parasomnias. It often accompanies the behavioral manifestations of either RBD or somnambulism. Stereotyped vocalizations can also be heard during nocturnal seizures. Recently, somniloquy (especially loud sleep talking) has been found helpful in the differential diagnosis of DLB versus Alzheimer's disease and other forms of dementia [391]. In most cases, however, somniloquy is idiopathic.

Prevalence

Although considered the most frequent parasomnia, somniloquy is usually without consequences and thus rarely a reason for consultation. Its prevalence among preschoolers (84 %) [82] is much higher than among older children and adolescents. A prevalence of 30 % was found for children ages 11–13 years using prospective reports [80], while in adults, an estimate of 24 % was found using a telephone sampling method [278]. A current prevalence of 17.7 % and a lifetime prevalence of 66.8 % were found for adults in a recent population-based Norwegian telephone interview study [392]. There is no apparent gender difference.

Treatment

There is no known treatment for somniloquy. It is usually considered too benign to treat.

Sleep-related Groaning

In ICSD-3 (see Chap. 27) this is classified under sleep related breathing disorder as an isolated symptom.

Clinical Presentation

Sleep-related groaning, also known as catathrenia, is defined as "a chronic, usually nightly, disorder characterized by expiratory groaning during sleep, particularly during the second half of the night." [2] Groaning or moaning sounds typically begin 2–6 h after sleep onset. The sounds produced are usually loud, but the pitch and timbre vary among individuals: groaning, loud humming, roaring, and high-pitched sounds have all been observed. The length of each groaning period was observed to be between 11 and 168 s [393]. By contrast, within individuals, the type of sound is usually fairly constant. Catathrenia is not associated with abnormal motor activity and is qualitatively different from somniloquy. Degree of concordance with sleep mentation is unknown. The affected individual is usually unaware of the problem and, apart from occasional complaints of daytime sleepiness, typically has no other sleep complaints. However, production of the sounds may disturb the bed partner. The identification of this disorder is relatively new, with less than 50 cases reported in the literature [394–398].

Catathrenia occurs during either REM or NREM sleep, but episodes arise predominantly from REM sleep [395]. Three-quarters to all of the groaning events occur in REM sleep, and most of the events were associated with arousals; the latter were preceding or coinciding with the groaning [393, 399]. Polysomnographic tracings reveal bradypneic events, often occurring in clusters, with deep inspirations followed by long expirations and monotonous vocalization (Fig. 50.6). There is a high night-to-night consistency of the groaning episodes [394]. Although catathrenia is associated with bradypneic events, only one [396] of the reported cases had significant obstructive apnea–hypopnea, and oxygen saturation remained above 90 % across the night; body position does not seem to have any influence [395]. In addition to the typical absence of apnea–hypopnea, the subjects are reportedly slim and young [398, 400, 401]. Whereas the loud sounds of snoring or obstructive sleep apneas occur during the inspiratory phase, the vocalizations of catathrenia occur during expiration. Unlike sleep apnea, sleep architecture for nocturnal groaners is usually preserved. However, a few patients will show either reduced total sleep time combined with reduced sleep efficiency, or a reduction of either slow-wave or REM sleep [395].

Associated Factors and Pathophysiology

No particular anomaly was found on neurologic and physical (including otorhinolaryngologic) examination, on routine laboratory testing, or in the medical history [394, 395, 398]. The close temporal association between microarousals and groaning episodes points to the involvement of arousal activation mechanisms in the pathogenesis of this parasomnia [399]. Bruxism is sometimes found in association with catathrenia [399, 402]. As is the case for many parasomnias, catathrenia is, at least in part, genetically determined. In about 15 % of cases, there is at least one family relative also affected, sometimes in a way consistent with an autosomal-dominant pattern of inheritance [395].

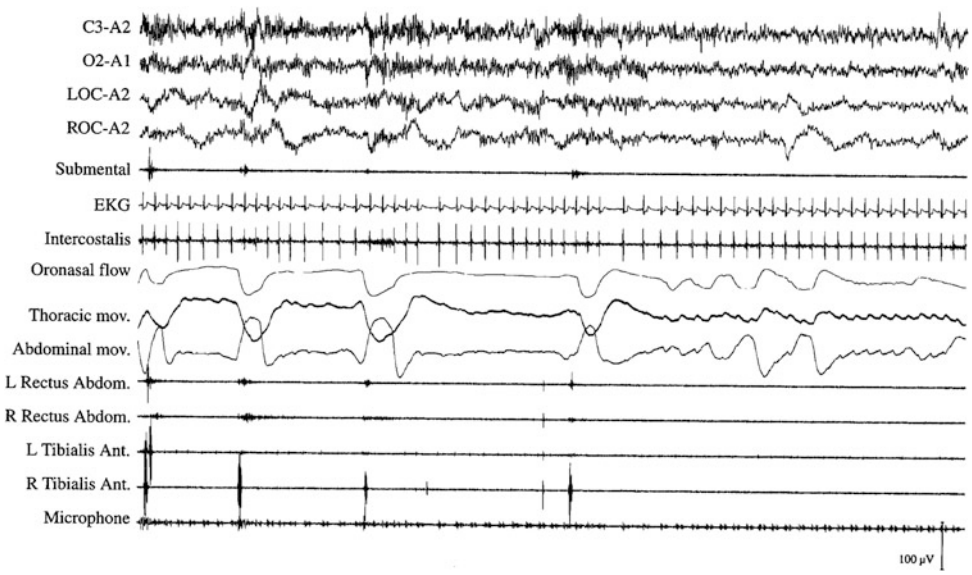

Fig. 50.6 PSG recording of a nocturnal groaning episode. A deep inspiration is followed by a short expiration and long, relatively flat period of reduced breathing during which the vocal groan is heard (reproduced with permission from Oldani et al. [395]

Prevalence

Nocturnal groaning represents less than 1 % of the population consulting at a sleep disorder center [393, 395]. However, since this parasomnia is without major consequences, there are probably a large number of affected individuals who do not seek medical help. It appears to be three times more prevalent in men than in women, although too few cases have been reported so far to be able to determine the gender ratio accurately. Onset is habitually during adolescence or early adulthood, and the parasomnia persists for several years [395]. The precise time course of the condition is unknown due to lack of follow-up on this recently identified condition.

Treatment

A few bedtime treatments have been tried with no sustained therapeutic effect: clonazepam, gabapentin, pramipexole, carbamazepine, trazodone, paroxetine, and dosulepin [394, 395]. Treatment with nasal continuous positive airway pressure produced inconsistent effects [394, 397, 400].

Conclusion

As stated in the DSM-5, some parasomnias, such as the disorders of arousal and RBD, "serve as a reminder that sleep and wakefulness are not mutually exclusive and that sleep is not necessarily a global, whole-brain phenomenon" [1].

Sleep Disorders in the Elderly

51

Sudhansu Chokroverty

Introduction

To understand sleep disorders of the elderly, it is important to know what changes in sleep structure and sleep cycle are normal in disease-free-aged individuals. It is also important to understand the neurology of aging and, in particular, changes in central nervous system (CNS) physiology and morphology in normal healthy older individuals.

In 1900, 4 % of the American population was older than age 65; according to the best current estimate, that figure was 13 % in the year 2000 and will be 21 % by 2050 [1]. It is the life expectancy that has been increasing rather than the human life span, which is determined biologically and genetically and remains fixed [2]. We do not know what determines aging and the changes associated with aging (see Behnke et al. [3] and Comfort [4] for a review of this topic). Older individuals are at risk for sleep disturbances owing to a variety of factors, including social and psychosocial problems; increasing prevalence of concurrent medical, psychiatric, and neurologic illnesses; increasing use of medications (often sedative hypnotics) and alcohol; and alterations in circadian rhythms.

Neurology of Aging

Clinical Aspects of Central Nervous System Changes

Before discussing the neurology of aging, it is important to define what is meant by *aging*. No standard definition is available, but for this discussion I arbitrarily define age 65 as the start of old age. A normal elderly person is one who is free of obvious diseases of the central and peripheral neurologic systems as well as of general systemic diseases (e.g., cardiovascular, respiratory, renal, metabolic, hematologic, skeletal, and muscular diseases). Accepting this definition, a variety of changes in mental functions and the general nervous system of healthy elderly individuals have been noted. At the outset, I must point out certain difficulties in studying the neurology of aging. It is difficult to get a large number of elderly subjects who meet the criteria by being free of neurologic and other systemic disorders. Even if a number of such subjects can be recruited, without many years' subsequent longitudinal study, it often remains problematic to decide whether certain abnormal findings are related to a subclinical affliction of the nervous system that is expressed in overt manifestations later in life [5]. A large number of elderly individuals have general medical and neurologic disorders, particularly mild cognitive impairment (MCI) and dementia of the Alzheimer's type. In addition, there could be subclinical cerebral infarction, as noted in large series of autopsy examinations [6] in which half the individuals with cerebral infarction remained asymptomatic. The following discussion of the neurologic changes of normal aging is written with these limitations in mind.

A variety of physiological changes occur in the CNS which increase with aging. On mental function examination, the most striking changes in old age are in learning new information and in central processing of information [5]. In the Wechsler Adult Intelligence Scale [7], the performance scale declines much more rapidly than the verbal tests [5, 8]. This has been confirmed in several cross-sectional and longitudinal studies comparing young and old individuals [7–11]. The past and the immediate memory remain relatively intact until approximately the middle 70s, but recent memory is impaired. There is often forgetfulness and difficulty remembering names and remembering several objects at one time, which suggests impairment of central processing time. Speed of learning is retarded, as is speed of processing new information [5]. The reaction time to simple and complex stimuli is often delayed, and there is

impairment of motor speed [12–16]. The cognitive impairment of the normal elderly is often termed *benign forgetfulness of senescence* [17] or *age-associated memory impairment* [18, 19]. The term MCI defines a transitional state between physiological aging and dementia [20]. It has been suggested that age-associated cognitive and other neurological changes may be mediated through subtle microvascular-induced damage to cerebral white matter as noted in neuroimaging [21]. In the Baltimore longitudinal study of aging, the investigators using serial imaging assessments sought to determine changes in cortical thickness in a cohort of 66 older adults (ages 60–84) without dementia over a mean follow-up of eight years [22]. They found widespread age-related decline in cortical thickness with an anterior–posterior gradient (frontal and parietal regions showing greater rates of decline than temporal and occipital areas). At the cellular level, researchers documented marked reduction in firing of prefrontal cortex (PFC) neurons with advancing age [23]. It is notable that the cognitive decline in normal aging (e.g., executive dysfunction, forgetfulness, distractibility) is thought to involve dorsolateral PFC dysfunction. The investigators had also shown that this age-related decline in the firing rate can be partially rescued by addressing molecular aspects of PFC circuits (e.g., by inhibiting cyclic-AMP signaling or by blocking HCN or KCNQ potassium channels).

In a classic paper in 1931, Critchley [24] first directed attention to certain changes in the nervous system of normal healthy elderly individuals. Since then, several studies have appeared in the literature documenting the presence of abnormal neurologic signs in a small number of such people [25, 26], but these signs may represent asymptomatic subclinical disease [5] (e.g., cerebrovascular disease or cervical spondylosis), and without longitudinal studies, it is impossible to exclude these definitely. Despite this limitation, there is a general consensus about the presence of certain findings in normal elderly individuals. There are changes in both the somatic and autonomic nervous systems (ANS) [5, 27, 28]. In the somatic system, an important finding is impairment of gait and stance [5, 29, 30]. It is difficult to stand on one leg with the eyes closed [25, 26, 30]. The so-called senile gait is characterized by stooped flexed posture accompanied by short steps, reduced arm swings, shortening of the stride, and impaired speed and balance [2, 5, 29]. The gait resembles that of patients in the early stage of Parkinson's disease, which may be due to the loss of dopaminergic neurons and striatal dopamine receptors [5, 29]. Grip strength declines with age [26]. The ankle reflex may be diminished, which may be related to the loss of large-diameter nerve fibers [5]. In the sensory examination, the striking abnormality is impairment of the vibration sense in the lower extremities [26]. Rowe and Troen [31] suggested that old age represents a hyperadrenergic state. If this is the case, sympathetic overactivity may explain some of the changes noted in the cardiovascular reflex, galvanic skin response, erection, maturation, and pupillary response of elders. Overactivity of the sympathetic nervous system may also interfere with cognitive function.

Physiologic Changes in Old Age

Electroencephalographic Changes

Awake Electroencephalography

The question remains whether electroencephalography (EEG) changes in old age are maturational changes or are related to pathologic alterations of the CNS. Many elderly individuals are afflicted with a variety of dementing illnesses, cerebrovascular disease, or systemic medical disorders that may cause metabolic encephalopathy [32]. Thus, it is important to select healthy elderly individuals who are free from any of these diseases for EEG study. Such a selection was made in the study of healthy septuagenarians by Katz and Horowitz [33]. The subjects were screened by careful neurologic, psychiatric, and neuropsychological examination and found to represent normative EEG data with an average alpha frequency of 9.8 Hz similar to that of young and middle-aged adults. This study can be contrasted with the report by Torres et al. [34], in which they found that 52 % of a group of normal volunteers with a mean age of 69 years had mild-to-moderate EEG abnormalities.

Obrist [35] summarized the EEG changes in old age as follows: slowing of the alpha rhythm and an increase in fast activities, diffuse slow activity, and focal slow waves. In an important longitudinal study by Obrist et al. [36], alpha frequency fell from 9.4 Hz at age 79 to 8 Hz intermixed with 6- to 7-Hz theta waves at age 89. Spectral analysis by Matejcek [37] and Nakano et al. [38] supported the progressive slowing of the alpha rhythm with aging. Duffy et al. [39] found no significant change in the frequency of the posterior EEG rhythm in a study of 63 men between 30 and 80 years of age. Oken and Kaye [40] analyzed conventional EEG and computerized EEG frequency in 22 extremely healthy subjects between 84 and 98 years old. The posterior peak frequency was higher than 8 Hz in those younger than 84, but between 7 and 8 Hz in 5 of 22 subjects older than 84 years. Alpha slowing appears to be related to the decline in mental function, which may be an early stage of progressive dementia of old age [41]. Alpha blocking and photic driving response to intermittent photic stimulation are also diminished in old age [42]. These findings may be related to the structural CNS alterations in elderly individuals (see *Pathologic Central Nervous System Changes of Normal Aging* later).

An increase in fast activity was noted by Busse and Obrist [43] in elderly volunteer community subjects, especially women. In an EEG spectral analysis, Brenner et al. [44] found more beta activities in elderly women than men. Kugler [45] also reported an increase in fast activity with the increase in age. The significance of this is uncertain, but Kugler [45] stated that the presence of fast activity in old age correlates with preserved mental functioning.

Intermittent focal slow waves in the temporal regions (particularly in the middle and anterior temporal regions and greater on the left side) are noted in 17–59 % of healthy elderly individuals (Fig. 51.1) [34, 35, 40, 46–48]. This temporal slow activity may be accompanied by sharp transients, which may be related to cerebral vascular disease causing asymptomatic small infarction of the temporal lobe [41], ventricular enlargement with cerebral atrophy [49], or white matter hyperintensities on magnetic resonance imaging (MRI) [40]. Klass and Brenner [50] listed some of the characteristics of what they called *benign temporal delta transients of the elderly* as follows: slow waves occur in patients older than 60 years and are maximally noted in the left temporal, particularly anterior temporal, region; the voltage is usually less than 70 μV, and these waves do not disrupt background activity; these delta transients are attenuated by mental alerting and eye opening and are increased by drowsiness and hyperventilation; the transients generally occur as single waves or in pairs but not in rhythmic trains; and the transient waves are present for up to 1 % of recording time. The elderly may also have an increased amount of theta activity [46, 51].

There is no clear relationship between intellectual deterioration and EEG slowing [35, 40]. Whether the EEG changes are correlated with cerebral blood flow (CBF) study remains controversial. There is no correlation, however, between areas that show the maximum blood flow reduction and those that show prominent EEG slowing, or between the blood flow changes and the alpha frequency changes in normal elderly subjects [52, 53]. The other suggestion is that the alpha slowing is related to the loss of choline acetyltransferase, the enzyme for synthesis of acetylcholine [5].

Sleep EEG Changes, Including Changes in Sleep Architecture and Organization

In addition to awake EEG changes, there are changes during sleep in the elderly (Box 51.1) [54, 55]. As early as 1945, Liberson [56] described paroxysmal bursts of sleeplike EEG lasting 1–10 s in the eyes-resting state in elderly subjects, and the incidence of these bursts increased with the age of the subject. Liberson [56] termed these episodes *microsleeps*. Transient bursts of anteriorly dominant rhythmic delta waves are often noted in elderly subjects in the early stage of sleep. Gibbs and Gibbs [57] used the term *anterior bradyrhythmia* for this finding. Katz and Horowitz [58] obtained sleep-onset frontal intermittent rhythmic delta activity in normal elderly subjects, which should be differentiated from that associated with a variety of neurologic disorders. These are highly stimulus-sensitive and disappear in deeper stages of sleep. In demented elders, however, one can see diffuse slow waves in the delta and theta frequencies.

Box 51.1 Age-related changes in EEG and Sleep Architecture

- Awake EEG
  - Progressive slowing of alpha frequency
  - Occasional focal temporal (left > right) sharp and slow transients
- Sleep Architecture
  - Reduced slow-wave sleep
  - Reduced sleep efficiency
  - Decreased night sleep time
  - Decreased sleep spindle density (number per minute), frequency, and amplitude
  - Decreased REM density (number of eye movement bursts per minute of REM sleep), but the percentage of REM sleep seems unaltered
  - Sleep fragmentation with multiple awakening including early morning awakening and arousals
  - Advanced circadian phase.

Normal elders show normal sleep patterns with certain modifications (Box 51.1). The delta waves during slow-wave sleep (SWS) are reduced in amplitude and incidence [27, 59, 60]. The amplitude of delta waves decreases, and therefore, in the standard scoring technique, SWS decreases. Feinberg et al. [61] discussed this point and suggested that quantification of the amount of time spent in a specified frequency be used for scoring SWS in elderly individuals, rather than using an amplitude criterion. Mann and Roschke [62] in a later study using EEG frequency and cross-correlation analysis in a group of 59 healthy young and middle-aged men confirmed a significant decline of the delta/theta bands during NREM sleep but an increase in EEG power in beta frequency during rapid eye movement (REM) sleep with increasing age. Recent authors [63–65] also commented on the age-related decline in slow waves. Mander et al. [64] thought that prefrontal atrophy, disrupted NREM slow waves, and hippocampal-dependent memory in aging are all interrelated. Colrain and co-investigators reported a linear decline in amplitude of sleep-evoked delta waves across the adult lifespan. This reduction in amplitude of delta waves could be related to the following factors: (1) reduction in neuronal synchronization in the neocortex [27, 58], (2) alterations in the skull [27, 60], (3) changes in the subarachnoid spaces [27, 60], (4) reduction in specific subpopulation

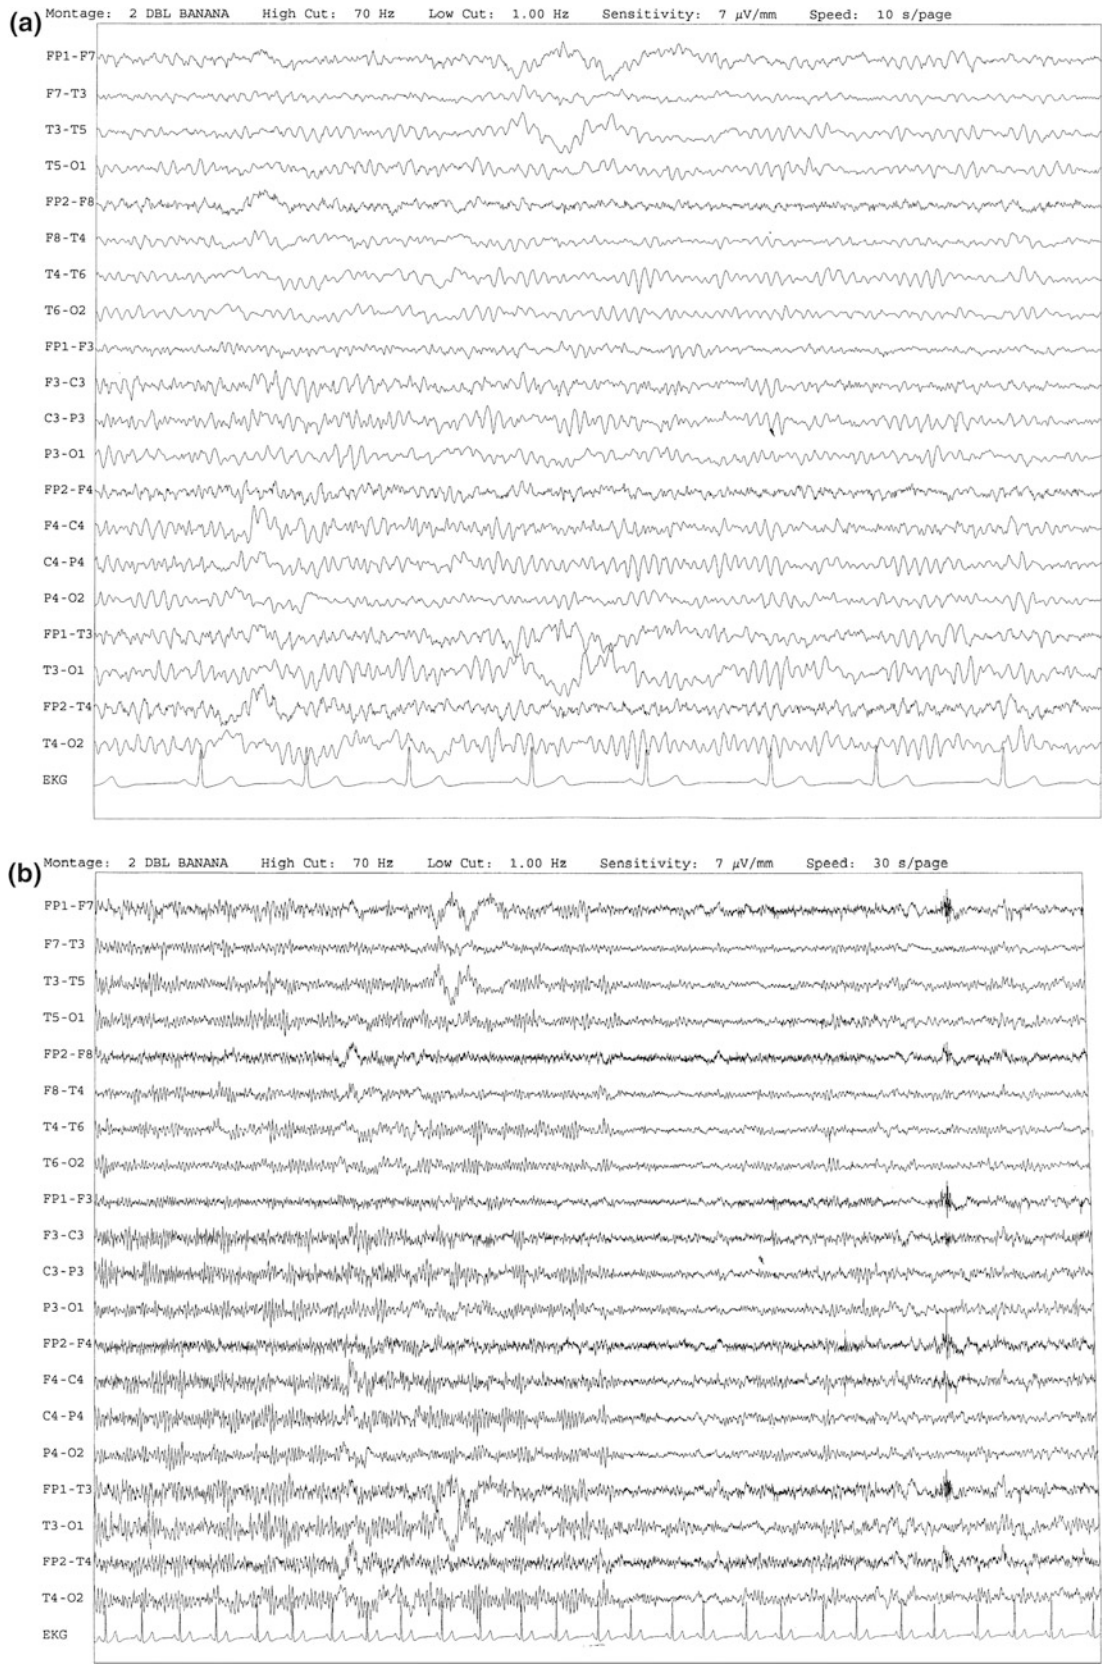

Fig. 51.1 **a** Electroencephalogram shows transient burst of delta activity in the left temporal, and occasionally also in the right temporal, region in a 94-year-old woman with a history of syncope. **b** Same subject data as in **a** viewed at a 30-s epoch. (From Chokroverty S, Bhatt M, Goldhammer T: Electroencephalography for the sleep specialists. In Chokroverty S, Thomas RJ, Bhatt M (eds), Atlas of Sleep Medicine. Philadelphia: Elsevier, 2005:29.)

(s) of neurons [66], (5) a steady decline of synaptic density resulting in a decline of intracerebral connectivity [67], and (6) changes in receptor functions and neurochemical alterations affecting synaptic communication and connectivity [68].

Sleep spindles may show a variety of changes in old age [69–71], including decreased frequency, amount, and amplitude. The frequency may decrease from 16 to 14 Hz, and then from 14 to 12 Hz. The spindles are often poorly formed and poorly developed. Sleep spindle changes thus resemble those noted with alpha frequency in old age.

The cyclic pattern from REM to NREM remains unchanged, but the first cycle may be reduced [27, 72, 73]. REM density (i.e., number of eye movement bursts per minute of REM sleep) and total REM sleep time are reduced, but the percentage of REM in relation to total sleep time (TST) remains unaltered [27, 74, 75]. Sleep fragmentation is due to frequent interruptions at night. In addition, there are frequent sleep stage shifts and, thus, frequent awakenings [27, 56]. Regarding nocturnal TST (lights out to lights on), there is discrepancy between subjective report and objective data based on the technician's schedule [27].

Nighttime sleep of elders usually is reported to be decreased (e.g., 5.5–6.5 h, in contrast to the usual 7.5–8.0 h TST average of young adults) [76]. This may not be an accurate observation, because elders often take daytime naps; 24-h TST of elders probably is no different from the 24-h TST of young adults.

Increased fragmentation of sleep and increased numbers of transient arousals accompanied by increased daytime sleepiness have been described in the studies by Carskadon et al. [77], Carskadon and Dement [78], and Boselli et al. [79]. Kales et al. [80] and Feinberg et al. [59] demonstrated the following changes in sleep with advancing age: state changes; frequent stage shifts; reduction in SWS and the EEG amplitude of delta waves; and increased NREM stage 1 owing to frequent arousals, decreased total nocturnal sleep, and reduction in total REM sleep time but normal REM percentage in relation to the TST.

Williams et al. [81] recruited 120 healthy seniors through advertisements, without mentioning sleep. They tried to carefully screen out sleep disorders by excluding those who had sleep complaints. These authors found that the seniors' sleep quality was poorer than that of young individuals. In particular, there was a decrease in stages 3 and 4 sleep and an increase in nighttime wakefulness [81, 82]. Prinz and Vitiello [83] considered these findings as a benchmark level of sleep change associated with aging per se. In another study involving the Veterans Administration Survey, Cashman et al. [84] found that nighttime hypoxemia, which correlated with sleep apnea, was worse in several medical disorders (i.e., diabetes, cardiovascular disease, history of alcoholism, and vascular headaches). Thus, the data suggest that the disease states may interact with sleep disorders.

Between the ages of 60 and 90 years, there are differences in the sleep architecture of men and women [71, 85]. Between 60 and 70 years, men have more frequent arousals and more decrements in slow-wave sleep. Between 60 and 80 years, women spend 9 % of TST in the slow-wave stage, whereas men spend only 2 %. The percentages of REM and total REM sleep are not different for men and women between 60 and 90 years. In a meta-analysis of normative sleep data across the human life span, Ohayon et al. [86] also reported a reduction in SWS beginning in middle age, with complete absence after the age of 90 years. In a recent population-based cross-sectional Sao Paulo epidemiological study [87, 88] including 1042 individuals (468 men and 574 women) with an age range of 20–80 years, Moraes et al. [87] noted after polysomnographic (PSG) study that their findings were similar to those of Ohayon et al. [86] except that the reduction in SWS percentage correlated with age in men but not in women, whereas the reduction in REM sleep percentage correlated with age in women but not in men.

In a longitudinal PSG and diary-based study, Hoch et al. [89] found deterioration of measures of sleep quality, continuity, and depth but not other sleep measures over a 3-year follow-up period in a group of 27 healthy "old old" subjects (75–87 years) as contrasted with a group of 23 "young old" subjects (61–74 years). The decline in sleep measures was manifested by impaired sleep efficiency, prolonged sleep latency, increased wakefulness after sleep onset, and decreased SWS percentage. These changes were accompanied by increased napping in the "old old" group.

Changes in the Circadian Rhythm

Circadian rhythm changes [85, 90] in the elderly result from fundamental changes in social activity, including family interaction. Interaction is governed by alterations of daily routine and activities, health needs, and psychosocial factors (e.g., loneliness, divorce) [27]. There may also be intrinsic changes in the circadian rhythm related to the pathologic changes noted in apparently normal individuals. Animal studies lend support to this conclusion [91–95]. In long-term care facilities, circadian rhythm disturbances may be related to alterations in *Zeitgebers* (external time cues), such as bedtime, medication time, mealtime, and special institutional regulations on lights out and lights on [17]. Wessler et al. [96] made an intensive study of 69- to 94-year-old institutionalized patients under strict environmentally controlled conditions and found a remarkable regularity in circadian synchronization. In a study involving 69- to 86-year-old subjects, however, Scheving et al. [97] did not find support for the other group's conclusion. In all of these studies

involving institutionalized patients, the effect of chronic illnesses must be considered in explanations of circadian rhythm disturbances. Thus, these changes may not be related to "normal" old age.

A study of evolution of sleep shows that the strong monophasic circadian rhythm of youth gives way to a polyphasic ultradian rhythm in old age. Frequent awakenings at night, with reduction in wakefulness, are accompanied by increased daytime naps. These physiologic changes may be related to the structural alterations noted in the suprachiasmatic nucleus (SCN) and brain stem hypnogenic neurons in experimental studies in several species of animals [98–100]. The human central circadian clock in the suprachiasmatic nucleus is subject age-associated changes [101] (e.g., molecular rhythms, ion channels, neurotransmitters, intracellular messenger); however, little is known about the underlying mechanisms. These changes may cause a reduction in the amplitude of the circadian timing signal, a deduction in amplitude of daily rhythms in physiology and a weakening of the peripheral oscillators. These changes partly explain some of the sleep disturbances in the elderly.

There is also phase advance in the elderly—that is, there is a tendency to go to sleep early and awaken early. These changes may be related to age-related changes in the core body temperature rhythm [102, 103]. In elderly individuals, the amplitude of the temperature rhythm is attenuated and phase-advanced [103].

Autonomic Nervous System Changes with Age

There are striking functional and structural changes noted in the elderly in the ANS [27, 28, 104–107]. Changes are found in autonomic nerves and ganglia; ANS-controlled cardiovascular, respiratory, and gastrointestinal functions; sympathetic nerve activity; thermoregulation; and nocturnal penile tumescence in men. The age-related structural alterations in the human superior cervical ganglia may explain the deterioration of neuronal functional capacity and affect neuronal plasticity and regenerative characteristics [106].

Sympathetic Nerve Activity

The most consistent abnormalities in old age are increased muscle sympathetic nerve activity and elevated plasma concentration of the sympathetic neurotransmitter norepinephrine [104, 108, 109]. Age-related changes are noted in circulating catecholamine levels and microneurographic recordings from sympathetic nerves of skeletal muscles. In contrast, the reactivity of the sympathetic and parasympathetic activities is reduced with aging [104].

Thermoregulation

Thermoregulation is impaired in old age [28]. In response to passive heating, the sweating response of elders is impaired [110]. They are susceptible to hypothermia (both postoperatively and in response to low ambient temperature in the environment) [111, 112] and hyperthermia [113]. There is a paucity of studies that show ANS changes during sleep in elders.

Cardiovascular Changes

Blood pressure (BP) and pulse rate fall at sleep onset, rise on awakening, and fluctuate during the night [114]. The increased incidence of stroke in elders during sleep may be related to these factors [27]. Orthostatic hypotension is common in elders and may be due to impaired baroreflex responsiveness and neuroeffector function [28]. Aging is associated with decreased cardiovagal baroreflex sensitivity (i.e., blunted reflex changes in the R–R interval in response to a change in BP) [105]. These alterations may cause increased levels in BP variability and increased risk of sudden cardiac death [105]. However, baroreflex control of sympathetic outflow is not impaired with age. Baroreflex functional changes with aging may cause an impaired ability to buffer BP changes.

Respiration

Age-related changes in the respiratory system and pulmonary function include a reduction in vital capacity, chest wall compliance, diffusion capacity, elastic recoil, and arterial oxygen tension; mismatch of the ventilation–perfusion ratio; decreased respiratory muscle strength; and respiratory center sensitivity [27, 115–117]. There is a higher incidence of periodic breathing, including Cheyne–Stokes breathing and snoring, in elders at night [114, 118–120]. Patients with chronic obstructive pulmonary disease, who are often elderly, are at special risk for periodic breathing during sleep (both at night and during the day) because of increasing oxygen desaturation, hypercapnia, and apnea during sleep [121, 122]. The recent population-based cross-sectional study also supported a decrease in oxygen saturation and an increase in apnea–hypopnea index (AHI) with aging [87].

Nocturnal Penile Tumescence

Penile erection occurs during REM sleep. This REM-related penile tumescence shows a linear decrease from youth to old age (from 88 % at 20–26 years old to 64–74 % at 60–90 years old) [123, 124].

Gastrointestinal Function

Selective degenerative changes may occur in the aging enteric nervous system, which regulates gastrointestinal functions [107]. These age-associated changes in intestinal innervation may contribute to the gastrointestinal disturbances that increase in incidence in the elderly (e.g., dysphagia, gastroesophageal reflux, constipation) [125].

Endocrine Changes with Age

Plasma Cortisol

Cortisol secretion has a circadian rhythmicity that remains intact in the elderly. There is an age-dependent increase in mean nocturnal cortisol levels and an advancement of the morning rise [126]. However, normal diurnal rhythm of salivary cortisol is maintained in older adults [127]. Magri et al. [128] observed a significant increase in nocturnal cortisol levels in 23 healthy elderly and 23 demented elderly individuals as compared with levels in 10 healthy young subjects. MRI of the brain correlated these higher nocturnal cortisol levels with a reduction in hippocampal volume in these elderly subjects. Poor sleep in the elderly may be related to an activation of the hypothalamic–pituitary–adrenal (HPA) axis associated with hypersecretion of cortisol and increased inflammatory cytokines (e.g., interleukin-6), which stimulate the HPA axis.

Growth Hormone

Sleep-related growth hormone release is diminished in old age [129], but the response of the growth hormone secretion to insulin hypoglycemia is normal [130]. There is a parallel decrease in SWS and growth hormone in the elderly [131].

Prolactin Secretion

Prolactin secretion in old age shows a normal pattern of episodic secretion with a sharp rise just after sleep onset and a sharp fall during morning awakening [27, 132]. Although older subjects wake up several times during the night and have daytime naps, these episodes are not correlated with the prolactin secretion pattern [27].

Gonadotropins (Follicle-Stimulating Hormone and Luteinizing Hormone)

No good studies correlate sleep changes in the elderly with gonadotropin secretion [27].

Plasma Insulin and Glucose

Insulin secretion shows a clear circadian variation in healthy young adults, but there is no adequate study of aged individuals [27].

Thyroid-Stimulating Hormone

Plasma thyroid-stimulating hormone shows a circadian periodicity in adults: Peak levels occur just before sleep onset at night [114, 133, 134]. In subjects older than 50 years, there are progressive changes in thyroid function causing a modest decrease in serum triiodothyronine concentration and minimal changes in thyroid-stimulating hormone and thyroxine concentrations [135].

Melatonin Secretion

Serum melatonin concentration shows an age-related decrease in old age [136]. Impaired melatonin secretion has been reported to be associated with sleep complaints in the elderly [137, 138].

Changes in Cerebral Blood Flow and Cerebral Metabolism

Despite some inconsistent early findings [5], there is a direct relationship between normal aging, CBF, and cerebral metabolism. The xenon-133 inhalation method related a clear-cut decline in the regional blood flow exclusively to advancing age, without the confounding factors of associated diseases [139, 140]. This decline with advancing age was noted more in the gray than in the white matter CBF values. Maximal declines were seen in the prefrontal and parietal regions and minimal declines in the frontal and frontotemporal regions [5]. This decline in old age seems to be related to a progressive decrease in the cerebral metabolic rate [141] and possibly also to the morphologic changes in the neurons in the brains of elderly individuals. It should be noted that the decrease in CBF during SWS and the increase during REM sleep are similar in normal subjects of all ages. In elderly sleep apnea patients, however, this decrease during SWS becomes excessive, placing elderly individuals at increasing risk for sudden death and development of stroke during sleep when combined with hypoxemia related to apnea.

Pathologic Central Nervous System Changes of Normal Aging

Aging represents biologic maturation, which may be accompanied by a variety of pathologic changes in the CNS. The neuropathologic changes of old age can be summarized as follows [5, 142]: Shrinkage of the brain; alterations in the outline; and loss of neurons in various locations; lipofuscin accumulation; collection of corpora amylacea; intraparenchymal vascular changes; loss of dendritic arbor and dendritic spines; and presence of senile plaques, amyloid deposits, neurofibrillary tangles, granulovacuolar degeneration, and Hirano bodies. The presence of senile plaques, amyloid deposits, neurofibrillary tangles, granulovacuolar degeneration, and Hirano bodies is correlated with dementia, but the other neuropathologic changes are considered nonspecific changes of aging.

From the standpoint of sleep disorders medicine, the cell loss in the locus coeruleus, pontine and midbrain reticular formation, selective hypothalamic regions, and SCN, as well as accumulation of neurofibrillary tangles and abnormal pigment in the hypothalamus, are important morphologic

correlates for widespread sleep disturbances in the elderly. Animal experiments on the SCN show the relationship between destruction of these nuclei and alteration of circadian rhythmicity of adrenal cortical secretion, body temperature, activity–rest cycle, and sleep cycle loss [27].

Sleep Complaints in Old Age

In an epidemiologic study, Ford and Kamerow [143] interviewed 7954 subjects and observed that 40 % of patients with insomnia and 46.5 % of those with hypersomnia had a psychiatric disorder, compared with 16 % of those with no sleep complaints. Complaints of persistent insomnia are important late in life. There is a high incidence of depression with insomnia in the elderly. Among the 1801 elderly respondents aged 65 and older, the prevalence of insomnia was 12 % and the incidence of insomnia was 7.3 % [143]. For hypersomnia, the figures for prevalence and incidence were 1.6 and 1.8 %, respectively. There was a strong association between persistent insomnia (longer than 1 month) and the risk of major depression. Clayton et al. [144] noted that, in late-life spousal bereavement, there is also a persistent and debilitating complaint of insomnia.

Brabbins et al. [145] noted an overall prevalence of 35 % for insomnia complaints (more in women) after an interview of 1070 noninstitutionalized elderly individuals. In contrast, after interviewing 59 institutionalized and 874 community-dwelling residents, Henderson et al. [146] found a prevalence of approximately 12 % in the institutionalized and approximately 16 % among the community-dwelling elderly at 70 years or older. Insomnia complaints are more prevalent among women; whites; and those with depression, pain, and poor health. In another study from Germany, Stepnowsky et al. [147] investigated the prevalence of insomnia in 330 patients older than 65 years attending the offices of five general practitioners. Using the *Diagnostic and Statistical Manual of Mental Disorders* (3rd revision) diagnostic criteria, they found severe insomnia in 23 %, moderate insomnia in 17 %, and mild insomnia in another 17 % of the patients. There was a significant association between insomnia, depression, and dementia.

Foley et al. [148] conducted an important epidemiologic study limited to interviews in more than 9000 elderly subjects aged 65 years and older from three communities in the United States in the National Institute on Aging's multicentered study entitled "Established Populations for Epidemiologic Studies of the Elderly". These authors observed at least one of the following complaints in over half the subjects: trouble falling asleep, multiple awakenings, early morning awakening, daytime naps, and tiredness. These complaints are more common in women than in men and are often associated with respiratory symptoms, depression, nonprescription and prescription medications, poor self-esteem, and physical disabilities. The authors observed 33 % of men and 19 % of women with snoring and 13 % of men and 4 % of women with observed apneas. In this cross-sectional study, the authors did not find a clear relationship of loud snoring, observed apneas, or daytime sleepiness to hypertension or cardiovascular disease in the elders. In a later epidemiologic study of 6800 persons over 3 years, Foley et al. [149] reported that 28 % of older adults had complaints of chronic insomnia but, in the absence of risk factors (e.g., depression, medical disorders, circadian rhythm disorders, medications), only 7 % had insomnia. In a 2003 National Sleep Foundation Sleep in America poll, sleep complaints common in older adults are found to be secondary to comorbidities rather than aging per se [149].

Excessive daytime somnolence (EDS) is often associated with fragmentation of nocturnal sleep, which may have been due to sleep-disordered breathing and periodic leg movements in sleep (PLMS) [150]. Other factors are changes in the circadian rhythms of temperature, alertness and sleepiness, and social time cues. Frequent daytime sleepiness in older adults is associated with an impairment of physical functioning and decreased exercise frequency [151]. Based on the National Sleep Foundation 2003 Sleep in America poll, Foley et al. [148] reported frequent napping associated with EDS, depression, pain, and nocturia in older adults.

Many other factors can disrupt sleep: Nocturia, leg cramps, pain, coughing or difficulty in breathing, temperature sensitivity, and dreams [149, 150]. There is an increased prevalence of nocturia in the elderly causing sleep disturbance [151–153]. Sleep disturbances, particularly complaints of insomnia, may contribute to increasing risk of falls and fractures in the elderly [150, 154–157]. There is controversy whether the increasing risk of falls in the elderly is related to the sleep disturbance per se or greater use of hypnotics by the elderly [154]. In a multicenter community-dwelling questionnaire-based study involving over 8000 white women aged 69 and older (mean = 77 years), self-reported long sleep (at least 10 h per 24 h) and daily napping were associated with greater risk of falls and fractures [155]. In a recent [157] prospective observational sleep study in 3101 community-dwelling men aged 67 and above (mean = 76 years), Stone et al. reported that subjective (Epworth Sleepiness Scale and Pittsburgh sleep quality index) and objective (actigraphy and in-home polysomnography) sleep disturbances were associated with risk of falls in older men, independent of confounders. These authors found that reduced hours of sleep (five hours or less compared with those with seven to eight hours) and nocturnal hypoxemia ($\geq$10 of sleep time with arterial oxygen saturation <90 %) but not apnea–hypopnea index were associated with greater risk of falls.

Vitiello and Prinz [158] found that CNS degenerative disorders (e.g., dementia of the Alzheimer's type) may cause

polyphasic sleep–wake patterns, which constitute a significant problem among old nursing home residents. In demented elderly subjects, nocturnal agitation, night wandering, shouting, and incontinence contribute to a variety of sleep disturbances. There are many other factors in the pathogenesis of nocturnal agitation, including loss of social *Zeitgebers* and circadian timekeeping, sleep apnea, REM-related parasomnias, low ambient light, and cold sensitivity [159].

An important behavioral disturbance during sleep late in life is snoring [150]. According to Koskenvuo et al. [160, 161], habitual snoring was found in 9 % of men and 3.6 % of women ages 40–69 years in their study done in Finland. Hypertension, ischemic heart disease, and stroke are risk factors for snoring. In an epidemiologic survey, Lugaresi et al. [162] found that approximately 60 % of men and 40 % of women between the ages of 41 and 64 years were habitual snorers. Enright et al. [163] recruited 5201 adults ages 65 and older who were participants in a cardiovascular health study that enrolled a random sample of Medicare subjects in four US communities. In this study, there was no positive correlation between aging and self-reported snoring. Loud snoring, however, was independently associated with body mass index, diabetes mellitus, and arthritis in older women, and with alcohol use in elderly men.

What is the relationship between sleep duration and mortality in elders? In 1989, Ancoli-Israel [164] re-examined the 1979 data of Kripke et al. [165] and concluded that 86 % of deaths associated with short (<7 h) or long (>8 h) sleep occurred among those older than 60 years. Thus, it could be concluded by extrapolation from these data that older individuals who sleep less than 5 h or more than 9 h may be at greater risk for death.

The high frequency of sleep complaints in aged individuals may be related to the physiologic sleep changes of normal aging as well as to concomitant medical, psychiatric, neurologic, and other disorders that are prevalent in this group [54, 85, 149, 153, 154, 159, 166]. Subjective sleep complaints are common in older subjects, as many reports attest [167–170]. The subjective complaints were corroborated by objective laboratory data. In contrast to the increasing incidence of subjective complaints from women, however, elderly men had more sleep disturbances than elderly women by objective reports [171].

Clinical Assessment of Sleep Disorders

Clinical assessment consists of a sleep, medical, drug, and psychiatric history. A general approach for making a clinical assessment is described in Chap. 26; only the points relevant to elders are emphasized in this section.

Sleep History

Kales et al. [172] developed excellent guidelines for taking an adequate sleep history, summarized as follows:

1. The specific sleep problem should first be defined from the history. It is important with elders to understand the significance of daytime fatigue, which may result either from insomnia at night or from EDS. The latter condition can be an indirect effect of repeated arousals at night owing to sleep-related respiratory disorders, with or without PLMS. The other important factor to note is that the sleep of elders becomes polyphasic, associated with frequent daytime naps and less sleep at night. Therefore, every daytime nap is not necessarily indicative of EDS.
2. The onset and the clinical course of the condition should be assessed from the history. The course of the illness in some sleep disorders (e.g., night terrors, nightmares, sleepwalking) is different [173]. Nightmares have a chronic course, whereas night terrors may be of recent onset. It should be noted that the relatively sudden onset of sleepwalking or night terrors in an elderly person is indicative of an organic CNS disorder, and appropriate investigation should be directed toward that diagnosis [174].
3. Inquiries should be made into a family history of a sleep disorder. Certain sleep disorders (e.g., narcolepsy, hypersomnia, sleep apnea, sleepwalking, night terrors, restless legs syndrome) may have a family history [172–178].
4. Various sleep disorders should be distinguished from one another, and any previous diagnosis should be reassessed.
5. It is important to obtain a complete 24-h sleep–wakefulness pattern. This is important in elderly individuals, because in old age the sleep cycle becomes polyphasic, rather than monophasic as in young adults. In elders, because of the tendency to take frequent naps, the sleep–wake schedule becomes irregular and may cause circadian rhythm disorders.
6. It might be important to keep a sleep diary or sleep log, and it is very important to question the bed partner or other caregivers about sleep disturbances of elders. Keeping a sleep diary may help assess the 24-h sleep–wake cycle pattern.
7. The bed partner or caregivers should be questioned carefully, as they may have clues to the diagnosis of sleep apnea syndrome (SAS). For example, excessively loud snoring, temporary cessation of breathing, or restless movements in the bed are important pointers to the diagnosis of SAS or PLMS.

8. It is essential to evaluate the impact of the sleep disorder and to determine the presence of other sleep disorders. The history may suggest a diagnosis of sleepwalking, night terrors, or REM sleep behavior disorder (RBD). A careful sleep history may also suggest nocturnal epilepsy, which is sometimes mistaken for a sleep disorder.

Medical History

It is vital that a complete medical history be obtained from the patient [172, 179]. Elderly individuals often have a variety of medical disorders, including congestive cardiac failure, hypertension, ischemic heart disease, chronic bronchopulmonary disorders, gastrointestinal disorders, arthritis and musculoskeletal pain syndromes, cancer, chronic renal disorders, endocrinopathies, and a variety of neurologic disorders. All of these conditions may disrupt sleep by virtue of the uncomfortable symptoms or because of the medications prescribed for them. Therefore, patients often complain of insomnia, but sometimes also of hypersomnia.

Drug History

It is important to obtain a drug history [172] because many medications can cause insomnia, including [180] CNS stimulants; bronchodilators; β blockers; antihypertensives; benzodiazepines, particularly the short-acting ones; steroids; and theophylline. Withdrawal from short- and intermediate-acting benzodiazepines and nonbenzodiazepine hypnotics causes rebound insomnia. Many CNS depressants, such as hypnotics, sedatives, and antidepressants, may cause EDS. Finally, drinking coffee or cola at night may cause difficulty initiating sleep. Alcohol consumption may cause difficulty maintaining sleep.

Psychiatric History

Psychophysiologic and psychiatric problems are the most common causes of insomnia in elders [180]. Elderly insomniacs can have a variety of psychological and psychiatric problems, such as anxiety, depression, organic psychosis, and obsessive–compulsive neurosis. A patient with depression complains of early morning awakenings, whereas a patient with obsessive–compulsive neurosis has difficulty initiating sleep. Some drugs (e.g., thioridazine) may increase nightmares [146]. Marital and sexual problems may give rise to interpersonal problems that cause sleep disturbances, particularly insomnia [179].

Sleep Disorders in Old Age

It is well known that the prevalence and intensity of sleep disturbances increase with age [149, 150, 179, 181–183]. Factors that affect the prevalence of sleep disturbances in the elderly are (1) physiologic (e.g., age-related changes in sleep patterns); (2) medical; (3) psychiatric; (4) pharmacologic (e.g., use, misuse, and abuse of drugs); and (5) social (changing rest–activity schedules, and, therefore, sleep–wake patterns) [149, 150, 179–185].

The prevalence of sleep-related breathing disorders, PLMS, and snoring are all greater among elders. The prevalence of sleep apnea increases with age and is greater in men than in women, and in menopausal women than in premenopausal women [164]. There is controversy over the exact prevalence of sleep apnea in the older population. The prevalence rates for sleep apnea—defined as repetitive episodes of upper airway obstruction—in elders in various studies have been estimated to range from 5.6 to 70 % [164, 186–194]. The prevalence is greater in the elderly than in younger adults, and in men than in women [195, 196]. There is a lack of consistency in study methods, so it is very difficult to generalize from these studies. In the Sleep Heart Health study involving a large cohort of about 6400 subjects (aged 40–98 years, with a mean of 63.5), Young et al. [194] reported an increased prevalence of SAS by 10-year age groups: 32 % of those ages 60–69 years had an apnea–hypopnea index (AHI) of 5–14 and 19 % had an AHI of ≥ 15; 33 % of those ages 70–79 years had an AHI of 5–14 and 21 % had an AHI of ≥ 15; and 36 % of those ages 80–98 years had an AHI 5–14; and 20 % had an AHI of ≥ 15. Thus, there was a small increase in the AHI index by 10-year age groups. In an earlier study, Hoch et al. [188] also found increased AHI and prevalence of SAS from 60 to 90 years. It should be noted, however, that based on a definition of 15 or more apneas or hypoapneas per hour of sleep accompanied by EDS, the recent Wisconsin sleep cohort study data listed prevalence of moderate-to-severe SAS at 10 % in men and 3 % in women among 30–49 years, but 17 % in men and 9 % in women among 50–70 years [197]. Because of the high prevalence of SAS in elders, questions have been raised as to the significance of sleep-disordered breathing in the elderly. Prinz et al. [198] stated that, because apneic episodes in the elderly may not have the same clinical symptoms as noted in younger people, it is more difficult to determine whether further investigations are needed. Fleury [199], suggested that SAS in the elderly not be considered different from SAS in middle-aged men, however, assuming that an appropriate diagnostic apnea index (AI) or respiratory disturbance index (RDI) was taken into consideration. Ancoli-Israel and Coy [193] agreed that, if SAS is severe enough to cause symptoms in the elderly, treatment should be similar to that in a younger patient.

The controversy as to whether SAS in the elderly represents a specific entity or the same disease in younger subjects continues [150, 200–202]. Further research is needed to resolve this issue. Launois et al. [201] contended that untreated SAS in the elderly appears to have less impact on mortality than in middle-aged adults; however, symptomatic elderly SAS patients tolerate continuous positive airway pressure (CPAP) as well as the younger patients. Based on a retrospective study in Poland, Bielicki et al. [202] concluded that SAS is more frequent in elderly than in younger patients but is more severe in younger patients requiring higher CPAP titration pressure. In an important longitudinal follow-up study of elderly patients with SAS for 18 years, Ancoli-Israel et al. [203] observed that the AHI did not continue to increase if the patient's body mass index remained stable. Some of the risk factors predisposing the elderly to SAS are as follows [204, 205]: age, gender, obesity, smoking, family history, race, upper airway anatomic configuration, use of sedative hypnotics, and alcohol consumption.

Reasons for the variation in the prevalence of sleep apnea could be the sampling of different populations without using a random sampling method, small sample size, or the use of different criteria to define sleep apnea. An important problem has been the scoring criteria for apnea and hypopnea and the definition of AI, AHI, or RDI. In the current American Academy of Sleep Medicine guidelines for scoring [206], these questions have been addressed and standardized (see Chap. 25). Another problem has been the clinical significance of an AI or RDI of 5. Some authors have suggested that an AI of 20 or more is related to increased risk of death [207]. In a survey among 427 randomly selected community-dwelling people, 65–95 years of age, in San Diego, California, Ancoli-Israel et al. [186] reported that 81 % of the subjects had an AHI of ≥ 5 with a prevalence rate of 62 % for an AHI of ≥ 10, 44 % for an AHI of ≥ 20, and 24 % for an AHI of ≥ 40. Night-to-night variability in sleep apnea has been the other confounding problem in the elderly [186, 208–211].

The question of the relationship between sleep apnea or sleep-disordered breathing and increased morbidity or mortality remains controversial, several studies, however, have found a positive relationship [207, 212, 213]. In a nearly 10-year follow-up of a randomly selected, population-based probability sample of 426 men and women (65–95 years old), Ancoli-Israel et al. [214] found that those with severe sleep-disordered breathing (RDI of 30 or more) had a significantly shorter survival but that the RDI was not an independent predictor of death. Similar results were reported from a sleep disorders clinic patient population study by Lavie et al. [215], Ancoli-Israel et al. [214] stated that other confounding variables such as age, hypertension, and cardiovascular or pulmonary disease might be responsible for the increased morbidity and mortality. Chronologic or biological age (determined by biological markers of physiologic aging) may be the single most important factor for increased morbidity and mortality in sleep-disordered breathing (i.e., sleep apnea may be an age-dependent condition). To address this controversy, well-designed controlled clinical studies are needed.

Diagnosis of Sleep Disorders in Old Age

Recognition of a variety of sleep disorders in elders is important for treatment of sleep disturbances and the associated medical or psychiatric conditions. Some examples of sleep disorders that have been recognized in the aged population [171, 198, 216–224] are insomnia; sleep-related respiratory dysfunction with periods of apneas and hypoapneas; PLMS; sleep disturbances secondary to a variety of medical or psychiatric illnesses (particularly depression in the elderly); sleep disturbances associated with dementia (particularly of the Alzheimer's type); and sleep disturbances related to the abuse of alcohol and sedative-hypnotic drugs, narcolepsy, restless legs syndrome, parasomnias, and circadian rhythm sleep disorders (Box 51.2).

Box 51.2 Common Sleep Problems in Old Age

Primary Sleep Disorders

- Insomnia
- Sleep-related breathing disorders
- Restless legs syndrome/periodic limb movements in sleep
- REM sleep behavior disorder
- Advanced sleep phase state.

Other Disorders associated with sleep difficulty

- Comorbid psychiatric illnesses
- Comorbid general medical disorders
- Comorbid neurodegenerative and other neurologic disorders
- Medication related
- Abuse of alcohol and use of sedative-hypnotic drugs
- Nocturia and sleep problems.

Insomnia and EDS are the two most common symptoms noted in normal aged individuals [198]. There is a high incidence of insomnia in the elderly, particularly elderly women [179] (see Chap. 37 for further details about insomnia). Epidemiological studies have shown that sleep

problems increase with age and are associated with comorbid insomnia, depression, dementia and cardiovascular disease, and increased mortality [225].

Sleep Apnea Syndrome

For the diagnosis of SAS, questioning the bed partner is very important. A history of loud snoring with periods of cessation of breathing at night accompanied by EDS and daytime fatigue suggests SAS [226]. The diagnosis is strongly suspected if the patient is also obese and hypertensive. For a definitive diagnosis, and to quantify the severity, an all-night PSG study is essential. The usual type is upper airway obstructive sleep apnea, but often it is mixed with central apnea, giving rise to mixed apnea (see Chap. 32). It is important to diagnose the condition because of possible adverse consequences [226], such as congestive cardiac failure, cardiac arrhythmias, hypertension, neuropsychological impairment [193, 224, 226, 227], increased risk of traffic accidents [228, 229], and increased mortality related to cardiovascular events [230, 231]. In a 6-year follow-up prospective longitudinal study in a population-based cohort of 394 noninstitutionalized elderly subjects (ages 70–100 years, median 77 years; 57 % men), Munoz et al. [230] found that severe obstructive sleep apnea–hypopnea (AHI index of ≥ 30) at baseline had an increased risk of ischemic stroke in the elderly population independent of known confounding factors (e.g., age, sex, smoking, alcohol consumption, body mass index, blood pressure, serum cholesterol levels, presence or absence of diabetes mellitus, and atrial fibrillation). Lugaresi et al. [162] reported a high prevalence of snoring in elderly individuals, and this can be the forerunner of full-blown SAS.

Periodic Limb Movements in Sleep

PLMS is reported more often in older normal subjects than in younger ones [189, 232–236]. According to Coleman et al. [234], the occurrence of PLMS may be related to disturbance of circadian sleep–wake rhythm in the elderly. In the study by Kripke et al. [233], 20–30 % of subjects 65 years and older had PLMS, whereas Ancoli-Israel et al. [232] reported an incidence of 37 % of PLMS in 24 older subjects. Pennestri et al. [236] noted PLMS rarely in normal subjects under the age of 40 years, but then the index increased dramatically after that age. They found a mean index of two/hour in subjects between 30 and 40, 11 between 40 and 50, 17 between 50 and 60, and 22 in those 60 years and older. PLMS is often associated with SAS independently of respiratory-related PLMS.

Sleep Disturbances and Medical Illnesses

A variety of medical disorders may be associated with insomnia—congestive cardiac failure; ischemic heart disease; arthritis and musculoskeletal pain syndrome; chronic respiratory disorder associated with bronchospasm; and dyspnea, which is often worse at night (see Chap. 11). Diabetics with autonomic neuropathy may have SAS [237]. Foley et al. [147] reported more sleep complaints in those with comorbid cardiopulmonary diseases and depression compared with those without associated medical disorders. Wilcox et al. [238] reported difficulty falling asleep in 31 % of patients with osteoarthritis and 66 % of those with chronic pain, whereas 81 % of patients with arthritis and 85 % with chronic pain complained of sleep-maintenance difficulty. There is an increasing prevalence of sleep-maintenance problems in patients with diabetes mellitus [239]. For information on medical disorders that cause sleep-disordered breathing, EDS, and other sleep disturbances, see Chap. 47. Treatment should be directed at the primary condition to alleviate secondary sleep disturbances.

Sleep Disturbances and Comorbid Psychiatric Illness

An important psychiatric illness that causes sleep disturbances in the elderly is depression [146, 216, 240–249], which should be carefully evaluated through a thorough psychiatric history. The condition is treatable, and misdiagnosis and prescription of hypnotics for insomnia would lead to a vicious cycle of worsening sleep complaints. An important sleep complaint in these patients is early morning awakening, resembling advanced sleep phase syndrome [240–242]. Untreated insomnia is also a strong predictor of depression [250]. Treating insomnia may also improve comorbid depression [251]. Anxiety disorders also cause sleep disturbances [243–245], and various psychotic disorders may cause both hypersomnolence and insomnia [242–245] (see Chap. 46).

Sleep Disturbances and Comorbid Neurodegenerative and Other Neurologic Disorders

Alzheimer's disease and related dementias in the elderly may cause sleep disturbances, including nocturnal confusional episodes (sundowning syndrome), which may require antipsychotic medication [250–253] (see Chap. 41). For information on other neurologic disorders causing sleep disturbances in the elderly, see Chap. 41).

Sleep Disturbances Associated with Drugs and Alcohol

A careful drug and alcohol history is important, as elderly individuals often take a variety of medications, including sedative hypnotics for associated medical conditions, and over-the-counter drugs to promote sleep [146, 149, 150, 171, 179, 216]. Sleeping medications produce secondary drug-related insomnia. Alcohol worsens sleep disturbances and may exacerbate existing SAS. Some examples of medications [149] that may cause insomnia include β blockers (probably by interfering with nocturnal melatonin secretion), bronchodilators, corticosteroids, decongestants (e.g., pseudoephedrine), and CNS stimulants (e.g., caffeine, theophylline), as well as drugs to treat gastroesophageal reflux (e.g., cimetidine), cardiovascular disorders (e.g., methyldopa, furosemide), neurologic diseases (e.g., phenytoin, modafinil, ritalin, amphetamines, dopaminergic drugs), and depression (e.g., bupropion, fluoxetine, venlafaxine, sertraline, paroxetine). Some antidepressants may cause sedation (e.g., nortriptyline, desipramine, amitriptyline, trazodone). Sedating medications should preferably be administered at bedtime and stimulating medications should be ingested during daytime hours.

Nocturia and Sleep Problems

The frequency of nocturia increases with age, and there is a significant association among nocturia, sleep-maintenance difficulty, bone fracture, and cardiovascular disease [254–258]. A recent study found an increased prevalence of EDS in elderly females with nocturia [259].

Narcolepsy

Narcolepsy (see Chap. 38) is a disease of earlier onset than old age, and the diagnosis will probably have been made much earlier, but it is a lifelong condition, and therefore, may be seen in older patients [260, 261]. The diagnosis rests on a history of sudden sleep attacks lasting a short time and associated with auxiliary symptoms such as cataplexy, hypnagogic hallucinations, and sleep paralysis. A history of narcoleptic sleep attacks and cataplexy is a strong indicator for diagnosis, but an all-night PSG study, followed by the Multiple Sleep Latency Test (MSLT), which will show reduced sleep-onset latency and sleep-onset REM (SOREM) in two of five recordings, is required for confirmation. (A SOREM within 15 min of sleep onset in previous nightly PSG may replace one of the SOREMs in the MSLT).

Restless Legs Syndrome

Restless legs syndrome (see Chap. 40) is primarily a lifelong condition, although it may be secondary to diabetic or uremic peripheral neuropathy. In addition to the characteristic features (five essential criteria) during quiescence and evening, nighttime sleep is severely disturbed. The prevalence increases with age, and the symptoms may occur initially in old age [262].

Parasomnias

The important parasomnias in the elderly are RBD, sleepwalking, and night terrors. The latter two conditions usually present in childhood or adolescence, but if they have a relatively sudden onset in an elderly person, an acute neurologic condition should be suspected and excluded by appropriate laboratory investigations [184]. RBD can be suspected from the history given by the bed partner and by simultaneous video-PSG evaluation at night (see Chap. 50 for a general discussion of parasomnias). RBD is frequently a preclinical manifestation of a neurodegenerative disorder, particularly synucleinopathies (e.g., Parkinson's disease, diffuse Lewy body dementia, and multiple system atrophy) in the elderly [263, 264].

Disorders of Circadian Function

Morgan et al. [265] reported that occasional sleep complaints are noted by 40 % of older individuals, and according to Garma et al. [266], older individuals complain of frequent and prolonged awakenings during the night. It has been speculated by Czeisler et al. [267] that these disorders may be due to changes in the human circadian pacemaker with advancing age. Work with light by Czeisler et al. [268, 269] showed that, with appropriately timed exposure to bright light, one can change the temperature cycle—that is, circadian phase—and may be able to correct the circadian sleep disorder. Further research is needed in this area.

In 1962, McGhie and Russell [168] reported that 15 % of older individuals complained of early morning awakenings, and in 1988 Mant and Eyland [270] reported that 33 % of elderly individuals woke up early in the morning several times a week. Sleep parameters thus show an advanced phase, which is also noted with other circadian markers such as activity rhythm, body temperature rhythm, and timing of REM sleep and the cortisol rhythm [267]. An advance in the

circadian phase due to a reduction in the endogenous period of the circadian pacemaker with advancing age is suggested by animal experiments [91, 271]. Human data for such studies are lacking, but a cross-sectional study by Weitzman's group [103] documented that the free-running period of the temperature rhythm was significantly shorter in six subjects aged 53–60 years than in six healthy young adults. A study by Czeisler et al. [268] suggested a strong relationship between period reduction and phase advance in the circadian rhythms of older people.

The pathophysiologic mechanism of these changes remains speculative. In 1972 [99, 272], a cluster of neurons was discovered in the anterior tip of the hypothalamus on either side of the third ventricle, the SCN. This is the circadian pacemaker. With advancing age, the volume of SCN cells shrinks—that is, the number of neurons decreases [273–275], which may result in functional impairment. Other factors may contribute to circadian dysrhythmia in the elderly [136, 150, 276]: gradual decrement of nocturnal endogenous melatonin secretion with age; and inadequate time spent in daylight, thus weakening exogenous cues (*Zeitgebers*) to entrain the circadian rhythm, causing sleep fragmentation and circadian dysrhythmia. In addition, weakening of the circadian and homeostatic mechanism in the elderly may explain age-related changes in sleep pattern and cognition [277, 278].

Laboratory Assessment

The diagnostic evaluation should begin with a thorough history of sleep disturbances, which may be EDS, difficulty initiating or maintaining sleep, and intrusions of unusual behavior during sleep. Physical examination may direct attention to systemic disease. Based on the history and findings of the physical examination, a decision should be made regarding referrals to specialized sleep centers for PSG and MSLT studies. Tests should be performed when clinical interview and examination cannot resolve the problems.

Most of the sleep disturbances of elders can be diagnosed by a careful history and physical examination. For some conditions, however, laboratory assessment is important. In SAS, it is important to have an all-night PSG study to quantify and determine the severity of sleep-related respiratory disturbances. Sleep apnea is a treatable condition, so it is important to make this diagnosis correctly. In addition, MSLT and PSG studies are important for a narcolepsy diagnosis, although in elderly people this diagnosis may have been made many years earlier. All-night video recordings are necessary to diagnose some conditions, such as RBD, that require the examiner to differentiate from among a number of sleep disorders with similar symptoms. Appropriate tests should be performed if other medical or neurologic disorders are suspected.

Treatment

The objective of treatment is to reduce the risk of mortality and morbidity and improve quality of life (Box 51.3) [279]. The first step is accurate assessment and diagnosis.

Box 51.3 Principles of Treatment of Sleep disturbances in the Elderly

- Initial step is an accurate assessment of diagnosis.
- Treat associated conditions causing or exacerbating sleep dysfunction.
- Treat primary sleep disorder according to standard medical practice (e.g., sleep apnea, insomnia, RLS-PLMS, RBD, advance sleep phase disorder).
- Consider altered pharmacokinetics and drug metabolism in the elderly (start with a small dose and gradually increase paying attention to drug–drug interactions).
- Pay special attention to lifestyle considerations, situational stress, and environmental situations.
- Encourage regular exercise (e.g., walking).
- Be aware of special situations in the elderly (e.g., confusional episodes, disorientation, and agitation) and treat accordingly.

Indications for Treatment of Obstructive Sleep Apnea

Indications for treatment of obstructive sleep apnea are reviewed briefly in this section; the reader is referred to Chaps. 32 and 34 for details. Obstructive sleep apnea is a major cause of hypersomnia in elders, and it is often a reversible condition if appropriately diagnosed and treated. For moderate-to-severe obstructive sleep apnea, treatment is recommended. Polysomnography should be able to decide the severity of the apnea when findings are considered with the AHI, the degree of oxygen saturation, and daytime sleepiness. Before instituting any specific treatment, certain general measures are recommended, including weight loss; smoking cessation; avoidance of alcohol, sedatives, and hypnotics before bedtime; avoidance of the supine sleep position; and management of nasopharyngeal disorders. The majority of patients respond to CPAP treatment. Weaver and Chasens [280] reviewed findings from clinical trials including CPAP therapy for older individuals. These studies clearly showed the benefit of CPAP therapy in an

older population, with improvement of cognition, memory, executive function, sleep quality, and cardiovascular function. CPAP treatment is well tolerated by older adults, and patterns of adherence are similar to those noted in younger adults. In general, older patients require lower CPAP titration pressure than younger patients, and this may be related to the physiologic differences in respiratory structure and function.

If all measures including CPAP fail, surgical procedures such as uvulopalatopharyngoplasty (UPP) may be appropriate, particularly if the site of obstruction is in the pharyngeal region. The success rate of UPP is variable. Tracheostomy, which is modified to keep the trachea closed during the day and open at night, has been an option in most severe cases. The primary criteria for recommending tracheostomy [175] include severe daytime symptoms that interfere with function, severe hypertension or dangerous cardiac arrhythmias, and an AI of 20 or greater or a decrease in oxygen saturation of more than 10 % below average baseline values. Tracheostomy is now rarely used and reserved for morbidly ill patients who cannot tolerate CPAP. In selected patients with a moderate degree of sleep apnea, oral appliances [281] have been tried with moderate success.

Indications for Treatment of Insomnia

Multiple factors are responsible for insomnia in elders, and, therefore, evaluation and treatment of insomnia should be multidisciplinary [179]. Elimination or avoidance of factors that are causing insomnia is the first step in treatment. The next important general measure is paying attention to sleep hygiene. See Chap. 37 for more information on the treatment of insomnia.

Insomnia is a very common complaint in the elderly and may be the result of a variety of medical or psychiatric conditions. Insomnia may also result from PLMS, or occasionally from sleep apnea. An important cause is pharmacologic agents (i.e., drugs and alcohol), so a careful history and physical examination are important before any treatment is instituted.

PLMS is an important condition in elders, but its incidence and natural history are unknown. Even the relationship between PLMS and insomnia is not clear. Therefore, any pharmacologic treatment for PLMS is subject to controversy, and the long-term effect of drug treatment on patients is unknown. For selected cases in which PLMS clearly disrupts sleep, therapy may be indicated (see Chap. 40).

Circadian rhythm disorder, another important cause of insomnia, results from changes in the daily routine or sleep pattern, shift work, or trans-meridian travel. Therefore, environmental control and adequate counseling should be the first line of treatment.

When a medical or psychiatric disorder causes insomnia, appropriate treatment should be directed toward the primary condition. In the case of depression, appropriate treatment with tricyclic antidepressants, often those with sedative effect (e.g., amitriptyline, doxepin, trazodone), or with selective serotonin reuptake inhibitors could be used to advantage.

Medical conditions such as cardiac failure, hyperthyroidism, respiratory disorders, arthritis and other painful conditions, and esophageal reflux syndrome should be treated appropriately. It should be remembered, however, that medications themselves may cause sleep disturbance.

For transient or temporary disturbances of sleep, short-term intermittent use of hypnotics and sedatives may be useful. Long-term use of hypnotics is not recommended (see Chap. 26). The National Institutes of Health State-of-the-Science Conference on Insomnia [282] concluded that there is no systematic evidence for the effectiveness of a variety of medications used to treat insomnia in the past and even now in the elderly (e.g., antihistamines, antidepressants, antipsychotics, anticonvulsants). The conference panel also warned about the risks of using these medications in the elderly. For chronic insomnia, nonpharmacologic treatment (see later and Chap. 37) is the mainstay of therapy.

Currently, the drugs of choice for treating insomnia in the elderly are the newer nonbenzodiazepine receptor agonists [149, 150, 283–287] (see Chap. 37). Before the advent of these agents, intermediate- and short-acting benzodiazepines were used to treat insomnia in the elderly [286, 288, 289] (see Chaps. 37, 55). The benzodiazepine group of drugs may have to be used even now in some patients if they fail to respond to the newer nonbenzodiazepine agonists or the recently approved Ramelteon, a melatonin agonist [290]. However, benzodiazepine hypnotics must be used conservatively and with caution in the elderly because of their adverse side effect profile, including next-day hangover effects with a risk of falls and fractures [291]. The specific type of insomnia (e.g., sleep-onset or sleep-maintenance insomnia) should be assessed first before determining the appropriate type of sleeping medication. The best agent for sleep-onset insomnia should be a short-acting, rapidly absorbing medication (e.g., zolpidem or zaleplon), whereas for sleep-maintenance insomnia an intermediate-acting hypnotic (e.g., zolpidem extended release, eszopiclone) is best [292, 293]. Zaleplon is an ultra-short-acting hypnotic that may be used at bedtime and again in the middle of the night if needed, but the patient must remain in bed for at least 4 h to avoid residual next-morning sedation. In an

open-label trial of long-term hypnotic therapy with zaleplon 5 and 10 mg, Ancoli-Israel et al. [293] found this to be safe and effective for insomnia treatment in older patients.

There is a relative lack of data regarding the use of nonbenzodiazepine receptor agonists in the elderly. In an earlier report, Reynolds et al. [294] reviewed 1082 patients in 23 randomized, double-blind trials in elderly patients with chronic insomnia and found scientific support for the short-term (up to 3 weeks) efficacy of zolpidem and triazolam in the elderly, as well as temazepam, flurazepam, and quazepam. Triazolam, an ultra-short-acting benzodiazepine hypnotic, has since been restricted by the US Food and Drug Administration and suspended in the UK because of serious behavioral disturbances. Dolder et al. [283] reviewed five drugs: zolpidem, zaleplon, eszopiclone, ramelteon, and zopiclone. Based on limited data, all these drugs are modestly effective and well tolerated for treatment of insomnia in older subjects [289, 292–294]. Comparative head-to-head trials of these drugs, however, are lacking.

Melatonin, an indoleamine secreted by the pineal gland at night, has received considerable attention as a hypnotic based mostly on anecdotal rather than scientific evidence. Garfinkel et al. [138] found melatonin to be superior to placebo in improving sleep efficiency in the elderly in a double-blind, placebo-controlled study. However, later studies did not find melatonin to be an effective hypnotic [282, 295]. In a subgroup of elderly insomniacs with a melatonin deficiency, Haimov et al. [296] found melatonin replacement therapy to be beneficial in the initiation and maintenance of sleep in these patients.

Special Pharmacologic Considerations

Vestal and Dawson [297] directed attention to the important factor of alterations of drug metabolism, with attendant changes in pharmacokinetics, in the elderly. It is important to start with a dose smaller than younger subjects require and then gradually to increase the dose, depending on the response. It is also extremely important to obtain a drug history, to prevent drug–drug interactions and exacerbation of sleep disturbances by hypnotics or other agents.

Situational and Lifestyle Considerations

Lifestyle factors are different for elders [216]. Retirement, with disturbance of the sleep–wake schedule (e.g., napping in the daytime and consequent inability to sleep at the scheduled nighttime); so-called empty nest syndrome that develops when children leave home; and bereavement over the death of a spouse or close friend may lead to loneliness and depression with attendant sleep disturbances. Other causes of sleep disturbances in the elderly include institutionalization, prolonged bed rest, poor sleep hygiene, unsatisfactory bed environment, poor dietary habits, and caffeine and alcohol consumption.

Treatment of Sleep Cycle Changes Related to Age

Treatment of sleep cycle changes related to age consists of educating the patient about sleep disruptions in old age, discouraging multiple naps, and urging participation in special interests and other activities and hobbies [150, 184].

For the treatment of circadian rhythm disorder in the elderly, bright light therapy is the treatment of choice [150] as light is the strongest cue for circadian sleep–wake cycle entrainment. In community-dwelling elderly patients and nursing home residents, evening exposure to light is found to delay circadian rhythms, correcting the advanced sleep phase state seen in the elderly [298]. Such patients are advised to avoid bright light in the morning and spend more time outdoors during late afternoon and early evening. Such light exposure outdoors or exposure to artificial light by a bright light box (5000–10,000 lx) not only may help correct the advanced circadian state in the elderly but also may improve sleep-maintenance insomnia in some subjects [298, 299].

Treatment of Situational Stress

Patients should be given supportive psychotherapy and behavior modification treatment, as well as clear explanations, to reduce stress and sleeplessness [184].

Treatment of Nocturnal Confusional Episodes

Nocturnal confusional episodes are characterized by disorientation, agitation, and wandering at night, and often result from acute or chronic organic neurologic dysfunction (see Chap. 41) [184, 300]. Relatively sudden onset of night terrors or sleepwalking indicates an organic brain disorder, and an appropriate investigation should be made. Nocturnal confusional episodes can be precipitated by other associated medical illnesses. The treatment should be directed toward the precipitating or causal factors for these confusional episodes. Often episodes are precipitated when the patient is transferred from home to an institution. As much as possible, the home environment of such patients should be preserved. The darkness of night often precipitates episodes, so a night light is helpful. A careful drug history should be obtained, and medications that are not absolutely necessary should be gradually reduced and eliminated. The use of hypnotics may further aggravate the condition. The treatment of choice is high-potency antipsychotics, such as haloperidol and thiothixene, in small doses [216, 300] or the newer antipsychotics (e.g., risperidone, olanzapine, quetiapine) [216, 300].

Treatment of Medication-Induced Sleep–Wakefulness Disturbances

Some medications cause insomnia, whereas others cause EDS. Elderly individuals often take a variety of medications because of the increased prevalence of other illnesses. Furthermore, because of their altered metabolism, they are susceptible to the side effects of various medications. The patient should avoid alcohol, caffeine, and cigarettes, and should gradually eliminate drugs that are not essential.

Special Environmental Considerations in Treatment

Treatment should be designed and tailored to different environmental situations (e.g., nursing home, hospital, home), as different types of sleep disturbances have been noted in different environments [54].

Exercise Program

Exercise, particularly 5–6 h before sleep, is thought to have a beneficial effect on sleep quality. However, there is a dearth of well-controlled studies. King et al. [301] found that older adults with moderate sleep complaints can improve self-rated sleep quality by initiating a regular, moderate-intensity, endurance exercise program. Sugaya et al. [302] reported an improvement of deep sleep and nocturia in 18 (60 %) of 30 men (average age 71 years) after walking rapidly for 30 min or longer in the evening for 8 weeks. Preliminary study findings by Gary and Lee [303] suggested that a progressive walking program may improve TST and quality of life in older women with diastolic heart failure. Some recent studies [304, 305] have confirmed previous observations that exercise exerts a beneficial effect on sleep irrespective of the timing (morning vs. evening) of the exercise in relation to bedtime.

Nonpharmacologic Treatment

Time-limited and sleep-focused nonpharmacologic interventions have been found to improve sleep in many chronic insomniacs [306–309] (see Chap. 37). The nonpharmacologic intervention consists of cognitive behavioral therapy, including stimulus control therapy, sleep restriction therapy, relaxation techniques, and sleep hygiene education. There are some limited studies combining nonpharmacologic interventions with pharmacotherapy to improve the quality of sleep [310–315], but none in elderly insomniacs.

Evolution of Sleep from Birth to Adolescence and Sleep Disorders in Children

52

Timothy F. Hoban

Introduction

The maturational changes that occur in sleep between infancy and adolescence exhibit complex interrelationships with the other physical and developmental changes that occur as children grow older. For example, the nighttime sleep of young infants is necessarily interrupted by the frequent feedings required at this age. During adolescence, the frequently observed tendency toward delayed sleep phase can make morning waking difficult for teenagers whose classes begin at an early hour. The first part of this chapter examines the evolution of sleep from birth through adolescence and how age-related changes influence vulnerability to the common non-respiratory sleep disorders of childhood. The second part of this chapter reviews sleep-related breathing disorders in children, including obstructive sleep apnea, hypoventilation, upper airway resistance syndrome, and snoring.

The Evolution of Sleep from Birth Through Adolescence

Infant Sleep

For extremely premature infants, sleep and wakefulness do not always represent distinct or easily recognizable states. Behavioral assessment of these states becomes possible after 28 weeks of gestation, when infants begin to demonstrate episodes of spontaneous alerting and when gentle stimulation during apparent sleep results in several minutes of increased alertness and activity [1]. Longer periods of spontaneously sustained alertness become apparent by 32 weeks and are accompanied by crying or otherwise easily recognized by 36 weeks.

Electroencephalography (EEG) in premature infants does not clearly distinguish between wakefulness and sleep prior to 36 weeks of gestation [2]. By 36 and 38 weeks of gestation, periods of quiet behavioral sleep come to be characterized by *tracé alternant,* a distinctive EEG background in which bursts of high-amplitude slow waves lasting several seconds alternate with 3–15 s periods of lower amplitude fast frequencies. This activity represents the major EEG marker of *quiet sleep*, the infant equivalent of non-REM sleep. Quiet sleep is additionally characterized by regular respiration, regular heart rate, and a paucity of body movements.

The EEG activity of *active sleep*—infant REM sleep—resembles that of wakefulness in many respects. Both states are characterized by continuous, low-to-medium voltage background activity associated with less regular respiratory rhythm and increased variability of heart rate. The presence of rapid eye movements and low EMG tone during active sleep usually allows the polysomnographer to distinguish this state from wakefulness, but concurrent video or behavioral assessment is sometimes required for complete certainty. This is particularly true for infants of less than 37 weeks of gestation, whose inhibition of muscle tone during active sleep may be variable or incomplete [3].

Healthy infants who are born at term often sleep in excess of 16 h daily in the form of short sleep periods lasting 2–4 h which are initially equally distributed throughout the daytime and nighttime hours. The fragmented nature of sleep in the newborn infant is thought to be related to both the biologic necessity for frequent feedings at this age and to the fact that circadian regulatory mechanisms may not yet be sufficiently strong or well-entrained to sustain longer periods of nighttime sleep [4]. Although there is initially little day-to-day consistency in the timing and duration of sleep periods for most newborns, subtle changes in the length and organization of sleep periods begin within weeks after birth [5]. Over the span of several months, recurring

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_52

environmental and social cues foster gradual lengthening and consolidation of nighttime sleep in a process known as *settling*. The majority of healthy infants achieve prolonged nighttime sleep periods—interrupted only briefly for feedings—by 3 months of age, but 10 % fail to achieve uninterrupted nighttime sleep during the first year of life [6].

As the first year of life progresses, daytime sleep diminishes and consolidates into several daily naps. Total duration of daily sleep declines to an average of 14.2 h at 6 months of age and 13.9 h at 1 year [7]. As napping and nighttime sleep achieve greater regularity, many families establish regular bedtime and naptime routines which provide cues and structure that supplement underlying circadian mechanisms in promoting transition to sleep. Nighttime feedings gradually diminish and disappear during the first year for most infants. Although nocturnal feedings are no longer a biological necessity for most healthy infants after 5–6 months of age, they may persist after that age as a learned habit for some [8]. Between 6 and 12 months of age, normal developmental milestones such as teething and separation anxiety have the potential to disrupt previously well-established sleep routines [9].

Persistent insomnia or chronically excessive night waking during infancy often occurs in the context of suboptimal sleep onset associations, where a child habitually settles to sleep while being fed, held, rocked, or having a parent present. Some children become so reliant upon these routines that they are unable to fall asleep or return to sleep without them. Treatment typically consists of parental education and extinction-based therapies designed to eliminate maladaptive sleep onset associations and provide infants with the opportunity to learn to fall asleep independently [10, 11].

Electroencephalography and polysomnography studies of infant sleep reveal profound differences in the character and organization of sleep compared to those of older children and adults. Within the first month of life, the tracé alternant pattern of quiet sleep evolves into more clearly recognizable non-REM patterns, including the high-amplitude delta activity of slow wave sleep [12]. Sleep spindles are first seen by about 4 weeks of age and are well developed by 6–8 weeks [8, 13]. K-complexes become evident by 6 months of age and demonstrate mature forms by 2 years [14].

REM sleep also evolves considerably during the first year of life. Newborns spend 50 % of total sleep time in REM sleep, declining to 40 % at 3–5 months and 30 % at 6–23 months [15, 16]. The question of whether the high proportion of REM sleep during infancy reflects any vital function remains unanswered, although it is postulated that the REM sleep may play an important role in brain maturation during early development [17, 18]. Newborns often enter sleep via an initial REM period, but by 3 months enter sleep through non-REM stages [8]. The recurring ultradian cycling of REM and non-REM states is shorter for infants (50–60 min) than for adults (90–100 min), and lengthens gradually through childhood and adolescence [15].

Sleep in Toddlers and Preschoolers

Sleep during the toddler and preschool years is characterized by further evolution of sleep duration and architecture. Total daily sleep duration declines from an average of 13.2 h at age two to 11.8 h at age four [7]. Daytime napping typically diminishes to a single nap during the second year of life, and most children outgrow regular naps after age three.

Sleep for toddlers and preschoolers is strongly influenced by the developmental and environmental factors. Intrinsic aspects of a child's temperament—particularly the ability to self-settle—may substantially affect the ease with which a child is able to fall asleep independently at bedtime or following nighttime waking [19]. Sleep may be transiently disturbed during the minor illnesses common at these ages or more persistently disrupted if well-established sleep routines and sleep schedule are suddenly changed.

Persistent bedtime struggles represent a common clinical problem in this age-group, affecting over 10 % of toddlers and preschoolers [20]. Bedtime resistance can take the form of crying, repeatedly leaving the bedroom, or engaging in other behaviors which delay or disrupt sleep onset. Lack of structured bedtime routines, irregular sleep habits, and inconsistent parental limit-setting at bedtime represents the most common predisposing influences and the primary focus of the structured behavioral interventions used for treatment in this age-group [21]. Cosleeping—sleeping with a parent or sibling—is also common in this population and associated with increased risk of both bedtime struggles and excessive night waking [22].

Polysomnography changes during these years are more modest and gradual compared to those seen during infancy. REM sleep declines to 20 % of total daytime sleep by age five, similar to older children and adults [16] Despite declines in REM sleep and total sleep time, the duration of non-REM sleep increases by about one hour daily between infancy and age three, with gradual reductions thereafter. PSGs of toddlers and preschoolers often exhibit lengthy and highly consolidated periods of slow wave sleep during the early portions of the night.

Sleep cycles in toddlers and preschoolers remain somewhat shorter than those of older children and adults, but overall sleep architecture rapidly assumes a mature pattern in which slow wave sleep is predominantly distributed during the first third of the night and REM sleep is more prominent in the last third. The temporal distribution of these sleep states is additionally reflected by the parasomnias often exhibited by toddlers and preschoolers. Sleep terrors,

confusional arousals, and other parasomnias arising from non-REM sleep tend to occur during the first hours of sleep, whereas nightmares—which arise from REM sleep—more often transpire during the latter hours of the child's habitual sleep period.

Sleep in Preadolescent Children

Overall sleep duration gradually declines for school-age, preadolescent children, from a mean of 11.4 h at five years of age to 9.3 h by age twelve [7]. Napping is uncommon for healthy children in this age range, and the presence of habitual napping is often an indication of insufficient nighttime sleep or an underlying sleep disorder. Declining sleep duration is associated with later bedtimes for most children as they grow older, but morning waking times often vary depending on the child's schedule for school and other activities [23].

Social, environmental, and developmental factors are integrally related to the most common clinical sleep problems encountered in this age-group. For many children, evening time activities such as homework, use of electronic devices, or athletic pursuits may be stimulating enough to delay bedtime or forestall sleep onset even if the regular bedtime can be maintained. Consumption of caffeinated beverages or use of sleep-influencing medications (e.g., antidepressants, stimulants prescribed for attention-deficit/hyperactivity disorder) can also disrupt sleep onset or continuity. Older children usually gain increasing autonomy with respect to bedtime and sleep schedule, commonly resulting in insufficient sleep for age and irregular sleep schedule. The clinical sequelae of insufficient or irregular sleep in preadolescent children often take the form of inattention, impaired school performance, or emotional/behavioral dysregulation rather than overt sleepiness [24]. Unfortunately, these daytime symptoms are often misattributed to causes other than the underlying sleep disorder, sometimes resulting in misdirected or suboptimal treatment.

There are limited data regarding the evolution of PSG findings for healthy preadolescent children. It is thought that the relative proportion of REM sleep remains fairly constant at 18.5 % to 20 % of total sleep time [16]. Although total non-REM sleep also remains relatively constant, slow wave sleep declines from 24 % of total sleep time for six- and seven-year-olds to 21 % for ten- and eleven-year-olds while stage 2 sleep increases from 47 to 52 % [25]. By ages ten and eleven, the average sleep cycle length of 87 min is close to that of mature sleepers.

Multiple sleep latency testing (MSLT) data for healthy school-age children reveal mean sleep latencies that are substantially higher than those for adolescents and adults, suggesting that preadolescents are normally less sleepy during daytime hours compared to teenagers and adults [26–28]. It has been postulated that this may represent one of the reasons why children with sleep disorders do not always "act sleepy" and are more likely to exhibit alternative daytime symptoms such as inattention, hyperactivity, or behavioral disturbances rather than frank somnolence.

Adolescent Sleep

Total sleep time declines further during adolescence, from a mean of 9.0 h at the age of thirteen years to 8.1 h by age sixteen in one large cohort [7]. Despite only gradual reduction in sleep duration during the adolescent years, mean sleep latency on the MSLT for healthy normals declines substantially during early adolescence and remains at a reduced level thereafter, suggesting that sleepiness and/or sleep need may increase during puberty [26, 29]. Reductions in mean sleep latency on the MSLT are more closely correlated with Tanner stage of sexual development than age, and detailed MSLT norms for children have been reported [26, 28].

Polysomnography findings evolve only modestly during adolescence. REM sleep remains constant at about 20 % of total sleep time [29, 30]. Slow wave sleep diminishes by 35 % during adolescence, balanced by proportionate increases in stage 2 sleep [26, 29]. Sleep cycling and overall sleep architecture otherwise approximate those of young adults.

Although a detailed review of sleep disorders affecting adolescents is beyond the scope of this chapter, several common sleep problems affecting this age-group merit brief discussion. Foremost among these is the well-recognized "night-owl" tendency toward delayed sleep phase affecting many adolescents and young adults [31]. While many teenagers successfully adapt their sleep times to meet the needs of their school schedule despite this tendency, others adapt less well and may experience difficulty falling asleep at their desired bedtime or waking up at the appropriate time in the morning. It is also common for adolescents to have longer sleep periods on non-school days—typically associated with delay of both bedtime and waking times—compared to the school day schedule [26, 29]. This irregularity of sleep schedule may contribute to clinically significant sleep disruption for some adolescents, particularly when the sleep schedule on non-school days reinforces an underlying phase delay which is often already problematic.

Mildly delayed sleep phase in adolescents sometimes responds to rigorous enforcement of the desired sleep schedule, including elimination of any daytime napping or "sleeping in" on non-school days. Severely delayed sleep phase is more effectively treated using chronotherapy, a treatment in which bedtime and waking time are delayed by

two or three hours on a daily basis until the desired sleep schedule is attained [32]. Although this treatment is safe, rapid, and non-pharmacologic, symptoms can quickly relapse if the target sleep schedule is not rigorously maintained for weeks to months.

It is also common for suboptimal sleep hygiene and other medical influences to negatively impact adolescent sleep. Teenagers typically have even greater autonomy in determining their sleep schedules than preadolescent children, whose bedtimes are more closely regulated by parents and caregivers. This often results in irregular sleep habits, habitually insufficient sleep, or otherwise suboptimal sleep hygiene. Evening time activities including reading, television or computer use, and use of portable electronic devices may be associated with decreased time in bed and higher levels of daytime tiredness [33, 34]. Consumption of caffeinated beverages—on average three times higher for adolescents than for preadolescents—may also disrupt sleep for some teenagers [35]. As is the case for younger children, prescription medications may disturb nighttime sleep or daytime alertness for adolescents. In addition, alcohol and drugs of abuse represent occasional but under-recognized causes of tiredness and sleep problems in this population [36].

Sleep-Disordered Breathing in Children

> It is not at all uncommon to find children who suffer from … enlargements of the lymphoid (tonsillar) tissues of the nasopharynx and fauces, described by their parents and teachers as backwards and stupid. … The fact, however, that children, the victims of nasal and pharyngeal obstructions, often suffer from headaches, especially when engaged in study, and frequently evince marked inability to fix their attention on their lessons or work for any length of time, has in recent years led many to suspect that these symptoms [are] in part a reflection of some evident hampering of the cerebral functions.
>
> —William Hill, B.Sc., M.B.Lond, 1889 [37]

History and Classification of Sleep-Disordered Breathing in Children

Astute observations regarding the clinical manifestations of sleep-disordered breathing (SDB) in children date from the late nineteenth century, as illustrated above. Sir William Osler eloquently reported: "At night, the child's sleep is greatly disturbed; the respirations are loud and snorting, and there are sometimes prolonged pauses, followed by deep noisy inspirations" [38]. It is thought that Charles Dickens may have provided a description of daytime somnolence secondary to SDB in the Posthumous Papers of the Pickwick Club, where the character Joe is depicted as an obese, red-faced, and perpetually sleepy child (Dickens Published in serial form, 1836–1837) [39].

Modern descriptions of childhood SDB date from 1965, with initial reports of reversible cor pulmonale in children with upper airway obstruction due to adenotonsillar enlargement [40]. **Obstructive sleep apnea** (OSA) affecting eight children between five and fourteen years of age was formally described by Guilleminault and colleagues in 1976 [41]. Subjects in this series had relatively severe disease—exhibiting 78–824 apneic episodes per night during PSG—with prominent daytime symptoms including headache, behavioral disturbances, poor school performance, hypertension, and excessive somnolence. This and subsequent reports initially characterized childhood OSA as consisting of episodic partial or complete airway obstruction resulting in hypoxemia, hypercapnia, or arousal from sleep similar to adult OSA (Figs. 52.1 and 52.2).

Over time, it was discovered that children with SDB often exhibit non-apneic respiratory disturbances during sleep, and it is currently thought that prolonged partial airway obstruction may represent the predominant form of respiratory disturbance for many children as opposed to discrete events such as apneas and hypopneas (Fig. 52.3) [42, 43]. **Obstructive hypoventilation** is characterized by prolonged partial obstruction resulting in diminished pulmonary ventilation causing hypercapnia and/or hypoxemia [44]. **Upper airway resistance syndrome** (UARS) represents a form of prolonged partial airway obstruction in which increased work of breathing disrupts the quality or continuity of sleep even in the absence of gas exchange abnormalities [45].

These varieties of sleep-related airway obstruction are not mutually exclusive, and it is common for children with obstructive SDB to exhibit elements of both chronic partial obstruction and "classic" OSA during PSG.

Sleep-disordered breathing in the absence of upper airway obstruction is substantially less common than obstructive SDB in children. **Non-obstructive hypoventilation** during sleep usually occurs in the context of diminished respiratory drive, weakness of the respiratory muscles, intrinsic lung disease, or a combination of these factors. Ventilation or gas exchange during sleep becomes insufficient to meet the body's needs, resulting in hypercapnia and/or hypoxemia. Predisposing conditions include disorders of the brainstem and cranial nerves (e.g., Chiari I malformation), cervical spinal cord injuries, neuromuscular disorders (e.g., Duchenne muscular dystrophy, myotonic dystrophy), and restrictive lung disease (e.g., severe scoliosis).

Congenital central hypoventilation syndrome (CCHS) is a distinct variety of non-obstructive hypoventilation that is usually present—but not always recognized—at birth. Affected children exhibit impaired ventilatory responses to hypercapnia and occasionally to hypoxemia [46]. As a

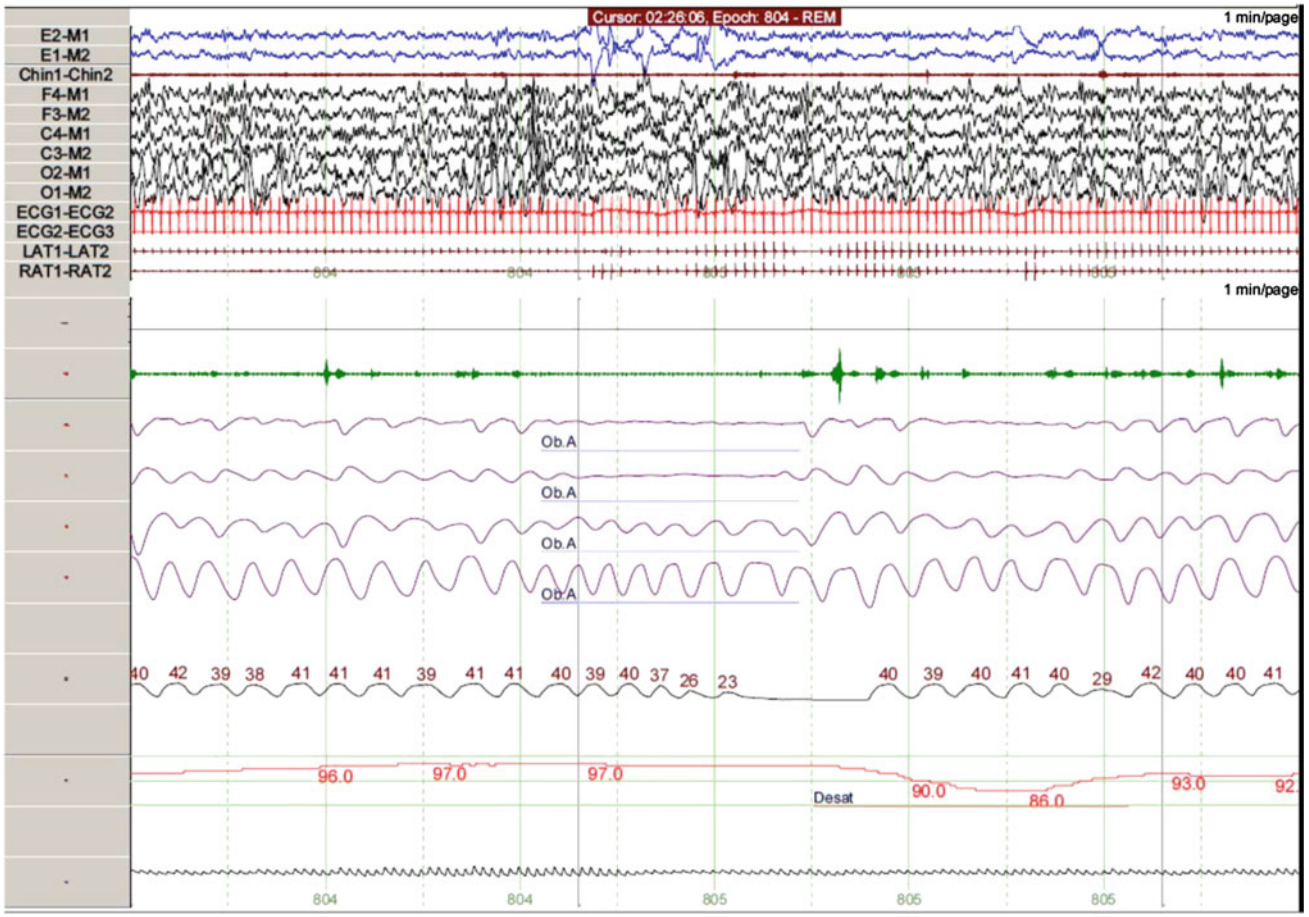

Fig. 52.1 Obstructive apnea during REM sleep (60 s PSG epoch). The event is characterized by cessation of nasal/oral (N/O) and nasal pressure (NPRE) airflow with preserved respiratory effort (THOR and ABD). Obstruction is associated with transient desaturation of SpO_2 from baseline. Note that cessation of flow on the capnogram is delayed compared to other measures of flow due to cannula transit time

result, ventilation during wakefulness may be normal or only modestly impaired, whereas ventilation during sleep is characterized by hypoventilation of a degree that may be life-threatening if the condition is not promptly identified and treated. Mutations of the PHOX2B gene have been identified in the majority of cases studied, and CCHS may be associated with Hirschsprung disease, neural crest tumors, and disturbances of cardiac autonomic regulation [47, 48]. Central hypoventilation syndromes are thought to be clinically and genetically heterogeneous, and late-onset forms with hypothalamic dysfunction have been described [49–51].

Central sleep apnea affecting children is identified most frequently in the context of **primary central sleep apnea of infancy**, formerly called apnea of prematurity. This condition is characterized by prolonged central apneas exceeding 20 s in duration or the presence of periodic breathing for greater than 5 % of total sleep time [52]. The central apneas that characterize this condition are sometimes accompanied by obstructive or mixed respiratory patterns as well. Primary sleep apnea in small or premature infants is thought to result primarily from dysmaturity of respiratory control mechanisms and usually improves with maturation. Apnea in infants may also occur as an associated manifestation of gastroesophageal reflux, infection, metabolic disturbance, upper airway obstruction, seizure, or other serious illness.

Clinically significant **central sleep apnea** is otherwise uncommon in children and has received scant scientific study. Brief central apneas are frequently observed during REM sleep or following arousals in otherwise healthy children, but seldom are accompanied by significant oxygen desaturation. Central apneas may also occur in the context of **periodic breathing**—recurring cycles of regular respiration interrupted by pauses lasting several seconds (Fig. 52.4). This stereotyped respiratory pattern is frequently observed in young infants, where it can be benign, and is occasionally seen in older children during sleep–wake transitions.

Primary snoring in children is defined as snoring which does not disrupt sleep, cause gas exchange abnormalities, or result in pathologic daytime symptoms [53]. Although this

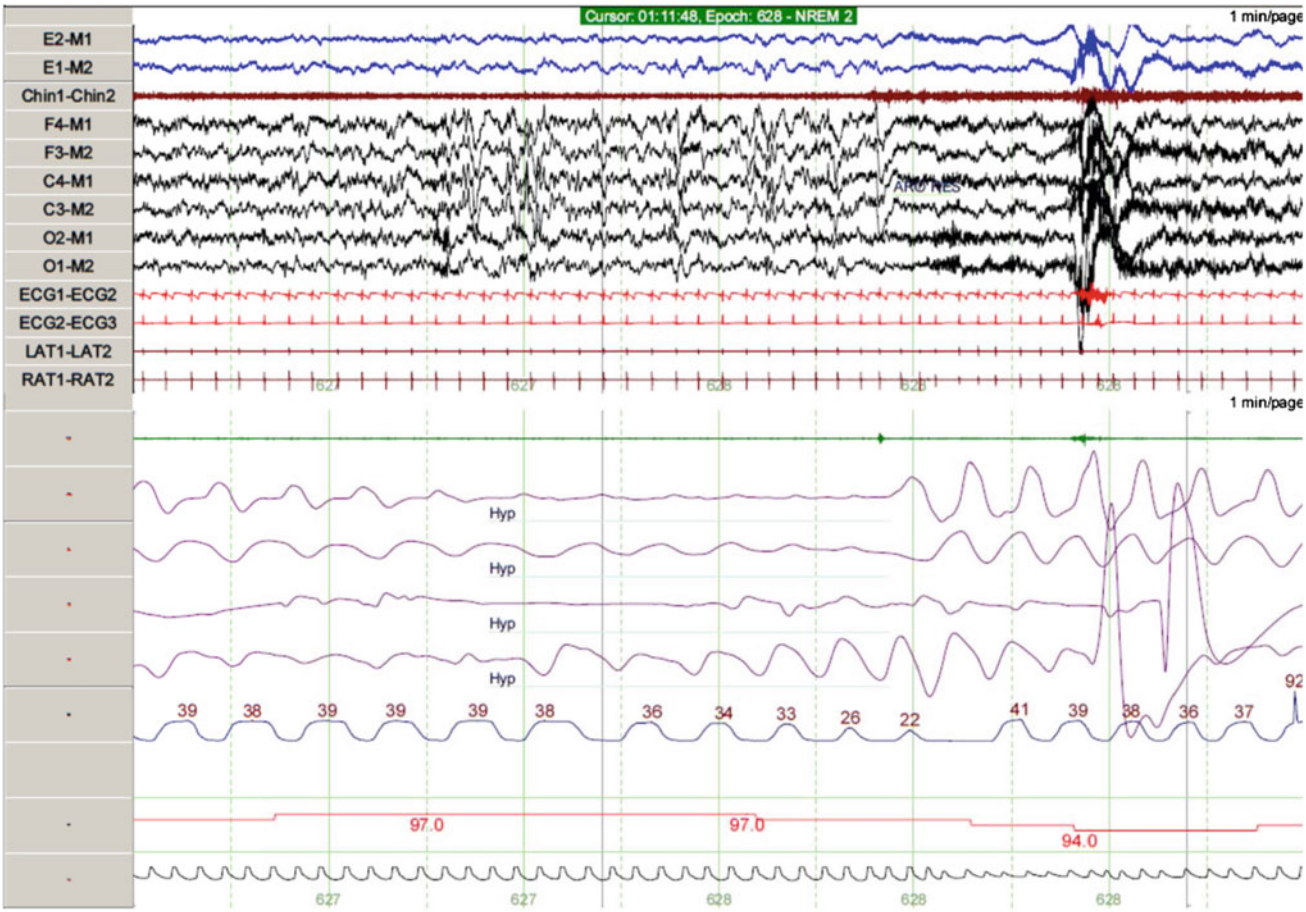

Fig. 52.2 Obstructive hypopnea (60 s PSG epoch). The event is characterized by diminished nasal pressure airflow (NPRE) and nasal–oral thermistor flow (N/O) associated with arousal and 3 % desaturation of SpO2 from baseline

condition by definition should not be associated with any secondary symptoms, subtle deficits in mood, behavior, and cognitive function have been reported in children with primary snoring compared to non-snoring controls [54–56]. It is thought that primary snoring may sometimes progress to more serious varieties of SDB. In one small series of children with PSG-documented primary snoring, 10 % were found to have developed OSA when reassessed 1–3 years later [57]. In a larger cohort, 37 % of school-age children with primary snoring had developed OSA at 4-year follow-up [58].

Epidemiology of Childhood SDB

Estimated prevalence rates for SDB in children remain imprecise because universally accepted diagnostic criteria for these conditions were only recently established and because large population-based studies using PSG have not been undertaken. It is estimated that between 5 and 12 % of children snore habitually, with some reports suggesting an increased risk of children exposed to tobacco smoke [59–63]. The prevalence of OSA in children is generally estimated to be 1–3 % [64–67].

Data are not available regarding the prevalence of UARS, central sleep apnea, and hypoventilation in children. CCHS is a rare disorder conservatively estimated to affect at least 300 children worldwide [46]. Prevalence for primary sleep apnea of infancy varies with size and gestational age. Symptomatic apnea of infancy affects 84 % of newborns weighing less than 1000 g, 25 % of newborns weighing less than 2500 g, and less than 0.5 % of term infants [52].

Clinical Features of Childhood SDB

The clinical manifestations of SDB in children (see also Chap. 32) differ from those exhibited by adults, as summarized in Table 52.1. Children with obstructive SDB tend to be noisy breathers during sleep, but severity may range from heroic snoring or stridor to only minimally loud respiration. Snoring may be continuous, intermittent, or vary with body

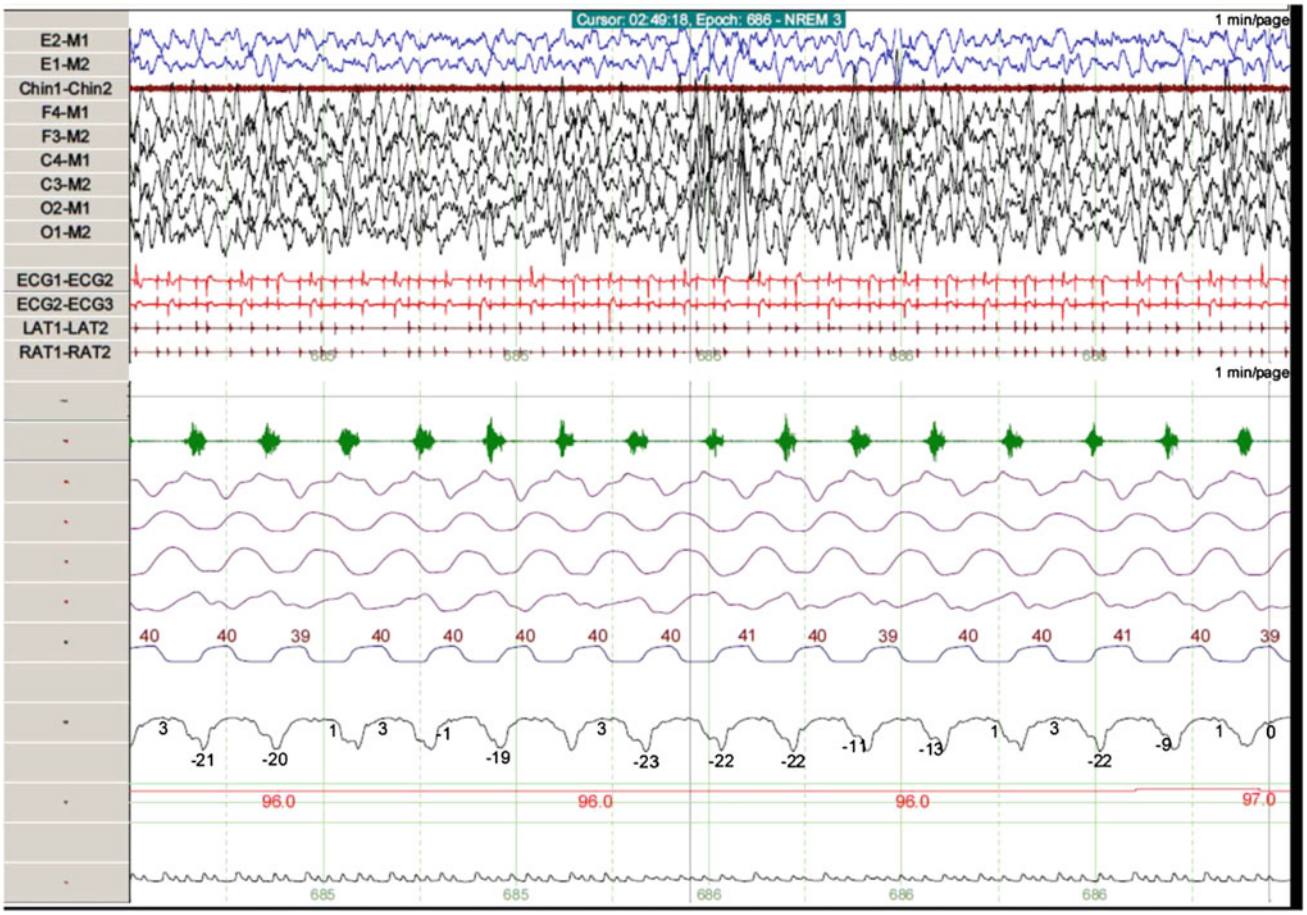

Fig. 52.3 Prolonged partial airway obstruction during stage N3 sleep (60 s epoch). Continuous snoring and excessively negative esophageal pressure fluctuations (measured peak-to-trough on ExPES with normal being 0 to −10 cm of water) indicate prolonged partial airway obstruction. *Note* normal oxygen saturation (SpO_2) and end-tidal CO_2 levels (CAPN) despite increased work of breathing

position. Snoring often worsens during upper respiratory infections or with exacerbations of allergic rhinitis and sometimes improves during treatment with decongestants or nasal steroids. Snoring in children with obstructive SDB is often accompanied by prominent mouth breathing and unusual sleeping positions such as neck hyperextension or excessive propping upon pillows, which represent compensatory mechanisms that may improve airway patency.

Witnessed apneas are only occasionally reported for children with obstructive SDB. This observation is consistent with the premise that prolonged partial airway obstruction during sleep is more common in children than the recurring episodes of brief obstruction followed by arousal that characterize typical adult OSA. When an obstructive apnea is witnessed in a child, parents may report paradoxical chest wall motion or the presence of snorting or gasping noises as respiration resumes.

Children with obstructive SDB demonstrate greater degrees of restlessness, enuresis, and perspiration during sleep than healthy controls [68]. Several reports additionally suggest that obstructive SDB may be associated with increased risk of parasomnias [69, 70].

In contrast to the prominent snoring and restlessness exhibited during the sleep of children with obstructive SDB, children with non-obstructive SDB tend to be quiet sleepers who only occasionally exhibit obvious respiratory symptoms at night. The lack of easily recognizable nighttime symptoms may lead to delays in diagnosis and treatment, particularly if sleepiness or other daytime symptoms are misattributed to other causes.

Children with obstructive SDB frequently exhibit sore throat, dry mouth, headache, or grogginess upon morning waking, although these symptoms are often transient and self-limited. Daytime mouth breathing is frequently seen in children with obstructive SDB, particularly when adenotonsillar hypertrophy is present [68]. Somnolence as a daytime symptom is seldom prominent in younger children unless their underlying SDB is severe [71]. When excessive somnolence is present, it is more often subtle or intermittent and sometimes evident only during sedentary activities such as riding in an automobile.

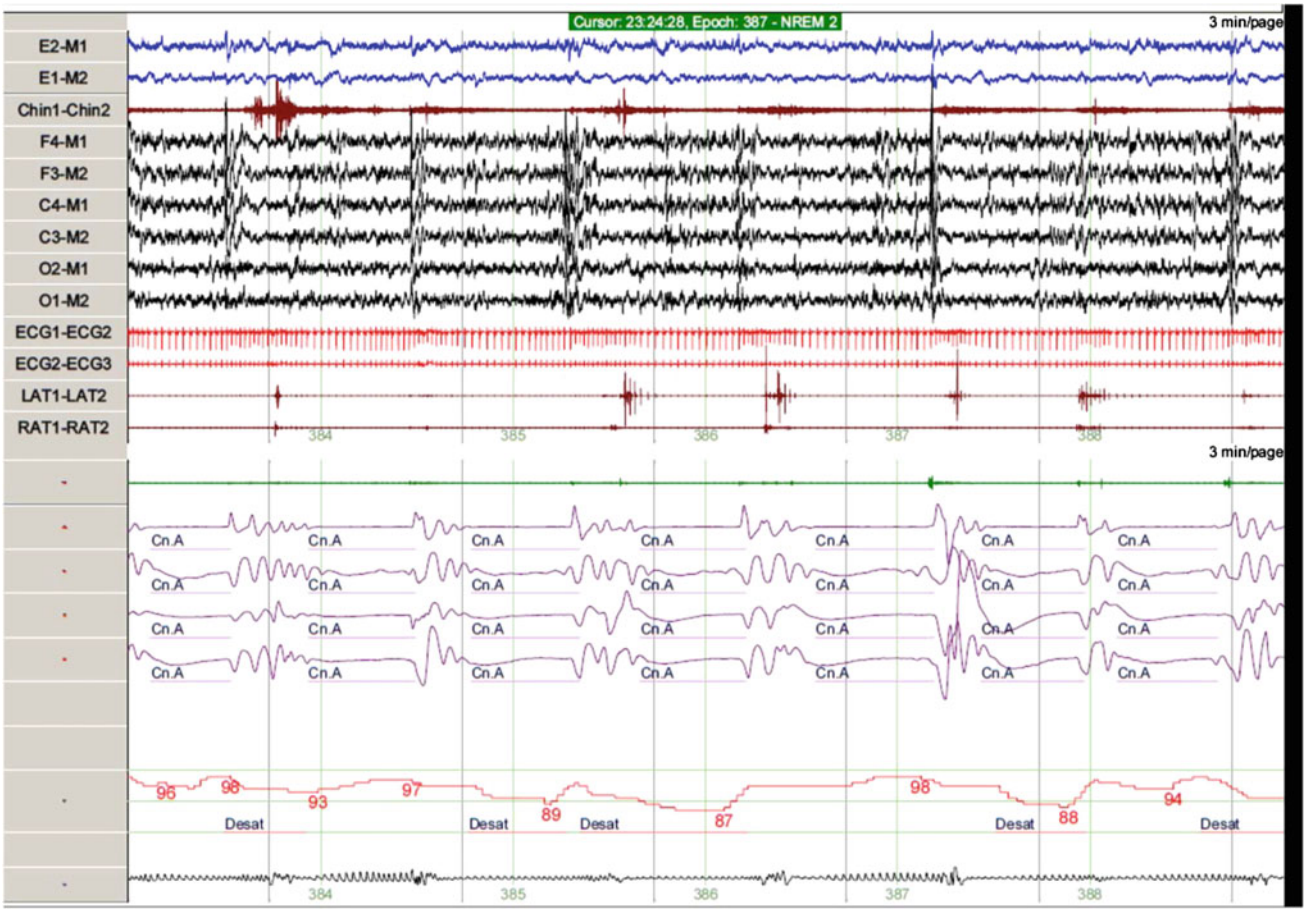

Fig. 52.4 Periodic respiration during stage N2 sleep (60 s epoch). Repetitive, stereotyped central apneas separated by several breaths (NPRE and N/O) are accompanied by cyclical desaturation of SpO_2 from baseline

Neurobehavioral deficits represent the most common and most variable daytime symptoms of childhood SDB. Early reports of childhood OSA, documenting relatively severe cases, identified a high prevalence of school problems, behavioral disturbances, and hyperactivity among affected children [41, 72, 73]. More recent reports have suggested that even less severe varieties of childhood SDB may be associated with the same daytime symptoms. Children with SDB have been reported to have higher rates of parentally reported behavior problems, lower scores on tests of sustained attention, and lower scores on neuropsychometric assessments of executive function [74–77]. Subtle neurocognitive deficits have also been reported for children with primary snoring [54, 76, 77, 78].

There is also compelling evidence that SDB is overrepresented in children with ADHD and learning problems. Snoring was reported to be three times as frequent among children with attention-deficit/hyperactivity disorder (ADHD) compared to non-ADHD controls drawn from general pediatric and child psychiatry clinics, with higher snoring scores being associated with greater levels of inattention and hyperactivity [79]. Among 297 first-grade children performing poorly in school, 54 (18 %) were found to have evidence of nocturnal hypoxemia or hypercapnia during limited, home-based sleep studies [80].

Physical Features Associated with Childhood SDB

The physical examination may be entirely normal in children with SDB, but predisposing anatomic features are often identified in affected children. Adenotonsillar enlargement, which is most common between 2 and 8 years of age, is associated with several physical findings [81]. In addition to visible tonsillar hypertrophy, "adenoid facies"—visible mouth breathing, pinched nose, and elongated facial appearance—is often observed. Narrow and high-arched hard palate, maxillary or mandibular hypoplasia, and macroglossia represent additional physical features which may predispose to SDB.

Table 52.1 Sleep-disordered breathing in children compared to adults

	Children	Adults
Physical characteristics		
Gender	Younger children: sexes equally affected Adolescents: males > females	Primarily males
Peak age	2–8 years	Middle age and older
Body weight	Usually normal, occasionally obese	Most often obese
Upper airway	Adenotonsillar enlargement frequent Redundant soft tissue occasional	Adenotonsillar enlargement occasional Redundant soft tissue frequent
Symptoms during sleep		
Snoring	Frequent, often continuous	Frequent, often interrupted by pauses
Witnessed apnea	Occasional	Frequent
PSG characteristics		
Obstruction	Prolonged partial obstruction > intermittent	Cyclical intermittent obstruction
Sleep architecture	Normal > fragmented	Frequent arousals with sleep fragmentation
Secondary symptoms		
Daytime sleepiness	Most often absent or intermittent	Frequent
Neurobehavioral	Inattention, hyperkinesis, disturbed behavior	Cognitive slowing
Cardiovascular	Hypertension, cor pulmonale	Hypertension, cor pulmonale, stroke

Obesity represents a risk factor for obstructive SDB in children, but this association is less robust in prepubertal children and more common during adolescence. In a group of 22 obese adolescents without sleep complaints, 10 (46 %) were reported to have abnormal PSGs [82]. Daytime sleepiness and AHI for this group both correlated with degree of obesity.

Some children with SDB—particularly infants and young children with severe airway obstruction—may present with decreased growth, low body weight, or failure-to-thrive [83, 84]. Treatment of these children may result in improved growth parameters and insulin-like growth factor 1 levels [85–87].

A variety of medical, genetic, and craniofacial conditions are associated with increased risk for SDB during childhood (Table 52.2). Detailed epidemiologic data are not available for most of these conditions; however, it is estimated that over 30 % of children with Down syndrome may exhibit SDB [88–91].

Secondary Sequelae of Childhood SDB

The long-term effects of childhood SDB are not well understood apart from limited data regarding cardiovascular effects. Reversible cor pulmonale and congestive heart failure have been reported in children with severe SDB [92–94]. In addition, electrocardiographic evidence of heart strain was reported for 3.3 % of 92 children referred for adenotonsillectomy [95]. The frequency with which hypertension affects children with SDB remains uncertain, but obesity and respiratory disturbance index (RDI) were found to be independently associated with increased blood pressure in a large cohort of 6- to 11-year-old children [96].

The public health impact of childhood SDB has also received little scrutiny. The extent to which affected children's neurobehavioral symptoms limit their long-term academic achievement and adult socioeconomic status has not been studied, although the effect is suspected to be substantial for at least some children with SDB. Perhaps the most dramatic evidence illustrating the public health impact of childhood SDB is data reporting substantially higher health care utilization for children with OSA compared to controls, including higher rates for hospitalization, medication use, and emergency department visits [97]. Treatment of OSA children with adenotonsillectomy resulted in a reduction of total annual health care costs by one-third, compared to no change for controls and untreated OSA children [98].

Clinical and Laboratory Assessment of Children with SDB

The assessment of a child with suspected SDB should begin with a detailed history and physical exam as outlined in

Table 52.2 Conditions associated with sleep-disordered breathing (SDB) in children

Craniofacial syndromes associated with maxillary or mandibular hypoplasia
Apert syndrome
Crouzon syndome
Goldenhar syndrome (hemifacial microsomia)
Hallermann-Streiff syndrome
Robin sequence (Pierre Robin syndrome)
Treacher Collins syndrome
Other syndromes with prominent craniofacial involvement
Achondroplasia
Klippel-Feil syndrome
Saethre-Chotzen syndrome
Velocardiofacial syndrome (Shprintzen syndrome)
Conditions associated with macroglossia
Beckwith-Wiedemann syndrome
Down syndrome
Hypothyroidism
Mucopolysaccharide storage disorders (Hunter, Hurler, and Scheie syndromes)
Conditions causing congenital upper airway abnormalities
Cleft palate
Choanal atresia
Fetal warfarin syndrome
Pfeiffer syndrome
Systemic neurological disorders
Structural lesions of the brainstem and medulla (eg, Chiari malformation)
Cranial neuropathies (eg, Fazio-Londe disease)
Neuromuscular disorders (eg, myasthenia gravis, Duchenne muscular dystrophy, myotonic dystrophy
Miscellaneous conditions
Prader–Willi syndrome

Table 52.3. The sleep history must thoroughly screen for the symptoms of SDB already discussed, but also should also include limited assessment for other sleep disorders whose clinical manifestations may mimic those of SDB. The medical history and physical examination should also include screening for other conditions that might cause or predispose toward SDB.

The history and physical examination are often supplemented by other assessment tools that are less expensive and more easily administered than PSG. A variety of standardized questionnaires have been developed with the goal of predicting whether sleepiness or SDB is likely to be present based on the presence and severity of specific symptoms. Questionnaires such as the Epworth Sleepiness Scale and Stanford Sleepiness scale are of limited usefulness in the assessment of children with suspected SDB due to limited validation data for this age-group and because the symptom that these measures assess—sleepiness—is often not obvious in affected children [99, 100]. Several questionnaires have been developed specifically for use in children, and limited validation data have been obtained regarding the use of the Pediatric Sleep Questionnaire and OSA-18 as screening tools for childhood SDB in clinical and research populations, [101–103]. The sensitivity of these tools for detection of SDB in clinical populations may be limited, however [104].

Although audio recordings of a child's snoring have long been recommended as a "$5.00 sleep study," this technique did not reliably distinguish primary snoring from SDB (AHI $\geq$ 5) in a blinded study assessing 29 snoring children [105]. Although home video recordings of a child's sleep are an easy and usually inexpensive supplement to the clinical history during evaluation of a child with suspected SDB, the sensitivity and specificity of this technique have not been rigorously assessed.

Overnight oximetry is not recommended for primary assessment of children with suspected SDB [106]. Although the technique is unobtrusive, inexpensive, and well tolerated by most children, it reliably detects SDB only when arterial

Table 52.3 Clinical assessment of the child with suspected sleep-disordered breathing (SDB)

Sleep history	Snoring: volume, frequency, character, changes over time Mouth breathing Unusual sleeping positions (eg, neck hyperextension, propping on pillows) Restlessness, limb movements Excessive perspiration Night waking: frequency, duration, and patterns Enuresis Symptoms upon waking: grogginess, headache, sore throat, dry mouth Sleep schedule Family history of SDB or other sleep disorders
Daytime symptoms	Mouth breathing Headache Behavior: irritability, distractibility, hyperkinesis, temperamental behavior School: attention, academic performance, decline in grades Sleepiness, especially in sedentary situations (e.g., automobile rides)
Medical history	ENT: adenotonsillar disease, allergic rhinitis, congenital anatomic abnormalities Endocrine: obesity, growth, thyroid disease Cardiovascular: hypertension, congenital heart disease Pulmonary: asthma, other intrinsic lung disease Neurologic: disorders affecting brainstem and cranial nerves or causing muscle weakness Development: developmental delay, infant failure-to-thrive Other: craniofacial disorders, genetic syndromes (eg, Prader–Willi Syndrome, Down Syndrome)
Physical examination	Vital signs: weight, height, body mass index, blood pressure, percentile ranks Oropharynx: tonsillar size, airway patency, palate, dentition, occlusion, tongue Nasopharynx: polyps, septal deviation, airflow, “pinched-nose” appearance Craniofacial: micrognathia, maxillary hypoplasia, occlusion, cleft palate, or other craniofacial syndrome Neck: thyroid, masses, circumference Thorax: cardiac exam, lung auscultation, evidence of scoliosis Neurologic: cranial nerve palsies, evidence of muscular weakness or neuropathy Behavior: attention, hyperkinesis, evidence of irritability or sleepiness Other: mouth breathing, noisy respiration, “adenoid facies”

oxygen desaturation is prominent and does not identify those children whose SDB is characterized primarily by hypercapnia or obstruction without desaturation. Among 210 children with PSG-documented OSA (AHI $\geq$ 1), 120 (57 %) had normal or inconclusive nocturnal oximetry, confirming that normal oximetry cannot be used to rule out SDB in children [107].

Other non-PSG diagnostic tests are used on selective basis for children with suspected SDB, primarily in children with predisposing conditions and children presenting with severe symptoms. Anatomic obstruction of the upper airway is often demonstrable on radiographic or endoscopic assessment [108, 109]. Children suspected to have severe SDB or concurrent cardiorespiratory problems sometimes require chest X-rays, electrocardiogram (ECG), echocardiogram, and formal pulmonary function testing for complete assessment. Children with prominent learning or behavioral problems usually benefit from neuropsychometric testing and age-appropriate behavioral assessment and intervention, even when such symptoms are secondary to SDB.

Polysomnography in Childhood SDB

Laboratory-based PSG represents the most sensitive and reliable tool presently available for the detection and classification of SDB in children. It is also a test that can be easily customized based on the clinical presentation of each patient. For example, 16-lead EEG can be added to standard PSG to provide increased sensitivity for the detection of interictal discharges or nocturnal seizures. Similarly, esophageal pressure monitoring (Pes) is sometimes performed for children felt to be at risk of UARS and other obstructive SDBs associated with prolonged partial airway obstruction.

PSG also has several limitations when used in children. The test itself is lengthy, expensive, and potentially stressful for both children and their parents. Laboratories having substantial experience in performing and interpreting PSG for children are limited in number and sometimes have lengthy waiting lists. Finally, routine PSG is not always sensitive for the detection of prolonged partial airway obstruction (e.g., UARS), but tools such as Pes make the

study more invasive and are not available in all pediatric sleep laboratories.

PSG should be performed when a child's symptoms, medical history, and physical examination suggest significant risk of clinically significant SDB. Isolated snoring—especially when it is only soft and occasional—is seldom a sufficient indication for PSG unless other symptoms or risk factors are also present. Practice guidelines that address respiratory indications for PSG in children have recently been issued by the American Academy of Sleep Medicine [106, 110]. Although it is common for otolaryngologists to perform adenotonsillectomy for suspected SDB without preoperative PSG, the safety and cost-effectiveness of this practice have been vigorously debated [111–113]. In addition, this practice can potentially result in children with noisy respiration, but no clinically significant SDB having surgery for which the overall health benefit is uncertain. Until validated practice guidelines address these issues, the author's practice is to apply the same standards presently used for adults: to obtain a baseline PSG for patients with clinically suspected SDB before decisions are made with respect to treatment.

PSG in children is performed in a manner comparable to adult studies, utilizing frontal, central, and occipital EEG channels, electrooculogram (EOG), and ECG, as well as chin and limb electromyogram (EMG). Respiratory monitoring at minimum includes oral and nasal airflow, chest and abdominal movement, arterial oxygen saturation, and measures of carbon dioxide (end-tidal and/or transcutaneous). Most laboratories use nasal pressure transducers—thought to be sensitive to flow limitation and subtle decrements in flow—to assess nasal airflow, but since many children breathe through their mouths, thermistor, or thermocouple sensors to monitor oral or oral–nasal flow remain necessary as well.

Many sleep laboratories have the capability to supplement standard recording techniques with additional modes of respiratory monitoring when clinically indicated. Pes may be added to improve the sensitivity of PSG for partial airway obstruction and increased work of breathing. Pes is minimally invasive—requiring insertion of a thin catheter through the nasopharynx into the esophagus—but the technique has negligible impact upon children's sleep and is the most sensitive method presently available for the measurement of increased upper airway resistance [114, 115]. Several less invasive techniques for the assessment of partial airway obstruction have been investigated for use in children, including *pulse transit time*, *peripheral arterial tonometry*, *respiratory cycle-related EEG changes*, and *intercostal EMG monitoring*, but none of these techniques are yet available for routine clinical use [116–121].

Scoring of sleep stages, movements, and arousals during pediatric PSG is performed in the same manner used for adult studies. Thirty-second epochs are reviewed and scored manually using standard criteria recently revised by the American Academy of Sleep Medicine [122–124]. Scoring of respiratory events for children differs slightly from that for adults. Whereas scoring of apneas, hypopneas, and respiratory effort-related arousals (RERAs) requires a minimum event duration of 10 s in adult studies, scoring of these events for pediatric studies requires only that the event last at least the duration of 2 missed breaths. This rule permits scoring of brief events in children whose baseline respiratory rate during sleep exceeds 12 breaths per minute.

Standards for interpreting the results of pediatric PSG have evolved over time. Normative PSG data for 50 healthy, asymptomatic children between 1 and 18 years of age were reported in 1992, as summarized in Table 52.4 [125]. Although these data have helped define the statistical limits of normality in healthy children, the point at which abnormal PSG parameters become associated with pathologic symptoms and outcomes has not been precisely determined. An AHI exceeding 5 events per hour is generally considered to be abnormal for adults. Although this threshold had previously been used for the diagnosis of OSA in children, the fact that children frequently demonstrate symptomatic OSA with AHIs below 5 has long suggested that a lower threshold is more appropriate for children [55, 56].

The current *International Classification of Sleep Disorders, Third edition (ICSD-3),* criteria for the diagnosis of pediatric OSA require the presence of one or more scorable obstructive events per hour of sleep or documentation of obstructive hypoventilation in conjunction with other clinical and PSG findings as outlined in Table 52.5 [52]. These revised criteria now permit many children who previously would have been classified as having nocturnal hypoventilation or UARS to be classified as having OSA. Further

Table 52.4 Polysomnographic (PSG) parameters in 50 healthy children aged 1–18 years

PSG parameter	Mean ± SD
Apnea index (events/hour)	0.1 ± 0.5
Minimum SaO_2 (%)	96 ± 2
Desaturations ≥4 % (per hour of total sleep time)	0.3 ± 0.7
Maximum $ETCO_2$ (mm Hg)	46 ± 4
Duration of hypoventilation (ETCO2 > 45 mm Hg) (percentage of total sleep time)	7 ± 19 %

Adapted from Marcus et al. [125]

Table 52.5 ICSD-3 criteria for pediatric obstructive sleep apnea

Criteria A and B must both be satisfied:
A. The presence of one or more of the following symptoms:
1. Snoring
2. Obstructed, labored, or paradoxical respiration during sleep
3. Hyperactivity, disturbed behavior, learning problems, or sleepiness
B. PSG demonstrates one or both of the following findings:
1. One or more obstructive apneas, hypopneas, or mixed apneas per hour of sleepOR
2. The presence of obstructive hypoventilation ($\geq$ 25 % of total sleep time spent with PCO_2 > 50 mm Hg) associated with one or more of the following findings:
a. Snoring
b. Flattening/ flow restriction of the inspiratory nasal pressure waveform
c. Paradoxical thoraco-abdominal effort

Adapted from The International Classification of Sleep Disorders, Third Edition [52]

outcomes-based research remains necessary to better define the thresholds at which abnormal respiratory parameters on PSG become associated with clinically significant sequelae.

ICSD-3 did not specify separate pediatric criteria for non-obstructive forms of hypoventilation, with the partial exception of congenital central hypoventilation syndrome, a genetically mediated condition secondary to mutations of the PHOX2B gene which typically presents during infancy [52]. Current American Academy of Sleep Medicine, PSG, scoring rules define sleep-related hypoventilation for children as consisting of PCO_2 levels exceeding 50 mm Hg for greater than 25 % of total sleep time [123] (Fig. 52.5).

Diagnostic criteria for UARS in children were not addressed in ICSD-3, although proposed criteria have been published elsewhere [55].

Treatment of SDB in Children

Adenotonsillectomy is the most commonly administered treatment for obstructive SDB in children [126]. Although this procedure is thought to be effective in alleviating upper airway obstruction for many symptomatic children, the frequency with which adenotonsillectomy "cures" SDB in children is variable.

Early case series assessing response of childhood OSA to adenotonsillectomy reported surgical cure rates exceeding 70 %; however, these studies were limited by substantial variability in patient selection and frequent use of adult rather than pediatric PSG criteria to define OSA [127, 128].

More recent studies have reported variable and sometimes lower operative success rates. Among one group of 110 children with OSA (AHI > 1, mean AHI 22.3), complete postoperative normalization of the AHI was observed in only 27 subjects (25 %) [129]. In another large cohort of successively seen children with OSA (AHI > 1), 94 of 199 subjects (47 %) demonstrated abnormal polysomnograms postoperatively [130]. Among 397 children with OSA enrolled in a large, randomized, multicenter trial, PSG findings normalized in 79 % of children treated with adenotonsillectomy compared to 46 % of those assigned to watchful waiting and supportive care [131]. These and other studies suggest that children with high Mallampati scores, high preoperative AHI, obesity, or atypical anatomy of the upper airway may be at elevated risk of residual SDB following adenotonsillectomy.

In addition to improvements in obstructive symptoms and PSG parameters, adenotonsillectomy for children with SDB may also be associated with tangible improvements in behavior, school performance, and quality of life measures [132–134]. In one large cohort of children assessed before and after clinically indicated adenotonsillectomy, half of the children having ADHD prior to surgery no longer qualified for the diagnosis when reassessed one year postoperatively [117, 118].

The potential clinical benefits of adenotonsillectomy in children with OSA should be considered with due attention to the possible complications of the procedure. Postoperative hemorrhage may occur in up to 8 % of pediatric patients [135]. Reports documenting the frequency of postoperative respiratory complications range from 0 to 27 % of children, with greatest risk of children who are young (especially less than age 2), exhibit high baseline AHIs, or have associated craniofacial or medical problems [136–138]. Children who fall into these high-risk groups benefit from close or prolonged cardiorespiratory monitoring in the immediate postoperative period.

Follow-up for children treated via adenotonsillectomy should commence with a postoperative clinical assessment. Repeat PSG is usually indicated for children who have residual symptoms postoperatively or whose OSA was severe prior to surgery. Delayed recurrence of SDB following childhood adenotonsillectomy has been reported, with recurrence in 20 of 40 children reassessed one year postoperatively in one report and in 3 of 13 patients reassessed during adolescence in another series [139, 140].

Nasal CPAP (continuous positive airway pressure) represents the most common non-surgical treatment for childhood SDB. Although children with adenotonsillar hypertrophy are most often treated via adenotonsillectomy,

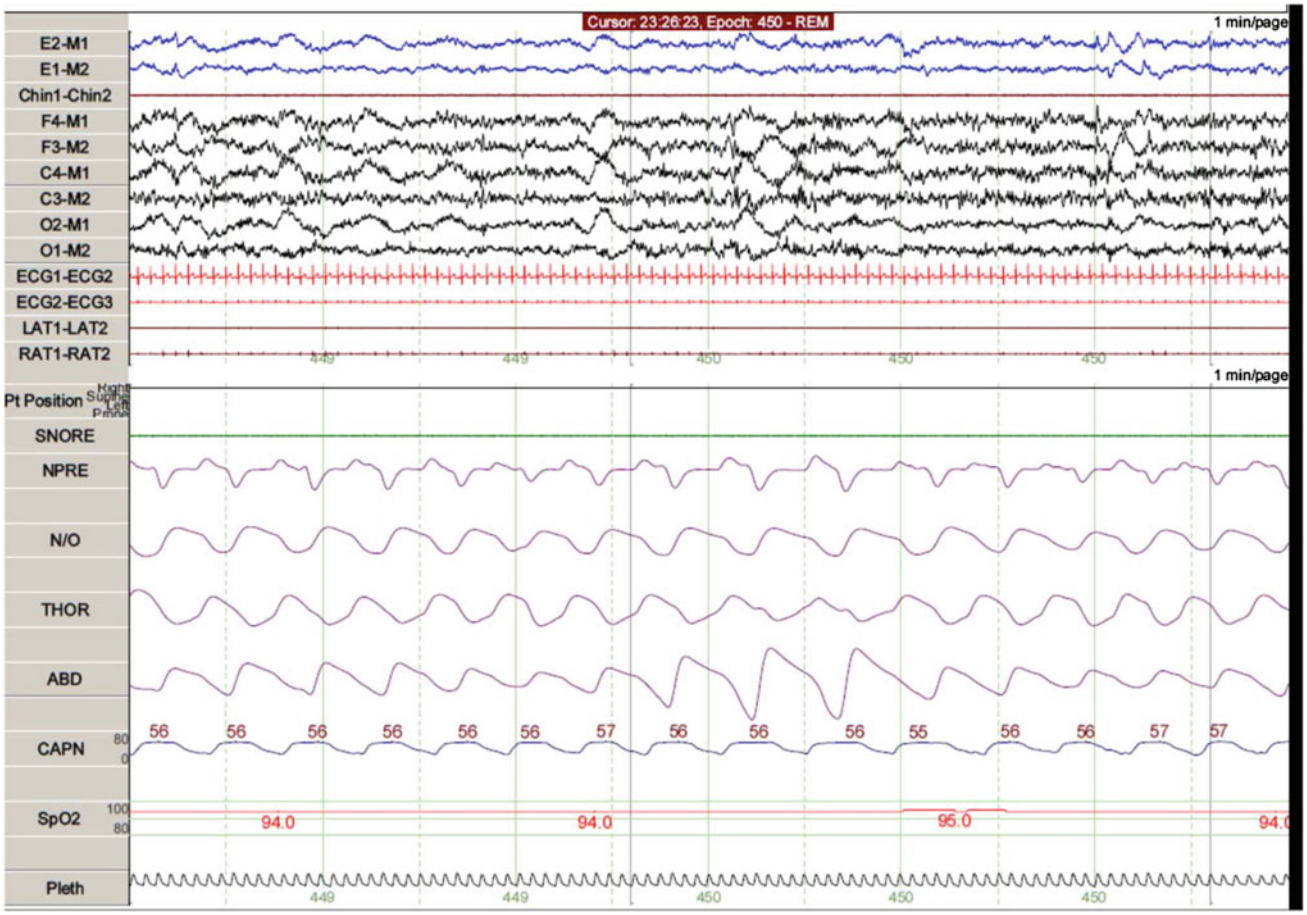

Fig. 52.5 Sleep-related hypoventilation (60 s epoch). Capnography (CAPN) demonstrates persistent elevations of end-tidal CO_2 above 50 mm Hg during REM sleep in the absence of desaturation and scorable respiratory events. Paradoxical respiratory effort is demonstrated in the thoracic (THOR) and abdominal (ABD) effort channels

CPAP represents the most common treatment for children with obstructive disease who are not appropriate candidates for adenotonsillectomy, for children whose obstruction persists despite adenotonsillectomy, and for children having non-obstructive varieties of SDB. CPAP has not been formally approved by the US Food and Drug Administration for use in children weighing less than 30 kg, but is nonetheless generally considered to be a first-line treatment for pediatric SDB, with reports of successful use in hundreds of children [65]. CPAP in children may be customized using a variety of interfaces, including nasal pillows, nasal or oral–nasal masks, and total face masks.

Effective use of CPAP as treatment for obstructive SDB has been reported in children of all ages (Table 52.6), although data are limited regarding long-term compliance and outcomes for the pediatric population. Side effects are generally mild, most often consisting of skin irritation, mask leak, or pressure sores, which are easily remedied by improving mask fit. Nasal dryness or congestion often improves with addition of a heated humidifier. Central apnea may occasionally complicate treatment with CPAP, particularly at higher pressure settings. Serious side effects are uncommon, but isolated cases of pneumothorax have been reported in children with concomitant neuromuscular disorders [141, 142]. Mid-face hypoplasia has been also been reported as a rare complication of long-term therapy [102, 103].

A child's compliance with the use of CPAP is influenced by several important factors. Disabled children who are unable to easily remove the CPAP mask will sometimes tolerate nasal CPAP once acclimated. Typically developing children and adolescents who are old enough to understand and accept the need for CPAP are also likely to achieve consistent long-term use. Compliance is most challenging for younger or disabled children who are able to remove their mask independently, for typically developing children who actively resist CPAP use, and for families who are

Table 52.6 Major pediatric reports assessing CPAP in the treatment of sleep-disordered breathing

Study	Population	Successful use	Effective pressures
[161]	94 patients Age: infants to 19 years OSA: PSG-documented, not otherwise defined	Successful: 86 % Unsuccessful: 1 % Non-compliant: 13 %	Median 8 cm H_2O (range 4–20 cm H_2O)

[168]	27 patients Age: 7–19 years OSA: AHI ≥ 5 or abnormal SaO_2/$ETCO_2$	Adherent: 70 % Non-adherent: 30 %	Mean 8.8 ± 2.1 cm H_2O
[169]	13 obese adolescents Age: 10–16 years OSA: mean obstructive AHI 9.3 (non-adherent), 10.0 (adherent)	Adherent: 46 % Non-adherent: 54 %	CPAP: mean 10.0 ± 2.7 cm H_2O (non-adherent); 9.2 ± 2.2 cm H_2O (adherent)
[170]	56 children, primarily obese Age: 2–16 years OSA: PSG-documented, mean AHI 19 ± 16	CPAP used ≥50 % of nights during first month, mean duration of nightly use 3 ± 3 h	CPAP: mean 8 ± 2 cm H_2O; BiPAP: mean 13 ± 3/7 ± 2 cm H_2O

unable to consistently incorporate CPAP into their child's bedtime routine. Sustained parental effort or age-appropriate desensitization programs with experienced providers can sometimes help these children achieve consistent use [143].

Data regarding use of CPAP for treatment of non-obstructive SDB are extremely limited, addressing small numbers of patients. Standard or bilevel CPAP may be effective in the treatment of hypoventilation, with most reports focusing on children with CCHS [144–146].

Alternative Surgical Treatments for Childhood SDB

Other surgical treatments besides adenotonsillectomy are only occasionally performed in children. **Septoplasty** and **turbinectomy** can sometimes alleviate non-adenoidal nasal obstruction. **Uvulopalatopharyngoplasty** (UPPP) is sometimes performed for children with low-lying soft palates or redundant lateral pharyngeal tissue. Despite reports of

clinical improvement in several small series of children treated with UPPP, efficacy as determined by PSG measures is not well established for the procedure [147, 148]. Soft tissue procedures such as **lingual tonsillectomy** and lingual reduction surgery have not been formally studied in children. **Radiofrequency ablation** procedures involving the tongue base and soft palate are rarely undertaken in children. Ablation procedures entail risk of potential complications including abscess, neuralgia, and mucosal sloughing [149].

For children having significant micrognathia, maxillary hypoplasia, or other craniofacial deformity, skeletal surgeries have the potential to improve upper airway obstruction. Mandibular reconstruction techniques used in children include **distraction osteogenesis** and, for older children, **mandibular advancement** via sagittal osteotomy [150]. For children with maxillary hypoplasia, **Lefort advancement** procedures can correct cosmetic deformity and sometimes alleviate nasopharyngeal obstruction. These procedures should only be considered in the context of significant skeletal deformity, since effectiveness for the purpose of treating childhood SDB has not been rigorously assessed.

Tracheostomy for treatment of childhood SDB is performed only when the underlying condition is severe and refractory to conventional therapy. The procedure is highly effective in alleviating upper airway obstruction but carries significant trade-offs in the form of ongoing stoma care, increased risk of infection or bacterial colonization involving the respiratory tract, and adverse impact upon overall quality of life [151, 152]. Because of these trade-offs, aggressive use of CPAP and skeletal or soft tissue surgery has been advocated to reduce reliance upon tracheostomy [153].

Alternative Medical Treatments for Childhood SDB

Supplemental oxygen has a limited role in the treatment of childhood SDB and is used most often for children who have failed first-line therapies or who have underlying pulmonary disease [154]. A randomized, double-blind study assessing the response of children with OSA to oxygen at one liter per minute reported modest improvements in oxygen saturation but no change in the frequency or severity of apnea [53]. In addition, two of 23 patients became significantly hypercapnic with treatment, consistent with the premise that some children may rely upon hypoxic respiratory drive during sleep to maintain adequate ventilation [65]. For this reason, and also because many varieties of SDB disrupt sleep and produce secondary symptoms even in the absence of hypoxemia, this therapy should be used cautiously and with due recognition of its limitations.

Respiratory stimulants are used frequently in the treatment of apnea of infancy but are seldom used and largely unstudied outside of this context. Methylxanthine agents—most frequently theophylline and caffeine—produce short-term improvement of infant apnea and reduce the need for mechanical ventilation, but their impact upon long-term outcome is unknown [155]. Acetazolamide is occasionally used for the treatment of central sleep apnea in children as well, although optimal dosing and long-term effectiveness have not been established [156].

Oral appliances are seldom used for the treatment of childhood SDB due to concerns that this therapy could result in orthodontic problems. **Positional therapy**—affixing a small ball to the back of patients' pajamas or nightclothes to prevent them from comfortably assuming a supine position—is sometimes recommended for children with OSA when obstructive symptoms are problematic primarily in that position. Although this technique has been reported to improve the AHI for adults with OSA, no pediatric trials have been undertaken [157].

Some reports suggest that the use of **nasal steroids** may be associated with improvements in the AHI for children with obstructive SDB. Trials of budesonide in children with OSA reported improvement of mean AHI from 5.2 to 3.2 following 4 weeks of treatment in one uncontrolled series and reduction in AHI from 8.4 to 1.2 following 6 weeks of treatment in another [158, 159]. In a randomized, placebo-controlled trial, 6 weeks of treatment using fluticasone propionate was associated with reduction in the obstructive AHI from 10.7 to 5.8 for children with OSA versus an increase in the placebo group. Because the post-treatment AHIs in these reports are often still abnormal as determined by current pediatric criteria for the diagnosis of OSA (AHI $\geq$ 1), and because no long-term studies have been performed, nasal steroids cannot yet be routinely recommended as a primary treatment for children with SDB. **Systemic steroids** have been found to be ineffective in treating OSA in children with adenotonsillar hypertrophy [160].

The Menstrual Cycle and the Effects on Sleep

Hormonal and Sleep-Related Changes Across the Menstrual Cycle

Cyclical changes in four reproductive hormones—luteinizing hormone (LH), follicle-stimulating hormone (FSH), estrogen, and progesterone—and in body temperature occur in a normal, ovulatory menstrual cycle. The cycle lasts 28 days on average (Fig. 53.1) but may range from 25 to 35 days. When menstruation starts (day 1), levels of all four key reproductive hormones are low. As FSH and estrogen rise, ovarian follicles develop and mature. This follicular phase precedes ovulation and may vary in length. LH peaks about 16 h prior to ovulation, and the appearance of LH in urine is a reliable marker of ovulation. At ovulation, an oocyte is released from the follicle. The corpus luteum then evolves from the ruptured follicle and secretes progesterone and estrogen during the luteal phase. If ovulation occurs, body temperature, measured at the same time every morning, increases by about 0.4 °C; this effect is mediated by progesterone [1–3]. In the absence of pregnancy, about 7 days after ovulation, the corpus luteum degenerates and hormone production begins to decline. The luteal phase lasts 14–16 days. Most negative menstrual symptoms are experienced as hormone concentrations decline toward the end of the luteal phase and during the first days of menstruation.

Subjective Reports of Sleep Across the Menstrual Cycle

Normally, subjective sleep quality is reduced both premenstrually and at menstruation [4–6]. Retrospective surveys have found that 16–32 % of women report increased fatigue, difficulty in concentrating, or lethargy in the premenstrual period [1, 7–9]. A telephone survey of 514 women for the National Sleep Foundation (NSF) in 1998 found that approximately 70 % of women report that their sleep is adversely affected on average 2½ days every month by menstrual symptoms such as cramps, bloating, tender breasts, and headaches [10].

Increased sleep disturbance around menstruation has been confirmed in some, but not all, prospective studies [4–6]. In a study of 32 women who kept daily diaries across two menstrual cycles, although there was no change in sleep duration in the late luteal compared to the mid-follicular phase, sleep disturbances increased, with poorer sleep quality. In the premenstrual period, sleep onset was delayed and there was an increased number of awakenings [5]. In contrast, there was no change in sleep quality or sleep duration in 30 young women with normal menstrual cycles [6]. In our study based on daily self-reports across one menstrual cycle, ovulation was confirmed in 26 young women without significant menstrual-associated complaints, sleep quality was reduced in the 3–6 premenstrual days and during the first 4 days of menstruation [4]. These studies, and other reviews [1, 7–9], highlight the challenges

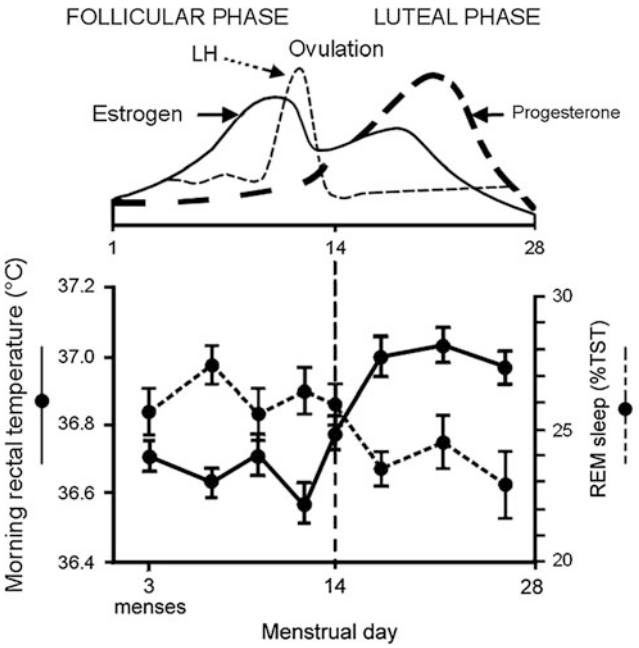

Fig. 53.1 Menstrual cycle changes across a 28-day ovulatory cycle. The day menstruation begins is generally considered the first day of the menstrual cycle, and ovulation occurs around day 14. *Top* The profile for luteinizing hormone (*LH*), which peaks before ovulation (*dotted line*), and the ovarian hormones estrogen and progesterone. *Bottom* Morning core body temperature (*solid line*, axis on the *left*) and REM sleep as a percentage of total sleep time (TST; *dashed line*, axis on the *right*) (Modified from Driver et al. [2] and Driver and Baker [1])

inherent in studying menstrual cycle effects, including variability in cycle length, the presence of ovulation, individual and cycle-to-cycle differences, changes with age, and the frequency of data sampling. Given the cyclical, though modest, reduction in sleep quality around the time of menstruation in women without sleep complaints, assessment of insomnia in naturally cycling women should consider the temporal relationship of sleep complaints and the phase of the menstrual cycle.

Polysomnographic Studies Across the Menstrual Cycle

Early laboratory studies were based on small sample sizes, usually in young women (<30 years of age), with heterogeneous groups including those with affective symptoms or those taking oral contraceptives (OCs), often without verification that ovulation had occurred [1, 7, 9]. Two studies addressed these issues [2, 11] by conducting more frequent recordings, at 3 nights per week [11] and every other night [2], in nonsymptomatic good sleepers with verified ovulatory cycles. These polysomnographic (PSG) studies included spectral analysis of the sleep electroencephalogram (EEG) and core body temperature measurements. Both studies revealed an increase in sleep spindle frequency [2, 11] in the mid- to late-luteal phase compared with the follicular phase. This effect on sleep spindles was reflected in a menstrual-associated variation in stage 2 sleep (higher in the luteal phase). Increased stage 2 sleep in the luteal phase compared to the follicular phase was also reported by Shechter and colleagues [12] who recorded sleep every third night in the laboratory in five healthy women and seven women with premenstrual dysphoric disorder (PMDD). This luteal phase increase in stage 2 and sleep spindle power may represent an interaction between endogenous progesterone metabolites and γ-aminobutyric acid (GABA) type A membrane receptors [2]. However, in a group of 16 healthy women and 18 women with severe premenstrual syndrome (PMS), Baker et al. [13] found no correlation between EEG sigma (12 to <15 Hz) power (i.e., sleep spindle frequency) and progesterone based on one night laboratory recording in the mid-follicular and the late-luteal phase.

No significant effect of menstrual cycle phase on slow-wave sleep (SWS, now N3) [2, 11–14] or EEG slow-wave spectral activity [2] has been reported suggesting that sleep homeostatic mechanisms are not altered by menstrual phase. With the higher nocturnal temperature of the luteal phase, rapid eye movement (REM) sleep is slightly reduced [2, 3, 14] particularly in the early-luteal compared to the early-follicular phase [12], with shorter REM sleep episodes in the first 3–4 cycles if not the whole night [13, 15]. No significant menstrual phase effect on sleep latency or sleep efficiency based on PSG has been reported. The few controlled PSG studies in young women with no menstrual-associated complaints show that sleep across the menstrual cycle is remarkably stable, aside from variation in sleep spindles and subjectively disturbed sleep in the premenstrual and menstrual periods [1–4, 7–9, 11].

Oral Contraceptives and Their Effect on Sleep

OCs are used by approximately 100 million women worldwide [16, 17], yet few studies have examined their effects on sleep. Studies are complicated by different levels of synthetic estrogen and progestin within the various OCs, which are available as monophasic and triphasic pills [16, 17]. OCs contain synthetic estrogen and/or progestin that prevent ovulation by suppressing endogenous reproductive hormones. While the progestin is responsible for the contraceptive effects, the estrogen component is included for cycle control, and ethinyl estradiol is a potent suppressor of pituitary gonadotropins. Side effects are reported by about half of the women who start taking OCs [17]. Among the most commonly reported are weight gain, painful periods, swollen legs, and heavy menstrual bleeding; a change in sleep is not a commonly reported side effect [16, 17].

Women taking monophasic combination OCs, which provide the same dosage of hormones through the entire 21-day active cycle followed by 7 days of inactive placebo, had persistently raised body temperatures when taking either the active OC or the placebo [3]. This increase in temperature with OCs has also been reported in a study of circadian rhythms during 24 h of sleep deprivation with 8 women in the follicular phase, 9 in the luteal phase, and 8 who were taking OCs (pseudo-luteal phase) in an environment free of time cues using a modified constant routine procedure [18]. There was also an increase in melatonin levels in the OC group when compared to the women studied in the follicular phase [18]. Women taking OCs had significantly more stage 2 sleep in the active phase of the OC compared to the placebo, and more stage 2 compared to the naturally cycling women in both menstrual cycle phases [3]. OC users also had less SWS than naturally cycling women in the luteal phase [3]. A reduction in SWS with OC use was reported based on an archival analysis that compared women diagnosed with major depressive disorder and healthy controls, although menstrual phase or type of contraceptive was not controlled [19]. Reduced REM latency has also been reported in healthy women taking OCs [19], but OC use does not affect sleep efficiency [3, 19] or subjective sleep quality [3].

On balance, because OC effects on sleep appear modest, for women with premenstrual and menstrual symptoms as described in the next sections, attenuation of pain and mood symptoms by OCs may improve sleep.

Premenstrual-Related Effects on Sleep: Premenstrual Syndrome and Premenstrual Dysphoric Disorder

Starting from puberty and lasting until menopause, women are at twice the lifetime risk of developing major depression as are men [20, 21]. Approximately 60 % of women experience mild premenstrual symptoms, referred to as premenstrual syndrome (PMS), but for 3–8 % of women, the cyclical pattern of symptoms is severe enough to be diagnosed as premenstrual dysphoric disorder (PMDD) [21]. Common symptoms that occur in the last week of the luteal phase and lessen after the onset of menstruation include irritability/anger, anxiety/tension, depression and mood swings, change in appetite, bloating, weight gain, fatigue, and problems with sleep [22]. Complicating the comparison of studies of sleep in premenstrual mood disturbance is the fact that definitions and severity of symptoms vary considerably as do the duration of symptoms [21, 23, 24]. Sleep disturbances include problems falling or staying asleep, hypersomnia, unpleasant dreams, wakening during the night, failure to wake at the expected time, and tiredness in the morning. Women with PMS perceive their sleep to be poor in the symptomatic phase with a decline in subjective ratings of sleep quality [13], with more unpleasant dreams [25]. These women report tossing and turning, frequent awakenings, and taking a long time to fall back asleep after an awakening during the night. Perhaps as a consequence of the disturbed sleep, or reflecting an underlying need for more sleep, women with severe PMS have increased daytime sleepiness [25–29]. Subjectively poorer sleep quality in women with severe PMS has been related to anxiety indicating the relationship of mood with sleep quality ratings [13].

Laboratory studies in symptomatic women have yielded conflicting findings, and only a small number of women have been studied [24]. There are reports of significantly more stage 2 sleep [14, 27] and less SWS [14] or more SWS [2, 12] and less REM sleep [27] compared to asymptomatic women in both phases of the menstrual cycle. Other studies show no objective change in sleep [28]. The finding of increased SWS (N3) in women with PMS/PMDD compared to controls while sleep efficiency was unaltered has been associated with psychological state [2] and with reduced nocturnal melatonin secretion [12] suggesting changes in homeostatic and circadian processes.

Women with increased severity of premenstrual symptoms have been found to have an increase in luteal phase daytime sleepiness [5]. In a study by Lamarche et al. [29], 10 women with significant emotional/behavioral premenstrual symptoms when compared with 9 women with minimal symptoms (mean age 26 years) were more sleepy and less alert in the late luteal phase than in the follicular phase. No menstrual phase change in sleepiness was found in the women with minimal symptoms. Women with more severe symptoms were significantly sleepier and less alert than women with minimal symptoms during the late luteal phase but not the follicular phase of the cycle. Using a midafternoon 40-min nap intervention, there were no group differences in sleep-onset latency, with both groups falling asleep within an average of 7 min. The short sleep-onset latency found for both groups of women suggests a high sleep need during the late luteal phase regardless of symptom severity, but may also be indicative of chronic sleep restriction in this age group.

Changes in nocturnal temperature rhythms and melatonin secretion suggest that women with PMDD have underlying circadian rhythm abnormalities that could impact sleep [20]. As reviewed by Baker et al. [24] in the symptomatic (luteal) phase, women with PMDD tend to have higher nocturnal temperatures and decreased melatonin secretion than normal controls; compared to their follicular phase, women with PMDD have delayed and decreased melatonin secretion. Therapeutic mood benefit has been reported by Parry et al. [30] from 1 night of partial sleep deprivation (4 h of sleep,

either 9:00 P.M. to 1:00 A.M. or 3:00 A.M. to 7:00 A.M.), with further improvements reported after a subsequent recovery night of sleep (11:00 P.M. to 7:00 A.M.). Initial findings indicate that appropriately timed light therapy may be a treatment strategy for PMDD, reducing depression, irritability, and physical premenstrual symptoms compared to a placebo condition. Thirty minutes of light therapy in the evening for 2 weeks during the luteal phase resulted in a significant improvement in premenstrual symptoms in women with PMS compared to baseline levels [31]. Larger trials with light therapy in this population are needed.

Painful Menstrual Conditions: Dysmenorrhea and Endometriosis

As many as 50 % of women suffer from dysmenorrhea and experience extremely painful cramps during menstruation, the pain is very severe in approximately 10–25 % of women [24, 32]. Similarly, women with endometriosis—who have misplaced uterine (endometrial) tissue in the abdominal and pelvic area—suffer extreme menstrual pain. Not surprisingly, these women report poorer sleep quality and higher anxiety during menstruation compared to symptom-free women.

Baker et al. [33] found that dysmenorrheic women had more disturbed sleep and subjective sleepiness than controls. Their sleep efficiency was reduced when experiencing menstrual pain, with increased wakefulness, movement, and stage 1 sleep compared with pain-free phases of their cycle. In a subsequent study of 10 women with primary dysmenorrhea, when experiencing menstrual pain, sleep efficiency was reduced with less REM sleep, and more stage 1 sleep during the night compared with a pain-free mid-follicular phase of their menstrual cycle [34]. Women with dysmenorrhea (like those with PMS/PMDD) had decreased REM sleep and increased core temperature during the luteal and menstrual phases compared to normal controls. Although progesterone concentrations in the luteal phase were similar to those in asymptomatic women, dysmenorrheic women had elevated morning estrogen levels in the follicular and luteal phase and higher prolactin levels in the luteal phase [21, 33]. Prostaglandins have been implicated as the mediators of the pain of primary dysmenorrhea, with the most common pharmacologic treatment for dysmenorrhea being nonsteroidal anti-inflammatory drugs (NSAID) [35]. Indeed, when dysmenorrheic pain was treated with the NSAID diclofenac potassium, given as two doses of 50 mg during the day and a 50 mg dose in the evening before bedtime, menstrual pain was attenuated and both objective and subjective sleep quality was restored with increased sleep efficiency and REM sleep compared to placebo [34].

Fibromyalgia (FM) and Functional Somatic Syndromes

Fibromyalgia is more common in women than in men, as are the other chronically widespread and regional painful, multi-symptom syndromes: irritable bowel syndrome, chronic pelvic pain, low back pain, temporomandibular joint disorder, and tension-type headache [36]. These conditions are sometimes referred to as functional somatic syndromes when pain hypersensitivity and stress-immune dysregulation are evident with emotional arousal and physiologic activation but no clear pathologic indicators [36]. With FM, painful regions and tender points have been associated with poorer sleep and increased alpha EEG [36, 37]. Complaints of pain and insomnia are more prevalent in women than in men, though little is known about the physiologic and behavioral mechanisms involved [37]. In chronic pain conditions, objective PSG measures show lighter and less consolidated sleep, possibly with more arousals, but no specific marker aside from a characteristic alpha EEG (7.5- to 11-Hz) intrusion into non-REM delta sleep (alpha-delta sleep, ADS); in patients with fibromyalgia, ADS was first described in 1975 by Moldofsky and colleagues [38]. However, not all studies have found differences in objectively measured sleep parameters. A recent study of female adolescents (n = 10, aged 16 years) with juvenile primary fibromyalgia syndrome revealed poorer sleep efficiency, more arousals/awakenings, and more ADS (70.3 % of total SWS versus 21.9 % SWS) than controls [39]. In the adolescent women, completion of a multidisciplinary pain treatment program over approximately 4 weeks that included intensive exercise therapy, improved pain, disability, and subjective sleep quality, but neither ADS nor other objective measurements of sleep quality changed after treatment [39]. Combining data from two randomized placebo-controlled double-blind trials of pregabalin (Lyrica®) for the management of FM in adults (n = 748 and 745, 95 % females, mean age 50 years), in addition to pain relief, improvements in subjective sleep quality and the severity of sleep disturbance compared to placebo showed clinically important differences [40].

Fibromyalgia has also been associated with a high prevalence of inspiratory flow limitation [41]. Conceivably, cortical arousability in response to increased upper airway resistance (UAR) may be reflected as increased EEG frequency and sleep fragmentation, causing more somatic

symptoms than those more commonly associated with obstructive sleep apnea (OSA), namely excessive daytime sleepiness and snoring.

Polycystic Ovarian Syndrome

Women with polycystic ovary syndrome (PCOS), a condition of irregular or anovulatory menstrual cycles, increased androgen production, and metabolic consequences related to insulin resistance and weight gain [42, 43], are more likely to develop OSA [42–46]. Sleep apnea is described in more detail in the next section on sleep-disordered breathing (SDB).

Four percent to 10 % of women of reproductive age may suffer from PCOS [42–47]. About half of these women are overweight [48] with metabolic-related disorders and visceral obesity [47]. Approximately 15 % of obese normal women have OSA [49], but in obese women with PCOS, the incidence of OSA is markedly increased at 41–58 % [42] interestingly their body mass index (BMI) itself does not correlate with their OSA severity [43–45]. In obese women with PCOS, fat distribution follows a male pattern, with increased waist-to-hip ratio [45, 46]. However, in adolescent girls (15 years) with PCOS (n = 31) compared with healthy obese girls without PCOS (n = 19) neither group had significant OSA although total sleep time (TST), percentage of REM sleep, and sleep efficiency were lower in the girls with PCOS [47]. Symptoms of PCOS usually begin in adolescence and perhaps OSA develops in a subgroup of females over time along with worsening insulin resistance. A relationship of OSA severity with waist-to-hip ratio, elevated serum testosterone [44], and higher fasting insulin levels [45] indicates the contribution of androgenization and insulin resistance to the higher prevalence of OSA in women with PCOS [42, 46].

Sleep-Disordered Breathing in Women

The range of SDB includes snoring, the upper airway resistance syndrome (UARS), OSA, and the obesity-hypoventilation syndrome (OHS) as well as central sleep apnea (CSA) and periodic breathing (Cheyne–Stokes respiration). Women with SDB may report snoring less frequently than men [50] but they report more fatigue [51] and nonspecific complaints [52, 53]. Young premenopausal women (<30 years) in particular more often present with these nonclassical symptoms of OSA such as insomnia and depression, as well as cranio-facial findings [54]. One study found that women were more likely than men to be treated for depression and have hypothyroidism at the time of diagnosis [55]. As reviewed by Banno and Kryger [56], women with a diagnosis of OSA had higher obesity and comorbid psychiatric conditions and received more antidepressants, hypnotics, and anxiolytics before OSA diagnosis, compared to men with OSA matched for age, BMI, and apnea-hypopnea index (AHI) [57].

The prevalence of CSA in women and OSA in premenopausal women is quite low, with women showing about half the prevalence of OSA as men, although this discrepancy declines in postmenopausal women [58–60]. More recent large cohort studies in the general population, coupled with changes in technology (e.g., more accurate airflow measurement via nasal cannula pressure transducers than with thermocouples), the increase in obesity with higher prevalence in women than men [48], and the referral bias in favor of men [55], indicate that OSA is more common in women than previously recognized. An association between lighter sleep (more high-frequency EEG beta) that is more fragmented and of lower sleep efficiency with the metabolic syndrome was reported in a group of 368 midlife women (age 46–57 years) enrolled in the SWAN study [61]. Sleep-disordered breathing, as measured by a clinical cutoff score AHI $\geq$ 15, and lower sleep efficiency were found to be independent correlates of the metabolic syndrome and were independent of race and menopausal status [61].

There is evidence that upper airway resistance (UAR) during sleep is higher in men [62], and the male airway is more collapsible than in women. Premenopausally, women are protected from developing sleep apnea. Indeed, there is a menstrual phase effect on UAR, with UAR being lower during the luteal phase than in the follicular phase [63], possibly related to progesterone effects. A number of other factors may contribute to the gender differences in SDB, such as differences in anatomy, upper airway collapsibility, the arousal response to increased inspiratory resistance, and ventilatory control [62, 63]. The clinical effect of lower airway resistance and less collapsibility in women is apparent in PSG differences: Women with OSA have more hypopneas than frank apneas with a shorter duration of apneas than in men [64], and lower apnea severity in the luteal versus follicular phase [65]. Women with OSA tend to have a clustering of respiratory events during REM sleep [66, 67], the frequency of which is related to BMI in both men and women [67]. The magnitude of the increase in blood pressure after apnea termination compared with immediately prior to apnea termination was higher during the luteal phase than during the follicular phase, despite lower OSA severity in the luteal phase [65]. The augmented luteal phase pressor response to apneas may effectively be enhancing the arousal response due to a combination of centrally mediated and peripheral sympathetic responses [65]. The arousal response in UARS to airflow limitation results in daytime sleepiness due to fragmented sleep [52]. Excessive sleepiness is a key presenting complaint for OSA. However, in women with recently

diagnosed OSA, insomnia was more likely to be a presenting complaint than it was in men [55, 68].

Clinically there is the potential that in some women, polysomnographically significant SDB may manifest in the follicular phase and could be missed by a diagnostic study in the luteal phase. Menstrual-related variability in the severity of sleep apnea may require a corresponding adjustment in management, such as varying the pressure requirement of continuous positive airway pressure (CPAP) therapy as could be achieved using long-term auto-adjusting positive airway pressure (APAP).

Sleep Disorders Associated with the Menstrual Cycle

There is very limited research on premenstrual sleep disorders, and its inclusion is based on isolated case reports. Three forms of "menstrual-associated" sleep disorders—premenstrual insomnia, premenstrual hypersomnia, and menopausal insomnia—were listed under the category of Proposed Sleep Disorders in the revised International Classification of Sleep Disorders (ICSD) published in 1997 [69]. In the second edition of the ICSD from 2005 [70], the only two disorders carried over were menstrual-related hypersomnia and menopausal insomnia. The third edition of the ICSD published in 2014 eliminated these as separate categories and listed menstrual-related hypersomnia as menstrual-related Kleine-Levin Syndrome (see Chap. 27).

Difficulty falling asleep or staying asleep, usually in the week before menstruation (premenstrual insomnia), should be distinguished from PMS and PMDD. Insomnia as the only premenstrual symptom is not considered sufficient to receive a diagnosis of PMS. Premenstrual hypersomnia occurring periodically around menses, preceding and into the early-follicular phase, has been successfully treated with hormonal treatment (conjugated estrogen or oral contraceptives) [71]. In another case of periodic hypersomnia, prolactin was elevated but did not respond to hormone replacement therapy and was symptomatically treated with methylphenidate [72].

Sleep During Pregnancy

Sleep disruption during pregnancy is a common and multifaceted problem [73, 74]. Contributing factors include hormonal changes, fetal movement, bladder distention, gastrointestinal discomfort, vomiting, and temperature fluctuations. There are significant changes in sleep architecture, and primary sleep disorders such as OSA and restless legs syndrome (RLS) may be more common. Most women accommodate to the changes in sleep, but for a proportion of them, the disruption will prove problematic and may result in medical and psychiatric complications.

Subjective Changes in Sleep

A large percentage (66–94 %) of women note alterations in their sleep during pregnancy [75–77]. During the first trimester, subjective sleep quality decreases and the number of nocturnal awakenings increases. Daytime sleepiness is more problematic. During the second trimester, women report that sleep normalizes, although 19 % of women continue to experience difficulties at this stage [77]. By the third trimester, women experience worsening insomnia, increased daytime sleepiness, and decreased alertness [76]. Reasons cited for the increased sleep disturbances were mainly urinary frequency, backache, fetal movement, abdominal discomfort, leg cramps, and heartburn. A survey of sleep disruption across pregnancy found that 97 % of women identified themselves as having disrupted sleep, while a third felt they had a "sleep disorder" [78]. The latter group may be biologically or psychologically more vulnerable to the detrimental effects of disrupted sleep. Factors such as a prior history of a psychiatric disorder, lack of a social support network, poor coping skills, and difficulty adjusting to the impending role of motherhood are likely important in this regard.

The 1998 NSF survey found that 79 % of women reported that their sleep was, or had been, disturbed during pregnancy [10]. Women who were currently pregnant or had been pregnant recently were more likely to report frequent insomnia (64 %) when compared to premenopausal or menopausal women. Of the women reporting sleep disturbance during pregnancy, 70 % reported that it interfered with daily functioning on at least a few days per month. It is unclear for what proportion it represented a *serious* problem. There are limitations to this survey, such as the fact that not all women were pregnant at the time of reporting and were hence providing retrospective accounts of their sleep during pregnancy, but it does shed light on the extent of subjective sleep disruption during pregnancy. The NSF 2007 "Sleep in America" telephone poll of 1003 women included 150 pregnant (second trimester, $n = 47$; third trimester, $n = 91$) and 151 postpartum women [79]. More pregnant women (84 %) experienced insomnia symptoms at least a few nights a week, compared to 67 % of the overall group. In response to whether they were getting a good night's sleep at least a few nights a week, 82 % of pregnant women felt they were doing so before their current pregnancy, compared to 60 % who felt this to be the case during their ongoing pregnancy. More women in their second trimester (72 %) said they got a good night's sleep at least a few nights a week than those in their third trimester (54 %). Reasons for sleep disturbance were to go to the bathroom (92 % in the third trimester and 75 % in the second trimester), and pain in their back, neck, or joints (66 and 47 % of third and second trimester women,

respectively). Two other reasons for disturbed sleep in the third trimester are leg cramps (54 %) and heartburn (51 %).

Objective Changes in Sleep

Pregnancy has a significant impact on sleep architecture and on the quantity and quality of sleep. Several excellent reviews [9, 80–82] show that the findings are not fully consistent and that more research into the changes in sleep architecture that accompany pregnancy is necessary. However, there is consensus that there is a "lightening" of sleep as pregnancy progresses, with a decrease in sleep efficiency, decreased total sleep time, increased wakefulness after sleep onset, and decreased REM sleep. Most studies show a decrease in SWS, especially in the third trimester [83, 84]. One study reports an *increase* in SWS from early to late pregnancy [85]. This last finding may relate to the fact that only primiparous women were included, while the other studies included both primiparous and multiparous subjects. The sleep of these two groups of women appears to differ; exactly in what way remains to be determined. According to one study, multiparous women have lower sleep efficiency at all time points across pregnancy [84]. Immediately postpartum, primiparous women have lower sleep efficiency, but at 3 months postpartum, their sleep had improved but did not revert to its prepregnancy baseline. This finding would suggest that pregnancy and childrearing has a prolonged impact on sleep architecture. Another study, following women's sleep using actigraphy during pregnancy and at 1 and 6 weeks postpartum, reported that primiparous women have lower sleep efficiency in general during pregnancy and postpartum, when they also had fewer sleep episodes than their multiparous counterparts [86]. Again, the discrepancy in findings could be secondary to varying assessment techniques (PSG, actigraphy) and relatively small sample sizes.

Primary Sleep Disorders Associated with Pregnancy

The risk for OSA increases substantially with obesity [48, 87] but the prevalence with the weight gain during pregnancy is unclear. Changes in respiratory physiology during pregnancy, such as decreased functional residual capacity [88], changes in the airway mucosa [89], and hyperventilation with increased sensitivity to CO_2 [90], may predispose to obstructive or central apneic events. Some investigators have found no decrease in nocturnal arterial oxygen saturation during pregnancy [91, 92]. Others, however, report significantly more nocturnal desaturation in pregnant women compared with controls [93, 94]. Hypertension in the mother at the time of birth and lower Apgar scores in the infant are significantly more common in women who reported snoring during pregnancy as compared to nonsnorers [95]. A large (n = 1091) prospective study of pregnant women suggests that severe snoring in the third trimester is a significant risk factor for fetal growth restriction and preterm birth [96]. A number of case series, using small numbers and relying on clinical examination rather than PSG, indicate that OSA may be associated with intrauterine growth retardation, especially if other complications such as maternal obesity and diabetes mellitus are present [97]. The control of partial upper airway obstruction and snoring using nasal CPAP in women with preeclampsia has been shown to decrease blood pressure significantly [98]. Edwards and Sullivan [99] have reviewed the risks and treatment options of SDB during pregnancy and with preeclampsia.

Restless legs syndrome (RLS) and periodic limb movements in sleep (PLMS) increase during pregnancy [81, 100]. Women cite restless legs as a common cause of sleep disruption during pregnancy [74]. Complaints of leg cramps during waking in the middle of the night should raise the possibility of RLS-PLMS, especially if the woman is experiencing daytime sleepiness or fatigue.

Risks Associated with Sleep Disruption During Pregnancy

The role of sleep disturbance in the development of psychiatric illness is a grave concern. Patients with persistent insomnia are at significant risk for developing depression [101]. This holds true even when there is a medical cause, such as sleep apnea, for the insomnia. Women with sleep disruption during pregnancy and in the weeks postpartum may be at higher risk for depressive symptoms during pregnancy [76] and for postpartum mood disorders, especially where there is a previous history of mental illness [102, 103]. Parity may play a role in this regard. One study which compared sleep and mood in primiparous women and multiparas noted that both parameters were better in the latter group [104].

Sleep disruption often heralds the onset of a manic or hypomanic episode among patients in the general population who suffer from bipolar illness [105, 106]. The risk of new-onset mania or recurrence of a preexisting illness during the postpartum period is significant. Women with a history of bipolar affective disorder (BAD) have a twofold increase in risk for symptom exacerbation during the immediate postpartum period. Furthermore, women with a prior history of BAD have a sevenfold increase in risk for a psychiatric admission in the puerperum when compared with nonpostpartum and nonpregnant women [107]. Even fathers with BAD are at increased risk of relapse in the postpartum period [108]. This suggests that the sleep disruption associated with

caring for a neonate may play an important role in the development or recurrence of postpartum psychiatric illness. The challenge for the clinician is to identify those women for whom sleep loss, an inevitable part of childbearing, will have serious consequences.

Patients with insomnia often resort to the use of alcohol and over-the-counter remedies. The NSF report [10] found that 7 % of pregnant women used over-the-counter medications and 7 % used alcohol at some point in the pregnancy to help them sleep, while 4 % used prescription medications for this purpose. The use of such sleep aids during pregnancy could have significant consequences for the developing fetus.

Research is being carried out on the impact of pregnancy-related sleep complaints and inflammatory markers. A study by Okun et al. [109] on 19 women during mid- and late-trimester pregnancy examined subjective sleep reports and the levels of circulating (naturally occurring) and secreted (experimentally stimulated peripheral blood mononuclear cells) interleukin-6 (IL-6). Complaints of shorter sleep duration and poor sleep efficiency at both stages of pregnancy were associated with higher levels of stimulated IL-6; while in late pregnancy, sleep complaints were also associated with higher levels of circulating IL-6. The implications of these findings for maternal well-being and fetal development remain to be determined.

Management of Pregnancy-Related Sleep Disruption

Significant sleep disruption during pregnancy is likely underreported by women. Hence, it is imperative that the primary caregiver inquire about it and determine to what extent it warrants further assessment and intervention. Potential medical causes should be considered (e.g., medications, thyroid problems, psychiatric illness) and treated where appropriate. Primary sleep disorders such as OSA and RLS/PLMS should be ruled out.

Significant respiratory disturbance can be treated with CPAP, which has been shown to be safe during pregnancy [97, 98]. Milder respiratory disturbances may respond to conservative measures such as positional therapy.

There is a relationship between low serum ferritin levels and RLS/PLMS. Iron supplementation should be instituted where this is the case. Conservative measures such as reducing caffeine intake or wearing supportive stockings should be implemented. The use of any form of medication during pregnancy must be approached with caution, and the patient must be made fully aware of the risks and benefits. Pregnant women are not included in drug trials, and the safety of many medications during pregnancy has not been determined. The safety of certain medications used to treat RLS/PLMS (e.g., pramipexole, gabapentin, ropinirole) is unknown. The benzodiazepine clonazepam carries concern about possible teratogenicity when used in the first trimester. However, judicious use in the second and third trimesters may be warranted. There is a risk of "floppy baby syndrome" if used close to the time of delivery, and the patient should be educated accordingly. Some patients with RLS/PLMS respond well to opioids such as codeine and oxycodone, and there is no evidence of teratogenicity, although there is a risk of a withdrawal syndrome or respiratory depression in the neonate.

During the postpartum period, the sleep of women with a history of a mood disorder must be protected since a recurrence at this time can have disastrous consequences for both mother and infant [106]. Prolongation of the hospital stay to enable the new mother to recover from the impact of labor and birth may be beneficial. The patient's partner and other family members should be encouraged to play an active role in nocturnal feeding.

Where no primary cause for the sleep disruption can be determined, nonpharmacologic treatments should be the primary intervention. Attention to sleep hygiene factors, such as a regular sleep–wake schedule, avoiding caffeinated beverages, reducing the amount of fluids consumed in the evening, and ensuring the temperature in the bedroom is comfortable, should be highlighted. There are no data concerning the efficacy of cognitive and behavioral techniques, such as cognitive behavioral therapy or stimulus control therapy, for insomnia during pregnancy. However, given that they are efficacious for insomnia in general, we would expect that they would be beneficial when applied during pregnancy.

The majority of women are likely to resist the use of sleeping medications, but where insomnia is having a severe effect, the use of a sleep aid may be warranted. The antihistamine dimenhydrinate has not been associated with fetal effects in animal studies. The nonbenzodiazapine hypnotics, zopiclone, zaleplon, and zolpidem, all considered Class C drugs by the America Academy of Pediatrics (AAP), should be limited during pregnancy until more data are available. A study of pregnancy outcome in 40 women exposed to zopiclone during the first trimester did not find an increase in the rate of major malformations when compared with a nonexposed group [110]. A population-based study in Taiwan compared the rates of adverse pregnancy outcomes (preterm delivery, small for gestation age, low birth weight infants) in a large number of women who were exposed to zolpidem during pregnancy with those in women who were not exposed. All adverse outcomes were significantly higher in the exposed group but the rate of *major congenital malformations* did not differ between the 2 groups [111]. There are many potential confounding factors that could not be accounted for (e.g., adherence with the medication, other medical or psychiatric factors, social factors such as

smoking, alcohol use, and nutrition status of the mother) but these data highlight the need to use this class of medications during pregnancy with caution.

The antidepressant trazodone may be beneficial for reducing sleep-onset latency and improving sleep quality in depressed patients [112]. The AAP stated that data are too limited to provide a recommendation on the use of this and other sedating antidepressants, such as mirtazapine and nefazadone (not available in Canada), during pregnancy [113]. No difference in pregnancy outcome (including rate of major malformations and gestational age at birth) has been found between patients taking nefazadone and trazodone during the first trimester when compared with women taking other nonteratogenic antidepressants or other nonteratogenic drugs (e.g., sumatriptin, dextromethorphan), matched for age, smoking, and alcohol use [114]. Both antidepressant groups, however, had a trend toward a higher rate of spontaneous abortion, although the difference was not statistically significant. The tricyclic antidepressant amitriptyline has considerable sedating properties, does not appear to have teratogenic effects, and is considered safe for use in pregnancy [113].

Benzodiazepines are frequently used to treat insomnia in the general population. The AAP [113] recommends that their use be limited during pregnancy since they can induce sedation, withdrawal signs (including restlessness, hypertonia, irritability, seizures, and abdominal distention), and floppy baby syndrome (muscular hypotonia, low Apgar scores, neurologic depression) in the neonate, effects that can last for up to 3 months. Hence, when benzodiazepines are used, they should be slowly tapered over a number of weeks prior to delivery. Use during the first trimester should be avoided if possible because of concerns about congenital malformations such as cleft palate [115]. However, no congenital defects have been associated with lorazepam or alprazolam [113]. Use of the former is preferred since it lacks active metabolites and is less likely to be associated with a withdrawal syndrome in the neonate.

Menopause and the Climacteric

Changes in menstrual cycle frequency and menstrual flow reflect the changing hormone milieu in the perimenopausal period. Menstrual cycle length decreases from 28 days for women in their 20 s to 26 days for women in their 40 s [116]. Between the ages of 45 and 55 years, production of estrogen and progesterone decreases, FSH levels increase, and menstrual cycles become irregular [116]. This transition occurs over a few years (mean 3.8 years) prior to the last menstrual period. There is no definitive way to distinguish transient amenorrhea from menopausal amenorrhea, and generally menopause is only confirmed when menstrual periods have stopped for a year (average age 51 years) [117]. The term *climacteric* is used to refer to the transition period (usually 7–10 years) preceding the last menses when ovarian function decreases, and afterward, when women experience hormonally induced physical and/or psychological changes [116].

Sleep Disturbance and Climacteric Symptoms

Women of any age are more likely than men to report dissatisfaction with their sleep and to experience daytime consequences. Insomnia is more prevalent in women than men [118] and this gender disparity increases with age [119]. Comparing the sex difference in the prevalence of insomnia among young adults (15–30 years), middle-aged (31–64 years), and elderly ($\geq$ 65 years), the overall relative risk (RR) for females compared to males increased from 1.28 in young adults to 1.46 in middle age and 1.73 in elderly [119]. In a Canadian survey of 2000 adults, by Morin and colleagues, 15.6 % of women and 11 % of men met all the criteria for insomnia showing that women have 1.5 times (95 % Confidence Interval: 1.15–1.95) the risk of presenting with insomnia syndrome than men [120]. This gender disparity increases with age—the female:male ratio of insomnia symptoms after 45 years of age is 1.7:1 [121]. There is evidence that the higher prevalence of affective disorders among women contributes toward their insomnia symptoms. Data from 148,938 postmenopausal women who were enrolled in the Women's Health Initiative study revealed that the strongest independent risk factors for sleep disturbance were depression, somatic symptoms, lower emotional well-being, and restlessness [122].

Menopause is often cited as the underlying cause for the gender disparity in sleep complaints in middle-aged individuals. Complaints of sleep disruption are higher in perimenopausal than in premenopausal women [121, 123, 124]. Sleep disturbances include waking at night (the most common problem) [124], waking early, and difficulty falling asleep [123]. Trouble sleeping has been associated with more depressive symptoms, vasomotor symptoms, mood swings, higher levels of stress, tension and anxiety, and palpitations, particularly during perimenopause [116, 123–127]. Furthermore, midlife women with disturbed sleep were found to have a twofold increase in menopausal symptoms [124].

Other menopausal symptoms that can be disruptive to sleep either directly or indirectly include weight gain, vaginal dryness and irritation, and urinary problems. Nocturia in postmenopausal women is reportedly improved with estrogen therapy [128]. However, as in men, the prevalence of nocturia increases with age (9 % in women <39 years old to 51 % of women $\geq$ 80 years old) [128], and OSA can

increase nocturnal diuresis through increased atrial natriuretic peptide production. Thus, aside from menopausal symptoms disturbing sleep, underlying chronic physical conditions or sleep disorders should also be considered.

The terms *hot flush, hot flash*, and *vasomotor symptoms* are used to describe the same phenomenon. Nocturnal hot flashes (also called night sweats) that can soak bedclothes, followed by chills as the body cools down, lead to sleep disruption [23, 129]. Vasomotor symptoms, including night sweats and hot flashes, are the primary reason for women to seek treatment at the time of menopause [130]. Up to 85 % of women experience hot flashes [116, 127, 129], with variation depending on ethnicity and culture [127, 129]. In a large (n = 14,906) multisite, multiethnic study in the USA of women's health across the nation (SWAN), the population group with the lowest incidence of night sweats were Japanese women at 9 % and the highest was African women at 32 % [131]. A further analysis from the SWAN study found that 38 % of all women reported subjective difficulty sleeping; the incidence was lowest in Japanese women (28 %) and highest in Caucasian women (40 %), and difficulty sleeping was associated with hot flashes [129]. In the SWAN study, an odds ratio for sleep problems in women with vasomotor symptoms was 2.0 compared to asymptomatic women. Furthermore, in a smaller study (n = 63) based on healthy women who had undergone hysterectomy, those with subjectively impaired sleep had more hot flashes and palpitations as well as mood-related symptoms (anxiety, depression, mood instability, memory problems) [132]. A study of 15 perimenopausal women who reported increased awakenings and dissatisfaction with sleep quality showed an increased number and duration of arousals and more movement activity on wrist actigraphy compared to 13 age-matched premenopausal controls [125].

Interestingly, PSG studies do not consistently show worse sleep quality peri- and postmenopausally than premenopausally [126, 132–136], or an association with climacteric vasomotor, somatic, or mood symptoms [132, 134, 135]. Although no significant differences in sleep were apparent, for 39 symptomatic versus 32 nonsymptomatic women, there was a trend toward lower sleep efficiency [133]. Young et al. [134] compared objective sleep data from a single night in 589 women of known menopausal status but, despite postmenopausal women reporting more dissatisfaction with their sleep than premenopausal women, PSG sleep efficiency was not lower in peri- and postmenopausal women. Indeed, the proportion of SWS was higher in postmenopause than premenopause. A study by Freedman and Roehrs [135] also found that 12 symptomatic versus 8 asymptomatic postmenopausal women and 11 premenopausal women did not have more sleep disturbance. Clearly there is a disconnect between objective and subjective sleep that merits further investigation.

Potential factors contributing to the disparity between subjective dissatisfaction with sleep and objective measures include (1) the severity of climacteric symptoms and the presence of hot flashes during the sleep recording, (2) effects on sleep microstructure—arousals, alpha EEG intrusion [37], and EEG cyclic alternating pattern (CAPS) [136]—rather than macrostructure, and (3) sympathetic activation. The association of hot flashes with subjectively poorer sleep suggests that they should be monitored during PSG studies. One study that used skin conductance to monitor hot flashes in women with nightly complaints of sweating found that after 4 weeks of conjugated estrogens (0.625 mg), there was a reduction in hot flashes associated with polysomnographically documented reduced CAPS rate and improved sleep efficiency [136]. Similarly, when monitoring hot flashes in breast cancer survivors with insomnia (n = 24), more sleep disruption and wake time around the time of hot flashes was observed; sleep efficiency was lower on nights with than on nights without hot flashes [137]. However, no association of sleep disturbance around the time of hot flashes measured by skin conductance has been found [135].

Hormone and Estrogen Replacement Therapy: A Role for Improving Sleep?

Vasomotor symptoms are reduced with estrogen alone (estrogen replacement therapy, ERT) [136, 138, 139] or in combination with progesterone therapy (hormone replacement therapy, HRT) [140–143], but in laboratory studies, they have not been found consistently to improve sleep. Findings from three studies highlight these inconsistencies. Polo-Kantola et al. [138] reported subjective sleep improvement with transdermal estrogen preparations compared with placebo (n = 70), associated with reduced hot flashes and sweating, but estrogen was no better than placebo in terms of sleep on PSG. Antonijevic et al. [144] in contrast found reduced wakefulness and increased REM sleep with an estradiol patch (n = 11). In a third study, an HRT with estrogen (Premarin 0.625 mg) and two different progesterone preparations—either micronized progesterone (Prometrium 200 mg) (n = 10), which gives rise to sedative metabolites, or medroxyprogesterone (Provera 5 mg) (n = 11)—showed improved sleep efficiency with micronized progesterone [143]. Despite the sleep improvement, daytime vigilance was unchanged with the micronized progesterone, whereas it improved with medroxyprogesterone. Overall, most studies of HRT on sleep show favorable effects including improved subjective sleep quality and reduced sleep fragmentation and wake on PSG [145, 146].

Clearly, more detailed studies of the effects of HRT are needed before firm conclusions can be drawn regarding their effects on sleep.

For those women whose menopausal symptoms and sleep may be alleviated on hormone therapy, safety concerns with HRT from the Women's Health Initiative (WHI) [139] posed a dilemma [130]. The large (n = 16,608), randomized, placebo-controlled WHI trial on the effect of conjugated equine estrogens (0.625 mg) combined with medroxyprogesterone acetate (2.5 mg) revealed increased risks for stroke, venous thromboembolism, coronary heart disease, and breast cancer [139]. These risks have been subsequently confirmed in other clinical trials that used a variety of estrogen and progestin products [147]. Given the fear of adverse events, over 50 % of women stop therapy after 1 year [148]. However, in the WHI trial, the average age of women at enrollment was 63 years (range 50–79), and women with severe menopausal symptoms were excluded, yet symptom relief is the reason most women initiate HRT. The choice of whether to use hormone therapy or not is a balance between age, symptoms, current quality of life, and potential risk [130, 149].

Subsequent analysis of health-related quality of life in nonsymptomatic women from the WHI trial [150] showed there was only a small and not clinically meaningful reduction in sleep disturbance in the first year that was not evident after 3 years. In contrast, from the Heart and Estrogen/Progestin Replacement Study (HERS)—another large (n = 2763) randomized, placebo-controlled trial of the same hormone concentrations as the WHI trial—women who experienced hot flushes had improved mental health and depressive symptoms [151]. Thus, the effects of HRT on quality of life appear to depend on the presence of menopausal symptoms with negative effects in women without vasomotor symptoms and improvements in women with vasomotor symptoms [151]. For women who experience significant disruptive menopausal symptoms, the smallest effective dose of estrogen may serve a useful short-term role in symptom management [147, 149, 152]. Family history and potential risk of disease should be taken into account when considering HRT for relief from disturbed sleep [130, 146, 147, 152].

Alternatives to Hormone Replacement Therapy for Sleep Disruption

With a decrease in HRT prescriptions since July 2002, there has been an increase in prescriptions of serotonergic antidepressants [153]. Some antidepressants that block the release of serotonin and norepinephrine (e.g., fluoxetine, paroxetine, venlafaxine) have been reported to alleviate climacteric symptoms [153, 154]. Norepinephrine and serotonin have a central role in the pathophysiology of hot flashes [149]; clonidine, an α_2-adrenergic agonist, has also been found to alleviate climacteric symptoms and accordingly related sleep problems.

An age-related decline in melatonin secretion occurs between 17 and 45 years in premenopausal women, with an increase during perimenopause (46–50 years), and a decline postmenopause [155]. In the first 15 years of postmenopause, there is a steep decline in melatonin, followed by a more gradual decline. The timing of melatonin secretion is also advanced in postmenopausal compared with premenopausal women [156]. Melatonin has chronobiotic (circadian effect) and hypnotic properties. Exogenous melatonin, as well as a controlled-release formulation of 2 mg melatonin Circadin®, and the melatonin agonist Ramelteon have been reported to promote sleep onset and improve sleep quality in middle-aged and elderly insomniacs [157].

Given the safety concerns related to hormone therapy, many women seek alternative therapies to relieve sleep disturbances. Hot flashes occur more frequently in warmer than cooler environments [127]; reducing ambient temperature (to 16–19 °C) may provide relief from hot flashes and sleep disruption [142, 149].

A telephone survey of 866 women on the use of eight alternative therapies to manage menopause symptoms found that 76 % of women had used at least one type of alternative therapy [158]. Women who experienced trouble sleeping were more likely to use alternative therapies such as dietary soy and stress management. Soy isoflavones are estrogen-like substances that have been investigated as an alternative therapy to relieve menopausal symptoms but have not been found consistently to have an appreciable effect [159].

Valerian is commonly used as a sleep aid and has been tested with conflicting results in small groups of older individuals. For example, Taibi et al. [160] found no improvement in sleep in 16 older women (69 years) who took 300 mg concentrated valerian extract for 2 weeks compared with placebo. Whereas Taavoni et al. [161] found that 50 menopausal women (aged 50–60 years) given 160 mg valerian with 80 mg lemon balm for one month improved subjective sleep quality (based on the Pittsburg Sleep Quality Index, PSQI) compared to a placebo control group. A meta-analysis of 18 RCTs of valerian (300–600 mg/d) suggested that it improves subjective sleep quality based on yes/no responses [162].

Though not well studied, black cohosh (a root extract from a North American perennial plant) may relieve hot flash symptoms, and gabapentin (a GABA analog) has been found to have a favorable effect compared to placebo [154] but concerns have been raised about liver toxicity [see 163]. Linseed (flaxseed) extract as well as Mediterranean pine bark extract have been reported to reduce vasomotor symptoms [163]. The hop-flavonoid (the hop flower is an ingredient in

beer) 8-prenylnaringenin, a stronger estrogen than soy isoflavones, has been studied in two RCTs for effectiveness in reducing vasomotor symptoms with conflicting findings suggesting no advantage over placebo [163]. Hypnotic drugs such as zolpidem (10 mg) in women with menopause-related insomnia ($n = 141$) reduced wake after sleep onset and improved subjective sleep quality [164].

Chronic heavy smoking in adulthood is a significant risk factor for insomnia. Compared with nonsmokers, midlife women who were chronic heavy smoker were more likely to report insomnia at mean age 65 (Adjusted OR = 2.76; 95 % CI = 1.10–6.92) [165]. However, women who quit smoking in midlife (43–48 years) by the age of 65 years did not have any more insomnia symptoms that a nonsmoking group.

Yoga has been found to improve insomnia severity scores and menopausal symptoms after 4 months of practice in 15 postmenopausal women not taking hormone therapy compared to passive stretching and a wait-control group [166]. Consistently high physical activity rated as sports/exercise (e.g., participation in recreational activity or sports) for 6 years preceding assessment has been associated with better sleep efficiency on PSG and better PSQI scores in 339 midlife women (mean age 52 years) in the SWAN study [167]. In menopausal women (mean age 54 years) with vasomotor symptoms, nonsupervised aerobic training four times per week for 50 min for 6 months improved subjective sleep quality and vasomotor symptoms in a group of 73 women compared with a control group of 76 women [168]. Thus, a more active lifestyle is recommended to improve sleep disruption in menopause.

Sleep-Disordered Breathing in the Menopause

Menopause increases the risk of SDB by three to four times, even after adjusting for known risk factors such as age and BMI, compared to premenopausal women [59, 169]. Increased age, hormone-related changes, and weight gain—including a change in fat distribution [116] with more visceral adiposity—are all contributing factors for increased OSA. Older, overweight women with high blood pressure, insomnia, disturbed sleep, or "fatigue" should be considered at high risk for having OSA.

Progesterone is a respiratory stimulant and, in women receiving HRT, the prevalence of OSA and SDB was found to be lower than women not taking HRT [59]. This finding needs to be confirmed in larger clinical trials. The prevalence of moderate-to-severe OSA in women in the Sleep Heart Health Study ($n = 2994$, age ≥ 50 years) among women using hormone replacement (either ERT or HRT) was half the prevalence in nonusers [170]. The reduction in SDB (estimated odds ratio, 0.55) for hormone users corresponded to the predicted effect of reducing BMI by 6.8 kg/m^2 [170]. Before recommending menopausal hormone replacement to treat apnea in women, however, many other factors need to be considered. The focus should instead be on using standard therapy such as weight loss, CPAP, an oral appliance, or positional therapy (side sleep) for milder OSA.

Other Factors Influencing Sleep During Menopause

The secretion of other endogenous hormones, such as thyrotropin, decreases with age: 25 % of postmenopausal women show clinical or subclinical thyroid disease, which often causes symptoms similar to those of the climacteric [149]. The cause of sleep problems around menopause is not always evident and possibly is multifactorial. Factors aside from menopause—such as systemic diseases, medications, depressed mood, stress, behavioral or cognitive factors, social and family situations, pain, and aging-associated increases in RLS and PLMS—may explain, or contribute to, decreases in sleep quality.

Conclusion

The changing hormone profile across the reproductive life of a woman, from puberty through the reproductive period to the postmenopausal years, has a significant influence on sleep. Abrupt changes in, or withdrawal of, female hormones may lead to sleep disruption. During pregnancy, however, multiple factors contribute to sleep disruption, and these will vary according to the stage of pregnancy. Certain sleep disorders such as OSA and RLS are influenced by stage of menstrual cycle or life cycle. This chapter has highlighted the impact of the reproductive and menstrual cycles on sleep. It is imperative that sleep clinicians take these factors into account when working with women. Women should be encouraged to track whether there is a cyclical change in their symptoms in association with hormone changes or if the symptom changes are due to age-related changes in hormonal profile.

Sleep, Violence, and Forensic Implications

54

Michel A. Cramer Bornemann and Carlos H. Schenck

Introduction

Increasingly, sleep medicine practitioners are asked to render formal opinions in a court of law regarding criminal allegations pertaining to violent or injurious behaviors arising from the sleep period. Automatic behaviors (automatisms) resulting in acts that may result in illegal behaviors have been described in many different conditions. Those automatisms arising from wakefulness are reasonably well understood. Recent advances in sleep medicine have made it apparent that some complex behaviors, occasionally resulting in forensic science implications, are exquisitely state dependent, meaning that they occur exclusively, or predominately, during the sleep period.

Case Examples

Two sleep forensics court cases involving sexual assault, one resulting in acquittal and the other resulting in a guilty verdict, will now be presented.

Acts done by a person asleep cannot be criminal, there being no consciousness [1].

Case 1

As reported by The Copenhagen Post and Associated Press on April 10, 2013, Danish legal history was made on that date when a sexual assault charge (i.e., molestation form of rape) for the first time resulted in acquittal by use of the "Sexsomnia Defense"—which is in regard to a NREM Parasomnia formally referred to as Sleep-related Abnormal Sexual Behavior. The Glostrup District Court cleared a 32-year-old man of "sex crime charges." Two years previously, in 2011, the man had fondled two 17-year-old females while they were sleeping in his suburban Copenhagen apartment after a party in 2011. (This raises the question about any use, and extent of any use, of alcohol by the accused during the party.) The girls awoke and stopped the man, and later reported him to police. The defendant said he had no recollection of what happened, as he claims to have been asleep.

"It is the first time that someone has been acquitted under these circumstances in Denmark," the man's lawyer, Andro Vrlic, stated. "The defendant had always claimed that he was asleep when the incident took place, but he was charged by police who did not believe his explanation."

> According to his explanation, he did not know that there was anything wrong with him," the prosecutor, Martin von Bülow, told Ekstra Bladet. "But when former girlfriends told him that they had experienced something similar while he slept, he sought out a sleep specialist [who tested him].

The man was subsequently studied in a sleep laboratory, and the conclusions were pronounced in court during the trial to support the diagnosis of Sleep-related Abnormal Sexual Behavior—but the details of the sleep laboratory findings were not disclosed to the public and were sealed in the court records. However, an expert for the defense testified in regard to the sleep laboratory findings: "It's not something that can be faked."

Von Bülow added that the testimony from the girls supported the man's claim that he was asleep when he touched one and made sexual motions against the other. He added

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_54

that given that the man's defense was supported both by the victims and by experts in court, he was not surprised by the acquittal.

One of the authors of this chapter (CHS) was interviewed by a Danish journalist, Nola Grace Gaardmand, shortly after the court ruling, who then published two related articles about this case (**see Add Reference Addendum** [103, 104]). Ms. Gaardmand provided more details about the case after interviewing the defendant's attorney.

The accused previously had dated the older sister of one of the 17-year-old girls, and after they terminated their relationship subsequently remained close friends over the years. Furthermore, the man and the younger sister were "kind-of like family, like an older brother–younger sister relationship," the lawyer explained. She had just moved to Copenhagen and was staying in a guest-room at his apartment until she found her own place; on the night of the assault, she happened to have a girlfriend stay over with her for that night. They slept together in a separate bedroom from the accused. According to the girls' lawyer, there were no lingering ill sentiments among any of them (the two girls, and the older sister [ex-girlfriend of the accused]) after the sexual assault and trial, and the man and the older sister (i.e., the man's ex-girlfriend) apparently have remained good friends.

Comments: The court testimony of previous recurrent episodes of Sleep-related Abnormal Sexual Behavior provided by the former girlfriend of the accused, with whom he had remained friends for years, considering themselves as "family" together with the younger sister of the former girlfriend (and sexual assault victim), was strong supportive evidence presented in favor of the "Sexsomnia Defense." The sleep laboratory evaluation reportedly provided additional strong support to sustain the argument in favor of the "Sexsomnia Defense," as acknowledged by the presiding judge. However, since details of this testing were not made available to the public, it remains indeterminate whether this was a legitimate, science-based finding that would be critically upheld after peer review consensus among experts in the fields of sleep medicine and sleep forensics. Finally, in regard to the party held at the apartment of the accused on the night of the sexual assault, the possible use, and extent of any use, any possible role of alcohol consumption in the sexual assault remains indeterminate. This could possibly have been a troublesome, confounding factor, which may contaminate the case and has been addressed carefully in the peer-reviewed literature (**see Add Reference Addendum** [104, 105]).

Case 2

This pertains to a court case in rural western Norway involving a 42-year-old married man, with acknowledged marital problems, who sexually assaulted a 12-year-old girl who was spending the night with his 12-year-old daughter at the family home. (The sleep medicine expert Stale Pallesen, PhD, from Bergen, Norway, informally consulted with one of the authors of this chapter [CHS] prior to rendering his opinion in court.) On the night in question, the accused and his wife drove from their home at 8 PM to visit friends, but did not consume any alcohol. They returned home at 12:30 AM. The accused had previously sustained significant physical injuries, and regularly struggled with persistent pain, for which he was prescribed codeine, paracetamol, and gabapentin, which he took nightly for the week leading up to the sexual assault. On the night of the assault, he also took some methotrimeprazine.

His wife then went to bed and fell asleep in their second floor bedroom; she had left the bedroom window open, creating a chill that the accused found uncomfortable in tandem with his pain. He decided to sleep on a couch on the first floor, as he subsequently claimed. He fell asleep in approximately 30 min. At 3 AM, he gradually awakened and found himself in a separate room, lying on the same mattress as the 12-year-old girl who was visiting his daughter. He was lying behind her with an erect penis pressed against her. According to her court statement, he tried to pry his hands between her thighs, which she attempted to keep tightly together. However, she believed that his fingers might have penetrated between her vaginal labia. She estimated that the incident lasted approximately 15 min, and she was too frightened to scream. Her friend (daughter of the accused) was sleeping 3 ft. away in her own bed—but she suffered from deafness. After the victim repeatedly tried to pull away, the assault suddenly ceased. The man looked at the girl, and believed she was asleep, and so he decided that "no good would come of it" were he to subsequently report what had transpired. He then went to the kitchen to drink some water, noticed the time of 3:15 AM, and then went to join his wife in their bed on the second floor. He slept until 10–11 AM.

The following day the girl told her parents about the incident, and the police was notified. At trial, he was eventually convicted of sexual assault, a decision which was then appealed whereby Dr. Stale Pallesen then consequently became involved as a court expert (not an expert hired by either the Defense or the Prosecution, a highly desired impartial forensic expert role that is not often available in the USA).

Although the patient and his wife subsequently were divorced, she testified that he had engaged in sexualized behaviors which apparently arose from sleep with her about 1–2 nights weekly during their 15-year marriage. However, the sexual behavior was limited to fondling and never penile penetration. She would typically push him away, which would immediately abort the "sexsomnia" episode. He had

previously been married and his first wife never recalled any such sexualized behavior in the midst of sleep on his part.

The accused had infrequent episodes of sleepwalking during childhood, including a cousin (with whom he shared a bedroom) who had observed at least one such episode. However, there had been no reported sleepwalking during adolescence or that which persisted into adulthood.

The accused lost his appeal, and his conviction was upheld. The role of the sleep forensics expert (as with all forensic experts in Norway) was to determine whether there was a greater or lesser probability than 50 % that the accused had engaged in the behavior for which he was claiming as his defense. In this case, the sleep medicine expert (Dr. Pallesen), after his informal consultation with one of the authors (CHS), gave the opinion of less than 50 % probability that a Sleep-related Abnormal Sexual Behavior had occurred, mainly for three reasons: first, the accused had not engaged in sleepwalking since childhood; second, the accused sought out his victim, which is quite rare in sleepwalking; (**see Add Reference Addendum** [107]) and third, in the preponderance of published cases on Sleep-related Abnormal Sexual Behavior, the sexual behaviors during sleep occurred in the context of confusional arousals with the individual remaining in bed, and in only a small percent of cases did sleepwalking proceed to culminate in a Sleep-related Abnormal Sexual Behavior (**see Add Reference Addendum** [108]).

Neurophysiology of Sleep-Related Violence

The State-Dependent Nature of Violence

The concept that sleep is simply the passive absence of wakefulness is no longer tenable. Not only is sleep an active rather than passive process; it is now clear that sleep comprises two completely different states: non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. Therefore, our lives are spent in three entirely different states of being: wakefulness, REM sleep, and NREM sleep. Studies have indicated that bizarre behavioral syndromes can occur as a result of the incomplete declaration or rapid oscillation of these states [2, 3]. Although the automatic behaviors of some "mixed states" are relatively benign (i.e., shoplifting in narcolepsy) [4], others may be associated with violent behaviors.

The fact that violent or injurious behaviors may arise in the absence of conscious wakefulness and without conscious awareness raises the crucial question of how such complex behavior can occur. Examination of extensive animal experimental studies provides preliminary answers. The widely held concept that the brain stem and other more "primitive" neural structures primarily participate in elemental/vegetative rather than behavioral activities is inaccurate. There are overwhelming data documenting that extremely complex emotional and motor behaviors can originate from these more primitive structures—without involvement of "higher" neural structures such as the prefrontal cortex [5–11].

Sleep-Related Disorders Associated with Violence

Violent sleep-related behaviors have been reviewed in the context of automatized behavior in general. There are well-documented cases of (1) somnambulistic homicide, attempted homicide, and suicide; (2) murders and other crimes with sleep drunkenness (confusional arousals); and (3) sleep terrors/sleepwalking with potential violence/injury. A wide variety of disorders may result in sleep-related violence [12, 13]. Conditions associated with sleep period-related violence are listed in Table 54.1. These conveniently fall into two major categories: neurologic and psychiatric.

Neurologic Conditions Associated with Violent Behaviors

Extrapolating from animal data to the human condition, it has been shown that structural lesions at multiple levels of the nervous system may result in wakeful violence [14–17]. The animal studies provide insights into violent behaviors in the disorders of arousal, REM sleep behavior disorder (RBD), and sleep-related seizures.

Disorders of Arousal (Confusional Arousals, Sleepwalking, Sleep Terrors)

The disorders of arousal comprise a spectrum ranging from confusional arousals (sleep drunkenness) to sleepwalking to sleep terrors [18]. Although there is usually amnesia for the event, vivid dream-like mentation may be experienced and reported [19]. Contrary to popular opinion, these disorders may actually begin in adulthood and are most often *not* associated with psychopathology [19]. The commonly held belief that sleepwalking and sleep terrors are always benign is erroneous: The accompanying behaviors may be violent, resulting in considerable injury to the individual or others, or damage to the environment.

Febrile illness, prior sleep deprivation, emotional stress, and the inadvertent interaction from those who may be sleeping in close proximity may serve to trigger disorders of arousal in susceptible individuals [20–22]. Sleep deprivation is well known to result in confusion, disorientation, and hallucinatory phenomena [23]. Medications such as

Table 54.1 Conditions associated with sleep-related violent behavior

Neurologic sleep disorders
• Disorders of arousal (confusional arousals [sleep drunkenness], sleepwalking, sleep terrors)[a]
– REM sleep behavior disorder[a]
– Nocturnal seizures[a]
– Automatic behavior
i Narcolepsy and idiopathic hypersomnia
ii Sleep apnea
iii Sleep deprivation (including jetlag)
Psychiatric sleep disorders
• Psychogenic dissociative states (may arise exclusively from sleep)
– Fugues
– Multiple personality disorder
– Psychogenic amnesia
• Malingering
• Munchausen syndrome by proxy

[a]Obstructive sleep apnea may mimic or trigger these episodes

sedative-hypnotics, neuroleptics, minor tranquilizers, stimulants, and antihistamines, often in combination with each other or with alcohol, may also play a role [18].

Confusional arousals (also termed *sleep drunkenness*) occur during the transition between sleep and wakefulness and represent a disturbance of cognition and attention despite the motor behavior of wakefulness, resulting in complex behavior without conscious awareness [24–26]. These may be potentiated by prior sleep deprivation or the ingestion of sedative-hypnotics before sleep onset [27]. These episodes of "automatic behavior" occur in the setting of chronic sleep deprivation or other conditions associated with state admixture. Examples of such behaviors cover a broad spectrum including sleep eating, sleep driving, and sleep texting, to cite but a few. In one unusual case, even shoplifting has been reported during a period of automatic behavior in an individual with narcolepsy [4, 28, 29] (**see Add Reference Addendum** [109]).

Numerous associations exist between obstructive sleep apnea (OSA) and confusional arousals. Patients suffering from OSA may experience frequent arousals that may serve to trigger arousal-induced precipitous motor activity [30]. Therefore, the observed clinical behavior—a confusional arousal—is actually the result of another underlying primary sleep disorder, OSA. Guilleminault and Silvestri have made the following observations [30]:

It is well known that adult patients with OSA syndrome may engage in nocturnal wandering during sleep. These patients frequently demonstrate yelling and screaming during sleep, as well as confusion, disorientation, and sleepwalking. The nocturnal hypoxia and the repetitive sleep disruptions secondary to the OSA syndrome readily explain these symptoms.

This is another example of why overnight polysomnographic (PSG) studies with extensive physiologic monitoring are mandatory in the evaluation of problematic motor parasomnias. Disorders of arousal may also be precipitated by inadequate or incomplete treatment of sleep apnea with nasal continuous positive airway pressure [31, 32].

To remind us that apparently criminal acts without conscious awareness occurring during sleep drunkenness (formerly termed *somnolentia*) are not a recently described condition, dramatic cases were described in a classic book on sleep well over a century ago. The author's conclusion regarding sleep drunkenness was: "It is a natural phenomenon, to which all are liable" [33]. Treatment of the disorders of arousal includes both pharmacologic (benzodiazepines and tricyclic antidepressants) and behavioral (hypnosis) approaches [34].

The behavioral similarities between documented sleepwalking and sleep terrors violence in humans and "sham rage," as exhibited in the "hypothalamic savage" syndrome, are striking [35]. Although it has been assumed that the "sham rage" animal preparations are "awake," there is some suggestion that similar preparations are behaviorally awake and yet (partially) physiologically asleep, with apparent "hallucinatory" behavior possibly representing cross interference of REM sleep dream mentation into wakefulness, dissociated from other REM state markers [36].

The neural bases of aggression and rage in the cat have been reviewed, indicating that there is clearly an anatomic basis for some forms of violent behavior [37]. The prosencephalic system may serve to control and promulgate, rather than initiate, behaviors originating from deeper structures [10]. In humans, during confusional arousals (sleep drunkenness), which can result in confusion or aggression, there is clear electroencephalographic (EEG) evidence of rapid oscillations between wakefulness and sleep [26, 38]. It may be that such behaviors occurring in states other than wakefulness are the expression of motor/affective activity generated by lower structures—unmonitored and unmodified by the cortex. As sleep is a very active process coupled with the generators or effectors of many components of both REM and NREM sleep that reside in the brain stem and other

"lower" centers, it is not surprising that, during sleep, prominent motoric and affective behaviors do occur given the close neuroanatomic real estate in which these reside.

Some very dramatic cases have been tried in a court of law to utilize confusional arousals as an explanation for an alleged criminal offense. This avenue for potential acquittal has been popularly referred to as the "Sleepwalking Defense." In one, the "Parks" case in Canada, the defendant drove alone 23 km across town, entered the home of his in-laws, killed his mother-in-law, and attempted to kill his father-in-law. Somnambulism was the legal defense, and he was acquitted [39]. In another, the "Butler, PA" case, a confusional arousal attributed to underlying OSA was offered as a criminal defense for a man who fatally shot his wife during his usual sleeping hours. He was found guilty [40]. In a highly publicized homicide case out of Phoenix, Arizona, a man stabbed his wife 44 times then left her body in the backyard pool. This case was particularly curious as both the prosecution and the defense were each able to secure the services of well-respected notable sleep medicine experts that offered sharply contrasting opposing opinions. He was found guilty of 1st Degree Murder and continues to serve his life sentence in prison without chance for parole [41].

Inappropriate sexual behaviors during the sleep state, presumably the results of an admixture of wakefulness and sleep, have been well described [42–51]. The "*Sleepwalking Defense*" has been well-received by defense attorneys and has been successfully applied in the USA in cases of purported "*Sexsomnia*" resulting in a complete acquittal, as in *State of Oregon v. James Kirchner* (**see Add Reference Addendum** [110]). Cramer Bornemann presented at SLEEP 2014 (the annual meeting of the Affiliated Professional Sleep Societies) in Minneapolis, Minnesota that over 33 % of the more than 260 forensics cases submitted between 2006 and 2013 for formal medico-legal review to a sleep forensics consulting consortium were associated with charges of sexual assault for which a Sleep-related Abnormal Sexual Behavior was considered (**see Add Reference Addendum** [111]). Furthermore, recurrent sexually oriented hypnagogic hallucinations experienced by patients with narcolepsy may be so vivid and convincing to the victim that they may serve as false accusations [52]. Despite the broad clinical acceptance of this condition and some success in the court of law, many in the legal community remain skeptical over the legitimacy of "Sexsomnia" as demonstrated by a recent update put forth by the National Center for the Prosecution of Child Abuse entitled "*Overcoming the Sleep Disorder Defense*" (**see Add Reference Addendum** [112]).

Sleep talking has also been addressed by the legal system; it is interesting to ponder whether utterances made during sleep are admissible in court [53].

Specific incidents of violence associated with disorders of arousal include [13]

1. Somnambulistic homicide and attempted homicide
2. Murders and other crimes during sleep drunkenness, including sleep apnea and narcolepsy
3. Suicide or suicide attempts [54, 55]
4. Violence/injury during sleep terrors or sleepwalking; these episodes may be drug-induced.

Violent sleep behaviors may result in post-traumatic stress disorder in the spouse or bed partner [56].

Other, very important factors beyond the scope of this chapter include (1) the known effect of genetics on violence and (2) the well-demonstrated effects of environmental and social factors upon the structure and function of the nervous system [57]. (In one study of 31 individuals awaiting trial or sentencing for murder, none was neurologically or psychiatrically normal [15].) The plasticity of the nervous system is greater than previously thought [58, 59]. These factors are undoubtedly operant in both wakeful and sleep-related violence.

REM Sleep Behavior Disorder

RBD represents an experiment of nature, predicted in 1965 by animal experiments [60] and more recently identified in humans [61]. Normally, during REM sleep, there is active paralysis of all somatic muscles (sparing the diaphragm and eye movement muscles). In RBD, there is the absence of REM sleep atonia, which permits the "acting out" of dreams, often with dramatic and violent or injurious behaviors. The oneiric (dream) behavior demonstrated by cats with bilateral peri-locus coeruleus lesions and by humans with spontaneously occurring RBD clearly arises from and continues to occur *during* REM sleep. These oneiric behaviors displayed by patients with RBD are often misdiagnosed as manifestations of a seizure or psychiatric disorder. Longitudinal research studies tracking RBD have revealed a compelling association between this condition and the eventual development of any of a number of chronic neurodegenerative disorders, most notably the synucleinopathies (Parkinson's disease, multiple system atrophy (Shy-Drager syndrome), and dementia with Lewy body disease). RBD may be the first manifestation of these conditions and may precede any other manifestation of the underlying neurodegenerative process by more than 10 years [62, 144] (**see Add Reference Addendum** [113, 114]). The overwhelming male predominance (90 %) of RBD raises interesting questions about the relationship of sexual hormones to aggression and violence [63, 64]. The violent and injurious nature of RBD behaviors has been extensively reviewed

elsewhere [62]. Treatment with clonazepam is highly effective [62].

As with the disorders of arousal, underlying sleep apnea may simulate RBD, again underscoring the necessity for thorough formal PSG evaluation of all bothersome complex behaviors arising during the sleep period [65].

Nocturnal Seizures

The association between seizures and violence has long been debated. It is plain that, on occasion, seizures may result in violent, murderous, or injurious behaviors [2, 66]. Of particular note is the frantic and elaborate nocturnal motor activity that may result from seizures originating in the orbital, mesial, or prefrontal region [67]. "Episodic nocturnal wanderings," a condition clinically indistinguishable from other forms of sleep-related motor activity such as complex sleepwalking, but that is responsive to anticonvulsant therapy, has also been described [68–70]. Aggression and violence may be seen pre-ictally, ictally, and postictally. The postictal violence is often induced or perpetuated by the good intentions of bystanders trying to "calm" the patient following a seizure [71]. As with disorders of arousal, OSA may masquerade as nocturnal seizures [72–74].

Psychiatric Conditions

Psychogenic Dissociative States

Waking dissociative states may result in violence [75]. It is now apparent that dissociative disorders may arise exclusively or predominately from the sleep period [2, 76]. Virtually all patients with nocturnal dissociative disorders evaluated at our center were victims of repeated physical and/or sexual abuse beginning in childhood [77].

Malingering

Although relatively uncommon in a clinical sleep medicine setting, malingering must also be considered in cases of apparent sleep-related violence In contrast, malingering is not uncommon in criminal proceedings and should be strongly suspected if: (i) the case is presented in a medico-legal context or has potential criminal implications, (ii) marked discrepancy between reported symptoms and objective findings, (iii) lack of cooperation with evaluation, and (iv) the presence of Anti-Social Personality Disorder (**see Add Reference Addendum** [115, 116]). Additionally, malingering should be distinguished from Factitious as well as somatoform disorders. In cases involving sleep-related violence, opportunistic malingering would appear to be the most relevant subtype of this condition with its potential for exploiting a naturally occurring event or preexisting condition. Our center has recently seen a young adult male who developed progressively violent behaviors, apparently arising from sleep, directed exclusively at his wife. This behavior included beating her and chasing her with a hammer. Following extensive neurologic, psychiatric, and PSG evaluation, it was determined that this behavior represented malingering.

Munchausen Syndrome by Proxy

In this syndrome, a child is reported to have apparently medically serious symptoms that, in fact, are induced by an adult—usually a caregiver, often a parent. The use of surreptitious video monitoring in sleep disorder centers during sleep (with the parent present) has documented the true etiology for reported sleep apnea and other unusual nocturnal spells [78–80].

Medicolegal Evaluation

Clinical and Laboratory Evaluation of Waking and Sleep Violence

The history of complex, violent, or potentially injurious motor behavior arising from the sleep period should suggest the possibility of one of the previously mentioned conditions. Our sleep forensics consulting consortium experience with over 300 adult cases of sleep-related injury/violence has repeatedly indicated that clinical differentiation, without PSG study, among RBD, disorders of arousal, sleep apnea, and sleep-related psychogenic dissociative states and other psychiatric conditions may be impossible [13]. It is likely that violence arising from the sleep period is more frequent than previously assumed.

The legal implications of automatic behavior have been discussed and debated in both the medical and legal literature [1, 81–83]. As with nonsleep automatisms, the identification of a specific underlying organic or psychiatric sleep violence condition does not establish causality for any given deed as the two are not temporally linked.

These conditions are diagnosable, and most are treatable. Clinical evaluation should include a complete review of sleep/wake complaints from both the victim and bed partner (if available). This should be followed by a thorough general physical, neurologic, and psychiatric examination. The diagnosis may only be suspected clinically. Extensive polygraphic study employing a full EEG montage, electromyographic monitoring of all four extremities, and continuous audiovisual recording is mandatory for correct diagnosis in atypical cases; and clinical and laboratory evaluations are best performed by experienced clinicians [13].

Establishing the diagnosis of nocturnal seizures may be extremely difficult, as the motor activity associated with the spell often obscures the EEG pattern. Further, there may be no scalp-EEG manifestation of the seizure activity. Numerous well-documented cases of scalp electrode EEG-negative but depth electrode EEG-positive electrical seizure activity or video-documented clinical seizure activity have been reported [84–86]. Another possible explanation for "scalp electrode EEG-negative" seizures is that some seizures manifest electrically with only generalized low-voltage fast activity, not followed by postictal slowing [87]. Such activity arising from EEG-recorded sleep may be misinterpreted as an "arousal," rather than as electrical seizure activity. Seizure activity arising in the limbic system may spread to other more "primitive" structures, with resultant clinical behaviors, without EEG involvement of the neocortex [9]. The treatment of nocturnal seizures is similar to that of diurnal seizures. The previously mentioned difficulties in evaluating nocturnal seizures (obscuring of the record by movement artifact, the absence of surface EEG abnormality or electrical seizure activity, lack of postictal slowing, misinterpretation of electrical seizure activity as an "arousal") emphasize the necessity of extensive, in-person laboratory monitoring. (Scantily channeled "ambulatory" EEG monitoring has led to the misdiagnosis of functional psychiatric disease in a number of our patients subsequently demonstrated to have bona fide nocturnal seizures.) If the history or physical examination suggests underlying neurologic disease, further studies such as magnetic resonance imaging or computed tomography scanning of the brain, multimodal (visual, auditory, and somatosensory) evoked potentials, and/or formal neuropsychometric evaluation are indicated.

While it is often possible to state that a given violent act may conceivably have arisen from the sleep period or from a mixed state of wakefulness and sleep, it is usually impossible to prove that a given incident did, in fact, represent a sleep-related phenomenon. To assist in the determination of the putative role of an underlying sleep disorder in a specific violent act, we have proposed guidelines, modified from Bonkalo (sleepwalking) [21], Walker (epilepsy) [88], and Glasgow (automatism in general) [89] and formulated from our clinical experience [2]:

1. There should be reason by history to suspect a *bona fide* sleep disorder. Similar episodes, with benign or morbid outcome, should have occurred previously. (It must be remembered that disorders of arousal may begin in adulthood.)
2. The duration of the action is usually brief (seconds), though action of longer duration (minutes) does not necessarily exclude a sleep disorder or a sleep-related behavior.
3. The behavior is usually abrupt, immediate, impulsive, and senseless—without apparent motivation. Although ostensibly purposeful, it is completely inappropriate to the total situation, out of (waking) character for the individual, and without evidence of premeditation.
4. The victim is someone who merely happened to be present, usually in proximity, and who may have been the stimulus for the arousal. Sleepwalkers rarely, if ever, seek out victims (**see Add Reference Addendum** [107])
5. Immediately following return of consciousness, there is perplexity or horror, without attempt to escape, conceal, or cover up the action. There is evidence of lack of awareness on the part of the individual during the event.
6. There is usually some degree of amnesia for the event; however, this amnesia need not be complete.
7. Sleep is an analgesic state. The sensory pathway for pain for the most part is considered "off-line" during sleep. Consequently, pain associated with acts committed during disorders of arousal may not be perceived until awakening after the event.
8. In the case of sleep terrors/sleepwalking or sleep inertia, the act:

   A. May occur upon awakening (rarely immediately upon falling asleep)—usually at least 1 h after sleep onset
   B. Occurs upon attempts to awaken the subject
   C. Has been potentiated by sedative-hypnotic administration or prior sleep deprivation
9. Polysomnographic studies performed "after the fact" are of absolutely no value in determining whether a parasomnia accounted for the remote act in question. Even capturing a parasomnia event during a sleep would indicate behavior at the time of the recording, not remotely. Furthermore, there is no scientific basis for attempting to replicate conditions surrounding the event in question (sleep deprivation, alcohol, or other substance ingestion) during a sleep study. Provocation tests to trigger parasomnias by any intoxicants or mind-altering agents would appear to be ethically challenged until well-controlled validated research studies have been performed.
10. Voluntary intoxication by alcohol over the legal limit, or other illicit mind-altering intoxicants, precludes the sleepwalking defense.
11. Lastly, the violent criminal allegation cannot be better explained by another mental disorder, medical condition, or substance use. This last guideline is also in accordance with the diagnostic guidelines for parasomnias as set forth in the most recent International Classification of Sleep Disorders 3rd edition (ICSD-3).

Sleep forensics has been defined as the application of the principles and tools of neuroscience as applied to Somnology and Sleep Medicine that have been widely accepted under international scientific peer review to the investigation in understanding unusual, irrational, and/or bizarre human behaviors associated with alleged criminal behavior which is to undergo further examination in a conflict resolution legal atmosphere and/or courtroom. The proposition that sleep disorders may be a legitimate defense in cases of violence arising from the sleep period has been met understandably with much skepticism [90] (**see Add Reference Addendum** [112]). For credibility, evaluations of such complex cases are best performed in experienced sleep disorders centers with interpretation by a veteran clinical polysomnographer. Due to the complex nature of many of these disorders, a multidisciplinary approach is highly recommended.

One fortunate, and unexplained, fact is that nocturnal sleep-related violence is seldom a recurrent phenomenon [90]. Very rarely, recurrence is reported, and possibly could be termed a "noninsane automatism." Thorough evaluation, effective treatment, and longitudinal clinical management are mandatory before the patient can be regarded as no longer a menace to society [91]. In other cases, clear precipitating events can be identified and must be avoided to be exonerated from legal culpability. This concept has led to the proposal of two new forensic categories: (1) "parasomnia with continuing danger as a noninsane automatism" and (2) "(intermittent) state-dependent continuing danger" [91].

Legal and Forensic Medicine Evaluation

With the identification of ever-increasing causes, manifestations, and consequences of sleep-related violence comes an opportunity for neurologists and sleep medicine specialists to educate the general public and practicing clinicians as to the occurrence and nature of such behaviors, and about their successful treatment. More important, the onus is on the sleep medicine professional to educate and assist the legal profession in cases of sleep-related violence that result in forensic medicine issues. This often presents difficult ethical problems, as most "expert witnesses" are retained by either the defense or the prosecution, leading to the tendency for expert witnesses to become advocates or partisans for either one side or the other. Historically, this has been fertile ground for the appearance of "junk science" in the courtroom [92]—from Bendectin to triazolam to breast implants. Junk science leads to junk justice, and altered standards of care [93]. Recently, much attention has been paid to the existence and prevalence of junk science in the courtroom, with recommendations to minimize its occurrence. Prior to accepting any given case, the sleep professional should familiarize him/herself with this most important issue. A good starting point is the highly informative book, *Galileo's Revenge: Junk Science in the Courtroom* [92]. There is some hope that the judicial system is paying more attention to the process of authentic science and may move to accept only valid scientific evidence [94, 95]. To address the problem of junk science in the courtroom, many professional societies are calling for, and some have developed guidelines for, expert witness qualifications and testimony. Similarly, the American Sleep Disorders Association (the American Academy of Sleep Medicine) and the American Academy of Neurology have adopted their own guidelines, which include [96, 97]:

A. Expert witness qualifications:
   1. Must have a current, valid, unrestricted medical ,or psychology license.
   2. Must be a Diplomat of the American Board of Sleep Medicine or have passed the American Board of Internal Medicine specialty examination in sleep medicine.
   3. Membership in the Sleep Research Society is strongly encouraged.
   4. Must be a recognized resource within the sleep medicine community and should have been actively involved in clinical practice in a manner consistent with the requirement of the criminal case at the time of the event.
   5. Given the essential position of *mens rea* in criminal law and the pivotal role of levels of consciousness must have significant direct experience in either neurology and/or neuroscience.

B. Guidelines for expert testimony:
   1. The practitioner must be impartial: The ultimate test for accuracy and impartiality is a willingness to prepare testimony that could be presented unchanged for use by either the plaintiff or the defendant.
   2. Fees should relate to time and effort, not be contingent upon the outcome of the claim. Fees should not exceed 20 % of the practitioner's annual income.
   3. The practitioner should be willing to submit such testimony for peer review.
   4. To establish consistency, the practitioner should make records from his or her previous expert witness testimony available to the attorneys and expert witnesses of both parties.
   5. The practitioner must not become a partisan or advocate in the legal proceeding.

Familiarizing oneself with these guidelines may be helpful in a given case, as the expert witnesses for each side should be held to the same standards [98].

The current legal system unfortunately must consider a parasomnia case strictly in terms of choosing between "insane" or "noninsane" automatism. Such a choice results in two very different consequences for the accused: either commitment to a mental hospital for an indefinite period of time if "insane" or acquittal without any mandated medical consultation or follow-up, or without any stipulated deterrent concerning a recurrence of the behavior with criminal charges that was induced by a recurrence of the high-risk behavior. One reasonable approach in dealing with these automatisms from a legal standpoint would be to add a category of acquittal that allowed for innocence based on lack of guilt consequent to set diagnoses—specific illnesses that could be categorized by a group of subspecialty clinicians in consultation with the legal profession [99]. Another suggestion has been a two-stage trial, which would first establish who committed the act and then deal separately with the issue of culpability. The first part would be held before a jury; the second would be held in front of a judge with medical advisors present [100].

Forensic Sleep Medicine Experts as Impartial Friends of the Court (Amicus Curae)

One infrequently used tactic to improve scientific testimony is to use a court-appointed "impartial expert" [92]. When approached to testify, volunteering to serve as a court-appointed expert, rather than one appointed by either the prosecution or defense, may encourage this practice. Other proposed measures include the development of a specific section in scientific journals dedicated to expert witness testimony extracted from public documents with request for opinions and consensus statements from appropriate specialists, or the development of a library of circulating expert testimony that could be used to discredit irresponsible "professional witnesses" [92]. Good science is determined not by the credentials of the expert witness, but rather by scientific consensus [93].

Summary and Directions for the Future

It is abundantly clear that violence may occur during any one of the three states of being. That which occurs during REM or NREM sleep may have occurred without conscious awareness and may be due to one of a number of completely different disorders. Violent behaviors during sleep may result in events that have forensic science implications. The apparent suicide (e.g., leaping to death from a third-story window), assault, or murder (e.g., molestation, strangulation, stabbing, shooting) may be the unintentional, nonculpable but catastrophic result of disorders of arousal, sleep-related seizures, RBD, or psychogenic dissociative states. The majority of these conditions are diagnosable and, more important, are treatable. The social and legal implications are obvious.

The fields of neurology and sleep medicine must pursue further productive study and discourse and request adequate funding to objectively study the following important questions: What is the true prevalence of these disorders? How are they best and most accurately diagnosed? How can the usually present prodromes be taken seriously? Why the male predominance in many? How can they best be treated or, better yet, prevented? Are "social stressors" truly more prevalent in this population? What is the best way to deal with forensic science issues? What to do with the offender? What is the likelihood of recurrence? Is such behavior a sane or an insane automatism? [101]. How to protect the potential victim?

More research, both basic science and clinical, is urgently needed to further identify and elaborate upon the components of both waking and sleep-related violence, with particular emphasis upon neurobiologic, neuroplastic, genetic, and socioenvironmental factors [15, 16, 102]. The study of violence and aggression will be greatly enhanced by close cooperation among clinicians, basic science researchers, and social scientists.

Introduction

Sleep is closely related to every facet of daily life. In this respect, disturbed sleep affects not only our health and well-being but also our quality of life. Dement and Kleitman [1] and Rechtschaffen and Kales [2] provided a description of sleep cycles and a classification system of sleep stages that comprise a waking state, four non-rapid eye movement sleep (NREMS) stages, and rapid eye movement sleep (REMS). Accordingly, the young adult was found to spend 20–28 % of a night's sleep (7–8 h) in REMS, 4–5 % in stage 1 (S1), 46–50 % in stage 2 (S2), 6–8 % in stage 3 (S3), and 10–16 % in stage 4 (S4). Agnew et al. [3] studied the sequence in which one sleep stage appeared after another during NREMS. When NREMS started deepening, a progression of only one stage at a time (from S1 to S4) was usually observed. When sleep was moving out of S4 sleep, stage-by-stage changes were also observed. However, comparatively higher amounts of abrupt shifts were evident. REMS follows a course independent of the NREMS stages. The first REM period appears about 90 min after falling asleep. NREMS preceding the first dream period distinctively shows large amounts of slow-wave sleep (SWS: S3 + S4). During a typical 8-h sleeping night, five to six REM periods occur at intervals of 80–100 min, with the duration of each period generally increasing over the night. Stage 4 sleep and REMS are differentially distributed during the night. Stage 4 sleep predominates during the early part of the night and REMS in the latter part. In 2007, the American Academy of Sleep Medicine (AASM) introduced a new

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_55

guideline for terminology, recording method, and scoring rules for sleep-related phenomena [4]. In the AASM classification, S1, S2, and S3 + S4 are referred to as N1, N2, and N3, respectively. NREMS and REMS latency, total sleep time, and sleep efficiency (SE) are not affected by the new scoring criteria, whereas wake time after sleep onset (WASO) is increased significantly. With respect to sleep architecture, light sleep (S1 vs. N1) and SWS or deep sleep (S3 + S4 vs. N3) are significantly increased, while intermediate sleep (S2 vs. N2) is reduced. The diagnostic criteria of sleep disturbances according to the International Classification of Sleep Disorders (ICSD-2) [5] do not depend on sleep laboratory findings (ICSD-3 [see Chap. 27] published in 2014 retains the same principle), which tend to indicate that the former would not be influenced directly by the AASM classification [6]. Sleep stages reported in polysomnographic studies that included either untreated or medicated patients with a diagnosis of primary or comorbid insomnia are mostly based on the sleep scoring rules and terminology developed by Rechtschaffen and Kales [2].

Electrographic activity of the rat, a species currently used in preclinical studies, has been assigned to the following categories based on the waveform: wakefulness (W) [low-voltage fast waves in frontal cortex, a mixed theta rhythm (4–7 Hz) in occipital cortex and relatively high electromyographic (EMG) activity]; light sleep [high-voltage slow cortical waves interrupted by low-voltage fast electroencephalographic (EEG) activity]; SWS (continuous high-amplitude slow frontal and occipital waves combined with a reduced EMG); and REMS (low-voltage fast frontal waves, a regular theta rhythm in the occipital cortex and a silent EMG except for occasional myoclonic twitchings).

Neurotransmitters and Circulating Factors Involved in the Regulation of Sleep and Wakefulness

Our present knowledge on the neurotransmitters and somnogens involved in the regulation of the behavioral state has helped to understand the mechanism of action of substances currently administered for the treatment of insomnia in man and to the development of new compounds with an improved therapeutic profile.

Wake-Promoting Structures and Neurotransmitters

The central nervous system (CNS) structures involved in the promotion of the waking state are located in the brainstem, hypothalamus, and basal forebrain (BFB). The nuclei found in the brainstem include the dorsal raphe nucleus (DRN) synthesizing serotonin (5-HT); locus coeruleus (LC) synthesizing norepinephrine (NE); ventral tegmental area (VTA), substantia nigra pars compacta (SNc) and ventral periaqueductal gray (vPAG) containing dopamine (DA); and laterodorsal and pedunculopontine tegmental nuclei (LDT/PPT) containing acetylcholine (ACh). The structures found in the hypothalamus comprise the tuberomammillary nucleus (TMN) and the posterior lateral hypothalamus around the fornix where histamine (HA)- and orexin (OX)-containing cells are located, respectively. The cholinergic and glutamatergic neurons of the BFB involved in the regulation of W have been characterized mainly in the diagonal band of Broca, substantia innominata, and medial septal area [7, 8]. Most of the neuroanatomical structures included in the arousal system show, in addition, a great variety of neuropeptide-containing neurons as well as γ-aminobutyric acid (GABA)-ergic cells. The monoamine-, acetylcholine-, and glutamate-containing neurons that participate in the regulation of W give rise to mainly ascending projections to (1) the thalamus (dorsal route) which in turn projects to the cerebral cortex and (2) the BFB (ventral route) where cells in turn project to the cerebral cortex and hippocampus. The DA-containing neurons of the VTA and SNc project to the basal ganglia and the prefrontal cortex, whereas those corresponding to the vPAG project predominantly to the BFB and midline thalamus. Furthermore, OX-containing cells carry projections to the entire forebrain and brainstem arousal systems [9]. Of note, isolated activation of each of the arousal systems already provokes W. However, under normal conditions, they all participate in the occurrence of behavioral and EEG arousal. This is partly related to the interconnections of most W-promoting structures. Additionally, the systems that foster W inhibit neural structures located in the brainstem and hypothalamus that promote and/or induce NREMS (light sleep + SWS in laboratory animals) and REMS [10].

NREM Sleep-Promoting Structures and Neurotransmitters

Neurons of the preoptic area and adjacent BFB constitute the NREMS-inducing system. NREMS active neurons of the preoptic area and BFB contain GABA and galanin, and project to brainstem and hypothalamic areas involved in the promotion of W [11]. Somnogens including adenosine (formed inside cells or extracellularly by the breakdown of adenosine nucleotides), prostaglandin D2 (produced by lipocalin-type prostaglandin synthase which is mainly present in the leptomeninges, choroid plexus, and oligodendrocytes, and released in the cerebrospinal fluid), nitric oxide

(NO) (synthesized at central sites mainly from L-arginine by neuronal NO synthase), and cytokines (interleukin-1 and tumor necrosis factor-α) promote also sleep, mainly NREM sleep, in laboratory animals and man [12–15].

REM Sleep-Promoting Structures and Neurotransmitters

Cholinergic (REM-on) neurons of the LDT/PPT have been identified as promoting REMS. Moreover, the subcoeruleus nucleus has been proposed as the critical area for REMS generation in the cat. Its equivalent in the rat and mouse is called the sublaterodorsal nucleus. It should be mentioned that the parabrachial area, nucleus pontis oralis, and nucleus pontis caudalis contribute also to the occurrence of a number of REMS signs [16]. The REMS induction regions include predominantly glutamatergic and GABAergic neurons. More recently, melanin-concentrating hormone (MCH) neurons located in the lateral hypothalamus and zona incerta have been proposed to participate also in the regulation of sleep, including NREMS and REMS [17]. With respect to the prospective role of GABAergic neurons in the regulation of REMS, the updated reciprocal interaction model [18] proposes that during REMS, REM-on cholinergic LDT/PPT neurons excite pontine reticular formation REM-on GABAergic cells which in turn inhibit REM-off monoaminergic neurons.

Role of Neurotransmitter Systems in the Regulation of the Behavioral State: Experimental Approaches

Strategies aimed at determining the role of neurotransmitter systems in the regulation of sleep and W have included electrophysiological, genetic, neurochemical, and neuropharmacological approaches.

During quiet W, 5-HT, NE, HA, and OX neurons fire in a slow and regular fashion. During active W, the neuronal activity shows a significant increase. As the animal enters NREMS, the mean discharge rate shows a progressive reduction, and during REMS, there is a further decrease or even a cessation of neuronal activity.

Mutant mice that do not express 5-HT1A or 5-HT1B receptor exhibit greater amounts of REMS than their wild-type counterparts. A similar outcome has been described in dopamine-β-hydroxylase and histidine decarboxylase (the enzymes responsible for converting DA to NE and histidine to HA, respectively)-deficient mice, or following the systemic administration of the neurotoxin DSP-4, which selectively lesions the NE neurons. Moreover, systemic injection of α-fluoromethylhistidine, a highly specific, irreversible inhibitor of histidine decarboxylase, induces a significant reduction of W, while NREMS and REMS are increased. Orexin knockout mice show severe sleepiness and are unable to maintain long periods of W during the dark phase. With respect to the dopaminergic system, behavioral arousal is impaired in D1 and D2 receptor-deficient mice, whereas it is facilitated in mutant mice lacking functional D3 receptor (Table 55.1).

Sleep and W have been studied in MCH knockout mice. The knockout animals sleep less during the light and the dark phase of the light/dark cycle under basal conditions. An increase of W and a reduction of SWS have been described in MCHR1 receptor knockout mice, which agrees with the proposed role of MCH in the regulation of the behavioral state [19].

Systemic or i.c.v. injection of full agonists of postsynaptic 5-HT1A, 5-HT1B, 5-HT2B, 5-HT2C, 5-HT3, 5-HT6, and 5-HT7 receptor; the selective NE α1 receptor agonist methoxamine or the NE reuptake inhibitors amphetamine and cocaine; the relatively selective HA H1 receptor agonist 2-thiazolylethylamine; the selective DA D1 receptor agonist SKF 38393; or the neuropeptide OX consistently increase W and reduce SWS and REMS in laboratory animals. In contrast, the DA D2 receptor agonists apomorphine, bromocriptine, or quinpirole produce biphasic effects, such that low doses decrease W and augment sleep, while large doses induce the opposite effects in the rat (Table 55.1).

A series of pharmacological studies have provided further evidence for the involvement of ACh in the regulation of W and REMS. Thus, systemic administration of the muscarinic receptor agonists pilocarpine and arecoline evokes a characteristic cortical arousal which is reduced by atropine, while microinjection of the broad-spectrum cholinergic agonist carbachol or the anticholinesterase agents physostigmine and neostigmine into the medial pontine reticular formation induces a long-lasting REMS-like state in the cat (Table 55.1).

The actions of GABA in the CNS are mediated by three different classes of receptors denominated GABA-A, GABA-B, and GABA-C receptors. The GABA-A receptor predominates at central sites. GABAergic neurons comprise many functionally different subgroups, as evident in recorded cells in the BFB, hypothalamus, and brainstem. As mentioned before, a majority of sleep-active cells of the preoptic area contain GABA, and project to the BFB and to brainstem and hypothalamic areas involved in the promotion of W. BFB GABAergic neurons have been shown to be involved in the occurrence of W; in this respect, they target inhibitory interneurons and through disinhibition activate pyramidal cells. BFB GABAergic cells have been proposed

to contribute also to the modulation of REMS via descending projections that induce direct inhibition of REMS-regulatory neurons located in the brainstem.

Of note, the GABA-A receptor is the site of action of several hypnotic drugs, including the benzodiazepine (BZD) (midazolam, temazepam), cyclopyrrolone (zopiclone, eszopiclone), imidazopyridine (zolpidem), and pyrazolopyrimidine (zaleplon) derivatives where they behave as allosteric modulators.

The injection of MCH into the left lateral ventricle of the rat at the beginning of the dark phase induced a significant and dose-dependent increase in REMS during the first 2 h of the recording period. Microinjection of MCH into the nucleus pontis oralis, DRN, LC, and BFB (horizontal limb of the diagonal band of Broca) produced also a marked increase in REMS in the cat and the rat, respectively [19].

Melatonin is synthesized in great measure in the pineal gland and released in close association with the increase in sleep propensity (night in primates and man). The finding that systemic administration of melatonin to laboratory animals reduces sleep onset latency and increases SWS supports the proposal that it is involved in the regulation of sleep. The sleep-promoting and sleep–wake rhythm-regulating effects of melatonin are related to the activation of MT1 and MT2 receptors expressed by cells located in the suprachiasmatic nucleus of the hypothalamus [20]. Ramelteon is a melatonin MT1/MT2 agonist that acts predominantly on the suprachiasmatic nucleus and is effective in reducing sleep latency in laboratory animals and man.

Insomnia: Diagnostic Criteria

Insomnia is characterized by one or more of the following: difficulty falling asleep (sleep latency of more than 30 min), insufficient sleep (total sleep time of less than 5.5–6 h), numerous nocturnal awakenings, early morning awakenings with inability to resume sleep, or non-restorative sleep. Common daytime complaints include somnolence, fatigue, irritability, and difficulty concentrating and performing everyday tasks. Because insomnia is associated with reduction in attention span, affected individuals can often be impulsive and experience impaired judgment, and thus are at an increased risk for having injuries at home or work, or involvement in accidents while driving.

The ICSD-2 [5] considers severity criteria as a guide to be applied in conjunction with the consideration of the patient's clinical status. Mild insomnia refers to complaints of an insufficient amount of sleep almost every night or of not feeling rested the following day. Moderate and severe insomnia refers to complaints of experiencing an insufficient amount of sleep every night or of not being rested after the impaired sleep episode, accompanied by moderate and severe impairment of social and/or occupational functioning, respectively. The duration of insomnia has been considered also an important guide to its evaluation and treatment. Individuals with transient insomnia are normal sleepers who experience an acute stress for a few days which disrupts their sleep. Short-term insomnia is usually associated with situational stress. This type of insomnia may last up to 3 weeks.

However, in some cases, short-term insomnia may progress into a chronic condition. Conventionally, long-term or chronic insomnia has been considered to be that which lasts for at least 21–30 nights. Usually, it persists for months or years, and its onset may or may not be associated with an identifiable stressor.

The ICSD-2 [5] has classified chronic insomnia in adult patients as primary or secondary. The term secondary insomnia has been replaced recently by comorbid insomnia, because during some instances, the sleep disturbance can show as a separate complaint and require a treatment different from that of the comorbid condition. When there is no other diagnosable condition directly associated with the chronic insomnia, it is diagnosed as primary insomnia. If the insomnia is precipitated or aggravated by a psychiatric or neurological disease, a general medical condition, another sleep disorder, a disturbance of circadian rhythm, or the direct effects of a medication or a substance of abuse, then the other disorder is termed primary and the insomnia comorbid. The ICSD-3 abandoned classifying insomnia into subtypes and instead retained a global view and classified insomnia into chronic, short-term and other insomnia disorders (see Chap. 27). The ICSD-3 also eliminated the severity criteria.

The prevalence of chronic insomnia has been shown to vary between 10 and 15 % of the adult population. It is higher in older adults, and in this group, women prevail significantly. Moreover, depression or anxiety disorders have been diagnosed in 40 % of patients with chronic insomnia [21, 22]. The determinants of comorbid insomnia and induced subjective and objective sleep changes are presented in Tables 55.2, 55.3, 55.4, and 55.5.

Treatment of Primary and Comorbid Insomnia

Any strategy to the effective management of primary and comorbid insomnia should appropriately combine both pharmacological and non-pharmacological measures. In patients with comorbid insomnia, the underlying disorder needs to be assessed and treated appropriately [23]. Several classes of medications have been prescribed as hypnotics over the years, including the BZD receptor agonists (either benzodiazepinic or non-benzodiazepinic agents); melatonin and the melatonin agonist ramelteon; and the tricyclic antidepressant doxepin. The BZD hypnotics (midazolam, triazolam, temazepam, flunitrazepam, flurazepam, quazepam) were introduced in the 1970s and rapidly increased in popularity because of their efficacy and relative safety compared with barbiturates, carbamates, chloral derivatives, and methaqualone. However, the occurrence of adverse events including somnolence, dizziness and fatigue, the contingency of rebound insomnia following the withdrawal of short- and intermediate-acting derivatives, the risk of falls

Table 55.2 Determinants of comorbid insomnia: mental disorders

Determinants of comorbid insomnia	Subjective sleep changes	Objective sleep changes
– **Depressive disorder** (lifetime prevalence of 16.2 %)	Difficulty falling asleep, fragmented sleep, disturbing dreams, early morning awakening, decreased amount of sleep, being tired during the day. Similar findings during bipolar depression	Increased W and reduced sleep efficiency; SOL is increased, while SWS and TST are reduced; REMS latency is shortened, and the duration of the first REM period is augmented
– **Anxiety disorders** Generalized anxiety disorder (lifetime prevalence of 6 %)	Difficulty falling asleep and staying asleep, early morning awakening	Increased SOL and WASO; reduced TST and sleep efficiency; less S2 sleep and SWS
Panic disorder (lifetime prevalence of 2–3 %)	Difficulty falling asleep and staying asleep; panic attacks can occur during sleep	Longer SOL and increased WASO; reduction in TST and SWS; increase of W. Sleep panic attacks are NREMS-related events, usually emerging from late S2 sleep or early S3 sleep
Obsessive–compulsive disorder (lifetime prevalence of 7–8 %)	Disturbed sleep continuity	Increased number of awakenings; decreased TST
Post-traumatic stress disorder (lifetime prevalence of 7–8 %)	Difficulty falling and staying asleep, early morning awakening	Anxiety arousals; REMS-related nightmares
– **Schizophrenia** (lifetime prevalence of 1 %)	Sleep induction and sleep maintenance are altered; total sleeplessness is frequently observed in patients with psychotic agitation	S2 sleep latency and WASO are increased; the majority of studies indicate that S4 sleep and REMS latency are reduced, whereas REMS duration tends to remain unmodified

REMS rapid eye movement sleep; *SE* sleep efficiency; *SOL* sleep onset latency; *SWS* slow-wave sleep; *TST* total sleep time; *W* wakefulness

Table 55.3 Determinants of comorbid insomnia: neurological diseases

Determinants of comorbid insomnia	Subjective sleep changes	Objective sleep changes
– **Alzheimer disease** (prevalence of sleep disturbances of 25–50 %)	Difficulty falling and staying asleep. The 24-h sleep–wake pattern can be disrupted to the point that patients spend as much as 30–40 % of their time in bed awake, and numerous daytime hours napping	Increased duration and frequency of awakenings and of S1 sleep; reduced SWS and REMS and lower sleep efficiency; EEG slowing during W and REMS
– **Parkinson disease** [prevalence of sleep disorders increases with age (1 % in patients aged 65–69 years old to 5 % among patients 80–84 years old)]	Difficulty falling and staying asleep. Factors that compromise sleep in these patients include tremor, akinesia, akathisia, PLM, painful dystonia, REMS behavioral disorder, nocturia, depression, and medications	Frequent awakenings; decrease in SWS and REMS; reduced sleep efficiency
– **Epilepsy** (about 25 % of patients with epilepsy have seizures during sleep)	Epileptic episodes may cause hypnic jerks, recurrent dreams, nightmares, or numerous arousals that may result in EDS or paroxismal awakenings and a complaint of insomnia	
– **Ischemic stroke**	Insomnia or hypersomnia and sleep-disordered breathing are often seen in patients who have an ischemic stroke	
– **Headache**	The headache can awaken the patient during the night. The attack may have the clinical features of a migraine, a cluster headache, or a chronic paroxismal hemicranea	

EDS excessive daytime sleepiness; *PLM* periodic limb movements; *REMS* rapid eye movement sleep

Table 55.4 Determinants of comorbid insomnia: medical conditions

Determinants of comorbid insomnia	Subjective and objective sleep changes
– Cardiovascular diseases	Congestive heart failure, hypertension, angina pectoris, and myocardial infarction are capable of disturbing sleep. Patients with ventricular insufficiency or mixed cardiopathy have more difficulty falling asleep, wake up more often, and have more daytime sleepiness as compared to normal subjects. In patients with acute or chronic coronary heart disease symptoms, sleep may be altered by angina, factors related to a myocardial infarction, antiarhythmic, and antihypertensive medication or the occurrence of anxiety and depression
– Respiratory disorders	Disturbances of sleep in COPD patients comprise increased SOL, frequent awakenings, increased WASO, and reduced TST. Moreover, obesity and menopausia are aggravating factors in the development of the sleep disturbance. Obstructive sleep apnea may coexist with COPD and contribute to the sleep-related symptoms Patients with nocturnal asthma awaken with dyspnea, wheezing, and cough. Attacks tend to develop mainly during S2 sleep or REMS and follow a random distribution. Patients complain of early awakenings, difficulty in maintaining sleep, daytime fatigue, and EDS
– Gastrointestinal disorders	The burning discomfort or pain in the chest during gastroesophageal reflux induces a fragmentation of sleep that can lead to a complaint of insomnia The pain of peptic ulcer disease can occur at night, producing arousal and awakenings that disturb sleep
– Renal diseases	Patients with end-stage renal disease complain very frequently of difficulty falling asleep, awakening in the middle of the night, restless legs, and EDS
– Endocrine diseases	Central sleep apnea is extremely common in patients with acromegaly. EDS is frequently observed in patients with hypothyroidism. Polysomnographic studies in these patients have shown that SOL and sleep continuity are not modified, while SWS is significantly reduced Usually, patients with asymptomatic hyperthyroidism do not complain of disturbed sleep. In contrast, most patients with thyrotoxicosis complain of insomnia characterized by an increase in the latency to sleep onset and frequent awakenings during the night Obstructive sleep apnea has been reported in patients with diabetic autonomic neuropathy. Apneic episodes have been noted mainly in type 1 patients. However, it was not a constant findings Insomnia is one of the somatic symptoms described in postmenopausal women. The sleep disturbance associated with menopause manifests as a sleep initiation and maintenance insomnia. The sleep complaints are mainly related to hot flashes, sweating, headaches, anxiety, depression, and sleep-disordered breathing

(continued)

Table 55.4 (continued)

Determinants of comorbid insomnia	Subjective and objective sleep changes
– Neoplastic diseases	Sleep disturbance is a frequent complaint among patients with neoplastic diseases Available evidence tends to indicate that between 30 and 50 % of cancer patients complain of difficulties initiating and/or maintaining sleep. In this respect, patients with breast and lung cancer seem more likely to have an insomnia complaint. In addition, environmental factors related to hospitalization, and oncologic treatments tend to aggravate the sleep disturbance
– HIV infection	Daytime fatigue and lethargy are common findings during the acute or preserum conversion phase of the disease. However, sleep disruption does not seem to be a major issue. In contrast, sleep complaints are frequently present during chronic infection with HIV. In these patients, SOL, TST, and S1 sleep are increased, whereas S2 sleep is reduced. There are also subjective complaints of non-restorative sleep. Medications used to treat HIV further disrupt sleep in these patients
– Rheumatic disorders	Disturbed sleep and daytime fatigue are frequent findings in patients with rheumatoid arthritis. There is a strong association between pain and the disruption of sleep referred by these patients. Sleep is also disturbed in other rheumatoid diseases, including lupus erythematosus, Sjögrens syndrome, osteoarthritis, and low back pain Fybromyalgia is associated in more that 75 % of patients with sleep disturbance and related daytime symptoms such as fatigue and morning stiffness. The non-restorative sleep depends mainly on the presence of pain. GAD and depression further add to the disruption of sleep

COPD chronic obstructive pulmonary disease; *EDS* excessive daytime sleepiness; *GAD* generalized anxiety disorder; *SOL* sleep onset latency; *SWS* slow-wave sleep; *TST* total sleep time; *WASO* wake time after sleep onset

Table 55.5 Determinants of comorbid insomnia: substance-induced sleep disorders

Determinants of comorbid insomnia	Subjective and objective sleep changes
– Methylated xantines	Caffeine behaves as a CNS stimulant. Acute or chronic use of caffeine-containing beverages or medications increases SOL, WASO, and the number of awakenings, whereas SWS is suppressed. These effects are more evident in patients with primary insomnia or anxiety disorders
– Nicotine	The rewarding actions of nicotine include alertness, improved cognitive functioning, and reduction in craving for cigarettes. SOL is frequently enhanced in smokers compared to non-smokers
– Antiepileptic drugs	Phenobarbital decreases SOL and improves sleep continuity during short-term administration to patients with epilepsy. In contrast, REMS is suppressed. At therapeutic doses, gabapentin improves sleep continuity in epileptic patients, while valproate only slightly affects sleep continuity. In contrast, vigabatrin and tiagabine do not significantly modify sleep variables. Carbamazepine has been shown to shorten SOL and to improve sleep continuity, whereas phenytoin increases S1 and S2 sleep and suppresses SWS. Lamotrigine administration has been associated with reduced SWS duration
– Antihypertensive agents	Several β-adrenoceptor antagonists are available for clinical use. At clinical doses, propranolol may cause visual perceptual disorders, vivid dreams, and occasional insomnia. Pindolol has been reported to increase TST and to reduce REMS percentage. In addition, the compound augments the incidence of recalled awakenings and dreams. Atenolol slightly decreases REMS as compared to baseline values. When given to normal subjects, the α2-adrenoceptor agonist clonidine strikingly reduced the duration of REMS. In contrast, sleep changes have not been reported during the administration of calcium antagonists to man
– Corticosteroids	There is increasing recognition of direct effects of corticosteroids on the CNS, including effects on sleep and mood. Polysomnographic studies have shown that dexamethasone given by oral route exerts a disrupting effect on sleep characterized by increased W and S1 sleep and reduced time spent in REMS. Changes of SWS were inconsistent

Substance-induced sleep disorders
SOL sleep onset latency; *TST* total sleep time; *WASO* wake time after sleep onset

and cognitive decline in elderly patients, the occasional loss of efficacy, and the development of physical dependence led to a decrease in their use in the recent years. The clinical need for medications that did not have these side effects was an important factor leading to the development of zolpidem, zopiclone, eszopiclone, zaleplon, ramelteon, and low-dose doxepin.

Melatonin is available in the USA as a nutritional supplement in doses generally between 1 and 5 mg. However, the formulations are not regulated by the Food and Drug

Administration (FDA) with respect to quality and quantity. A long-acting prescription formulation (prolonged-release melatonin 2 mg) was approved by the European Medicines Evaluation Agency (EU-EMEA) in 2007 for the treatment of primary insomnia in patients aged 55 years and over.

Sedating antihistamines including chlorpheniramine and diphenhydramine are used in a number of countries as sleep aids. However, sedating antihistamines are compared unfavorably with zopidem, zopiclone, eszopiclone, and zaleplon because they produce acute tolerance, residual daytime sedation, diminished cognitive function, and other adverse effects, including dry mouth, blurred vision, urinary retention, constipation, and risk of increased intraocular pressure [24]. As an exception, low-dose doxepin is devoid of the above-mentioned side effects.

Preclinical Pharmacology of BZD and Non-BZD Hypnotics

The BZD hypnotics induce a sedative effect with doses that are similar or greater than those producing anticonvulsant or myorelaxant effects. Preclinical studies have shown zolpidem to exhibit also sedative, anticonvulsant, and myorelaxant activities. However, in contrast to the BZDs, zolpidem is more potent in suppressing locomotor activity (sedative effect) than pentylenetetrazol convulsions (anticonvulsant activity) and rotarod performance (muscle relaxation) in rats. In relation to the effects of zolpidem on sleep, a spectral analysis of sleep EEG in curarized rats revealed that its power density in SWS is predominantly increased in the low-frequency band (1.0–4.0 Hz). Moreover, in freely moving animals, zolpidem has been found to augment the duration of SWS and to reduce W. On the other hand, variable results have been reported in regard to REMS, such that an increase and a reduction in the behavioral state have been described in rats recorded during the light period [25].

Preclinical studies have shown zopiclone to exhibit sedative–hypnotic, anticonvulsant, myorelaxant, anti-aggressive, and anticonflict activities. With regard to the sedative–hypnotic activity, zopiclone decreases locomotor activity, reduces W, and increases SWS in the rat. Spectral analysis of the electrocorticogram after zopiclone administration has shown an increase in power density in the 2.0–4.0 Hz (delta) and the 12.0–16.0 Hz (beta) bands in the rat. Eszopiclone, the dextrorotatory enantiomer of racemic zopiclone, shares the sedative–hypnotic properties of zopiclone [26].

Zaleplon has been shown to reduce locomotor activity and to produce motor deficits in the rotarod and grid tests in the rat. In addition, the pyrazolopyrimidine derivative blocked electroshock-, pentylenetetrazole-, and isoniazid-induced convulsions. Zaleplon increased SWS and the relative EEG power density in the delta frequency band of rats prepared for chronic sleep recordings. REMS values showed no significant changes [27].

The sleep-promoting action of ramelteon has been studied on daytime and nighttime sleep in rats, cats, and monkeys. Systemic injection of ramelteon exerted a sleep-promoting effect in the rat characterized by a reduction in SWS latency and a short-lasting increase in SWS duration [28]. Ramelteon given by the oral route to freely moving cats significantly reduced W and increased SWS and REMS, while sleep latency was not modified. Exogenous melatonin was about 10 times less potent than ramelteon [29]. Oral administration of ramelteon significantly shortened sleep onset latency (SOL) and increased total sleep time (TST) in freely moving monkeys (*Macaca fascicularis*); the effect of melatonin was limited to a reduction in latency to sleep onset. Neither ramelteon nor melatonin affected the EEG spectra or the general behavior of the monkeys [30]. Compared with placebo, ramelteon had no effect on learning and memory, motor performance, and rewarding properties in rats and mice. Moreover, ramelteon showed neither a positive reinforcing effect nor produced BZD-like discriminative stimulus effects on tasks used to determine abuse potential and dependence in monkeys [31].

The basic actions of doxepin, a tricyclic antidepressant, are similar to those of other compounds of the group, including imipramine and amitryptiline. Doxepin inhibits the reuptake of 5-HT and NE. Additionally, the compound behaves as an antagonist of histaminergic (H_1), cholinergic (M_1), and noradrenergic (α_1) receptors [32].

Mechanism of Action of BZD and Non-BZD Hypnotics

γ-Aminobutyric acid is the most important inhibitory neurotransmitter in the mammalian brain and localizes to approximately 30 % of CNS synapses. The majority of GABA-A receptors consists of α, β, and γ subunits, which contain multiple isoforms or variants: α_1–α_6, β_1–β_3, and γ_1–γ_3. Zolpidem, zopiclone, eszopiclone, and zaleplon share with the BZDs the property of bindings to α subunits of the GABA-A receptor/chloride channel complex, however, with a decisive difference in selectivity concerning the subtypes. The sedative–hypnotic activity of BZDs is dependent on the integrity of the α_1 subtype. On the other hand, the anxiolytic, anticonvulsant, myorelaxant, ataxic, and withdrawal effects depend upon their predominant affinity for the α_2- and α_3-containing receptors. Similar to the BZD hypnotics, zolpidem and zaleplon bind at the GABA-A receptor, yet, unlike BZDs, they have more selectivity for the α_1 subtype. Zopiclone and eszopiclone have been proposed to bind at all GABA-A subtypes. Notwithstanding this, the mechanism of action of the cyclopyrrolone derivatives may not be identical

to that of the BZD hypnotics. In other words, the cyclopyrrolone derivatives might have more selectivity for certain subunits of the GABA-A receptor. This could tentatively explain the difference in effects on sleep architecture and the lower incidence of adverse events during their administration to patients with insomnia [26].

Melatonin receptors have been classified as MT1, MT2, and MT3. The former two receptors belong to the family of G-protein-coupled receptors linked to the inhibition of adenylate cyclase and have been detected in the suprachiasmatic nucleus (SCN), while MT3 is a melatonin-sensitive form of quinone reductase 2. MT1 mediates the inhibition of neuronal firing in the SCN by melatonin, while MT2 is involved in the coordination of mammalian circadian rhythms. Ramelteon is a highly selective MT1/MT2 agonist. Compared to melatonin, it shows a sixfold higher affinity for the human MT1 and a threefold higher binding potency for the human MT2. Of note, ramelteon has no affinity for GABAergic, monoaminergic, cholinergic, and opioid receptors [33, 34].

Low-dose doxepin acts as a selective HA H_1 antagonist. At the doses approved for insomnia treatment, pharmacological effects related to NE and 5-HT reuptake inhibition, and α_1 adrenergic and M_1 cholinergic blockade are not evident.

Pharmacokinetics of BZD and Non-BZD Hypnotics in Healthy Adults and Populations at Risk

Hypnotic drugs approved by governmental agencies for the treatment of primary and comorbid insomnia differ significantly in pharmacokinetic properties, including elimination half-life ($t_{1/2}$) and the presence of active metabolites. On the other hand, the majority of them have in common short absorption and distribution times. As a result, in most circumstances, they induce sleep rapidly. According to their elimination, half-life hypnotics can be divided into short-, intermediate-, or long-acting derivatives. The BZD hypnotics midazolam and triazolam, together with zolpidem, zopiclone, eszopiclone, zaleplon, and ramelteon, are short-acting derivatives. The BZDs flunitrazepam and temazepam, and low-dose doxepin are intermediate-acting hypnotics, whereas flurazepam is a long-acting derivative (Table 55.6). BZD hypnotics are rapidly absorbed after oral administration, and peak plasma concentrations are attained in 0.3–1.0 h. Metabolism takes place in the liver, and biotransformation products often have hypnotic activity (Table 55.6). For BZDs, the mechanisms of inactivation comprise hydroxylation, methylation, oxidation, and conjugation to form glucuronides. A reduced clearance and an increased $t_{1/2}$ of the BZD hypnotics have been reported in patients of 65 years and older. Furthermore, hepatic disease leads to impaired removal of these drugs from the body. The clearance of oxidatively metabolized BZDs (triazolam, flunitrazepam, flurazepam) is much more affected than those that undergo glucuronidation (temazepam). Renal failure can also affect the pharmacokinetics of BZD hypnotics. The reduction in plasma binding frequently associated with renal disease is the major causative factor in this type of patient. This results in an increase in the unbound fraction of the drug in plasma. The clearance of BZD hypnotics that are metabolized by glucuronidation is also affected in renal disease.

Zolpidem immediate-release (IR) is rapidly absorbed and extensively distributed to body tissues including the brain. Bioavailability is reported to be in the range of 70 %. A large fraction is bound to plasma protein (92.5 %), independently of concentrations between 40 and 790 ng/ml. After administration of a single therapeutic dose of 10 mg zolpidem IR to healthy adults, peak plasma concentrations (T_{max}) are attained in 60 min, (range 45–90 min) and the mean $t_{1/2}$ amounts to about 2.4 h [35] (Table 55.6).

Table 55.6 Pharmacokinetic parameters for benzodiazepine and nonbenzodiazepine hypnotics

Drugs	$t_{1/2}$ (h)	T_{max} (h)	Time to onset	Active metabolite(s)
Short-acting agents				
Midazolam	1.2–2.5	0.3	15–30	No
Triazolam	2.1–6.0	1.0	15–30	No
Zopiclone	3.5–6.0	0.5–2.0	15–30	*N*-oxide derivative
Eszopiclone	5.0–7.0	1.0	15–30	*N*-oxide derivative
Zolpidem	2.0–2.5	1.0	30	No
Zaleplon	1.0	1.0	15–30	No
Ramelteon	1.0–2.0	0.5–1.5	15–30	Hydroxylated derivative (M-II)
Intermediate-acting agents				
Temazepam	10.0–20.0	1.0–1.5	45–60	No
Flunitrazepam	9.0–31.0	1.0	20–30	7-amino derivative *N*-demethyl derivative
Doxepin	20.0	2.0–6.0	30–45	No
Long-acting agent				
Flurazepam	40.0–150.0	1.0	30–60	Hydroxyethylflurazepam

Zolpidem extended-release (ER) in its 12.5 mg formulation consists of a coated two-layer tablet. The primary release comprising about 60 % of the content is as fast as that of zolpidem IR 10 mg, and the rise in plasma concentration within the first 30 min does not differ from the IR values. Between 45 and 120 min, plasma levels are very similar in healthy subjects, but the ER formulation leads to a subsequently higher concentration over more than 6.0 h.

Sublingual zolpidem (SL) for middle-of the-night awakening shows a duration of action of approximately 4 h at the available dosages of 3.5 and 1.75 mg.

Zolpidem is metabolized in the liver by a number of cytochrome P450 isoenzymes, but predominantly CYP3A4, to inactive metabolites. The major routes of metabolism are oxidation and hydroxylation. After oral administration, zolpidem metabolites are largely excreted in the urine.

The metabolic clearance of zolpidem is reduced in elderly patients, aged 65 years and older, resulting in increases in maximum plasma concentration (C_{max}), area under the concentration curve (AUC) and $t_{1/2}$, the latter amounting to approximately 2.9 h. Thus, a reduction in the initial dose from 10 to 5 mg in the elderly is recommended. These changes largely reflect an age-related decrease in hepatic metabolism. The clearance of zolpidem from the body is also impaired in patients with severe hepatic insufficiency, thus requiring dose reduction. On the other hand, the clearance of the hypnotic drug is not altered in patients with compromised renal function.

Zopiclone is available as a racemic mixture. Zopiclone 7.5 mg administered at nighttime is rapidly absorbed. It has a bioavailability of approximately 75 %, a T_{max} of 0.5–2.0 h, and a C_{max} of 1.6 h. The compound undergoes oxidation to the *N*-oxide metabolite, which is pharmacologically active, and demethylation to the inactive *N*-demethyl-zopiclone. The $t_{1/2}$ of zopiclone and its active metabolite ranges from 3.5 to 6 h (Table 55.6).

Eszopiclone, the dextrorotatory enantiomer of racemic zopiclone, is currently used for the treatment of insomnia. (S)-zopiclone is responsible for the hypnotic effect of zopiclone, whereas the (R)-isomer has no hypnotic properties. Eszopiclone is rapidly absorbed and extensively distributed to body tissues including the brain. It is weakly bound to plasma protein (52–59 %). Moreover, its T_{max} is attained 1.0–1.6 h after a single therapeutic dose of 3 mg, and the $t_{1/2}$ amounts to approximately 6.0 h. Eszopiclone is metabolized in the liver to form (S)-zopiclone-*N*-oxide and (S)-*N*-demethyl zopiclone. In vitro studies have shown that CYP3A4 and CYP2E1 are the major enzymes involved in eszopiclone metabolism. After oral administration, eszopiclone is excreted in the urine, primarily as metabolites (Table 55.6). The metabolic clearance of eszopiclone is reduced in elderly subjects, aged 65 years and older, resulting in increases in C_{max} and $t_{1/2}$, the latter amounting to approximately 9.0 h. The removal of eszopiclone from the body is also impaired in patients with severe hepatic insufficiency, thus requiring dose reduction. On the other hand, the clearance of the compound is not altered in patients with renal insufficiency. Thus, based on the available evidence, a reduction in the initial dose of eszopiclone is recommended in elderly subjects and patients with severe hepatic insufficiency [36].

Zaleplon is rapidly and almost completely absorbed following the oral administration of a 10 mg dose. The compound undergoes significant first-pass hepatic metabolism after absorption. As a result, its bioavailability amounts to only 30 %. The derivative attains maximum plasma concentration in approximately 1.0 h and has a $t_{1/2}$ of 1.0 h. Zaleplon is primarily metabolized by aldehyde oxidase, and all of its metabolites are pharmacologically inactive (Table 55.6). The pharmacokinetics of zaleplon in elderly patients, including those over 75 years of age, is not significantly different from that in young healthy subjects. The clearance of zaleplon is reduced in cirrhotic patients, leading to a marked increase in C_{max} and AUC. Thus, the hypnotic drug should not be administered to patients with severe hepatic impairment. The pharmacokinetics of the compound is not altered in patients with mild-to-moderate renal insufficiency [37].

Ramelteon is absorbed rapidly with peak plasma concentrations occurring at 45 min (range 30–90 min) after oral administration. Its absolute oral bioavailability is only 1.8 % due to extensive first-pass metabolism. Protein binding of ramelteon is approximately 82 % in human serum. The metabolism of ramelteon consists primarily of oxidation to hydroxyl and carbonyl derivatives, with secondary metabolism producing glucuronide conjugates. CYP1A2 is the major enzyme involved in the hepatic metabolism of ramelteon. M-II is the major metabolite of ramelteon and contributes to the pharmacological effects of the parent drug. The $t_{1/2}$ of ramelteon is in the range of 1–2 h, while that of M-II is 2–4 h (Table 55.6). Ramelteon clearance is significantly reduced in elderly versus young subjects, and $t_{1/2}$ significantly increased. The ramelteon exposure parameters (C_{max}, AUC) are increased in patients with mild-to-moderate hepatic impairment. To date, the derivative has not been evaluated in patients with severe hepatic impairment. The pharmacokinetics of ramelteon has been studied also in patients with mild-to-severe renal impairment; no effect on C_{max} or AUC of the parent drug or M-II was detected in any of the treatment groups. Furthermore, mild-to-moderate obstructive sleep apnea and chronic obstructive pulmonary disease (COPD) were not exacerbated by the compound [38, 39].

Doxepin is rapidly absorbed following the oral administration of 1, 3, and 6 mg doses. It undergoes first-pass metabolism and is extensively protein bound (up to 95 %). The compound attains maximum plasma concentration in 2.0–6.0 h and has a $t_{1/2}$ of 20.0 h (range 10.0–30.0 h).

Doxepin is metabolized in the liver to form *N*-demethyl doxepin, and CYP2C19 and CYP2D6 are the major enzymes involved in its hepatic metabolism (Table 55.6). The metabolic clearance of doxepin is decreased in elderly subjects [40].

The Effects of BZD and Non-BZD Hypnotics in Patients with Primary Insomnia and Comorbid Insomnia

The main findings obtained with drugs used for the treatment of insomnia are based on questionnaires (subjective self-evaluation) and on objective measures obtained by polysomnography. The efficacy end points used in many studies included SOL, latency to persistent sleep (LPS), WASO, the number of awakenings, TST, SE, quality of sleep, fatigue, daytime sleepiness, cognitive impairment, mood disturbance, impaired work function, and impaired interpersonal function.

Benzodiazepine Hypnotics

The sleep induced by BZD hypnotics, including midazolam, triazolam, temazepam, flunitrazepam, quazepam, and flurazepam in patients with chronic primary insomnia, is characterized by a shortened SOL, decreased number of nocturnal awakenings, reduced time spent awake, increase in S2 sleep, consistent reduction in SWS (S3 + S4), dose-dependent suppression of REMS, and improvement in the subjective quality of sleep when compared with no treatment [41, 42]. Clinical and polysomnographic studies of triazolam 0.5 mg, temazepam 30 mg, and flurazepam 30 mg per night have found improvement in sleep over 4–5 weeks [43, 44]. The commonly reported adverse effects of BZD hypnotics are drowsiness, tiredness, dysarthria, ataxia, depression, and anterograde amnesia. Memory impairment and rebound insomnia have been reported more often with BZDs that have short half-life, such as triazolam and midazolam. Daytime functioning can be negatively affected, as evidenced by the effects on measures of psychomotor performance in patients taking a long-acting BZD such as flurazepam. Increased daytime sleepiness as quantified by the multiple sleep latency test can occur (Table 55.7). The elderly are particularly susceptible to the adverse effects of BZDs, due to the age-related alterations in pharmacokinetics as a result of changes in hepatic metabolism and renal excretion [45].

Non-benzodiazepine Hypnotics

Zolpidem

The therapeutic efficacy of zolpidem formulations has been investigated in a number of studies with either evening or middle-of-the-night dosing. Outcome measures in such studies have employed objective measures obtained in the sleep laboratory as well as subjective ratings of improved sleep.

Zolpidem Immediate-Release in Patients with Chronic Primary Insomnia

Considerable research attention has been given to the suitability of zolpidem IR for chronic insomnia. In this respect, the effectiveness of zolpidem IR has been assessed in 13 studies involving outpatients and inpatients who have not been taking hypnotic medication prior to the study for periods ranging from 4 to 30 nights. Zolpidem IR was administered for the extent of time ranging from 7 to 35 nights. Six of the studies used polysomnography and either a single-blind or double-blind experimental design to evaluate the effect of the medication on sleep variables in patients with a diagnosis of chronic primary insomnia. Results with zolpidem IR 10 mg indicate that the compound is capable of reducing SOL and WASO, and, with certain qualifications, can augment TST and SE. The number of nocturnal awakenings was not significantly modified. The predominant reduction in WASO during the first part of the night and the absence of an effect on the number of nocturnal awakenings could be related to zolpidem's short elimination half-life. This could also explain the inconsistencies observed in supporting sleep maintenance. However, the subjective feeling of being more refreshed on awakening, as reported by many patients, should not be underrated, even when not supported by objective measures. With respect to sleep architecture, zolpidem tended to increase S2 sleep, whereas SWS (S3 + S4), REMS latency, and REMS in min or as percentage of TST were not significantly modified (Table 55.7) [25, 46].

Spectral analysis in patients with moderate-to-severe chronic primary insomnia under treatment with 10 mg zolpidem IR for 15 nights showed only moderate effects. Power density of SWS was significantly increased in the delta (0.25–1.0 Hz) band only during the first two-hour interval, during both short and intermediate-term treatments. In contrast to BZD hypnotics, zolpidem did not suppress low-frequency EEG activity in patients with a sleep disorder [47].

Table 55.7 Effects of hypnotic drugs on sleep variables in patients with chronic primary insomnia: benzodiazepine and non-benzodiazepine GABA-A receptor allosteric agonists

Variable	Benzodiazepines	Zolpidem	Zopiclone–Eszopiclone	Zaleplon
Sleep induction				
– Sleep onset latency	Decrease	Decrease	Decrease	Decrease
Sleep maintenance				
Number of awakenings	Decrease	No change (IR) Decrease (ER)	Decrease	Variable effects
– Wake time after sleep onset	Decrease	Decrease (IR) Decrease (ER)	Decrease	No change
– Total sleep time	Increase	Inconsistent (IR) Increase (ER) Increase (SL)	Increase	Variable effects
Subjective measure of sleep				
– Sleep quality	Improved	Improved (IR, ER, SL)	Improved	Variable effects
Sleep architecture				
– Stage 2 sleep – Slow-wave sleep – REM sleep	Increase Decrease Decrease	Increase No change No change	Increase No change No change	Variable effects Variable effects Variable effects
Adverse events	Drowsiness Tiredness Dysarthria Ataxia Anterograde amnesia Depression	Zolpidem IR/ER Headache Drowsiness Dizziness Nausea Diarrhea Myalgia Bizarre behaviors	Bitter taste Headache Dyspepsia Pain Diarrhea Dry mouth Dizziness	Asthenia Dizziness Somnolence
Dosage (mg/night—adult/elderly)	Midazolam: 15/7.5 Triazolam: 0.25/0.125 Temazepam: 30-15/15-7.5 Flunitrazepam: 1/0.5 Flurazepam 30/15	IR: 10/5 ER: 12.5/6.25 SL: 3.50/1.75	Zopiclone: 7.5/3.5 Eszopiclone: 3/2	10/5

ER extended-release; *IR* immediate-release; *SL* sublingual

Sublingual Low-Dose Zolpidem

A low-dose sublingual formulation of zolpidem IR has been developed to be administered following the middle-of-the-night (MOTN) awakenings in patients with sleep maintenance difficulties. In a study that included middle-aged patients with a diagnosis of chronic primary insomnia, the administration of sublingual zolpidem 3.5 or 1.75 mg for 2 consecutive nights after MOTN awakenings significantly reduced latency to return to sleep and increased TST and sleep quality in comparison with placebo. The increase in TST was limited to the first 2 h following the scheduled MOTN awakening. Subject-reported estimates of sleep variables paralleled the polysomnographic findings. The hypnotic medication was well tolerated [48].

The efficacy and safety of 3.5 mg sublingual zolpidem as needed were evaluated during 28 nights in middle-aged patients with insomnia characterized by difficulty returning to sleep after MOTN awakenings. The response to the hypnotic medication was confirmed on the basis of subjective measures. Sublingual zolpidem decreased SOL over the 28-night treatment period compared with placebo. In addition, there was an improvement of sleep quality and morning sleepiness/alertness scores [49].

The long-term use of hypnotic drugs has been generally discouraged on the grounds of risk of rebound insomnia, withdrawal reactions, and/or dependence. Although this recommendation is mainly relevant to the BZDs, it has nevertheless been extended to many of the recently introduced non-BZD hypnotics. Concerning zolpidem, evidence from accumulated clinical practice and controlled studies tends to indicate that long-term treatment of insomnia with the medication is efficacious and safe. More recent studies with zolpidem ER over 6 months support this conclusion (see below).

Non-nightly Administration of Zolpidem Immediate-Release

Non-nightly zolpidem administration has been proposed as an alternative option to nightly drug intake. Administration of 10 mg zolpidem IR for 5 nights followed by 2 nights of placebo per week for 2 weeks induced an improvement of sleep that was comparable to nightly zolpidem treatment in patients with chronic insomnia [50]. Rebound insomnia did not occur on the nights during which zolpidem was substituted by a placebo. Similar improvements in sleep quality were observed when the 2 placebo nights per week were randomly assigned. More recently, zolpidem IR 10 mg or placebo was administered for 12 weeks to patients with a diagnosis of chronic primary insomnia. The patients were instructed to take no fewer than 3 and no more than 5 pills per weeks. Patients receiving zolpidem exhibited an improvement of sleep induction and maintenance that persisted over time. There was no evidence of either rebound insomnia or dose escalation [51]. Thus, the currently available data suggest that long-term non-nightly administration of zolpidem 10 mg for patients with chronic primary insomnia is an effective alternative to its continued nightly use.

Zolpidem Extended-Release in Patients with Chronic Primary Insomnia

Zolpidem ER 12.5 mg has been administered in several placebo-controlled studies to patients with chronic primary insomnia. In middle-aged patients treated nightly for 3 weeks, polysomnographic and subjective measures revealed significant improvements in sleep quality, in particular with respect to LPS, WASO during the first 6 h of sleep, and SE, as well as self-reported SOL, WASO, the number of awakenings, and TST [52]. In another study comprising insomnia patients, based on self-ratings, subjective SOL, WASO, the number of awakenings, and sleep quality were improved at a significant level [53]. In conclusion, the available data tend to indicate that zolpidem ER is effective for the treatment of insomnia characterized by difficulties with sleep onset and/or sleep maintenance [54].

Zolpidem Immediate-Release and Extended-Release in Patients with Comorbid Insomnia

In the study by Joffe et al. [55], breast cancer patients, who had hot flashes in association with nocturnal awakenings and were receiving venlafaxine 75 mg, were randomized to double-blind treatment with zolpidem IR 10 mg or placebo for 5 weeks. Augmentation of venlafaxine with zolpidem IR significantly improved sleep and quality of life in the breast cancer women.

The effect of zolpidem ER has been demonstrated also in patients with comorbid insomnia and major depressive disorder (MDD) or generalized anxiety disorder (GAD), in either case with concurrent escitalopram therapy. In a multicenter study, adult MDD patients received open-label escitalopram (10 mg/day) and were randomized to concomitant zolpidem ER 12.5 mg/night or placebo for 8 weeks (phase I). Responders continued 16 weeks of double-blind treatment (phase II). Significant improvements were observed during phase I in SOL, WASO, TST, and sleep quality, and some measures of sleep-related next-day functioning. Depressive symptoms remained unchanged. During phase II improvements in the zolpidem, ER/escitalopram group were restricted to an increase in TST [56]. Another phase I and phase II trials in MDD patients treated with zolpidem ER in combination with escitalopram showed likewise improvements of sleep impact [57].

In a multicenter double-blind study that included GAD patients treated with either zolpidem ER/escitalopram or placebo/escitalopram, there were significant improvements in SOL, WASO, TST, SE, next-day morning energy, morning concentration, and sleep impact on daily activities in the patients receiving the hypnotic medication. There was no substantial change in the psychiatric symptoms [58].

Safety and Adverse Effects of Zolpidem

The safety profile of zolpidem IR and ER is very similar. The most commonly observed adverse events associated with the use of zolpidem IR are headache, drowsiness, dizziness, nausea, diarrhea, and myalgia, but these complaints occur only with moderate frequency. Rebound insomnia is not evident after discontinuation of the hypnotic agent [44]. Of interest, in a double-blind, placebo-controlled, clinical trial, it was found that 12 months of nightly zolpidem IR 10 mg did not lead to dose escalation in non-elderly primary insomniacs [59]. The nature of adverse events reported in adult patients receiving zolpidem IR 10 mg was similar to that described by elderly patients being given zolpidem IR 5 mg [60]. The most frequently observed adverse events in adults and elderly patients treated with zolpidem ER at daily doses of 12.5 and 6.25 mg, respectively, were next-day somnolence, headache, and dizziness [61, 46]. Precautions have to be considered and require surveillance in patients with hepatic impairment, respiratory diseases (especially obstructive sleep apnea syndrome and COPD), pregnancy, or concomitant use of other CNS depressants.

Several case reports have described behavioral changes caused by zolpidem, including the occurrence of bizarre behaviors, agitation, and sleep-related complex behaviors, such as sleep eating, sleep walking, sleep conversations, sleep driving, and sleep shopping, frequently with amnesia for the event [62]. With these exceptions, the general and overwhelming impression remains that zolpidem, whether IR or ER, is a remarkably safe hypnotic, having few adverse effects in conjunction with considerable efficacy relative to other options in sleep medicine, especially in comparison with BZDs.

Zopiclone and Eszopiclone

Zopiclone and Eszopiclone in Patients with Chronic Primary Insomnia

Zopiclone is effective in inducing and maintaining sleep in patients with chronic primary insomnia. The increase in TST is related to greater amounts of S2 sleep.

In adult and elderly patients with insomnia, zopiclone 7.5 and 3.5 mg increased, decreased, or had no effect on S3 sleep and S4 sleep as percentage of TST. No significant change has been observed in REMS duration as a percentage of TST, although REMS latency may be delayed. No development of tolerance has been described in studies of zolpiclone that lasted up to 4 weeks [63, 64].

Non-elderly and elderly patients with chronic primary insomnia and comorbid insomnia have been included in the studies that assessed the efficacy and safety of eszopiclone. However, to date much of the published information on the effect of eszopiclone on sleep variables has been gathered from studies that included subjects with chronic primary insomnia.

The effects of eszopiclone 3 mg or a placebo have been evaluated in non-elderly patients with moderate primary insomnia during 44 nights. SOL and WASO showed a significant decrease after eszopiclone relative to placebo, while TST and SE were enhanced. Tolerance did not develop during the eszopiclone 3 mg administration period. With respect to sleep architecture, the inferred increase in NREMS was coupled with significantly higher levels of S2 sleep, whereas S3 sleep and S4 sleep were not significantly different between 3 mg eszopiclone and placebo. A similar outcome was observed in relation to time spent in REMS. Subjective evaluation was correlated with the sleep laboratory findings. Accordingly, eszopiclone 3 mg improved subjective ratings of the perceived ease of getting to sleep, the duration of sleep, and the quality and depth of sleep [65].

The use of eszopiclone to improve sleep over a longer period of time has been evaluated also in middle-aged subjects suffering from chronic primary insomnia [66]. The study was conducted according to a double-blind, placebo-controlled design with randomization. The efficacy of eszopiclone 3 mg and a placebo was assessed once a week during 6 months using an interactive voice response system. Eszopiclone significantly reduced SOL, WASO, the number of nocturnal awakenings per night, and the number of nocturnal awakenings per week. TST was increased compared with baseline at the end of the first week and through months 1 to 6. Sleep quality, daytime ability to function, alertness, and physical well-being also improved significantly.

The safety of eszopiclone during an additional 6-month period was evaluated by Roth et al. [67] in the patients originally included in the study by Krystal et al. [66]. The sustained improvement in sleep and daytime functioning reported in the previous study during the double-blind phase of the investigation was confirmed during the second 6-month, open-label, phase of the study. There was no evidence of tolerance.

The effects of eszopiclone administration have been assessed also in elderly patients with chronic primary insomnia. These were randomized, double-blind, placebo-controlled studies. In a 2-week study, patients were given either eszopiclone 1 mg or 2 mg or placebo nightly. Efficacy was assessed using an interactive voice response system. Eszopiclone 2 mg was effective in reducing SOL, WASO, and the number of awakenings, while TST was increased. Additionally, sleep quality and depth, daytime alertness, and quality of life were improved compared with placebo [68]. In another chronic primary insomnia study where patients received also eszopiclone 2 mg or placebo for 2 weeks, efficacy was assessed by means of polysomnography and patients' reports. Eszopiclone administration significantly reduced LPS and WASO, whereas TST and SE showed significant increments. S2 sleep was significantly augmented, whereas S1 sleep, SWS (S3 + S4), and REMS in min were not modified. Subjective evaluation was relatively well correlated with the sleep laboratory findings [69] (Table 55.7).

In conclusion, during the active treatment period eszopiclone improved sleep induction and maintenance compared with placebo in middle-aged and elderly patients with chronic primary insomnia.

Eszopiclone in Patients with Comorbid Insomnia

Insomnia related to depression may be alleviated by treating the underlying mood disorder with antidepressant drugs. However, this is not always the case since a stimulant effect may appear during treatment. This is particularly true with the selective serotonin reuptake inhibitors, which according to pharmacoEEG studies behave as activating antidepressants.

The disruption of sleep continuity is more pronounced after fluoxetine administration compared with other SSRIs [70].

The effect of adding eszopiclone to fluoxetine was evaluated in non-elderly patients who met DSM-IV criteria for MDD and comorbid insomnia. Patients who had been receiving fluoxetine (dose range 20–40 mg/day) were randomized to receive either eszopiclone 3 mg or placebo double-blind for 8 weeks. Patients' self-reports of various sleep parameters, daytime functioning, and depressive symptoms were obtained with an interactive voice recording system. Sleep induction, sleep maintenance, and daytime function showed a significant improvement in the patients in the eszopiclone plus fluoxetine group compared with the placebo plus fluoxetine group during the 8-week treatment period. In addition, scores in the Hamilton Depression-17 Rating Scale were significantly lower at week 4 and week 8 [71].

Pollack et al. [72] determined the efficacy of eszopiclone combined with escitalopram in treating insomnia comorbid with GAD. The double-blind, placebo-controlled study included adult patients meeting DSM-IV-TR criteria. Subjects received escitalopram 10 mg and were randomized to receive also either eszopiclone 3 mg or placebo nightly for 8 weeks. The association of eszopiclone with escitalopram resulted in significantly improved sleep variables (SOL, WASO, the number of awakenings, TST), daytime functioning (alertness, ability to function and to concentrate, and physical well-being), and anxiety (Hamilton Anxiety Scale response). There was no evidence of tolerance. Moreover, rebound insomnia did not show after eszopiclone withdrawal.

In another randomized controlled study, Soares et al. [73] evaluated the efficacy of 3 mg of eszopiclone for the treatment of insomnia in perimenopausal and early postmenopausal women. The study concluded with the finding that eszopiclone significantly improved many sleep characteristics (sleep induction, maintenance, duration, quality, and next-day functioning). The study showed also a positive impact on the mood, quality of life, and other subjective menopausal-related symptoms in post-menopausal women with insomnia.

Adverse Events of Eszopiclone

The most commonly reported side effects in non-elderly and elderly patients who received zopiclone (7.5/3.5 mg) or eszopiclone (3/2 mg) were unpleasant or bitter taste, headache, dyspepsia, pain, diarrhea, dry mouth, dizziness, and accidental injury. There is no evidence of an addicting potential of eszopiclone in individuals without known history of drug abuse.

Zaleplon

Zaleplon in Patients with Chronic Primary Insomnia

A number of placebo-controlled trials have determined the efficacy of zaleplon in improving sleep in non-elderly patients with chronic primary insomnia.

Walsh et al. [74] evaluated the efficacy of zaleplon 10 mg during 5-week administration in adult patients with primary insomnia. Polysomnographic data and subjective measures showed that zaleplon significantly decreased LPS relative to placebo during all 5 weeks. No consistent effects on WASO, TST, or the number of awakenings were seen with the hypnotic drug. Furthermore, zaleplon administration induced inconsistent changes of sleep architecture, including S2 sleep, SWS (S3 + S4), and REMS.

In an outpatient study of adults with primary insomnia, the subjects were given zaleplon, 5 mg, 10 mg, and 20 mg, or placebo during 4 weeks. Zaleplon 5 mg significantly reduced the subjectively reported SOL over the first 3 weeks of treatment, and for zaleplon 10 and 20 mg over all 4 weeks. The number of awakenings during the night was not significantly affected by the medication [75].

Using a similar protocol, Fry et al. [76] reproduced the findings by Elie et al. [75] with respect to subjective sleep latency. In addition, zaleplon 20 mg significantly, but variably, improved subjective TST, the number of awakenings and sleep quality.

The efficacy and safety of zaleplon 5 and 10 mg were investigated also in elderly patients with chronic insomnia. Sleep induction and sleep maintenance were assessed by using morning questionnaires completed during baseline nights, double-blind treatment nights, and after discontinuation of the hypnotic medication. The 10 mg zaleplon dose induced better subjective sleep onset during both weeks of the study, while zaleplon 5 mg decreased sleep latency only during the second treatment week. TST was significantly increased with zaleplon 5 mg during the whole treatment period and with zaleplon 10 mg during week 1 [77]. Similar effects on subjective sleep latency were obtained by Hedner et al. [78], following the administration of zaleplon 5 and 10 mg over a period of 2 weeks to elderly patients with primary insomnia. Moreover, zaleplon 10 mg increased TST and reduced the number of awakenings during the first treatment week.

Adverse Events of Zaleplon

Evening administration of zaleplon 5 and 10 mg to non-elderly and elderly patients was associated with minimal next-day residual sedation and impairment. Of note, the

effectiveness of zaleplon 10 mg was maintained over 6–12 months of use, and weak or no rebound insomnia occurred upon discontinuation of the medication [79] (Table 55.7).

In conclusion, available evidence tends to indicate that zaleplon is suitable for the treatment of primary insomnia associated with sleep onset difficulty.

Ramelteon

Ramelteon in Patients with Chronic Primary Insomnia

A number of studies have investigated the effects of ramelteon in adult and elderly patients with chronic primary insomnia.

In a randomized, double-blind, placebo-controlled trial, Erman et al. [80] evaluated the use of ramelteon at doses ranging from 4 mg to 32 mg in adult subjects with chronic primary insomnia. Patients received all 5 treatments, with a washout period of 5–12 days between treatments. In this study, all doses of ramelteon resulted in a statistically significant reduction in SOL and increase in TST as quantified by polysomnography.

Zammit et al. [81] conducted a 35-night double-blind, randomized study to evaluate the efficacy of ramelteon 8, 16 mg, and placebo in adult patients with primary insomnia. Compared with the placebo group, ramelteon 8 and 16 mg significantly reduced polysomnographically recorded SOL throughout the treatment period. Patient-reported sleep latency was significantly reduced with ramelteon 8 mg at weeks 1, 3, and 5, and ramelteon 16 mg at weeks 1 and 3. In addition, both ramelteon doses significantly increased TST and improved SE at week 1. The number of awakenings, WASO, and sleep architecture were not significantly modified by the hypnotic drug. Rebound insomnia and withdrawal effects were not evident following discontinuation of the medication.

In the randomized, double-blind, placebo-controlled study by Mayer et al. [82], efficacy and safety of ramelteon 8 mg administered nightly for 6 months was evaluated in adult patients with chronic primary insomnia by using polysomnography and a post-sleep questionnaire. Ramelteon 8 mg significantly decreased LPS at week 1 and months 1, 3, 5, and 6. A significant increase in TST was detected at week 1 only. Furthermore, the compound induced a small but significant increase in S2 sleep and reduction of SWS (S3 + S4) compared with placebo at each time point. REMS values remained unchanged along the study. Subjective sleep latency was reduced at week 1, month 1, and month 5. In contrast, subjective WASO, the number of awakenings, TST, and sleep quality showed no significant differences compared to placebo.

The efficacy and safety of ramelteon were assessed also in elderly patients with chronic primary insomnia. To this purpose, ramelteon 4 and 8 mg, and placebo were administered in 3 consecutive phases for 2 consecutive nights. Sleep was quantified via polysomnography and a postsleep questionnaire. Ramelteon 4 mg and 8 mg significantly decreased LPS and augmented TST and SE. Reductions in subjective sleep latency were reported with ramelteon 4 mg only [83].

In a randomized double-blind placebo-controlled study involving elderly patients with insomnia, ramelteon in doses of either 4 or 8 mg was given at night for 5 weeks. The long-term nightly effect of ramelteon was evaluated using a sleep diary [84]. Sleep latency for both ramelteon doses was significantly reduced from the first week onwards and became increasingly more pronounced until week 5. These findings were similar for both dosage regimens of the medication. TST was significantly increased in the 4 mg group for the week 1 and week 3 assessments. There were no significant differences in the number of awakenings and quality of sleep (Table 55.8).

Ramelteon in Patients with Comorbid Insomnia

The effect of ramelteon 8 mg was evaluated in peri- and postmenopausal women with insomnia by DeFronzo Dobkin et al. [85]. This was an open-label trial where patients completed sleep-wake diaries on a daily basis for six weeks. Patients reported significant improvements in SOL, TST, SE, quality of life, and mood during ramelteon administration. There was no evidence of tolerance or rebound insomnia after cessation of the treatment.

The effect of ramelteon for insomnia was examined in adults with GAD partially responsive to a selective serotonin reuptake inhibitor or a serotonin–norepinephrine reuptake inhibitor. Patients were given openly ramelteon 8 mg at bedtime for 10 weeks. As a result, they reported falling asleep faster and sleeping longer during the treatment period [86].

Gooneratne et al. [87] evaluated in a randomized, double-blind, placebo-controlled study, the effectiveness of ramelteon for insomnia symptoms in older adults with obstructive sleep apnea. Patients received ramelteon 8 mg or placebo for 4 weeks. Ramelteon administration was associated with a significant reduction in SOL as measured by polysomnography. However, no change was observed in subjective SOL or SE. Of note, the apnea–hypopnea index showed no statistically significant changes during the administration of the hypnotic drug.

Table 55.8 Effects of hypnotic drugs on sleep variables in patients with chronic primary insomnia: ramelteon (melatonin MT1 and MT2 receptor agonist) and low-dose doxepin (histamine H1 receptor antagonist)

Variable	Ramelteon	Doxepin
Sleep induction		
– Sleep onset latency	Decrease	No change or decrease
Sleep maintenance		
Number of awakenings – Wake time after sleep onset – Total sleep time	No change No change Small increase	Decrease Decrease Increase
Subjective measure of sleep		
– Sleep quality	No change or small improvement	Improved
Sleep architecture		
Stage 2 sleep Slow-wave sleep REM sleep	Increase Decrease No change	Increase No change No change or decrease
Adverse events	Somnolence Headache Dizziness Fatigue	Somnolence
Dosage (mg/night—adult/elderly)	8	6/3

Safety and Adverse Effects of Ramelteon

Generally, the incidence of side effects resulting from the continued use of ramelteon was not significantly different from that of placebo. The most commonly reported symptoms were somnolence, headache, dizziness, fatigue, and nausea. In addition, ramelteon was well tolerated and without significant cognitive, memory, or psychomotor effects.

Doxepin

Doxepin in Patients with Chronic Primary Insomnia

The effectiveness of low-dose doxepin in adult and elderly patients with chronic primary insomnia has been evaluated in 5 studies.

In an outpatient study of adults with chronic primary insomnia, the subjects were randomly assigned to one of four sequences of 1, 3, and 6 mg of doxepin, and placebo. The efficacy of doxepin was evaluated across 2 nights for each dose using polysomnography and patient reports. All 3 doses significantly improved WASO, TST, and SE. In addition, the doxepin 6 mg dose reduced subjective SOL. There was a significant increase in min of S2 sleep after the whole range of doses administered, whereas REMS percentage was reduced at the 3 and 6 mg dose. Values corresponding to SWS (S3 + S4) remained unchanged [88].

The efficacy of doxepin 3 and 6 mg in adults with chronic primary insomnia was confirmed in a placebo-controlled 5-week trial. Doxepin 3 mg and 6 mg improved WASO and TST on nights 1, 15, and 29 in polysomnographic sleep recordings. LPS was decreased only on night 1. Doxepin improved also early morning awakenings and SE in the last quarter of the night. There was no evidence of rebound insomnia after discontinuation of the medication [89].

Scharf et al. [90] determined the efficacy and safety of doxepin 1, 3 mg, and 6 mg in elderly patients with chronic primary insomnia. Each treatment period consisted of 2 polysomnographic assessment nights. All 3 doxepin doses significantly increased WASO, TST, and SE versus placebo. The 6 mg dose induced also a significant reduction in SOL. Subjective sleep maintenance was also improved.

A 12-week sleep laboratory trial of elderly chronic insomnia subjects assessed the long-term efficacy of doxepin with a comparison of 1 mg and 3 mg doses with placebo. Doxepin 3 mg significantly decreased WASO and augmented TST and SE during weeks 1, 4, and 12. In addition, the medication improved patient-reported SOL, TST, and sleep quality. Regarding doxepin 1 mg, sleep maintenance was also improved at several time points [91].

A 4-week outpatient study of doxepin was performed in elderly chronic primary insomnia subjects. The participants were randomly divided into groups dosed with nightly doxepin 6 mg or placebo. Efficacy was assessed using patient reports and clinician ratings. Doxepin 6 mg reduced WASO and increased TST and sleep quality during the treatment period. SOL was not modified [92] (Table 55.7).

Safety and Adverse Effects of Doxepin

The clinical efficacy trials described above have monitored potential adverse effects of doxepin. All 3 doxepin doses had side effect profiles comparable to placebo. There was no evidence of next-day sedation, memory impairment, anticholinergic effects, or rebound insomnia.

It can be concluded that the administration of low-dose doxepin improves sleep, including SE in the last quarter of the night, in adult and elderly patients with chronic primary insomnia as measured by polysomnography and patient self-report.

Sleep and Alternative Medicine: I

56

Divya Gupta

Introduction

In the year 2000, the World Health Organization (WHO) defined Traditional Medicine (TM) as "the sum-total of the knowledge, skills, and practices based on the theories, beliefs, and experiences indigenous to different cultures, whether explicable or note, used in the maintenance of health as well as in the prevention, diagnosis, and improvement or treatment of physical and mental illness" [1]. Complementary and alternative medicine (CAM) is often used interchangeably with TM [2]. Complementary medicine refers to medicine given as a complement to conventional therapies, whereas alternative medicine is that which is given in lieu of conventional therapy [3].

CAM includes a large and diverse set of systems of diagnosis, treatment, and prevention based on philosophies and techniques other than those used in conventional Western medicine, often derived from traditions of medical practice used in other (non-Western) cultures. Such practices may be described as alternative that exists as a body separate from and as a replacement for conventional Western medicine, or complementary, that is, used in addition to conventional Western practice. CAM is characterized by its focus on the whole person as a unique individual, on the energy of the body and its influence on health and disease, on the healing power of nature and the mobilization of the body's own resources to heal itself, and on the treatment of the underlying causes, rather than symptoms of disease. Many of the techniques used are subject to controversy and have not been validated by randomized double-blind, placebo controlled studies, thus setting CAM apart from conventional (allopathic) medicine. Congress in 1992 established an office of Alternative Medicine within the National Institutes of Health (NIH) to evaluate alternative therapies. In 1994, Congress exempted these remedies from regulation by Federal Drug Administration (FDA). Randomized controlled trials (RCTs) using these alternative products so far have not generated rich scientific data. Marcia Angell and Jerome Kassirer, editors of the New England Journal of Medicine, noted in an editorial [4] in 1998: "There cannot be two kinds of medicine—conventional and alternative. There is only medicine that has been adequately tested and medicine that has not, medicine that works, and medicine that may or may not work."

Rationale: Many prescription medications and over-the-counter sleep aids are widely advertised and used for sleep disorders; most have side effects and are intended for short-term use. These treatment options have less side effects such as tolerance (lowering of effectiveness following chronic use), rebound of sleep disturbance (sleep problems that develop after stopping a sleep aid), decrease in slow-wave, and REM sleep. Sometimes they treat multiple diseases.

Problems

Persons using alternative therapies should always tell their doctors what, how much, and how often they are taking them. Some of them, especially herbal preparations interact with prescription medications.

Also, potency of the preparation may vary from brand to brand and from batch to batch within the same brand. Hence, clinical effect may vary from patient to patient, or may fluctuate in the same patient over time.

There are limited studies in the literature for evidence based CAM in sleep disorders regarding efficacy of alternative treatments. Since there are no randomized controlled trials, dose regulation and side effect data are lacking. In fact, some side effects may be unknown. Such preparations are best avoided during pregnancy and lactation.

Since the preparations are outside the regulation of oversight organizations such as the US Food and Drug Administration (FDA), the ingredients and production process may introduce contaminants or toxic substances into the preparations that have not been inspected or tested.

Placebo and Nocebo Effects

Placebo effect, also called the **placebo** response is a remarkable phenomenon in which a **placebo**—a fake treatment, an inactive substance such as sugar, distilled water, or saline solution—can sometimes improve a patient's condition simply because the person has the expectation that it will be helpful.

Nocebo effect: Negative suggestion can induce symptoms of illness [5]. Nocebo effects are the adverse events that occur during sham treatment or the result of negative expectations. While the positive counterpart—the placebo effect—has been intensively studied in recent years, the scientific literature contains few studies on nocebo phenomena.

Description and classification of CAM therapies: CAM therapies are broadly classified into the following five categories [6]:

1. Biologically based therapies (e.g., herbal medicines);
2. Manipulative and body-based methods (e.g., chiropractic, massage and acupuncture);
3. Alternative medical systems (e.g., Chinese Traditional Medicine [TCM] and ayurvedic medicine);
4. Mind–body interventions (e.g., meditation, hypnosis, and prayer);
5. Energy therapies (e.g., Reiki).

1. **Biologically based therapies**: These use substances found in nature.

Herbal Preparations are popularly used for insomnia.

Aromatherapy is the use of fragrant plant extracts and essential oils in massage or baths. The use of essential oils of bergamot, lavender, basil, chamomile, neroli, marjoram, or rose helps reduce stress. Preliminary research showed some sleep inducing effects, but more studies are needed. The herb Chamomile is commonly used as bedtime tea, but scientific evidence of its effectiveness is lacking. Likewise, the herb Kava has been used for insomnia. FDA has issued a warning that kava supplements have been linked to a risk of severe liver damage. Valerian is the most popular herbal supplement used for sleep problems in USA. It has also been used for nervousness, trembling, headaches, heart palpitations, gastrointestinal spasms and distress, epileptic seizures, and attention-deficit hyperactive disorder [7, 9]. Like any other herbal product scientific evidence is not sufficient to support its use. Studies by Taavoni et al. [7] in menopausal women showed that Valerian/lemon balm may assist in reducing symptoms of sleep disorder during the menopause (Table 56.1). German government has approved certain herbs (valerian, hops, and lemon balm) for the relief of sleep problems. A recent meta-analysis reviewing the efficacy and safety of Chinese herbal medicine (CHM) for subjects with insomnia showed that CHM alone was more effective than placebo by reducing Pittsburg Sleep Quality Index scores. However, there was no significant difference between CHM and placebo as far as the frequency of adverse events [8].

Other herbal remedies that are helpful in relieving insomnia include [23]:

- catnip (*Nepeta cataria*): poor sleep
- chrysanthemum (*Chrysanthemum morifolium*): insomnia
- hops (*Humulus lupulus*): overactive mind
- lime blossom (*Tilia cordata*): anxiety
- linden (*Tilia* species): anxiety
- oats (*Avena sativa*): poor sleep and nervous exhaustion
- passionflower (*Passiflora incarnata*): anxiety and muscle cramps
- skullcap (*Scutellaria lateriflora*): nervous tension
- squawvine (*Mitchella repens*): insomnia
- St. John's wort (*Hypericum perforatum*): depression
- vervain (*Verbena officinalis*): nervous tension, sleep apnea

Dietary supplements such as Vitamins B_6, B_{12}, and D, and Calcium and magnesium may also be helpful.

Melatonin is a naturally occurring hormone associated with sleep. According to a recent randomized controlled study, melatonin supplements may help improve sleep in people with high blood pressure (hypertension) who take beta-blockers [10]. Beta-blockers are prescribed to treat a number of health problems and are the most commonly prescribed class of drugs for hypertension. However, frequent side effects of these drugs are difficulty sleeping and daytime fatigue, which may result from their suppression of

Table 56.1 List of sleep symptoms and biological therapy used

Symptoms	CAM
Nervousness, trembling, headaches, heart palpitations, gastrointestinal spasms and distress, epileptic seizures, and attention-deficit hyperactive disorder, during menopause	Valerian
Nervous tension	Skull cap, valerian
Depression	St. John's wort
Sleep apnea	Vervain
Anxiety	Passion flower, lime blossom, linden, arsenicum
Nervous exhaustion	Oats
Overactive mind	Hops
Muscle cramps	Passion flower
During menopause	Valerian, lemon balm
HTN on beta–blockers	Melatonin
Jet lag	Melatonin
Hysteria	Dragon bones, magnetite
Alcohol or substance-related sleeplessness	Nux Vomica
Emotional upset	*Ignatia*
Mental stress, aches, and pains	Passiflora
Talking and laughing during sleep	Lycopodium
Pain	Acupuncture, acupressure, reflexology, chiropractic, biofeedback
Mental stress	Yoga, tai chi, exercise, biofeedback
Muscle tension	Massage, biofeedback, yoga
Circadian rhythm disorders	Melatonin, light/dark therapy

melatonin; a hormone that promotes sleep. Since beta-blockers are taken typically for life in these patients, melatonin supplements would be highly beneficial [11, 12]. However, larger effects of melatonin are observed in patients whose sleep problems are caused by a circadian rhythm abnormality (disruption of the body's internal "clock") and may be helpful in decreasing sleep disturbance caused by jet lag. Dietary supplements containing melatonin "precursors"—**L-tryptophan** and 5-hydroxytryptophan (**5-HTP**)—are also used as sleep aids. (The amino acid L-tryptophan is converted to 5-HTP, which is converted to serotonin and then melatonin.) However, these supplements have not been proven effective in treating insomnia, and there are concerns that they may be linked to eosinophilia–myalgia syndrome (EMS), a complex and debilitating systemic condition with multiple symptoms including severe muscle pain.

Practitioners of traditional Chinese medicine usually treat insomnia as a symptom of excess yang (positive) energy. Either magnetite or "dragon bones" are recommended for insomnia associated with hysteria or fear.

Dietary factors: It has been proved that intake of some nutrients is associated with sleep problems [13]. Those nutrients include alpha-carotene, selenium, dodecanoic acid, calcium and hexadecanoic acid, salt (OR = 1.19), butanoic acid, carbohydrate, vitamin D, lycopene, hexanoic acid, vitamin C (OR = 0.92), cholesterol, moisture, theobromine, and potassium. Avoiding taking these nutrients in excess may be beneficial. Some naturopaths recommend Vitamins B_6, B_{12}, and D for the relief of insomnia. Calcium and magnesium are natural sedatives, which help to explain the traditional folk recommendation of drinking a glass of warm milk at bedtime. Tryptophan may relieve insomnia; as turkey is high in tryptophan, a turkey sandwich as a bedtime snack may be helpful. Melatonin is widely used to induce sleep although adequate studies of its effectiveness are lacking [14].

2. **Manipulative and Body-Based Methods** based on manipulation and/or movement of one or more parts of the body.

Acupuncture is a traditional Chinese medicine which is shown to have improved the sleep quality. This procedure involves the insertion of very fine needles sometimes in combination with electrical stimulus or with heat produced by burning specific herbs into the skin at specific acupuncture points in order to influence the functioning of the body [15, 16].

Acupressure: Acupressure involves stimulating the same points as in acupuncture, but by using finger pressure rather than inserting needles. Acupressure is used in various disorders and painful conditions. The pressure points on both heels, the base of the head, forehead part in between the eyebrows, and on the inner side of the wrists can be used to relieve sleeplessness. It can be performed by lay people and so it is easily and economically accessible. Acupressure therapy can also be used to improve fatigue, stress, and sexual dysfunction and to enhance the immune system.

Reflexology: Reflexology is a form of touch therapy in which pain is relieved by stimulating certain pressure points on the feet and hands. Reflexologists work from maps of certain pressure points that are located on the hands and feet. These pressure points are believed to connect directly through the nervous system, affecting the body's organs and glands. The reflexologist manipulates the pressure points according to specific techniques of reflexology therapy. By means of this touch therapy, any part of the body that is the source of pain, illness, or potential debility can be strengthened through the application of pressure at the respective foot or hand location. The use of the reflexology points for the diaphragm, pancreas, ovary/testicle, pituitary, parathyroid, thyroid, and adrenal gland helps to relieve insomnia. However there is no clear evidence of its role in insomnia [17].

Chiropractic is also a kind of holistic medicine. Chiropractic is derived from Greek words meaning done by hand. It is grounded in the principle that the body can heal itself when the skeletal system is correctly aligned and the nervous system is functioning properly. To achieve this, the practitioner uses his or her hands or an adjusting tool to perform specific manipulations of the vertebrae. Chiropractic care includes adjustments, massage, and physical therapy that can all be beneficial to aid with sleep problems. Spinal manipulation can reduce stress upon the nervous system, thus allowing relaxation. Further studies are needed to prove its efficacy as minimal evidence is available [18].

Exercise: Physical activity [19] has been shown to have beneficial effects on sleep in the general population. Results of the study by Andrews et al. [19] in patients with chronic pain suggest engagement in high intensity activity and high fluctuations in activity is associated with poorer sleep at night; hence, activity modulation may be a key treatment strategy to address sleep complaints in individuals with chronic pain. Regular exercise [20, 21] deepens sleep in young adults with or without sleep disorders.

Massage. Therapeutic massage can relieve the muscular tension associated with chronic insomnia.

3. **Alternative medical system**: This mode of treatment is used in place of conventional medicine which includes ayurvedic medicine, homeopathy, naturopathy, and traditional Chinese Medicine (TCM). **Ayurvedic medicine** [22] is a practice of holistic medicine from India that is based on bringing humans into harmony with nature. It provides guidance regarding diet and lifestyle, to enhance health and improve disease. Therapies include diet, herbal, visual, and audio therapies, aroma therapy, and meditation. Ayurvedic treatments for insomnia or nightmares include scalp and soles massage with essential oils such as sesame, brahmi, a warm bath, or a nutmeg paste applied to the forehead. Tranquility tea (jatamansi, brahmi, ginkgo, and licorice root), and yoga are also found to be helpful. Sleep apnea is treated by avoiding sleeping on the back, using a humidifier for ambient air, and using nose drops with warm brahmi ghee (clarified butter) [23].

Homeopathy is a system for treating disease based on the administration of minute doses of a drug that in massive amounts produces symptoms in healthy persons similar to those of the disease. Homeopathic remedies are chosen according to the specific causes of insomnia [24–26]). They may include: *Nux vomica* (alcohol or substance-related sleeplessness), *Ignatia* (emotional upset), *Arsenicum* (anxiety), *Passiflora* (mental stress, aches, and pains), and *Lycopodium* (talking and laughing during sleep).

4. **Mind–body interventions**:

Progressive muscle relaxation is a therapy in which the therapist instructs patients to contract and release different muscle groups. Studies suggest that relaxation techniques may help people with insomnia, although, the effects appear to be short lived. Cognitive forms [27] of relaxation such as **Meditation** have slightly better results than somatic forms such as progressive muscle relaxation. Regular meditation practice can counteract emotional stress. Several studies have shown that regular meditation practice either alone or part of yoga practice results in higher blood levels of melatonin. **Yoga** is a mind–body approach that has components of meditation, breathing, and postures. Preliminary studies [28, 29] suggest Yoga can promote relaxation by releasing muscular tension and improve quality of sleep. When these forms of relaxation are combined with other components of cognitive-behavioral therapy (e.g., sleep restriction and stimulus control), lasting improvements in sleep have been observed.

Music therapy uses music prescribed in a skilled manner by a music therapist. Wang et al. [30] found that Music has significant impact in improving sleep quality of patients with acute and chronic sleep disorders. For chronic sleep disorders, music showed a cumulative dose effect and a treatment

duration of more than three weeks is required to assess its effectiveness. There is scientific evidence that music therapy can have sleep benefits for older adults and children [31, 32].

Biofeedback, or applied psycho-physiological feedback, is a patient-guided treatment that teaches an individual to control muscle tension, pain, body temperature, brain waves, and other bodily functions, and processes through relaxation, visualization, and other cognitive control techniques. The name biofeedback refers to the active physiological monitoring of biological signals (such as electromyography activity) that are fed back, or returned, to the patient in real time in order for the patient to develop techniques of manipulating them. This technique can help in improvising quality of sleep by promoting relaxation.

Tai chi is a Chinese exercise system that uses slow, smooth body movements to achieve a state of relaxation of both body and mind, thus strengthening cardiovascular and immune systems [33, 34]. Recent studies have shown that it improves sleep quality in older adults and in patients with heart failure who experience insomnia and impaired breathing during sleep. It is not yet proven as to which component of tai chi meditation, relaxation or physical activity, is responsible for its beneficial effects on sleep.

Visualization may also help to promote relaxation.

5. **Energy Therapies**

Light/dark therapy involves making the bedroom very dark at night and exposing the patient to early morning sunlight (or a light box). It also helps to treat depression. Bright Light Therapy is used to manage circadian rhythm disorders such as delayed sleep phase syndrome (DSPS), a condition which shifts the normal sleeping pattern outside what is considered the social norm. Treatment with true green light can balance the nervous system and may relieve insomnia. Low-energy emission therapy (LEET) is a clinically proven treatment for chronic insomnia [35–37]. LEET treatment involves delivering electromagnetic fields through a mouthpiece.

Neural therapy is a modified form of acupuncture with local anesthetic injections.

Naturopathic medicine is a multimodal therapy including diet, herbs, nutritional supplements, homeopathy, physical medicine, and counseling. It emphasizes prevention, treatment, and optimal health through the use of therapeutic methods and substances that encourage individuals' inherent self-healing process. It has been used for treatment of insomnia in adults as well as children [38].

CAM and Insomnia: Insomnia is a disorder of sleep initiation or maintenance difficulties or unrefreshing sleep. Research on CAM and insomnia has produced promising results for some CAM therapies. However, evidence of effectiveness is still limited for most therapies, and additional research is needed. This section summarizes what is known about some of the CAM approaches that people use for insomnia.

Herbs

Aromatherapy using essential oils from herbs such as lavender or chamomile is a popular sleep aid; preliminary research suggests some sleep-inducing effects, but more studies are needed. The herb **chamomile** is commonly used as a bedtime tea, but scientific evidence of its effectiveness for insomnia is lacking.

The herb **kava** has been used for insomnia, but there is no evidence of its efficacy. The US FDA has issued a warning that kava supplements have been linked to a risk of severe liver damage.

The Herbal supplement **valerian** is one of the most popular CAM therapies for insomnia. Several studies suggest that valerian (for up to 4-to-6 weeks) can improve the quality of sleep and slightly reduce the time it takes to fall asleep. However, not all of the evidence is positive. One systematic review of the research concluded that although valerian is commonly used as a sleep aid, the scientific evidence does not support its efficacy for insomnia [39]. Researchers have concluded that valerian appears to be safe at recommended doses for short-term use. Some "sleep formula" products combine valerian with other herbs such as **hops, lavender, lemon balm,** and **skullcap**. Although many of these other herbs have sedative properties, there is no reliable evidence that they improve insomnia or that combination products are more effective than valerian alone [39, 40].

The findings of a Chinese study in mice suggest that treatment with Wen-Dan Decoction, a formula of traditional Chinese medicine, may improve sleep deprivation-induced negative emotions by regulating orexin-A and leptin expression [41].

Recently, a study in Bangladesh, evaluating sedative and hypnotic effect of the ethanolic extract of whole plants of *Scoparia dulcis* (EESD) in mice, showed significantly decreased induction time to sleep and prolonged the duration of sleeping, induced by thiopental sodium [42].

The seeds of *Ziziphus mauritiana* Lam are popularly used as a sedative and hypnotic drug in China, and Southeast Asia. A study from Thailand correlated the hypnotic effect of these seeds with the contents of total phenolics and total flavonoids in the extract and assessed weight-based doses effective in mice [43].

Si Ni San freeze-dried powder is a traditional Chinese medicine, consisting of four herbs that are bupleurum, white

peony, immature bitter orange, and licorice. A Chinese study in rats showed that it extended the total sleep time and prolonged slow wave sleep (SWS) and REM sleep for both insomniac and normal rats [44].

Melatonin and Related Supplements

Like valerian, melatonin supplements are widely used and researched for insomnia. A 2013 evaluation of the results of 19 studies concluded that melatonin may help people with insomnia fall asleep faster, sleep longer, and sleep better, but the effect of melatonin is small compared to that of other treatments for insomnia. Greater effects are observed in patients with circadian rhythm sleep disorders. Studies of melatonin in children with sleep problems suggest that it may be helpful, both in healthy children and in those with conditions such as autism or attention-deficit hyperactivity disorder. However, both the number of studies and the number of children who participated in the studies are small, and all of the studies tested melatonin only for short periods of time [46].

Melatonin supplements appear to be relatively safe for short-term use, although the use of melatonin was linked to bad moods in elderly people (most of whom had dementia) in one study. The long-term safety of melatonin supplements has not been established.

Dietary supplements containing substances that can be changed into melatonin in the body—L-tryptophan and 5-HTP—have been researched as sleep aids.

Dietary supplements containing melatonin "precursors"—**L-tryptophan** and **5-HTP**—are also used as sleep aids. The amino acid L-tryptophan is converted to 5-HTP, which is converted to serotonin and then to melatonin. Studies of L-tryptophan supplements as an insomnia treatment have had inconsistent results, and the effects of 5-HTP supplements on insomnia have not been established. Also, there are concerns that they may be linked to eosinophilia–myalgia syndrome (EMS), a complex and debilitating systemic condition with multiple symptoms including severe muscle pain.

Other CAM Approaches

Traditional Chinese medicine commonly uses **acupuncture** to treat insomnia. A review of available studies found some evidence of benefits, but many studies had design flaws that make it difficult to draw firm conclusions. According to a Chinese study, differential activation patterns of functional MRI in sleep-deprived brain may explain the restoring effects of acupuncture [45]. A randomized control trial done in China to study efficacy of acupuncture for primary insomnia found that verum acupuncture appeared to be more effective in increasing sleep quality and daytime functioning than sham acupuncture and estazolam [47]. A recent study of acupuncture for residual insomnia associated with major depressive disorders (MDD) showed that the efficacy is similar to that of placebo acupuncture raising doubts about the value of acupuncture in the treatment of residual insomnia in MDD [48]. Of note, in a small trial placebo acupuncture significantly reduced insomnia severity index (ISI) score in 18 respondents out of 86 participants (those with primary insomnia and residual insomnia in MDD) [49]. A Taiwanese study suggests that low level laser stimulation at the palm, might be conducive to falling into sleep in patients with sleep problems [50] based on EEG changes in subjects with closed eyes.

Studies suggest that **relaxation** techniques may help people with insomnia, although the effects appear to be short-lived. Cognitive forms of relaxation (such as **meditation**) have had slightly better results than somatic forms (such as progressive muscle relaxation) [51, 52]. Preliminary studies suggest that **yoga** may also improve sleep quality. In addition, when these forms of relaxation are combined with other components of cognitive-behavioral therapy (e.g., sleep restriction and stimulus control), lasting improvements in sleep have been observed. Again, additional research is needed in these areas.

Chinese health Qigong exercise, characterized by eight simple, slow, and relaxing movements, each of which can enhance the function of certain organs or parts of the body according to Chinese medicine theory [53]. "Baduanjin" Qigong is easy to learn and less physically or cognitively demanding. A study in Hong Kong has found that the number of Qigong lessons attended and the amount of Qigong self-practice were significantly associated with sleep, fatigue, anxiety, and depressive symptom improvement, and may be helpful to treat chronic fatigue syndrome type of illness [53].

CAM and Other Sleep Disorders

Snoring and Obstructive Sleep Apnea: Sleep apnea is a sleep disorder characterized by pauses in breathing or instances of shallow or infrequent breathing during sleep. In obstructive sleep apnea, there is effort to breathe but reduced airflow due to upper airway collapse in sleep. In central sleep apnea, there are pauses in effort to breathe as well as in airflow, and it can occur in the setting of stroke, trauma, and heart failure. In a survey study, approximately 60 % patients with a diagnosis of Obstructive Sleep Apnea/ Hypopnoea Syndrome (***OSAHS***) reported previous or current use, and interest in future use, of CAM; 20 % reported having used CAM specifically for improving sleep. This serves as a reminder for sleep medicine providers to inquire about CAM use and underscores the need to conduct future studies of

CAM in patients with OSAHS [54]. In this study, CAM included biological treatments such as melatonin and other CAM techniques but excluded use of nasal strips and throat sprays.

Alternative therapies may help treat sleep apnea caused by allergies. Homeopathy and nutrition are most likely to have a positive effect. While some manufacturers promote supplements for weight loss, none of these products have been proven to work as well as eating less and exercising more [55].

Nutrition and Supplements [56]

- Diet—It is recommended to avoid mucus-producing foods (such as bananas). Aerobic exercise, as tolerated, along with a healthy diet will help to reduce weight. Diet should include a balanced mix of fruits and vegetables, healthier fats such as olive oil, whole grains, and low fat dairy products.
- Use of Chromium may be beneficial in building lean muscle mass but large doses can cause renal damage.

Homeopathy

This is based on the principle that "like cures like" e.g., an allergy medicine may contain a minute dose (very, very dilute) of allergen which causes mild allergic reaction (e.g., runny nose). Few studies are available regarding its efficacy. It may be helpful as an adjunctive therapy. Providers determine a person's constitutional type including physical, emotional, and intellectual parameters to assess the appropriate therapy. Some of the substances that have been reported to be beneficial include *Arsenicum album*, *Lachesis* (for morning depression), *Opium*, *Sambucus (for feeling of suffocation)*, *Spongia (for chest tightness),* and *Sulfur* (for heat intolerance).

Acupuncture

Some evidence suggests that a type of acupuncture called auriculotherapy acupoint pressure may help treat sleep apnea.

Acupuncture has also been examined in small studies, as a treatment of sleep apnea.

In one study published in 2009 [57], for instance, researchers assigned 30 people with obstructive sleep apnea to treatment with three to five acupuncture sessions per week. After 30 sessions, the patients showed significant improvements in factors such as hypoxia. An earlier study of 26 patients with obstructive sleep apnea found that those assigned to 10 weeks of weekly acupuncture treatment had greater relief of sleep apnea-related respiratory problems (compared to those who received no treatment [58]) possibly, by strengthening of the genioglossus muscle, to reduce airway blockage in sleep, but others have questioned that claim. Acupuncture also appeared to reduce inflammation in the genioglossus.

Efficacy of external and internal nasal dilators, nasal lubricants, oral dietary supplements, and magnetic therapy (magnetic pillows and mattresses) has not been proven [59].

CAM and Parasomnias: **Parasomnias** are a category of sleep disorders that involve abnormal movements, behaviors, emotions, perceptions, dreams, and autonomic nervous system activity, that occur while falling asleep, during sleep, in between sleep stages, or during arousal from sleep. CAM therapies that may be more frequently used for parasomnias include acupuncture, homeopathy, herbs and supplements, aromatherapy, timed awakenings, and hypnosis. There are very few clinical studies utilizing CAM therapies for parasomnias. However, the following observations can be made: Treatment of nocturnal enuresis has the most supportive evidence with clinical studies advocating the use of acupuncture, homeopathy (homotoxicology), and hypnosis. Overall, hypnosis proves to be the most versatile for treatment of parasomnias with clinical studies supporting its use in nocturnal enuresis, sleepwalking, night terrors, and nightmares.

The most often mentioned alternative approach to bedwetting, or enuresis, is chiropractic manipulation of spine. **Chiropractic care** for nocturnal enuresis treats the bladder through manipulation of the lower spine and pelvis. Since the nerve supply to the muscles, which control urinary emptying, are connected to the brain through the spinal cord, it is believed that aligning the spine will correct any slow messaging or incomplete signals between the brain and the bladder. **Hypnosis** is another option for parents seeking non-invasive methods of treatment for bedwetting. The hypnotist works with the subconscious brain to make positive connections with the conscious goal of awakening to visit the toilet in the night. Instead of using negative reinforcements from an alarm system, the child is trained through self-hypnosis and visual imaging to respond to physical symptoms of a filling bladder before an accident. This method emphasizes relaxation, self-control, and independence. The National Kidney Foundation reports that children who can benefit from this treatment usually show improvement within four to six sessions, but they caution that more studies are needed to determine its true effectiveness. There are other methods which are less popular such as acupuncture, touch therapy, acupressure, shiatsu, reflexology, and homeotherapy.

Scheduled awakenings work well for children who have sleep terrors or sleep walking at the same time almost every night. However, this treatment can take 2–4 weeks, and parent must be consistent every night for it to be effective. Scheduled awakenings should occur 15–30 min before the child typically has his/her first event of the night. Child is gently aroused with a light touch or a soft verbal prompt. Once he/she arouses (i.e., opens eyes, changes positions, and/or says that he/she is awake), allow the child to return to sleep [60].

Narcolepsy and CAM: Narcolepsy is a disorder of excessive daytime sleepiness with symptoms of REM-related phenomena, the most specific of which is cataplexy (episodes of sudden loss of muscle tone, focal or generalized, without loss of consciousness) that is usually triggered by emotions such as laughter and excitement.

Web-based sources [61] have described the beneficial role of nutrients such as tryptophan, amino acids, minerals, and vitamins. However, data regarding their efficacy is not available. Avoiding allergy-producing foods, such as dairy and gluten, is also advised.

Circadian rhythm sleep disorders and CAM: Circadian rhythm Sleep disorders are caused by alteration of the circadian time keeping system (internal clock), its entrainment mechanisms (to light dark cycle) or misalignment of the endogenous circadian rhythm and external environment. People with circadian rhythm disorders respond well with behavioral therapy such as chronotherapy, bright light therapy, and melatonin supplements. Chronotherapy consists of gradually shifting the sleep time in accordance with your desired schedule. For example, if you have trouble getting to sleep at your desired bedtime, you would delay your bedtime by a few hours each night until you reach your desired bedtime hour. The reverse would be true if you are falling asleep earlier than your desired bedtime; you would then advance your bedtime by a few hours each night until the desired bedtime is achieved. Once your desired bedtime has been established, you must adhere to this schedule on a regular basis.

Enhancing environmental cues: Keep a dark and quiet room during sleep and a well-lit room upon awakening. Avoid bright light exposure in the evening and enforce regular hours for eating and other activities.

Bright light therapy [62]: Circadian rhythm sleep disorders are characterized by asynchrony in the patient's internal clock or time-keeping system, with the external environment, for example, the patient's wake–sleep pattern may be misaligned from the environmental light–dark cycle. This may result in symptoms of insomnia, fatigue, and psychomotor slowing. Exposure to bright light at the appropriate time of the day stimulates the retinal-hypothalamic pathway and helps to synchronize the person's internal clock and wake–sleep times to the environmental time. This will help to achieve restorative sleep and improve daytime energy and alertness levels. Blue light is most effective and the direction of shift of the patient's internal clock depends on the time during the internal circadian cycle that the light exposure is received. Luminescence of 2500–10,000 lux is required to be effective, and morning exposure helps phase advance sleep onset in Delayed Sleep Phase Syndrome. Evening exposure helps to delay sleep onset in Advanced Sleep Phase syndrome, by suppressing night-time release of melatonin. Light therapy is also used for entrainment in non-24 h sleep wake syndrome in sighted individuals, and for adaptation to shift work and jet lag. However, chronic exposure to bright light may impose oxidative stress on the light receptor cells in the retina.

Melatonin (described above).

Restless Legs Syndrome (RLS) and CAM

RLS is a sleep-related neurological movement disorder with an urge to move the legs with or without uncomfortable sensation at bedtime, or after prolonged inactivity, that is partially relieved by stretching or moving the legs and is worse or exclusively present in the evenings, at least in the early stage of illness. Research indicates that the needle-based traditional Chinese therapy known as acupuncture may help relieve restless leg syndrome. Recently, a Japanese study evaluated the effects of acupuncture in patients with RLS by actigraphic recordings and found that standard acupuncture might improve the abnormal leg activity in RLS patients, and thus is a potentially suitable integrative treatment for long-term use [63].

In a 2007 study, scientists found that receiving massage therapy that targets the lower body could help ward off restless leg syndrome symptoms for several weeks. Managing your stress may help stave off restless leg syndrome symptoms, so make sure to include a stress-reducing practice (such as deep breathing or meditation) in your everyday routine. Since maintaining sufficient levels of calcium and magnesium is thought to keep muscles and nerves functioning properly, taking a daily multivitamin/multimineral may help restless legs syndrome symptoms (there is, however, no scientific study to support this). In many cases, low levels of iron can result in restless leg syndrome. However, since too much iron can be toxic to the body, iron supplements should not be used without first consulting with the physician. Certain foods such as beans, dark green leafy vegetables, nuts, and seeds are rich in iron. Applying a warm or cold compress to the affected area, or alternating hot and cold therapy, may soothe restless legs syndrome symptoms. Exercise (in moderation and not heavy) may benefit restless leg syndrome as well.

Table 56.2 Differences between conventional and alternative medicine

Criterion	Conventional medicine	Alternative medicine
Definition of health	Normal function (a specific disease or dysfunction is not present)	Intactness of the mind, body and spirit and optimal balance in between them
Definition of illness	Disease based: Dysfunction of organs or metabolic processes	Symptom and individual based: Imbalance between mind, body and spirit
Concept of life force	Life processes involve physical and metabolic events	A nonphysical life force integrates mind and body, and interconnects all living beings, and is the essence of health
Understanding of consciousness	Results only from physical processes in the brain	Not limited to the brain only; it can exert healing effects on the body
Method of treatment	External interventions (e.g., drugs, surgical procedures, radiation therapy etc.)	Support and strengthen the patient's intrinsic capability for self-healing

Calf muscle vibration pad [64] provides 30 min of vibratory counter stimulation, gradually ramping down and shutting off without waking the patient. Results from two randomized controlled trials indicated that the device was superior to placebo pads for improving sleep quality in patients with primary RLS.

Bega and Malkani [65] recently reviewed the role of various alternative therapies in RLS and concluded that high-quality randomized controlled trials are warranted to support and verify the data presented.

Interaction of CAM therapies with conventional/Allopathic medicine and differences are listed in Table 56.2 [66].

Safety of CAM treatment relies on history of use for millennia without seemingly causing harm. Evidence for safety of most of the treatments is not based on rigorously controlled scientific trials or studies. Therefore, it is important to keep in mind some safety considerations such as:

- Avoid use of an alternative approach to treat a medical emergency or life-threatening disorder for which effective conventional treatments exist (e.g., pneumonia, hypertensive urgency, thyroid storm)
- There can be toxic effects from certain herbal preparations (e.g., pyrrolizidine and kava can cause liver damage and aristolochia can affect the kidneys)
- Harmful contaminants may be present in herbal preparations (e.g., heavy metal may be present in some Chinese and Ayurvedic preparations; other drugs may be inter-mixed in some Chinese herbs)
- CAM therapies may interact with each other (e.g., herbal preparations and other dietary supplements) and with other drugs (e.g., induction of cytochrome P-450 [CYP3A4] enzymes by St. John's wort, resulting in reduced activity of antiretroviral medications. Elmer et al have reported risk of bleeding due to use of ginkgo, garlic, or ginseng together with aspirin, warfarin, ticlopidine, or pentoxifylline [67])
- There is potential for injury to the body or organs by physical manipulation (e.g., inappropriate spinal manipulation could damage nerves or spinal cord in predisposed patients or cause internal bleeding in patients with bleeding disorders)

Safety alerts about harmful dietary supplements are available at the FDA web site [68]. FDA regulations require that manufacturing processes should assure the quality and safety of supplements.

To help reduce risk of injury or complications due to physical manipulations, patients should look for providers who have credentials from accredited training programs and have a professional license.

Points to Consider for Selecting Complementary Health Approaches for Sleep Problems [69]

- Patient should discuss with their health care providers about the complementary health approach they are considering and ask any questions they may have. It is important that patient discuss their sleep-related symptoms with their health care providers before trying any complementary health product or practice. Because trouble sleeping can be an indication of a more serious condition, and because some prescription and over-the-counter drugs can contribute to sleep problems.
- Patient should exercise caution about using any sleep product—prescription medications, over-the-counter medications, dietary supplements, or homeopathic

remedies. They should find out about potential side effects and any risks from long-term use or various combining products.

- Patients should remember that "natural" does not always mean safe. For example, kava products can cause serious harm to the liver. Also, a manufacturer's use of the term "standardized" (or "verified" or "certified") does not necessarily guarantee product quality or consistency. Natural products can cause health problems if not used correctly. The health care providers that the patient sees about his/her sleep problems can advise him/her.
- If a woman is pregnant, nursing a child, or considering giving a child a dietary supplement or other natural health product, it is especially important for her to consult with her (or her child's) health care provider.
- Also, patients who are considering a practitioner-provided complementary health practice, should check with their insurer to see if the services will be covered and ask a trusted source (such as the health care provider or a nearby hospital or medical school) to recommend a practitioner.
- Patient should inform their health care providers about any complementary health approaches that they use so that the providers have a full picture of what the patient does to manage their health. This will help ensure coordinated and safe care. National Center for Complementary and Integrative Health (***NCCIH***) has a Time to Talk campaign that gives tips about talking with one's health care providers about complementary health approaches.

Kamalesh K. Gulia, Arathi Radhakrishnan, and Velayudhan Mohan Kumar

Introduction

Ayurveda is a reflection of anatomical, physiological, psychological, pathological, and therapeutic views, expressed in the *Vedas* (meaning "*sacred knowledge*" or "*wisdom*"), *Upanishads* (which means the "inner or mystic teaching") and *Smritis* (means "that which is remembered"). The literal meaning of the word *Upanishad* is "sitting in front of" (i.e., sitting at the master's feet and receiving instructions). This refers to the practice of disciples gathering before Vedic seer-sages (*rishis*) for discussions on religious concepts, experiences, and revelations of Hinduism, such as the Universe (world or infinite), Soul (or *Brahman*), and the Universal Self (or *Atman* or *purusha* or pure awareness) [1]. The *Upanishads*, which embody the experiences of the sages, date back well before the age of Buddha, some 2500 years ago [1–3]. Sleep, consciousness, and dreaming have been dealt with in detail in the *Upanishads.* These scriptures mentioned about sleep, both with and without dream, much before the modern scientific world described REM and non-REM sleep [4, 5].

The meaning of the term *Ayurveda* is knowledge of life [6–8]. Though the word *Ayurveda* sounds as if it is related to the *Vedic* period, it originated much later. According to traditional Indian religious belief, Brahma, the creator, also provided the knowledge contained in Ayurveda. Ayurveda in its original form is not available now, but most of its contents are revealed in the *Samhitas* (encyclopedias) written by *Acharyas* Charaka and Sushruta in about 1000 BC [9–11]. Along with these encyclopedias, *Astangasangraha* and *Astangahrdayasamhita,* written much later (may be about 500 or 600 AD) by *Acharya* Vagbhata, are the most important classical writings in Ayurveda. In Ayurvedic literature, the three factors, i.e., *Ahara* (diet), *Nidra* (sleep), and *Brahmacharya* (celibacy), are mentioned as the three *Upastambhas* (supporting sub-pillars) which play an important role in maintaining good health [12]. *Acharya* Charaka called sleep *Bhootadaatri,* meaning supporter of being [13]. *Acharya* Sushruta considered sleep as *Vaishnavimaaya* (i.e., which provides nourishment to the living body and maintains the health) [14]. He has included sleep-related disorders in the list of serious morbidities [15].

Ayurvedic Concept of *Dhatus* (*Doshas*) and Sleep

Ayurvedic medical traditions have a unique understanding of physiology, pathogenesis, pharmacology, and pharmaceuticals which are different from modern Western biomedicine. According to Ayurveda, when *Pancha Mahabhootas* (five basic elements of nature) are impregnated by *Atma* (the life element), the living human being is created. The five basic elements of nature are *Prithvi* (Earth), *Jala* (Water), *Teja* (Fire), *Vayu* (Wind), and *Aakasha* (Ether). From these five basic elements of nature are formed the three *Dhatus* (basic factors), namely *Vata, Pitta,* and *Kapha*. These *Dhatus* decide the status of the health of an individual. All these terminologies cannot be appropriately translated into any other language, as they do not have equivalent terms in modern physics, physiology, and medicine. This unique concept of psychophysiological body types forms the cardinal principle in the Ayurvedic approach to health. So, it is essential to mention about this concept here as Ayurvedic physicians believe that sleep disturbances (like all other health problems) are caused by the deviations in these *Dhatus*. In recent years, some attempts have been made to validate the concept of *Dhatus* [16–19].

Dhatus determine our physical composition or constitution of our body. Thus, they decide the physical and mental peculiarities with which each of us is born. When these basic factors are in equilibrium, or in their natural state, they provide the individual with strength, happiness, and long life. On the other hand, if these *Dhatus* are aggravated or deranged, they bring about health problems. For example, increase in *Kapha* can cause *nidradhikya* (excessive sleep), and *asvapna* (sleeplessness) can result from increase in *Vata*. Children sleep more because they have predominance of *Kapha* [20].

Ayurvedic Concepts About Sleep Types and Factors Modifying It

According to Ayurvedic texts, sleep is a natural urge and suppression of it will lead to several physiological and psychological problems [21]. *Acharya* Charaka has dealt with sleep and sleep disorders in great detail in his *Samhita,* and it gives details about his approach to sleep problems [22]. According to *Charaka Samhita,* "When the mind gets tired, when the senses get dulled and incapable, the man goes to sleep."

Acharya Charaka has stated that happiness and sorrow, growth and wasting of body mass, strength and weakness, virility and impotence, knowledge and ignorance, and existence of life and its cessation depend on the quality of one's *Nidra* (sleep). The *Charaka Samhita* goes on to say that as happiness and longevity are dependent on proper sleep, its deficiency as well as its excess will result in just the opposite. According to him, *Nidra* gives *Pushti* (Anabolic effect) and *Jagarana* (vigil) produces *Karshana* (Catabolic effect) of the body. There is also emphasis on diet regimentation for getting proper sleep.

Sleeping during daytime is advocated only for very young children, weak, tired, and those suffering from various diseases. During summer season (when the night becomes shorter), some sleep during the day can be indulged in by all. Although any comfortable position of the body may be regarded as suitable for sleep, sleeping on one's right side (*daksirasana*) is considered the most favorable position for sleep. According to them, sleeping in sitting posture does not produce any harm. Roughness in the body is caused by keeping awake at night. Obesity and emaciation are specially mentioned as two conditions caused by improper sleep and diet. *Acharya* Charaka has classified sleep into six, laying emphasis on causative factors (see Box 57.1) [23], whereas *Sushruta Samhita* classified sleep into three categories (see Box 57.2) [24] and *Acharya* Vagbhata has classified sleep into seven types (see Box 57.3) [25].

Box 57.1: Classification of Sleep into Six types according to causative factors (Acharya Charaka, c 1000 BC)

- *Tamobhava*—caused by *tama* (mental perplexity).
- *Slesmasamudbhava*—caused by vitiated (phlegm).
- *Manah-sarir srama saambha*—caused by mental exertion.
- *Agantuki*—indicative of bad prognosis leading to imminent death.
- *Vyadhi-anuvartini*—caused as a complication of diseases such as fever.
- *Ratri-swabhava prabhava*—caused by night during light dark cycle.

Box 57.2. Sushruta Samhita Classification of Sleep (c 1000 BC)

- *Tamsi*—when sense organs get filled with *Kapha* and are dominated by *tamoguna* (mental perplexity), *tamsik* sleep is produced.
  - *Swabhaviki*—this is the normal sleep.
  - *Vaikariki*—if there is any disturbance to mind and body, normal sleep does not occur. But the sleep that occurs in such a situation is called *vaikariki nidra* (modified sleep).

Box 57.3. Seven Types of Sleep (*Acharya* Vagbhata, c 500–600 AD)

- *Kalaswabhawaj*—it is the normal sleep that occurs at night.
- *Amayaja*—it is the sleep that is produced due to some disease.
- By fatigue of *mana*—sleep produced by mental fatigue.
- By fatigue of *sharer*—sleep produced by physical fatigue.
- *Shleshmaprabhavaj*—it is produced due to predominance of *Kapha dosha*.
- *Agantuka*—this is the type of sleep resulting from trauma.
- *Tamobhava*—it is produced by predominance of *tamoguna.*

According to *Acharya* Vagbhata, diseases, purgation, emesis, fear, anxiety, anger, smoking, blood-letting, fasting, uncomfortable bed, irregular sleep pattern, and old age are considered as causes of insomnia. According to *Acharya*

Charaka, there are four causes for the disturbance in sleep [26]. They are as follows:

- Differences in *Dhatus* (basic factors) that constitute the body. A person having predominance of *Vata* shows shorter duration of sleep, whereas those with *Kapha* predominance have longer sleep.
- Age-related change in sleep is also explained in terms of changes in *Dhatus.*

Predominance of *Kapha Dosha* produces more sleep in children, whereas *Vata Dosha* brings about diminished sleep during old age.

- Excessive exercise or work and nighttime work cause disturbances in the sleep.
- Disturbances in sleep produced by other diseases are also explained on the basis of deviations in *Dhatus*.

As can be seen from above descriptions, good sleep is that which occurs at night. It is described as that which "nurses all the living beings." The sleep which is caused by *Tamas* is considered as "the root cause of sinful acts." It is interesting to note that insomnia has been classified by *Acharya* Charaka as primary (*Pranashta*) and secondary (*Nimitta*).

Ayurvedic Concept of Dreams and *Dhatus*

Charaka Samhita also deals at length with the theories of dream. Not only *Acharya* Charaka but also *Acharya* Sushruta and *Acharya* Vagbhata did believe that dreams are produced when the vital equilibrium between the three *Dhatus* is disturbed. It may be noted that *Acharya* Charaka had recognized the lack of meaning in most of our dreams. At the same time, he and *Acharya* Vagbhata had mentioned about seven types of dreams that are significant [27–29] (see Box 57.4).

Box 57.4. Types of Dreams (Acharya Vagbhata, c 500–600 AD)

- Objects seen earlier (*Dr'shta*).
- Things which we have heard earlier (*S'r'uta*).
- Past experience (*Anubhoota*).
- Wish fulfillment (*Praar'tita*).
- Imagination (*Kalpita*).
- Premonition (*Bhaavika*).
- Morbid things (*Dhoshaja*).

Acharya Sushruta had devoted one complete chapter on the analysis of dreams. He considered them as omens. According to him, a favorable or unfavorable termination of a disease could be predicted from the dreams. Curiously enough, in many places in the ancient literature it is mentioned that dreams are produced by "*Svapnavha nadi*" (sleep/dream center). According to *Sushruta Samhita*, ten "*nadis*" (nerve centers) control the various functions of the body. Man goes to sleep by using two of them, and with the help of two others, he wakes up [30].

Treatments for Sleep Disorders in Ayurveda

There is a great similarity in the approach to sleep disorders in different *Samhitas.*

In due course of time, several later writers on Ayurveda have also added their wisdom in treating sleep disorders. Treatment of insomnia (*anidra*) is described more extensively than hypersomnia (*nidradhikya*) in Ayurvedic literature. Hypersomnia is considered a disorder due to increased *Kapha.* Apart from many causative factors, decreased *Kapha* can also produce insomnia. As per Ayurveda, disease is nothing but the distortion of natural order of the body. Holistic approach in Ayurveda in the management of sleep disorders involves avoidance of causative factors. So a relaxation technique, along with other therapies, is the mainstay in the treatment for insomnia. Ensuring happiness and encouraging activities which please the mind are considered part of the management of sleeplessness.

Ayurveda stresses on the importance of purification of the body (*panchakarma*) for treatment of many disorders, including sleep disorders. Many of these purification procedures are aimed at giving physical and mental relaxation to the patient. Mental relaxation is given a lot of importance in the management of sleep disorders, especially insomnia. Some of the Ayurvedic treatments for both *anidra* (insomnia) and *nidradhikya* (hypersomnia) are aimed at purification of the body. Thus, the approach to both these diseases may be identical at times. Some treatments would require purification of the body before other corrective measures are taken. In addition, treatment for the same disorder in two different individuals may also differ, depending on the *Dhatus* that are predominant in him or her. The efficiency of the treatment will also depend on the ability of the physician to recognize the *Dhatus* predominant in the patient. Clinical assessment of the patient is done on the basis of a prolonged interview with the patient (or patient's relatives) and some physical examination of the patient.

During clinical examination, the parameters used by the Ayurvedic physician for evaluation of sleep disorder may differ from those employed in modern medicine. Parameters used by them include assessment of drowsiness and yawning, which have obvious bearing on sleep, but it also includes parameters which may not be so obviously related to sleep such as malaise, fatigue, inertness, headache, lack of

concentration, loss of memory, poor sensory perception, indigestion, constipation, weight gain or loss, and even skin luster [31]. Recently, some research studies have been undertaken to evaluate the efficacy of various Ayurvedic treatments in many Indian universities, devoted to indigenous system of medicine. Many of these studies were part of the thesis work of postgraduates. Unfortunately, in none of them was sleep assessed on the basis of polysomnographic studies. They have employed their own clinical assessment based on Ayurvedic principles, in addition to sleep diaries maintained by the patient, for assessment of sleep. Because of these deficiencies, the results of many of these studies have not been published in standard medical journals. Ayurvedic physicians believe that polysomnographic assessment is not of much significance, if it cannot reflect correctly the patient's own feeling about his sleep. Without disputing their concern about the patient's satisfaction in any treatment, we have to accept that if Ayurvedic medical therapies are to be considered as viable stand-alone or adjuvant treatments for sleep disorders, future researchers will have to use acceptable methodology, including appropriate sample sizes, adequate controls, and appropriate statistical analysis, in addition to any other technique that they may use to assess sleep [32].

In most traditional medical interventions, complex treatment methods such as individualized diagnosis, herbal medications, and other procedures are employed [33].

There is an emphasis on maximizing the body's innate ability to heal itself and a "whole systems" approach, wherein the physical, mental, and spiritual attributes of a patient are emphasized, rather than a focus on the disease as in conventional modern medicine. Many of the studies undertaken in Indian universities on sleep disorders have also employed combination of procedures such as herbal medicine, diet regulation, and lifestyle regimens. This also makes it difficult to attribute the effect of treatment to any one of the procedures. The very nature of traditional medicine itself poses several problems in designing a research study that is acceptable in standard journals [34]. Choosing traditional medicine as a therapy could itself be considered as a criterion for exclusion. Selecting a suitable placebo, and alternate intervention, and masking and blinding are also very difficult. Selecting a sham treatment, which is identical to the Ayurvedic procedure, is also not easy.

Different approaches to sleep disorders in Ayurvedic medicine include prayer, yoga, physical procedures, sleep hygiene (including psychological manipulation), drug administration, and diet regulations. Apart from the herbal formulations mentioned in classical literatures, there are also formulations in the market such as *Insomrid* and *Tagara Kwatha* for insomnia, which are not part of classical herbal formulations.

Physical Procedures

Exercise

Exercise as a treatment is suggested for both insomnia and hypersomnia. The type of exercise that is suggested depends on the constitution and age of the patient. Though walking and exercise in the sun are suggested, patients are always instructed to avoid too much exposure to sun. Modern physicians do advise exercises such as jogging, bicycling, and aerobics. The effect of exercise on sleep is something that has been studied extensively using modern scientific techniques, including polysomnography [35–38]. Though these investigations were not done to validate Ayurvedic approach to sleep problems, the inferences drawn from these studies do support the traditional beliefs.

Letting Oil Drip on Head

This procedure called *Shirodhara* is a form of Ayurvedic therapy that involves pouring liquids gently over the forehead. This is one of the most commonly used procedures for sleep disorders. This is also a procedure employed for cleansing of the body (*panchakarma*) according to Ayurvedic concepts. Though this procedure is primarily used for insomnia, it is also recommended for hypersomnia. The name *Shirodhara* comes from the Sanskrit words *shiro* (head) and *dhara* (flow). The liquids used in *Shirodhara* depend on what is being treated, but can include oil, milk, buttermilk, coconut water, or even plain water. It is very commonly used in modern spas for relaxation. A clinical study conducted for evaluation of *Shirodhara* with milk has claimed significant improvement in insomnia [39]. Sleep diary and clinical assessment based on Ayurvedic principles were the methods used for evaluation of the treatment. It is claimed that *Apamargadi Vati,* a decoction containing *Apamarga* (*Achyranthes aspera*), *Kokilaksha* (*Asteracantha Longifolia*), *Kakajangha* (*Peristrophe Paniculata*), and *Bakuchi* (*Psoralea coryifolia*), given in *Shirodhara* provided 89.5 % improvement in sleep quality and 95.3 % relief in mood [40]. A more recent study of *Shirodhara* with *Brahmi* (*Bacopa monnieri*) oil, which evaluated insomnia using patient's self-report questionnaire, also claimed beneficial effect [31].

Making Medicated Oil Stand Over the Scalp for a Prescribed Period of Time

This procedure (*Shirobasti*), which is also meant to purify the body (*Panchakarma*), is another widely used treatment for sleep disorders. During the procedure, warm oil is retained at a level of one inch above the head for around 30 min. It is preferably applied on a clean shaved head. A leather belt is tied around the head, and the sides are sealed with black gram paste to retain oil. This is followed

by gentle massage over back, shoulder, neck, head, and mandible. *Shirobasti* is normally given for seven days and can be repeated if required. Studies in two postgraduate theses on clinical evaluation of *Shirobasti* on patients of insomnia were conducted at two Ayurvedic medical colleges at Rajiv Gandhi University of Health Sciences, Bangalore, India. These studies, which were carried out using sleep diary and clinical assessment based on Ayurvedic principles, have also claimed improvement in insomnia [41].

Application of Medicinal Paste on the Head

Shiro lepa (application of paste on the head) is another form of therapy in which pastes of various medicinal powders and herbs are applied on the scalp. After that, the scalp is covered and tied with certain leaves. This procedure is supposed to allow the herbs to act on the scalp and nourish the head. The most common paste that is used in *Shiro lepa* therapy is *Amalika* (*Emblica officinalis*) and buttermilk. This technique is supposed to help in the treatment of insomnia by reducing tension.

Herbal Face Pack

Application of paste on face (*Mukhalepam*) is an Ayurvedic treatment, which is more or less like the modern facial treatment. The herbs to be used for making the paste are carefully chosen after studying the skin type of the person. This is very important because if the ingredients are not accurate, there will not be any desired effect from the *Mukhalepam* therapy.

Anointing, Massage, and Bath

In simple anointing (*Utsadana*), the medicine mixed with oil or water in a paste form is applied over the body with gentle friction by an expert hand before bath. Application of *til* oil (gingelly oil) and sour fermented drink called *kanjika* on the head, legs, and heels is supposed to produce sleep. *Kanjika* (Indian functional food, also abbreviated as *Kanji*) is a dish in which lactic fermentation is the terminal step in food processing. It is considered suitable even for vegans as it is prepared from raw material of plant origin and devoid of dairy product. Application of paste prepared from *nilotpala* (*Nymphaea stellata*) and seeds of *Sigru* (*Moringa oleifera*) and *Naga kesara* (*Mesua ferrea*) prevents excessive sleep [6].

There is enough evidence to show that sleep can be induced in adults and children by body massage [42–44]. Various types of massages are employed in treatment of sleep disorders in *Ayurveda*. In *Abhyanga* massage, medicated oil is applied all over the body with pressure. The efficiency of the treatment depends on the expertise of the person giving the massage. The type of oil and the ingredients added to the oil depend on the *dosha* of the individual [45, 46].

Whole-body massage using light pressure (*Samvahana*) promotes circulation and helps the patient to relax. The word *Samvahana* denotes the massage technique which predominantly involves long sweeping and soft stroking motions to activate the so-called energy channels (*Nadis*) of the body. The gentle massage using warm organic herbal oils is performed by one or two therapists working in unison. It is claimed to have a soothing and balancing effect and is performed on patients of insomnia caused by excess *Pitta* and *Vata*.

Massage of the feet (*Padabhyanga*) is considered very important in Ayurveda as stimulation of the nerves terminating in the feet helps in restoring health. The vital point (*marma*) in the feet when massaged balances the *Dosha,* and it is very helpful for people with insomnia.

Bath (*Snana*) has been suggested as a practice for inducing sleep. *Snana* is given to the patient at the end of anointing procedures and body massage. Daily bath is an essential part of Ayurvedic medical advice for healthy living. Usually a bath is taken after the application of prescribed medicated oil on the head and body. Warm water, boiled with herbs, is preferred for bath. However, the water should be cooled to a comfortable level before the bath. Green gram powder and herbal shampoos are part of a complete herbal bath. Herbal bath is believed to soothe the body and soul to regain the lost grace and harmony of a person's bio-balance, and to produce deep sleep. The valerian root is one of the commonest herbs added to the bath water to promote sleep [47]. Exposing the body to steam from the boiling herbal water was also in practice. Modern Ayurvedic therapists use steam bath tents to expose the body to steam from the boiling herbal water. The advocated time for bath is morning or just before the sunset. Having a bath at noon is not considered ideal. Bathing immediately after taking food is not advised.

Tying Herbs on the Head (Hair Lock)

It is claimed in classical literature that when roots of *Apamarga, Kokilaksha, Kakajangha,* and *Bakuchi* are tied onto the lock of hair on the head, it could induce sleep. Putting flowers and fragrant leaves on the hair has been a practice by women in ancient India. In olden days, even men used to have long hair or keep a tuft of hair on top of the shaven head.

Harita Samhita mentions about a mixture of *Kantakaridwaya* (*Solanum xanthocarpum*), *Vasa* (*Adhatoda vasica*), *Kakamachi* (*Solanum nigrum Linn*), *Punarnava* (*Boerhavia diffusa*), and *Vartakimoola* (*Solanum melongena*) which can be used in the above-mentioned manner.

Kaka jangha (*Peristrophe bicalyculata*) is a flowering plant in the family of *Acanthaceae*, native to warm temperate-to-tropical regions of Asia. Root of *kaka jangha* tied onto the head is believed to produce sleep.

Herbal Medication

There are descriptions of about 700 medicinal plants, 64 preparations from mineral sources, and 57 preparations based on animal sources in classical Ayurvedic literature [48]. Indian Council for Medical Research has published several volumes on Indian Medicinal Plants [49]. Central Council for Research in Ayurveda and *Siddha* (*CCRAS*), Govt. of India, has a database on medicinal plants used in Ayurveda [50, 51]. Though medicinal plants are found throughout India, the natural habitat of many of the herbs mentioned in Ayurveda is in the Himalayan range. The Himalayan kingdom of Nepal is home to about 700 species of medicinal plants, about 250 of which are endemic to the country. Medicinal plants are one of the important export items from this country. Indian Western Ghats with its species diversity is a treasure house for about 700 medicinal plants. It is also believed that the potency of many of the herbs depends on their source of collection [52–56]. Not only the place from where it is collected but also the way it is collected and stored is considered important for their potency in treatment [52–56]. Many experts believe that the active principles extracted from these herbs cannot be as effective as the herbal plant itself [52–56]. Botanic Gardens Conservation International believes that many of the medicinal plants are at risk from over-collection and deforestation [57]. Coupled with this, their short life span makes their availability difficult. Unfortunately, only a few researches were conducted on the herbs mentioned in *Ayurveda*. Therefore, before they disappear from their source of supply, there is an urgent need for initiating proper studies of their phytochemical and pharmacological properties.

A list of herbs that have been reported to have sedative activity and those that have alerting property is given in Box 57.5 [58].

Box 57.5. List of herbs showing sedative and CNS stimulant properties

Sedative herbs		Stimulant herbs
Acorus calamus Linn	*Erythrina indica* Lam	*Aconitum ferox* Wall[b]
Actaea racemosa (Linn) Nutt	*Euphorbia hirta* Linn	*Alstonia venenata*
Alangium begoniaefolium (Roxb)	*Ferula sumbul*	*Anamirta cocculus* (Linn)
Alstonia scholaris (Linn)	*Fumaria officinalis* Linn	*Bassia longifolia* Koen
Anacardium occidentale Linn	*Garcinia mangostana* Linn	*Camellia sinensis* (Linn)
Anemone obtusiloba	*Humulus lupulus* Linn	*Cinnamomum zeylanicum*[c]
Anthemis nobilis Linn	*Hyoscyamus niger* Linn	*Coffea arabica* Linn
Apium graveolens	*Jasminum officinale* Linn	*Cyperus scariosus*
Areca catechu Linn	*Lactuca virosa* Linn	*Eryngium caeruleum* Bieb
Artemisia capillaris	*Lavandula angustifolia* Mill	*Heracleum candicans* Wall
Avena sativa Linn	*Leonurus cardiaca* Linn	*Ilex paraguariensis*
Atropa acuminata Royle ex Lindl	*Leucas lavandulaefolia* Rees	*Panax pseudoginseng* Wall[a]
Azadirachta indica	*Marsilea minuta* Linn	*Piper longum* Linn[d]
Bacopa monnieri (Linn) Wettst	*Melia azedarach* Linn	*Rivea corymbosa*
Berberis vulgaris Linn	*Melilotus officinalis* Linn	*Rosmarinus officinalis* Linn
Blumea balsamifera DC	*Melissa officinalis* Linn	*Selenicereus grandiflorus*
Boswellia serrata Roxb	*Myristica fragrans* Houtt	*Strychnos ignatii* Bergius
Butea superba Roxb	*Nardostachys jatamansi* DC	*Strychnos nux-vomica* Linn
Calendula officinalis Linn	*Nelumbo nucifera* Gaertn	*Taraxacum officinale*
Calophyllum inophyllum Linn	*Nepeta hindostana* (Roth)	*Theobroma cacao* Linn
Cannabis sativa Linn	*Nyctanthes arbor-tristis* Linn	
Canscora decussata Schult	*Origanum majorana* Linn	
Capparis zeylanica Linn	*Panax pseudoginseng* Wall[a]	
Cardiospermum halicacabum Linn	*Papaver somniferum* Linn	

(continued)

Sedative herbs		Stimulant herbs
Carthamus tinctorius Linn	*Passiflora incarnata* Linn	
Cassia fistula Linn	*Perilla frutescens* (Linn)	
Catharanthus roseus (Linn)	*Phaseolus trilobus*	
Cedrus deodara (Roxb)	*Piper longum* Linn	
Celastrus paniculatus Willd	*Piper nigrum* Linn	
Centella asiatica (Linn)	*Pongamia pinnata* (Linn)	
Cichorium intybus Linn	*Prunus amygdalus*	
Cinnamomum camphora (Linn)	*Rauvolfia serpentine*	
Cissus quadrangula Linn	*Scutellaria galericulata* Linn	
Citrus maxima (Burm)	*Selinum vaginatum*	
Clerodendrum phlomidis Linn	*Sida rhombifolia* Linn	
Clitoria ternatea Linn	*Sonchus arvensis* Linn	
Cochlospermum gossypium	*Stephania glabra* Miers	
Convolvulus pluricaulis Choisy	*Strobilanthes callosus* Nees	
Cymbopogon citratus (DC) Stapf	*Valeriana officinalis* Linn	
Cyperus rotundus Linn	*Waltheria indica* Linn	
Datura stramonium Linn	*Withania somnifera* (Linn)	
Delphinium denudatum Wall	*Xylosma longifolium* Clos	
Eclipta alba (Linn) Hassk	*Ziziphus jujuba* Mill	
Elaeocarpus ganitrus Roxb		

Latin names of the herbs are given in the alphabetical order in the table
[a]Ginsenosides Rb and Rc are "diols," while Rg is a "triol" ("triol" group is arousing; "diol" is sedative)
[b]Roots possess depressant activity, but after mitigation in cow's milk for 2–3 days, they exhibit stimulant activity
[c]At high doses
[d]Piperine is a CNS stimulant

Though Box 57.5 gives a long list, some of the herbs that are commonly suggested for treatment of insomnia by Ayurvedic physicians in India are *Bijapoora* (*Citrus medica Linn*), *Kakajangha* (*Peristrophe Paniculata*), *Apamarga* (*Achyranthes aspera*), *Kokilaksha* (*Asteracantha Longifolia*), *Kantakaridwaya* (*Solanum xanthocarpum*), *Vasa* (*Adhatoda vasica*), *Kakamachi* (*Solanum nigrum linn*), *Punarnava* (*Boerhavia diffusa*), and *Vrntaka* (*Solanum melongeva*).

Jeevaneeya Mahakashaya is a group of drugs that is given great importance in the original classics of Ayurveda. *Jeevaneeya Mahakashaya* means a group of substances that are extremely beneficial for life. The ten herbal drugs mentioned in *Jeevaneeya Mahakashaya* are *Jeevaka, Rhshabhaka, Meda Madhura, Mahameda, Kakoli, Ksheerakakoli, Mudgaparni, Mashaparni, Jeevanti*, and *Madhuka*. The drugs of this *Mahakashaya* have not been evaluated scientifically till date, though they are believed to be beneficial to sleep [59]. Decoction of *Jeevaneeya* group of drugs is administered with milk and ghee (melted butter), as per tradition. Herbs such as *Acorus calamus* (*Vacha*), *Papaver somniferum* (*Ahiphena*), and *Rauwolfia serpentina* (*Sarpagandha*) are used infrequently as it is believed that they have other effects. Ayurvedic drugs are given either orally or applied onto the skin. External application is given as much importance as oral medication. External application can vary from anointing to using it with body massage and bath. External application can be on the head or throughout the body. Application of herbal drugs on the head is one of the preferred treatments in sleep medicine. *Valerian* (*Tagara*), *Piper longum* (*Pippalimoola*), *Citrus medica linn* (*Bijapooraka*), *Withania somnifera* (*Ashwagandha*), *Acorus calamus* (*Vacha*), and *Acorus gramineus* (*Bhutanashini*) are some of the herbs where some kind of scientific evaluation for their use in sleep medicine is ongoing.

Valerian (*Tagara*)

The herb *Tagara* (known as Indian *Valerian* or *Valeriana wallichi*) is a perennial herb, found in plenty all over India, Pakistan, and Afghanistan. It is considered an important medicinal herb and is mentioned in all scriptures of Ayurveda. *Valerian* is one Asian herb which has been studied rather extensively using randomized placebo-controlled trials, mostly outside India [60]. There is a mild subjective improvement in sleep, especially when used for two weeks or more, though objective testing had shown less consistent results. One study has reported an increase in slow-wave sleep after consumption of this herb [61].

Root of *Piper longum* (*Pippalimoola*)

Root of *Pippalimoola* is usually administered with jaggery (*Guda Pippalimoola*). According to traditional belief, the powder of *Pippalimoola* boiled with *Guda* can be used as linctus to cure even chronic sleeplessness. Beneficial effects of this preparation on patients of insomnia are mentioned in a thesis submitted to a health university in Mysore (India) in 2010. The study showed that the administration of *Guda Pippalimoola* along with practice of yoga and diet regimentation gave the most beneficial effect. Though administration of *Guda Pippalimoola* with yoga was also beneficial to some extent, diet regimen alone did not show any positive effect. Sleep was not assessed on the basis of polysomnography in this study [62].

Citrus medica Linn (*Bijapooraka*)

Bijapooraka is an important plant of mentioned in *Materia Medica of Ayurveda*. Though its various parts are widely used to treat many ailments in traditional system of medicine, the powder of *Bijapooraka* leaves is used with honey to treat insomnia [63]. The leaf of *Bijapooraka* contains lysigenous cavities with the presence of oil globules, calcium oxalate crystals, paracytic stomata, and incomplete ring of sclerenchyma [64].

Withania somnifera (*Ashwagandha*)

Ashwagandha is a shrub cultivated in India and North America whose roots have been used for thousands of years by Ayurvedic practitioners as a folk remedy. *Ashwagandha* is consumed in various forms. In traditional medicine, its powder is mixed with sugar and ghee for consumption. In experimental animals, systemic application of the defined extract from *Ashwagandha* led to slightly enhanced acetylcholine esterase activity in the lateral septum and *globus pallidus*, whereas in the vertical diagonal band acetylcholine esterase activity was reduced [65]. Oral administration of *Ashwagandha* (100 mg/kg) prevented the rise in lipid peroxidation in stress-induced rabbits and mice [66]. In a clinical study, 18 apparently healthy volunteers received *Ashwagandha* capsules (aqueous extract, 8:1) daily in two divided doses with increase in daily dosage every 10 days for 30 days (750 mg/day × 10 days, 1000 mg/day × 10 days, 1250 mg/day × 10 days). Six subjects reported improvement in quality of sleep [67]. The most useful action of *Ashwagandha* is to reduce stress and perhaps indirectly aid in sleep.

Acorus calamus Linn. (Araceae)

Araceae, commonly known as "sweet flag" or "calamus," is a semiaquatic, perennial, aromatic herb with creeping rhizomes. The plant is found in the northern temperate and subtropical regions of Asia, North America, and Europe [68]. *Araceae* rhizome and its constituents, particularly alpha- and beta-asarone, possess a wide range of pharmacological activities such as sedative, CNS depressant, behavior-modifying, anticonvulsant, acetylcholinesterase-inhibitory, memory-enhancing, anti-inflammatory, antioxidant, antispasmodic, cardiovascular, hypolipidemic, immunosuppressive, cytoprotective, antidiarrheal, antimicrobial, anthelmintic, insecticidal, adulticidal, diuretic, genotoxic, and mutagenic activities [58, 68]. Roots and rhizomes of *Araceae* prolong the behaviorally assessed "sleeping time" of mice and rats when used with pentobarbital, hexobarbital, and ethanol [69, 70]. The essential oil and alcoholic and aqueous extracts showed depressant action on normotensive mongrel dogs [71]. The hypnotic potentiating action has been claimed to be mediated through serotonin and catecholamines [72]. Alpha-asarone, one of the active principles of *Araceae*, potentiated the pentobarbital-induced-sleeping time periods by two- to threefold [73]. Assessment of sleep using electrophysiological signal has shown that alpha-asarone could induce sleep and decrease in body temperature in rats [74].

Acorus gramineus (Bhutanashini)

Acorus gramineus is an evergreen perennial herb which is native to Japan and occasionally seen in Sikkim [58]. Rhizome of this herb (0.5–5.0 g/kg) dose-dependently decreased the locomotor activity and increased the pentobarbital-induced "sleeping time" [75].

Polyherbal Preparations

Loknath Ras is an Ayurvedic medicine in tablet or powder form. Active ingredients of it are *Kajjali, Abhrak Bhasma, Tamra Bhasma, Laugh Bhasma*, and *Kapardak Bhasma*. This medicine contains heavy metal ingredients, and hence should only be taken under strict medical supervision. It is traditionally administered along with long pepper, honey, jaggery, *Haritaki* (*Chebulic myrobalan*), cow's urine, cumin seeds, etc. It is administered with *Cannabis* (*Bhang*) powder and honey at night for treating insomnia [76].

A polyherbal preparation of *Nardostachys jatamansi, Rauwolfia serpentina*, and *Tinospora cordifolia* is found to be effective in the treatment of insomnia, as it reduces wakefulness and increases total sleep in patients subjected to polysomnographic analysis [77]. A soup containing *Sali parni* (*Orygza sativa*), *Bala* (*Sida Cordifolia*), *Eranda* (*Ricnus communis*), *Yava* (*Solanum melongeva*), and *Mudga Parni* (*Phaseolus mungo*) is also given to induce sleep [6].

Sleeping Environment and Psychological Factors

Comfortable bed, safe home environment, and sleeping time are given importance in Ayurvedic texts. Patients of insomnia and hypersomnia are advised to avoid daytime

sleep. Pleasant smell, sound, touch, or anything that is pleasurable, and gives a sense of satisfaction, is considered good for proper sleep. Having good fragrance in the bedroom and listening to some agreeable music are some of the suggestions given for inducing sleep. There are studies which support these ideas [78–83]. One is also advised to think about things that are pleasant and desirable when going to bed to get good sleep. Though celibacy is mentioned as one of the three pillars supporting good health, a good bed partner is also recommended for having good sleep.

Diet Regulations

Dietary advice always forms part of any Ayurvedic treatment. Consuming milk, rice with curd, alcohol, and meat soup are some of the most common suggestions given for getting good sleep [6, 8]. Other diets suitable for patients of insomnia are creamy or oily food, milk of buffalo, milk product, wheat, dough preparations, sugar, sugar cane, grape, meat of boar, jaggery, fish, curd, black gram, and soup of pulses. It is believed that these dietary substances will control the causative factor, i.e., aggravated *Vata*. The patient is supposed to get the sleep when *Vata* is controlled.

As excessive sleep is believed to be due to the dominance of *Kapha*, diets that cause *Kapha* depression such as spicy or hot foods and light soups are prescribed for them. *Kapha*-pacifying diets include fruits such as apples and pears. Grains such as barley, buckwheat, millet, and corn are also suggested for them. Honey is the only sweetener recommended for *Kapha*-dominant people. They are advised to minimize oils, fats, wheat, rice, cold food, sweets, nuts, rich desserts, red meat, and most dairy products. The use of so-called heating herbs such as ginger, pepper, and turmeric is encouraged. Drinking ginger tea is considered good.

Yoga and Meditation

Ayurvedic physicians do recommend yogic exercises and meditation to improve the sleep quality. Several research studies have shown that yogic practice and meditation are effective in improving sleep of all age groups. Readers can get more details of these practices on sleep from other references [84–90].

Prayer

Ayurveda does recognize prayer as one form of treatment. The goddess of sleep *Nidra devi* is invoked to grant sleep to the patient suffering from insomnia [6]. The following *mantra* (prayer) should be chanted to get sleep: "*Om shuddhe yu yogini maha nidre svaha*." Along with it, white *tila* (sacred powder) is put on the body of the patient. Patient is expected to get sleep through this procedure.

Summary

There is growing public interest in complementary and alternative medicine for the treatment of sleep disorders [91]. Though Ayurvedic literature claims great efficacy and potency for treatment of sleep disorders, there are no comprehensive studies done to validate these claims. Though there are some systematic studies on some alternative systems of medicines such as acupuncture, acupressure, yoga, tai chi, massage, and aromatherapy, there is a definite need to look into the claims of Ayurvedic medicines for the treatment of sleep disorders.

Sleep in Extreme Environment

58

Sudhansu Chokroverty

General Introduction

Following centuries of neglect in understanding sleep and its disorders, twentieth century has witnessed a spectacular growth in the science and practice of sleep medicine. We know a great deal about sleep and its disorders under natural conditions in temperate climates, but sleep scientists have largely neglected what happens to sleep health under extreme environmental conditions. Man is an adventurous and curiosity-seeking animal and thirsty to know the unknown. Hence, there is a natural eagerness to know what is there in the outer space, in the polar regions, at high altitude, in deep down the ocean, and in other extreme environment. It is, therefore, important for sleep scientists to expand their curiosity to understand the impact of extreme environmental conditions on human sleep and how those effects on sleep impact health of the individual [1]. This is the first step, and the next step will be to understand the pathophysiological, preventive, and therapeutic aspects of sleep disorders in these extreme environments.

Sleep in Extreme Environment

Webster's dictionary defines environment as the conditions, circumstances, or objects by which one is surrounded. Environmental conditions could sometimes be extreme, e.g., exotic climates such as in tropical (extreme heat) or polar (extreme cold or high latitudes) regions or other extreme situations such as high altitudes (mountain climbers), deep-sea diving (underwater activity), or space travel (microgravity).

The importance of environment was recognized since the days of Hippocrates [2]

> …… Whoever wishes to pursue properly the science of medicine must proceed thus. First …. Consider what effects each season of the year can produce… the hot winds and the cold… the properties of the water. The soil too, whether bare and dry or wooded and watered, hollow and hot or high and cold.
>
> *Hippocrates, Airs, Waters, Places*

In this chapter, I will briefly describe sleep and its impact on health in certain extreme situations, e.g., space travel, polar regions, mountain climbers, deep-sea divers, and tropical extremely hot climates.

Sleep in Space Travel

There is a lack of adequate data including objective and subjective investigations about sleep in space travel in a large number of subjects with sufficient long-term follow-up of collection of these data [1, 3]. Despite this limitation, sufficient data are available as derived from various space missions, simulated space environmental, and a few experimental studies to succinctly summarize these findings in this section [3]. Travel in outer space takes place in an environment of microgravity. Gravity (G) is defined as a force governing motion (or oscillation) throughout the universe. G-force is responsible for holding us to the ground and keeping the moon in orbit around the Earth. Microgravity is synonymous with weightlessness or very weak force of gravity (not necessarily zero gravity), which is responsible for astronauts floating in the spacecraft. The question is often asked whether microgravity is responsible for sleep loss in the astronauts. We will examine the factors (see further on) responsible for sleep disruption in spaceflight.

Summary of Sleep Dysfuction in Space

Sleep alteration in astronauts during space flight mission (preflight, intra-flight, and post-flight periods) may result directly from sleep dysfunction and other non-sleep comorbidities which may affect sleep indirectly. Sleep [1, 3, 4–6] disruption and fatigue are common complaints among astronauts and cosmonauts [1, 2, 4–16]. Sleep duration during microgravity environment in space flight (intra-flight sleep duration) is usually 1.5 h less than during the control period on Earth. Sleep architecture shows reduced slow wave (SWS) and rapid eye movement (REM) sleep, decreased sleep efficiency (SE), and increased arousals. The preflight sleep is also disturbed because of anxiety and apprehension, and work demand resulting from the preparation of the mission. Sleep dysfunction persists for some time in the post-flight period as a result of cumulative sleep debt. Sleep disruption causes fatigue, impaired concentration, and performance. At least 50 % of the astronauts have used hypnotic medication without necessarily improving the quality and quantity of sleep, suggesting that microgravity environment itself is somehow responsible for sleep disruption.

An unexpected and a notable feature, so far remaining inexplicable, is the observation by Elliott et al. [17] that microgravity improves sleep-disordered breathing events, reduces time spent snoring, and decreases arousals. Their group [18] also noted a reduction in the human ventilatory response to hypoxia but not hypercapnia for sleep disruption. Elliott and co-investigators [17] performed PSG recordings in five healthy astronauts before spaceflight, during a 16- or 9-day space shuttle mission, and shortly after return to Earth. They noted that microgravity was associated with 55 % reduction in apnea–hypopnea index (AHI). These observations highlight the importance of gravity playing a key role in upper airway resistance and obstruction (ventilatory mechanics) as well as chemoreceptor function, and arousals during sleep. One suggestion [19] for reduced sleep duration during spaceflight is consolidated and efficient sleep without much sleep fragmentation due to reduction in upper airway resistance and arousals.

Literature Review

Stampi [5] in 1994 critically reviewed research in the last three decades on sleep and circadian rhythms in space. He also enumerated factors (see further on) responsible for sleep dysfunction in space and countermeasures for optimal performance by the astronauts. Later in 2005, Mallis and DeRoshia [6] succinctly summarized circadian rhythms, sleep, and performance in space citing several factors (see Section "Pathophysiology and Factors Responsible for Sleep Dysfunction in Spaceflight") responsible for such sleep dysfunction. There is no information on sleep and circadian rhythms in most of the early manned spaceflights [5] as these were too short for attempting to sleep (e.g., Yuri Gagarin in Vostok-1 April 1, 1961; American astronaut John Glenn and others in Mercury Project, 1961–1963). The first person to sleep in space was the Soviet Cosmonaut Titov during Vostok-2 mission, August 1961 [6]. The first American astronaut to sleep in space was Gordon Cooper, May 1963 [6]. The first EEG of sleep in space was recorded from astronaut Borman during Gemini-7 mission [20]. The result of first polysomnographic (PSG) study, recorded during 1988–1989 MIR mission, was recorded by Gundel et al. [21] in 2001. Earlier Gundel et al. [10] performed polygraphic and body temperature recordings from one astronaut in space for eight days and during a baseline period preceding the mission. They found that the circadian rhythm of body temperature and alertness were delayed compared with baseline data making a phase shift or transition to a free-running rhythm. Sleep duration was shorter and more disturbed than baseline, and sleep structure showed less REM sleep with redistribution of SWS. The alterations in sleep quality and quantity resulted in post-flight fatigue. Monk et al. [11] reported sleep and circadian rhythms in 1998 in four orbiting astronauts during STS-78 mission. Next year, Monk and co-investigators [22] reported the results of PSG and actigraphic measurements from the same four male orbiting astronauts. They found a good correlation between actigraphic and PSG findings in terms of sleep duration and SE.

Putcha et al. [7] (1999) reported about sleep medication use among the astronauts. The authors reviewed 79 space shuttle missions and noted that 45 % of astronauts consistently used medication for sleep disturbance. Temazepam, zolpidem, triazolam, and flurazepam were the most commonly used sleeping medications [3]. Medications were also used for space motion sickness by 47 % of the astronauts. Their findings confirmed the results of Newberg et al. [23] as well as those of Santy and co-investigatiors [15]. The field-based research data since 2003 from the National Aeronautics and Space Administration (NASA) Task Book continued to document sleep quality and quantity using actigraphy to determine the effects of short-term and long-term space missions on sleep, circadian disruption, and performance decrement. These data should help develop countermeasures to manage sleep disruption and performance in future space missions.

Buguet [1] while reviewing sleep under extreme environment stated that between 1961 and 2007 more than 400 US and a few Russian astronauts have traveled in space. The first sleep recording (sleep state was determined from EEG data) in space was obtained during the 14 day Gemini-7 mission in December 1965 [20]. Sleep was disturbed in the narrow cabin caused by sitting posture, noise, rapid

90–120-min light–dark cycle in the orbital flight (although window covering was used), emotional factor, demand of work, and other factors (see further on). However, in the Apollo II mission [24], sleep was better but crew fatigue was significant due to large circadian shifts, noise, and discomfort from space suits. During the Skylab program in 1973 and 1974 [16], PSG recordings and subjective sleep assessment showed short sleep duration in space with excessive awakenings. During spaceflight, there is circadian dysrhythmia which may cause advancement of body temperature phase, and body temperature was higher in space than on Earth. After identifying contributing factors for sleep disruption, NASA has introduced countermeasures to improve sleep (see further on).

In a recent observational study, Barger et al. [8] obtained data from 64 astronauts participating in 80 space shuttle missions and 21 astronauts on 13 International space stations (ISS) between 2001 and 2011 involving both inflight experiments and ISS expeditions. Sleep was recorded objectively by wrist actigraphy (for two weeks) and subjectively by daily sleep logs. Data were collected three months and 11 days before launch, and for seven days on return to Earth. Sleep deficiency was prevalent in both preflight and intra-flight missions. More than 50 % of the crew members took sleeping medication (commonly zolpidem during inflight missions), but the hypnotic intake (which was pervasive) did not make a significant difference in objectively measured sleep duration. This raises a fundamental question [9] whether spaceflight reduces the need for sleep or whether it reduces the ability to sleep and not sleep need. Basner and Dinges [9] suggested that neurobehavioral performance measurement in space is needed to answer this question.

Zavalko et al. [25] studied the effects of long-term isolation on night sleep during international ground simulation of an interplanetary manned flight—"Mars-500." The PSG recordings of six men before, four times, during, and after 520 days of confinement showed decreased SE and increased sleep latency (SL) during the isolation period, whereas two weeks after the landing simulation nights with low SE significantly decreased.

Wolfe and Rummel [26] as well as Nicogossian et al. [27] reported the adverse effects of microgravity on bodily functions and suggested possible countermeasures. Wolfe and Rummel [26] described fluid shifts with decreased plasma volume causing cardiovascular deconditioning and orthostatic intolerance. Exercise is mentioned as one countermeasure, but may not be feasible on a long mission. In 1992, Nicogossian and co-investigators [27] mentioned that long-duration space mission will become commonplace in not too distant future and prolonged expose to microgravity will result in altered bodily functions. Environmental health, radiation hazards, physical deconditioning, bone loss (due to negative calcium balance), and muscle wasting are some of the concerns in such missions. Biological effects of radiation remain the most serious unknown adverse events which may increase the risk of cancer in the long term.

Jennings et al. [28] mentioned about space motion sickness which may affect up to 73 % of crew members in the first 2–3 days of the flight, and this will have adverse consequences on the astronauts' sleep indirectly. Intramuscular promethazine has been found to be the most effective pharmacologic management for space motion sickness. Such motion sickness may reappear (characterized by nausea, vomiting, and incoordination) on returning to Earth due to readaptation difficulty.

Pathophysiology and Factors Responsible for Sleep Dysfunction in Spaceflight

Box 58.1. Factors Affecting Sleep in Space

- Noise
- Anxiety and stress
- Excitement of space travel
- Fear of life-threatening risk and fear of death
- Work demand
- Slam shifts (irregular sleep–wake schedule)
- Rapid oscillations (90–120 min) of light–dark cycles
- Excessive environmental light
- Circadian rhythm disturbances
- Sleeping conditions and posture (including confinement to sleeping bags and sleeping vertically)
- Small crowded space inside spacecraft
- Uncomfortable temperature inside spacecraft (often too cold but sometimes too warm)
- Motion sickness and medication used for this
- Rostral fluid shift with facial swelling
- Obscuration of vision with increased intraocular pressure
- Low back pain

Several factors are responsible for sleep disruption which is prevalent in space missions [1, 3, 5, 6] (Box 58.1) that may impair performance and attention during spaceflight.

i. **Microgravity** itself can impair sleep quality as a result of the following six subfactors:
   1. There is a rostral fluid shift with diminution of plasma volume causing swelling of the upper body and face (Fig. 58.1) and orthostatic intolerance;

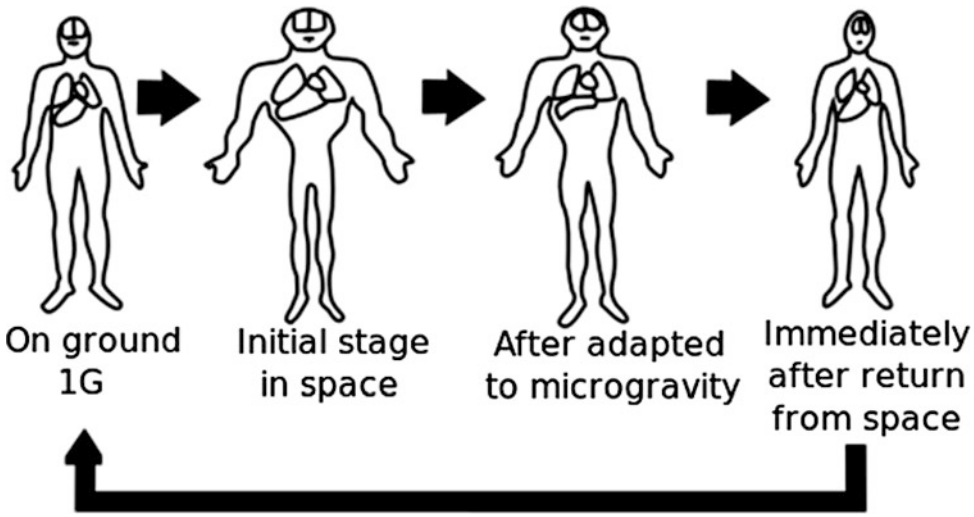

Fig. 58.1 Effects of microgravity on fluid redistribution of upper trunk and face in the first few days in space (From the Internet domain of nasa.gov website)

2. Low back pain due to osteoporosis associated with mineral (calcium) loss;
3. The absence of body pressure associated with "floating" feeling in the spacecraft;
4. Lack of sufficient motor activity reducing sleep quality;
5. Discomfort from the space suits; and
6. Space motion sickness in the first two days of mission (characterized by malaise, drowsiness, and illusion of position and motion) [23, 29] can be a problem compounded by the effects of medication used to treat it (e.g., intramuscular promethazine) causing drowsiness, alteration of alertness, and sleep loss.

ii. **Noise**

The background noise within a spacecraft may reduce sleep quality. This noise may be produced by fans and other life support system, pumps, electrical engines, and frequent communications with ground mission control.

iii. **Psychological Factors**

Excitement of spaceflight, fear of death, or fear of life-threatening failure of the mission, stress and demand for mission work, unfamiliar environment, monotony and feeling of confinement within a closed space, and prolonged isolation causing visual and auditory hallucinations all of which can cause considerable sleep disruption.

iv. **Sleeping Medication**

This is used by about 50 % of astronauts as a short-term solution which may have a negative effect on performance.

v. **Circadian Dysrhthmia**

It has clearly been demonstrated that there are circadian rhythm changes during spaceflight (i.e., mismatch between the body's internal clock and the geophysical environment as a result of rapid oscillations during light–dark cycles). While orbiting the Earth, the astronauts experience 90-minute light–dark cycle (i.e., 16 sunsets per day) disrupting the body's intrinsic circadian rhythm.

vi. **Space Environment**

Excessively low temperature and occasional excessively high cabin temperature as well as excessive environmental light disturb sleep quality. There are other environment factors identified as contributing to sleep loss (e.g., spacecraft vibration, cosmic radiation, increased CO_2 levels).

vii. **Sleeping Condition and Posture**

Confinement to sleeping bags, sleeping vertically and small crowded space inside spacecraft are not conducive to sleep (Fig. 58.2).

viii. **Post-Flight Fatigue**

The cause of this is not known, but most likely results from severely compromised post-flight adaptation to gravity for several days after returning to the Earth after an extended space mission and cumulative sleep loss in space [19].

ix. **Miscellaneous Other Factors**

a. Thinning of the muscle mass from inactivity (not using to overcome gravity).

Fig. 58.2 Sleeping positions of four crew members of the STS-112 on the middeck of the space shuttle Atlantis (From the Internet domain of nasa.gov website)

b. Obscuration of vision and other eyesight problems (e.g., cataract) are noted after long space mission in men. Many astronauts also experience sudden phosphenes or light flashes [30] often noted before sleep with a sense of motion. It was noted in 47 out of 59 respondents in a survey, and some thought that light flashes disturbed their sleep.
c. Cosmic radiation effect. It is not known whether there is a cosmic radiation effect in space mission posing as a risk factor for the development of cancer in the future.
d. Some astronauts are more sensitive to sleep loss in space than on Earth. This susceptibility is dependent on individual characteristics (e.g., circadian chronotype, gender, and genetic susceptibility), which must be considered in pathophysiological mechanism and in designing individual treatment strategy.

Countermeasures and Therapy

Several lines of treatment and countermeasures have been suggested and tried to treat sleep disruption in space and its adverse effects, but further research is needed to optimize sleep and performance in spaceflight missions.

i. **Exercise**

Strenuous exercise as a countermeasure to prevent muscle atrophy and cardiovascular deconditioning was employed on Soviet spaceflights in the past [6, 31]. However, strenuous exercise can have adverse effects on sleep and mood [32]. On the other hand, timely performed exercise has shown to induce phase shifts in the melatonin circadian rhythm [6, 33, 34]: Phase advances were induced by late afternoon or early evening exercise, whereas late evening exercise induced phase delays. Timed exposure to exercise sessions could be used as countermeasures to facilitate adaptation of circadian rhythms in space missions [6, 33, 35].

ii. **An understanding of circadian physiology** is essential to treat circadian dysrhythmia of the astronauts. Effective countermeasures to promote sleep in space include [1, 5, 6, 8, 13, 36–38] modifications of sleep–wake schedule including scheduled naps, strategically timed exposure of bright light of specific wavelength, intensity, color and duration, intermittently or continuously as well as behavioral strategies including sleep hygiene measures. Another suggested strategy [38, 39] is to replace the adult monophasic sleep pattern by polyphasic patterns of childhood (ultrashort sleep schedule) which has shown to decrease total sleep requirement without impairing performance levels.
iii. **A comprehensive management approach** should include education about sleep, sleep–wake schedule, following a common sense sleep hygiene measures as well as scheduling policies and procedures, and employment of specific fatigue countermeasures, and remedies including fatigue training workshops [40, 41].
iv. **Pharmacologic strategy** using melatonin (0.3 mg) [13] and sleeping medications [1, 8] to improve sleep duration and shorten sleep latency has not been very effective.

Intramuscular phenothiazine has been successfully used to treat space motion sickness [6], but may cause drowsiness and impaired performance in space crews.

v. **Other measures to improve sleep** and performance in space mission crews include use of earplugs to minimize noise, window shades in space ships to protect crews from exposure to bright light, use of sleep-restraint bags attached to the wall (Fig. 58.2) in any position (vertical or horizontal) [1, 42], psychological services to the astronauts and their families, and mental monitoring to minimize external stressors.

vi. The other suggestion for improving sleep, fatigue, and performance skill is acquisition of a strong coping mechanism to handle extreme environment—which shows considerable individual variation. This requires the development of high physiological, psychological, and social coping skills [1, 43].

Sleep at High Attitude

Climbing to high altitude (e.g., mountaineers at about 3000 meters above the sea level) exposes human to extreme environmental condition as a result of low barometric pressure associated with hypoxemia (hypobaric hypoxia) causing profound physiological changes in the body [1, 3]. The adverse consequences include periodic breathing and altered sleep–wake rhythms depending on individual susceptibility, speed of ascent, and the actual altitude reached. Those with pre-existing obstructive sleep apnea (OSA) show exacerbation of sleep-related breathing events. Altitude-related illnesses that have major impact on sleep include acute mountain sickness, chronic mountain sickness (Monge's disease), as well as high-altitude pulmonary and cerebral edema [3]. Gradual ascent to altitude promoting acclimatization as a preventive measure and pharmacotherapy for sleep disturbances have been found to be useful in several clinical studies. The readers are referred to Chap. 33 for further details.

Sleep in the Polar Regions

Studies are very limited to make a firm conclusion about sleep and its disorders in the polar regions. Most of these came from Josephine Arendt and her group [44–51] as well as from Buguet and his group [52–54], and Palinkas and co-investigators [55, 56] (these authors mainly dealt with psychological–psychiatric aspects and sleep). A symposium in 1973 gave comprehensive overview of Polar Human Biology published as proceedings [57].

i. It is extremely cold in the polar regions (Arctic 60°N and above; Antarctic 60°S and below), and people are deprived of natural sunlight in winter but have continuous daylight in the summer ("the midnight sun") months (October to March in the Antarctic and April to September in the Arctic). There is no permanent human population at 60°s in Antarctica, which does not belong to any country, and has no government. There is a transient sparse population of scientists and researchers at several scientific bases (about 1000 population in winter and up to 4000 in summer). On the other hand, permanent human population north of 60° N in the Arctic amounts to over four million including indigenous people ("The Inuit"). The arctic region is governed by several nations—USA (Alaska), Russia (Siberia), Canada, Denmark (Greenland), Iceland, Norway, Sweden, and Finland.

ii. There are reports of sleep problems in the polar regions. Because of deprivation of natural sunlight in winter, there is a delay in circadian rhythm in the evening, including melatonin rhythm with delayed sleep onset, decrements in SE, sleep duration, and quality associated with fatigue and tiredness in the morning [44–50]. A few people desynchronize with free-running rhythm showing their intrinsic circadian period longer than 24 h. Timed exposure of light (blue-enriched light appears to be more effective than standard white light) on awakening in the morning combined with exogenous melatonin intake in the evening plus wearing sunglasses in the evening helps restore normal phase and sleep.

iii. Palinkas and co-investigators [55, 56, 58] reported on psychological and psychiatric problems associated with sleep disturbance as a result of long periods of isolation and confinement in the polar regions. A small percentage of people on polar expeditions suffer from mood and sleep disorders [55, 58]. These authors examined sleep (self-reported) and mood measured by profile of mood states (POMS) in 91 American men and women who spent the 1991 Austral (refers to Southern Hemisphere) Winter (March to October) at three different research stations in Antarctica [56]. They made the observation that mood changes were preceded by changes in sleep characteristics.

iv. Sleep in the polar regions was documented objectively by PSG study in the early 1970s in small and limited studies, but more comprehensive PSG evaluations were made later by Buguet et al. [53, 54] and other investigators [59]. PSG recordings [53, 54] in subjects sleeping in unheated tents in sleeping bags showed that SWS was preserved in the first half of the night as in neutral condition.

There were numerous awakenings due to midnight hypothermia (rectal temperature = 34.9 °C). Thermoregulatory shivering and body movements disappeared during REM sleep. REM sleep episodes were shorter in the cold compared with thermoneutral condition resulting in REM sleep deprivation. In a later PSG study of eight individual, Buguet et al. [52] concluded that they could not draw a statistical conclusion as sleep patterns between individuals showed considerable variation.

Bhattacharyya et al. [59] performed PSG study in six members of the Indian expedition team during their winter stay at Maitri, the permanent research station of Indian Antarctica (70°S). PSG findings included reduced sleep duration, SE, and SWS during the winter months. This study showed a prevailing general trend of sleep disturbance among overwintering members in a modern Antarctic station.

v. Joern et al. [60] studied long-term sleep patterns in summer campaigners in South Pole Station (90° south and at 2804-m altitude) by PSG recordings which showed a loss of SWS in all subjects and REM sleep in the oldest subject (50 years old) which was thought to be related to altitude [1]. Long-term sleep patterns were also studied by PSG recordings in four Antartic winterers at South Pole Station (temperature of −78 °C) [61]. In Antarctica, sleep duration was same, but sleep latency was longer than in the USA and SWS decreased, and even disappeared, and REM sleep decreased during the winter. These changes were thought to be due to altitude. Similar findings (decreased SWS and REM sleep) were also noted at the Halley Station (built by the British Antarctic Survey in 1955) in 10 winterers for 38 nights using an Oxford Holter System [62]. SWS and REM sleep increased in summer, and the changes were most likely related to daylight variations.

vi. **An important observation** has been made regarding polar insomnia including midwinter insomnia in the Arctic and the Antarctic continents [44, 46, 63–65]. Midwinter insomnia (delayed sleep onset) has been noted in a large survey in Tromso, a Norwegian City north of the Arctic cycle [64], and the frequency increased with increasing age. This finding of delayed sleep onset along with early morning awakening during winter was confirmed in a recent prospective study [65] using sleep diary and questionnaire in a sample of 162 young adults across three seasons (September, December, and March) in Tromso, Norway at 69°N.

vii. There is no clear evidence for increasing prevalence of seasonal affective depression (SAD), but there is some evidence for subsyndromal SAD (low mood) in polar regions [44, 56, 58, 66].

Arendt [44] suggested that it is important to define the optimal conditions for maintaining circadian phase in the Arctic and Antarctic regions for good quality sleep. The treatment of choice is properly timed light exposure and melatonin treatment. However, uncertainties remain regarding exact duration and spectral composition of light, as well as the dose and timing of melatonin.

Sleep in Hot Tropical Climate

There are some limited data from Buguet and his group on sleep behavior using PSG recording from 34 African students and six French military expatriates living in Niamey (Niger) [dry tropical climate], as well as 11 African subjects in the city of Abidjan, and 17 African volunteers from remote villages 400 km north of Abidjan (hot and humid conditions). The findings under laboratory conditions in hot day tropical climate in Niamey included increased amount of SWS (more in the hot than in the cool season) which was proportional to the environmental heat, increased Stage N1, and nighttime awakenings in both the Caucasian and African groups [67, 68]. In contrast, sleeping under warm humid conditions in Abidjan region did not cause changes noted in the hot and dry climatic condition in Niger [1, 67, 68]. Sleep, however, remained unstable with numerous interruptions, but SWS did not increase in the Abidjan subjects. Buguet's group [69] also made a questionnaire-based sleep behavior study in Africans and Europeans living in the Ivory Coast of Africa during "hot-dry" (n = 53) and "cool-dry" (n = 88) season. There were no major seasonal variations except for an increased number of awakenings during the hot season. Same questionnaire was used in Abidjan on 78 medical students [69]. The Abidjan subjects adopted shorter sleep duration compared with Niamey (Niger) students without any effect on sleep quality. Another questionnaire-based study in Nigerian undergraduates [70] showed no essential difference in night sleep duration from that in Western countries except for more frequent intra-night awakenings and increased duration of afternoon nap in the Nigerian students.

Sleep and Deep-Sea Diving

There are very limited data available for a meaningful conclusion on sleep patterns in professional divers at different depths and breathing compressed air with different concentrations of nitrogen–oxygen (N2-02) and helium–oxygen (He-02) [1, 71–79]. Many of these studies were undertaken under simulated conditions in hyperbaric facilities. PSG recordings revealed alterations of normal sleep patterns (e.g., prolonged SL, decreased sleep durations, SE, and SWS as well as increased awakenings and fatigue) irrespective of the

breathing mixture. There was worsening of sleep changes with increasing depth, and these alterations were also dependent upon the speed of the compression pressure (descent) and decompression (ascent). These sleep changes were thought to be related to a lack of physical activity and confinement to a closed environment. There was no recovery sleep during the post-dive period.

Conclusion

The future of sleep medicine lies in understanding various factors responsible for deterioration of sleep in these extreme environmental situations, acclimatization, and adaptation to those extreme environments, and in findings appropriate countermeasures and optimal treatment for sleep dysfunction [80]. This knowledge is particularly important for space medicine as man's curiosity to know the unknown and to explore the outer space (particularly the Mars mission) is incessant.

Epilogue

This book is primarily directed at sleep clinicians with heavy emphasis on clinical aspects of sleep medicine including diagnosis, differential diagnosis, and laboratory procedures to confirm clinical diagnosis as well as treatment. In order to have a critical depth of such knowledge, sleep clinicians must have sufficient knowledge about basic science aspects without delving into greater depth of molecular, cellular, biological and neurochemical aspects of basic science of sleep. These clinicians also must be acquainted with various technical aspects of sleep recording including instrumentation and statistical principles without going into complex details of electronics and statistics. This is exactly what this edition of the book attempts to do and whether I have achieved these goals will be determined by the readers.

We have come a long way in our quest for knowledge in sleep medicine from the ancient Babylonian, Assyrian, Egyptian, Indian and Chinese civilizations (circa 4000–5000 BC) to Hippocrates (circa 460–370 BC) and contemporary sleep medicine which is still evolving.

Considering the pace of growth of sleep medicine, I would like to conclude this book by summarizing my thoughts in this epilogue on areas where there may be future developments of sleep medicine: (1) Increasing application of telemedicine (telemetric transmission and monitoring of data) [currently in its infancy] in diagnosis, therapy and follow-up because of rapidly improving information and communication technology (ICT); (2) Improvement of technical aspects of home sleep apnea testing (HSAT) including incorporation of home video recording so that its indications will expand to include some or all that are now considered contraindications. This will encourage increasing use of HSAT for patient comfort and convenience and better reimbursement; (3) Study of sleep in extreme environment (see Chap. 58) as these situations will be increasingly encountered; (4) Improved software for computerized scoring of sleep and other physiological characteristics, thus eliminating inconvenience and saving cost of manual scoring; (5) Recording of many physiological characteristics throughout the day and night for days to weeks using improved smart phones (of course it has its dangers of both false positive and false negative data); (6) New understanding of insomnia along with development of better hypnotic medication and improved cognitive behavioral therapy (CBT); (7) Emerging treatment of narcolepsy which will include immunotherapy, hypocretin agonists, gene therapy, and stem cell transplantation; (8) Development of pharmacotherapy and better non-invasive treatment devices for obstructive sleep apnea (OSA) including oral appliances; (9) Finding a specific biomarker(s) in REM behavior disorder (RBD) and neuroprotective therapy to prevent its progression to neurodegenerative diseases; (10) Better treatment of circadian rhythm sleep disorder using bright light therapy of a particular wavelength, intensity, color and duration, and better exogenous melatonin, melatonin receptor agonists or other drugs to entrain the body's rhythms.

The woods are lovely, dark and deep,
But I have promises to keep,
And miles to go before I sleep,
And miles to go before I sleep.

Robert Frost, "Stopping by Woods on a Snowy Evening" (last stanza), 1923
