Preface

A spectacular progress in uncovering the mysteries of sleep took place in the twentieth century which is continuing in the twenty-first century. What once remained shrouded in mystery and in the realm of vivid imagination of writers, scholars, artists, philosophers, poets, and religious leaders is now finding its rightful place beyond the fantasy of dreamers in the real world of neuroscience. We now know a great deal about neurobiology of sleep and dream, but much remains to be solved. Why do we remain awake? What happens if we are sleep deprived? Why do we need sleep? These questions keep popping up without a satisfactory answer. Sleep is an indispensable state of human existence and is noted in all mammalian and non-mammalian including avian and reptilian species. We have learned a lot from the animal kingdom. We know that the newborn dolphins continue to swim immediately after birth along with mother dolphins (to protect the newborn), totally sleep deprived for weeks without any long-term adverse effects on the brain or the body. In contrast, sleep deprivation experiments of Rechtschaffen and co-workers in rats on a carousel ("the disk-over-water" technique) produced emaciated animals despite increased food intake but with eventual death. Later sleep deprivation experiments using different techniques failed to reproduce similar results. Of course, it is not possible to perform complete sleep deprivation experiments on humans. Another mysterious finding is unihemispheric sleep in dolphins, porpoise, and pilot whales. This is thought to represent adaptation to life in water. Do humans have similar asymmetric or unihemispheric sleep? There are indications from polysomnographic recordings of severe obstructive sleep apnea (OSA) patients with hypoxemia using sophisticated computerized coherence analysis that such interhemispheric slow wave sleep asymmetry is also present in human maximally during apneic arousals and REM sleep, probably related to some brain stress or some unknown physiological adaptive mechanism. Another notable feature is the coexistence of sleeping and waking brain regions in arousal parasomnias which is reminiscent of sleeping brain in one half and waking brain in the other half of the cetaceans. Another example of such similarity is simultaneous presence of local sleep and waking regions during normal human sleep.

Sleep has been described in all different ways by poets and writers.

"What is more gentle than a wind in summer?
...What is more tranquil than a musk-rose blowing?
...What, but thee Sleep? Soft closer of our eyes!
...Thee for enlivening all the cheerful eyes
That glance so brightly at the new sun-rise.

—John Keats, *"Sleep and Poetry"*

"Not poppy nor mandragora
Nor all the drowsy syrups of the world,
Shall ever medicine thee to that sweet sleep
Which thou owedst yesterday."

—William Shakespeare, *Othello*
Act iii, Scene 3

"Sleep…
The death of each day's life, sore labour's bath,
Balm of hurt minds, great nature's second course,
Chief nourisher in life's feast."

—William Shakespeare, *Macbeth*
Act ii, Scene 2

Famous novelists of the past centuries have on occasion given colorful descriptions of characters seemingly having symptoms of sleep disorders long before these entities entered into the scientific literature. A case in point is a description of narcolepsy-like symptoms in Edgar Allan Poe's "Premature Burial" (published in 1844, 36 years before Gelineau's introduction of the term narcolepsy in 1880). There are other examples: A description of sleep paralysis in the character "Ishmael" in Herman Melville's "Moby-Dick" published in 1851 (25 years before the use of the term "night palsy" by Weir Mitchell in 1876); a description of RBD-like symptoms in Don Quixote by Miguel Cervantes in "Man of La Mancha" published in 1605 (381 years before the clinical description of RBD in 1986); and William Shakespeare's description of sleep walking of Lady Macbeth around 1606 long before scientific studies to characterize this arousal parasomnia were performed in the twentieth century.

Despite electrifying progress in sleep research, the public and profession alike are still not sufficiently cognizant of the fact that "sleep attack" or sleep deprivation (especially when combined with alcohol) can be as lethal as a "heart attack" or "brain attack" (stroke).

Most of the sleep problems do not present acutely (but some may initiate acute and emergent events triggering as much drama as a heart attack or stroke; for example, there are reports of sudden cardiac arrhythmias or even sudden death associated with OSA and severe hypoxemia).

Unquestionably, considerable progress has been made in the last three to four decades encompassing basic science, technical, clinical, and therapeutic aspects of sleep medicine. Dedicated sleep scientists and clinicians, many organizations and foundations (regional, national, and international) should be credited for pushing the topic of sleep medicine forward. Sleep medicine is now recognized to be an independent specialty with its own training program. We are all dreaming and eagerly awaiting the day when sleep medicine will be considered an independent department with its own administrative, clinical, and research staff similar to other disciplines (e.g., departments of medicine, surgery, obgyn, and others).

Since the publication of the first edition in 1994, the second edition in 1999, and the third edition in 2009, many new advances have been made and hence the need for this fourth edition. There are 19 new chapters in this edition to address new advances (Chaps. 4, 9, 10, 12, 15, 16, 25, 31, 33, 35, 40, 42, 43, 49, 55, 56, 57, 58) including some topics (e.g., Chaps. 25, 33, and 36) which had not been addressed in depth in the last edition. I will highlight a few of these new chapters (numbers 10, 15, 16, 35, 43, 58). These are unique chapters and are highly relevant to the science and practice of sleep medicine, but unfortunately, not addressed adequately in most of the available standard textbooks of sleep medicine. There are considerable similarities and differences between altered consciousness induced by anesthetic agents and sleep, and sleep clinicians and scientists must be aware of these facts (Chap. 10). Anyone involved in clinical trial must have some basic knowledge about statistical principles, and hence, a new chapter (no. 15) is devoted to this topic, outlining the principles in a lucid and easily comprehensible manner. A sleep clinician involved in interpretation and recording of polysomnographic and other technical recordings should have some fundamental knowledge about instrumentation and signal analysis (Chap. 16) to appreciate the fallacies and pitfalls of such recordings. Occult sleep disordered breathing (SDB) may pose imminent danger to any patient about to undergo a surgical procedure. It is, therefore, important to be aware of the presence of SDB in the preoperative, perioperative, and postoperative periods (Chap. 35). Another important topic for sleep clinicians and scientists to understand is the difference among sleep, coma, and vegetative and minimally conscious states, but again these topics are

not addressed in the standard textbooks of sleep medicine. I am fortunate and grateful to have the world's leading expert, Dr. Steven Laureys, addressing these subjects as the lead author (Chap. 43). Complementary and alternative medicine (CAM; Chaps. 56 and 57) is increasingly becoming popular although valid scientific data after randomized control trials (RCTs) are not available for most of the CAM therapies. Finally, a fascinating topic (Chap. 58) is sleep in extreme environment (e.g., space travel) for which we have some limited data but which, I believe, will be a hot topic in future sleep medicine. Chap. 40 dealing with evaluation and management of PLMS and RLS written by a leading authority on these topics is a new chapter in this edition but was included in the chapter on "Motor function and dysfunction of sleep" by Wayne Henning as the lead author in the third edition. The other three new chapters in this edition address Phylogeny of Sleep (Chap. 9), Sleep and Immune Regulation (Chap. 12), and Fatigue in Clinical Practice (Chap. 42). The chapter on the phylogeny of sleep is important to understand evolution of sleep from inframammalian to mammalian species which may help understand the function of and need for sleep. The role of sleep in immune regulation and fatigue, noted in many neurological and other conditions, and often mistaken for sleep or secondary to sleep deprivation is included in two new chapters in this edition. REM behavior disorder (RBD) is addressed as part of parasomnia chapter (no. 50), but in this edition, I have also included RBD as a separate chapter (no. 49) because of its increasing recognition as a forerunner to a neurodegenerative disease and the exciting possibilities of finding a biomarker for this. New authors and co-authors have been invited for several chapters (number 1, 4, 5, 6, 7, 8, 13, 14, 18, 23, 24, 28, 32, 34, 38, 39, 41, 44, and 54). Clifford Saper, a leading neuroscientist and researcher in basic science of sleep, replaced William Dement in writing the introductory chapter (no. 1). For the circadian timing and sleep–wake regulation chapter (6), Philip Boudreau and co-authors replaced Robert Y. Moore. For Chap. 14 (Dreaming and Sleep Disorder), James. F. Pagel and Seithikurippu R. Pandi-Perumal replaced Rosalind Cartwright.

The basic layout of the fourth edition remains same as in the third edition, dividing the book into three major sections: basic science, technical considerations, and clinical aspects. However, because of increased size of this edition to conform to the policy of Springer, the fourth edition of the book is published in two volumes (volume one dealing with basic science and technical aspects and volume two dealing with clinical consideration). As in the third edition, the purpose of this edition remains the same, namely to provide a comprehensive text for both the beginners and seasoned practitioners of sleep medicine. Hence, the book is directed at neurologists, internists (especially those specializing in pulmonary, cardiovascular, gastrointestinal, and renal and endocrine medicine), family physicians, pediatricians, psychiatrists, psychologists, otolaryngologists, dentists, neurosurgeons, neuroscientists, and intensivists, as well as those interested in advancing their knowledge in sleep and its disorders (e.g., technologists, nurses, and other healthcare professionals).

I end this preface by announcing with heavy heart and profound sadness the death of three giants in contemporary sleep medicine since the publication of the third edition, Professor Elio Lugaresi, Professor Pasquale Montagna, and Professor Arthur Spielman. These three distinguished scholars made robust scientific contributions in sleep medicine and sleep science. Their scholarly contributions left indelible marks in the scientific world. I dedicate this book to these three gentlemen and scholars. Their memory will remain forever with us. They are not physically present today, but their souls are indestructible, unvanquished, and eternal. May they rest in peace. We shall never forget what they have done as living mortals to promote sleep science.

South Orange and Edison, New Jersey, USA Sudhansu Chokroverty

Acknowledgements

First, I must thank all the contributors and express my gratitude to them for their lucid and scholarly writing. I am certain that these contributions will make this edition a valuable source to the rapidly growing field of sleep medicine. I am especially indebted to Clifford Saper, a remarkable neuroscientist and basic researcher to unravel the mysteries of sleep, for writing the introduction of the topic of Sleep Science. I wish to thank all the authors, editors and publishers as well as NASA for granting permission to reproduce illustrations and tables that were published in other books, journals, and Web sites. I must also acknowledge my appreciation and indebtedness to Gregory Sutorius, Senior Editor of Clinical Medicine at Springer Science+Business Media, New York, NY, for his splendid support, professionalism, and thoughtfulness and for efficiently moving forward various steps of production. It is my pleasure to also acknowledge the valuable support of Kevin Wright, developmental editor, and all the other publishing staff at the Springer production office for their dedication, care, and professionalism in making the publication of this book in an efficient manner.

I would like to thank Toni Bacala, the editorial assistant to the *Sleep Medicine* Journal, for her splendid support and uncomplaining and helpful attitude in organizing the chapters, making corrections, typing, editing, corresponding with the contributors and publisher, and making computer-generated schematic diagrams for some chapters in addition to her busy schedule as editorial assistant for the journal. Her unfinished job was later taken over by Jamie Winder, the current editorial assistant. I also thank Jenny Rodriguez, my secretary at the Institute, for her help in typing some parts of the chapters. As always, I owe an enormous gratitude and thanks to my lifelong partner, Manisha Chokroverty, MD, for encouraging me from the very beginning to get involved in promoting and disseminating sleep medicine and sleep health throughout the world and for supporting my effort in editing and compiling each and every edition of this book with love and forbearance throughout all stages of production of the book. I remain indebted to her forever for her unfailing support and tolerance.

Part I
Basic Science of Sleep

Introduction to the Topic

1

Clifford B. Saper

While sleep occupies almost a third of our lives (and half or more of the lives of many animals), the processes that go on in the brain during sleep remain mysterious and in the realm of basic investigation. On the other hand, we have made enormous strides in recent years in identifying the cellular basis that underlies many of the phenomena of sleep and circadian rhythms, and in the process are beginning to frame some cogent ideas about the ultimate function of sleep. The chapters that follow in this section provide a detailed look at the basic science of sleep, from the perspectives of anatomy, physiology, pharmacology, and behavior.

Our understanding of the basic brain circuitry that regulates sleep and wakefulness has advanced considerably in recent years and continues to grow as this work remains at the cutting edge of the field [1, 2]. Although the outlines of the classic cholinergic and monoaminergic wake-promoting systems have been known since the 1980s, studies that have placed lesions in these pathways have demonstrated disappointingly little effect on amounts of baseline wake–sleep [3–5]. Recent studies have uncovered additional components of the ascending arousal system, including the parabrachial nucleus [6] and portions of the basal ganglia [7, 8], that have augmented our understanding of it and have added new pieces to the puzzle.

Similarly, our understanding of the sleep-promoting circuitry of the brain has progressed enormously in recent years. In addition to the contribution of the ventrolateral preoptic nucleus to causing sleep [2], evidence has emerged for the role of the median preoptic nucleus in accumulating sleep need [9]. Other neurons in the nucleus accumbens and in the parafacial zone in the medulla have been described [8, 10, 11], which also appear to promote sleep. Sleep-active neurons that are putatively inhibitory have been identified in the cerebral cortex [12] as well as the melanin-concentrating hormone cell group in the lateral hypothalamus [13, 14]. Their respective roles in sleep promotion are only now being explored.

There have also been major gains in our understanding of both the homeostatic and circadian regulation of sleep. Studies have uncovered the role of adenosine in causing sleepiness [15] and have identified the site in the nucleus accumbens at which caffeine acts on A2A receptors to combat sleepiness [11]. The immune interactions with sleep promotion have also been studied, identifying the role for prostaglandin D2 as a somnogen [16]. At the same time, the pathways have been worked out by which the suprachiasmatic nucleus influences wake–sleep cycles [17].

In addition to understanding the basic neuronal mechanisms that regulate sleep–wake, there has been substantial progress in understanding the interactions between sleep and a myriad of other physiological processes that it affects. These range from interactions with basic physiological systems, such as autonomic, respiratory, and immune systems [18, 19], to the effect of sleep fragmentation or loss on cognitive processes, ranging from attention to memory [20]. In particular, there is an emerging consensus that loss of specific stages of sleep may impair specific types of memory formation [21]. Understanding the cellular mechanisms that underlie this vulnerability will be critical to determining the biological function of sleep.

Finally, as our understanding of sleep neuroscience has broadened, we have come to understand how disruption of this delicate physiological mechanism can produce the range of sleep disorders that we see as clinicians. For example, the effects of stress-induced insomnia on wake–sleep circuitry support insomnia being a distinct state, neither wake nor sleep, with activation of both sleep-promoting and limbic and arousal systems at the same time [22, 23]. Our knowledge about the mechanisms of atonia during REM sleep has illuminated our understanding of both cataplexy and REM behavior disorder [24, 25]. In patients with sleep apnea, we

e-mail: csaper@bidmc.harvard.edu

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_1

are beginning to understand the arousal mechanisms that lead to frequent arousals [26], and how these interact with the control of the upper airway muscles that are necessary for ventilation.

Our ultimate goal as sleep clinicians is to improve the lot of our patients. As we better understand the diseases we treat, we are able to come up with novel therapies that are informed by the underlying pathophysiology. For example, the current development of orexin antagonists as sleep-promoting drugs is based upon our understanding of the biology of orexins and their contribution to maintaining wakefulness [27]. Conversely, the development of H3 antagonists as wake-promoting drugs depends upon our understanding of the histamine arousal system and its pharmacology [28].

The ideal situation in basic science is for our most basic observations to inform our bedside diagnosis and treatment abilities and to carry back information from the bedside that stirs the next generation of basic science questions. This has certainly been the case in the sleep field, as the chapters that follow in this basic science section demonstrate, and the ones in succeeding in the clinical sections emphasize.

Overview of Normal Sleep

2

Sudhansu Chokroverty

Historical Perspective

The history of sleep medicine and sleep research is a history of remarkable progress and remarkable ignorance. In the 1940s and 1950s, sleep had been in the forefront of neuroscience, and then again in the late 1990s, there has been a resurgence of our understanding of the neurobiology of sleep. Sleeping and waking brain cycles can now be studied by sophisticated neuroimaging techniques which have shown remarkable progress by mapping different areas of the brain during sleep states and stages. Electrophysiological research has shown that even a single neuron sleeps as evidenced by the electrophysiological correlates of sleep–waking at the cellular (single cell) level. Despite recent progress, we are still groping for answers to two fundamental questions: What is sleep? and why do we sleep? Sleep is not simply an absence of wakefulness and perception nor is it just a suspension of sensorial processes but is a result of a combination of a passive withdrawal of afferent stimuli to the brain and functional activation of certain neurons in selective brain areas. The more important question, however, is "How do we stay awake?" In the mother's womb, we were all asleep, and we wake up the moment we are born. But even in the newborn, sleep occupies 16 out of 24 h. Therefore, the fundamental inquiry should be directed at the mechanism of wakefulness.

Since the dawn of civilization, the mysteries of sleep have intrigued poets, artists, philosophers, and mythologists. The fascination with sleep is reflected in the literature, folklore, religion, and medicine. *Upanishad* [1, 2] (circa 1000 B.C.), the ancient Indian textbook of philosophy, sought to divide human existence into four states: the waking, the dreaming, the deep dreamless sleep, and the superconscious ("the very self"). This is reminiscent of modern classification of three states of existence (see later). One finds the description of pathologic sleepiness (possibly a case of Kleine–Levin syndrome) in the mythologic character Kumbhakarna in the great Indian epic *Ramayana* [3, 4] (circa 1000 B.C.). Kumbhakarna would sleep for months at a time, then get up to eat and drink voraciously before falling asleep again (Fig. 2.1). The ancient Chinese believed in two basic principles of life: *yang*, the active, light, and positive; and *yin,* the passive, dark, and negative. The *yin–yang* concept, originated with *Fu Hsi* (circa 2900 B.C.), has since become a symbol for sleep and wakefulness [5].

Throughout the literature, a close relationship between sleep and death has been perceived, but the rapid reversibility of sleep episodes differentiates sleep from coma and death. There are myriad references to sleep, death, and dream in poetic and religious writings, including the following quotations: "The deepest sleep resembles death" (*The Bible*, I Samuel 26:12); "sleep and death are similar … sleep is one-sixtieth [i.e., one piece] of death" (*The Talmud*, Berachoth 576); "There she [Aphrodite] met sleep, the brother of death" (Homer's *Iliad*, circa 700 B.C.); "To sleep perchance to dream … For in that sleep of death what dreams may come?" (Shakespeare's *Hamlet*); "How wonderful is death; Death and his brother sleep" (Shelly's "Queen Mab").

The 3 major behavioral states in human—wakefulness, non-rapid eye movement (NREM), and rapid eye movement (REM) sleep—are three basic biological processes that have independent functions and controls. The reader should consult Borbely's monograph *Secrets of Sleep* [2] for an interesting historical introduction to sleep.

What is the origin of sleep? The words *sleep* and *somnolence* are derived from the Latin word somnus; the German words *sleps*, *slaf*, or *schlaf*; and the Greek word *hypnos*. Hippocrates, the father of medicine, postulated a humoral mechanism for sleep and asserted that sleep was caused by the retreat of blood and warmth into the inner regions of the body, whereas the Greek philosopher Aristotle thought sleep was related to food, which generates heat and causes sleepiness. Paracelsus, a sixteenth-century physician, wrote that "natural" sleep lasted 6 h, eliminating tiredness and refreshing the sleeper. He also suggested that people not sleep too much or too little, but awake when the sun rises and go to bed at sunset. This advice from Paracelsus is strikingly similar to modern thinking about sleep. Views about sleep in the seventeenth and eighteenth centuries were expressed by Alexander Stuart, the British physician and physiologist, and by the Swiss physician, Albrecht von Haller. According to Stuart, sleep was due to a deficit of the "animal spirits"; von Haller wrote that the flow of the "spirits" to the nerves was cut off by the thickened blood in the heart, resulting in sleep. Nineteenth-century scientists used principles of physiology and chemistry to explain sleep. Both Humboldt and Pfluger thought that sleep resulted from a reduction or lack of oxygen in the brain [2].

Ideas about sleep were not based on solid scientific experiments until the twentieth century. Ishimori [6] in 1909, and Legendre and Pieron [7] in 1913, observed sleep-promoting substances in the cerebrospinal fluid of animals during prolonged wakefulness. The discovery of the EEG waves in dogs by the English physician Caton [8] in 1875 and of the alpha waves from the surface of the human brain by the German physician Berger [9] in 1929 provided the framework for contemporary sleep research. It is interesting to note that Kohlschutter, a nineteenth-century German physiologist, thought sleep was deepest in the first few hours and became lighter as time went on [2]. Modern sleep laboratory studies have generally confirmed these observations.

The golden age of sleep research began in 1937 with the discovery by American physiologist Loomis et al. [10] of different stages of sleep reflected in EEG changes. Aserinsky and Kleitman's [11] discovery of REM sleep in the 1950s at the University of Chicago electrified the scientific community and propelled sleep research to the forefront. Observations of muscle atonia in cats by Jouvet and Michel in 1959 [12] and in human laryngeal muscles by Berger in 1960 [13] completed the discovery of all major components of REM sleep. Following this, Rechtschaffen and Kales produced the standard sleep scoring technique monograph in 1968 (R–K

scoring technique) [14] which remained the gold standard until now. Recently, the American Academy of Sleep Medicine (AASM) published the AASM manual for the scoring of sleep and associated events [15] which modified the R–K technique and extended the scoring rules. The other significant milestone in the history of sleep medicine was the discovery of the site of obstruction in the upper airway in obstructive sleep apnea syndrome (OSAS) independently by Gastaut et al. [16] in France as well as Jung and Kuhlo [17] in Germany in 1965, followed by the polygraphic observations in the same year by Lugaresi et al. [18] of obstructive central and mixed apnea in these patients associated with periodic fall of blood pressure (BP) during apnea and rise above the baseline on resumption of breathing. The next milestone was the demonstration of dramatic relief of symptoms in these patients following tracheostomy (which bypasses the upper airway obstruction) by Kuhlo et al. [19]. In 1969 in a brief polygraphic report, Chokroverty et al. [20] made two important observations in patients with obesity hypoventilation syndrome (Pickwickian syndrome): Oxygen inhalation produced more prolonged and frequent episodes of apneas–hypopneas indicating the importance of peripheral chemoreceptor-driven hypoxemia causing respiratory stimulation and arousal in the presence of chronic daytime hypercapnia (these findings were later confirmed by other investigators [21]); the other observation is that following weight loss of 100–150-pound patients' symptoms improved, daytime arterial carbon dioxide normalized but apneas–hypopneas persisted, though these were less frequent than before weight loss. Subsequently, numerous papers were published by Guilleminault et al. [22] who coined the term *sleep apnea syndrome*. Then came the seminal paper by Sullivan and associates in 1981 [23] of continuous positive airway pressure (CPAP) titration to eliminate such obstruction as the standard treatment modality for moderate-to-severe OSAS. Finally, identification of 2 neuropeptides, hypocretin 1 and 2 (orexin A and B) in the lateral hypothalamus and perifornical regions [24, 25] followed by an animal model of a human narcolepsy phenotype in dogs by mutation of hypocretin 2 receptors ($HCTR_2$) by Lin et al. [26], the creation of similar phenotype in pre-prohypocretin knockout mice [27] and transgenic mice, [28] documentation of decreased hypocretin 1 in the cerebrospinal fluid in humans, [29] and decreased hypocretin neurons in the hypothalamus at autopsy [30, 31] in human narcolepsy patients opened a new and exciting era of sleep research.

Definition of Sleep

Sleep is "…great nature's second course, chief nourisher in life's feast" (Wm. Shakespeare).

The definition of sleep and a description of its functions have always baffled scientists. Moruzzi [32] while describing the historical development of the deafferentation hypothesis of sleep quoted the concept Lucretius articulated 2000 years ago—that sleep is the *absence of wakefulness*. A variation of the same concept was expressed by Hartley [33] in 1749, and again in 1830 by Macnish [34] who defined sleep as *suspension of sensorial power*, in which the voluntary functions are in abeyance, but the involuntary powers, such as circulation or respiration, remain intact. It is easy to comprehend what sleep is if one asks oneself that question as one is trying to get to sleep. Human sleep can be defined as an altered state in which there is impaired conscious awareness of the external world with different controls, rhythms, emotions, and dreams. It is a transient natural, periodic, physiologic phenomenon which is reversible, thus differentiating it from irreversible coma and death. Consciousness requires two components: awareness (function of cerebral cortex) and arousal (function of ascending reticular activating system). Sleep differs from unconscious state or coma (a pathological state) in the following manner: Sleep besides being a reversible physiological state also shows differences from coma in terms of brain metabolism and circulation which show marked depression and impairment in coma but slight alterations in sleep. Persistent vegetative state, minimally conscious state, and coma are distinctly different from sleep state although superficially may resemble those other states (see Chap. 43). Modern sleep researchers define sleep on the basis of both behavior of the person while asleep and the related physiologic changes that occur to the waking brain's electrical rhythm in sleep [35–38]. The behavioral criteria (Table 2.1) include lack of mobility or slight mobility, closed eyes, a characteristic species-specific sleeping posture, reduced response to external stimulation, quiescence, increased reaction time, elevated arousal threshold, impaired cognitive function, and a reversible unconscious state. Sleep is an active anabolic state (e.g., promoting growth, stimulating immune system) and is observed in all mammals, birds, reptiles, amphibians, and fish. The physiologic criteria (see Sleep Architecture and Sleep Profile) based on the findings from electroencephalography (EEG), electrooculography (EOG), and electromyography (EMG) as well as other physiological changes in ventilation and circulation. While trying to define the process of falling asleep, we must differentiate sleepiness from fatigue or tiredness. Fatigue (see also Chap. 41) can be defined as a state of sustained lack of energy coupled with a lack of motivation and drive but does not require the behavioral criteria of sleepiness such as heaviness and drooping of the eyelids, sagging or nodding of the head, yawning, and an ability to nap given the opportunity to fall asleep. On the other hand, fatigue is often a secondary consequence of sleepiness.

Table 2.1 Behavioral criteria of wakefulness and sleep

Criteria	Awake	Non-rapid eye movement sleep	Rapid eye movement sleep
Posture	Erect, sitting, or recumbent	Recumbent	Recumbent
Mobility	Normal	Slightly reduced or immobile; postural shifts	Moderately reduced or immobile; myoclonic jerks
Response to stimulation	Normal	Mildly to moderately reduced	Moderately reduced to no response
Level of alertness	Alert	Unconscious but reversible	Unconscious but reversible
Eyelids	Open	Closed	Closed
Eye movements	Waking eye movements	Slow rolling eye movements	Rapid eye movements

The Moment of Sleep Onset and Offset

There is no exact moment of sleep onset—there are gradual changes in many behavioral and physiological characteristics including EEG rhythms, cognition, and mental processing including reaction time. Sleepiness begins at sleep onset even before reaching stage 1 NREM sleep (as defined later) with heaviness and drooping of the eyelids; clouding of the sensorium; and inability to see, hear, or perceive things in a rational or logical manner. At this point, an individual trying to get to sleep is now entering into another world in which the person has no control and the brain cannot respond logically and adequately. This is the stage coined by McDonald Critchley as the "Pre-Dormitum" [39] who also mentioned that Gowers used "sleepening" for this stage, and this is opposite of "awakening." Slow rolling eye movements (SEMs) begin at sleep onset and continue through stage 1 NREM sleep. At sleep onset, there is a progressive decline in thinking process, and sometimes there may be hypnagogic imagery and hypnic myoclonus [40].

Similar to sleep onset, the moment of awakening or sleep offset (post-dormitum) is also a gradual process from the fully established sleep stages. This period is sometimes described as manifesting sleep inertia or sleep drunkenness. There is a gradual return to a state of alertness or wakefulness.

Sleep Architecture and Sleep Profile

Based on three physiologic measurements (EEG, EOG, and EMG), sleep is divided into two states [41] with independent functions and controls: NREM sleep and REM sleep. Table 2.2 lists the physiologic criteria of wakefulness and sleep and Table 2.3 summaries NREM and REM sleep states. In an ideal situation (which may not be seen in all

Table 2.2 Physiologic criteria of wakefulness and sleep

Criteria	Awake	Non-rapid eye movement sleep	Rapid eye movement sleep
Electroencephalography	Alpha waves; desynchronized	Synchronized	Theta or saw tooth waves; desynchronized
Electromyography (muscle tone)	Normal	Mildly reduced	Moderately to severely reduced or absent
Electrooculography	Waking eye movements	Slow rolling eye movements	Rapid eye movements

Table 2.3 Summary of non-rapid eye movement and rapid eye movement sleep states

Sleep state	Sleep time (%)
NREM sleep	75–80
N1	3–8
N2	45–55
N3	15–23
REM sleep	20–25
Tonic stage	–
Phasic stage	–

NREM Non-rapid eye movement; *REM* Rapid eye movement

normal individuals), NREM and REM alternate in a cyclic manner, each cycle lasting on an average from 90 to 110 mins. During a normal sleep period in adults, 4–6 such cycles are noted. The first two cycles are dominated by slow-wave sleep (SWS) (R–K stages 3 and 4 NREM and AASM stage N3 sleep); subsequent cycles contain less SWS, and sometimes SWS does not occur at all. In contrast, the REM sleep cycle increases from the first to the last cycle, and the longest REM sleep episode toward the end of the night may last for an hour. Thus, in human adult sleep, the first third is dominated by the SWS and the last third is dominated by REM sleep. It is important to be aware of these facts because certain abnormal motor activities are characteristically associated with SWS and REM sleep.

Non-rapid Eye Movement (NREM) Sleep—NREM sleep accounts for 75–80 % of sleep time in an adult human. According to R–K scoring manual, [14] NREM sleep is further divided into four stages (stages 1–4), and according to the recent AASM scoring manual, [15] this is subdivided into three stages (N1, N2, and N3), primarily on the basis of EEG criteria. Stage 1 NREM (N1) sleep occupies 3–8 % of sleep time; stage 2 (N2) comprises 45–55 % of sleep time; and stage N3 or SWS makes up 15–23 % of total sleep time. The dominant rhythm during adult human wakefulness consists of the alpha rhythm (8–13 Hz) noted predominantly in the posterior region intermixed with small amount of beta rhythm (>13 Hz) seen mainly in the anterior head regions (Fig. 24.1). This state called stage W may be accompanied by conjugate waking eye movements (WEMs) which may comprise vertical, horizontal, oblique, slow, or fast eye movements. In stage 1 NREM sleep (stage N1), alpha rhythm diminishes to less than 50 % in an epoch (i.e., a 30-second segment of the polysomnographic tracing with the monitor screen speed of 10 mm/s) intermixed with slower theta rhythms (4–7 Hz) and beta waves (Fig. 24.2). Electromyographic activity decreases slightly, and slow eye movements (SEMs) appear. Toward the end of this stage, vertex sharp waves are noted. Stage 2 NREM (stage N2) begins after approximately 10–12 min of stage 1. Sleep spindles (11–16 Hz, mostly 12–14 Hz) and K-complexes intermixed with vertex sharp waves herald the onset of stage N2 sleep (Fig. 24.3). Sleep spindles could be divided into two types: fast spindles (13–15 Hz) seen predominantly in the centroparietal region and slow spindles (11 ≤ 13 Hz) seen mostly in the frontal region. EEG at this stage also shows theta waves and slow waves (0.5–2 Hz) that occupy less than 20 % of the epoch. After about 30–60 mins of stage 2 NREM sleep (stage N2), stage 3 sleep begins and slow waves comprise 20–100 % of the epoch (Fig. 24.4). As stated above, R–K stages 3 and 4 NREM are grouped together as SWS and are replaced by stage N3 in the new AASM scoring manual. Body movements often are recorded as artifacts in PSG recordings toward the end of SWS as sleep is lightening. Stage N3 is briefly interrupted by stage 2 NREM (stage N2), which is followed by the first REM sleep approximately 60–90 mins after sleep onset.

Rapid Eye Movement (REM) Sleep—REM sleep accounts for 20–25 % of total sleep time. Based on EEG, EMG, and EOG characteristics, REM can be subdivided into two stages (tonic and phasic). This subdivision is not recognized in the recent AASM scoring manual. A desynchronized EEG, hypotonia or atonia of major muscle groups with the exception of the diaphragm and the oculomotor muscles, and depression of monosynaptic and polysynaptic reflexes are characteristics of tonic REM sleep. This tonic stage persists throughout the REM sleep, whereas the phasic stage is discontinuous and superimposed on the tonic stage. Phasic REM sleep is characterized by bursts of rapid eye movements (REMs) in all directions, in singlets or clusters. Phasic swings in blood pressure and heart rate, irregular respiration, spontaneous middle ear muscle activity (MEMA), periorbital integrated potentials (PIPs) [42], and myoclonic twitching of the facial and limb muscle and tongue movements [43] are all characteristics of phasic REM sleep (Fig. 2.2). These and other phasic phenomena of REM sleep are listed in Box 2.1. A few periods of apnea or hypopnea may occur during REM sleep. Electroencephalographic tracing during REM sleep consists of low-amplitude fast pattern in the beta frequency range mixed with a small amount of theta rhythms, some of which may have a "saw tooth" appearance (Fig. 2.2). Saw tooth waves are trains of sharply contoured, often serrated, 2–6 Hz waves usually with rapid ascent and slow descent seen maximally over the central regions and are thought to be the gateway to REM sleep, often preceding a burst of REMs. PIPs are seen during REMs (Fig. 2.2) but not all REMs are accompanied by PIPs. During REM sleep, there may be some intermittent intrusions of alpha rhythms in the EEG lasting for a few seconds. The first REM sleep lasts only a few minutes. Sleep then progresses to stage 2 followed by stage N3 before the second REM sleep begins.

Box 2.1. Lists of Phasic Events of REM Sleep

- Rapid eye movements (REMs)
- Phasic muscle bursts (myoclonic or transient muscle bursts)
- Phasic tongue movements
- Periorbital integrated potentials (PIPS)
- Middle ear muscle activity (MEMA)
- Ponto-geniculo-occipital waves (PGO or P waves) [rats and cats; also reported in human during corticography while performing epilepsy surgery]
- Phasic alterations of breathing (brady-tachypnea)
- Phasic swings of BP (up and down)
- Phasic swings of heart rate (brady-tachyarrhythmia)
- Hippocampal theta waves (rhythms) [animal study]

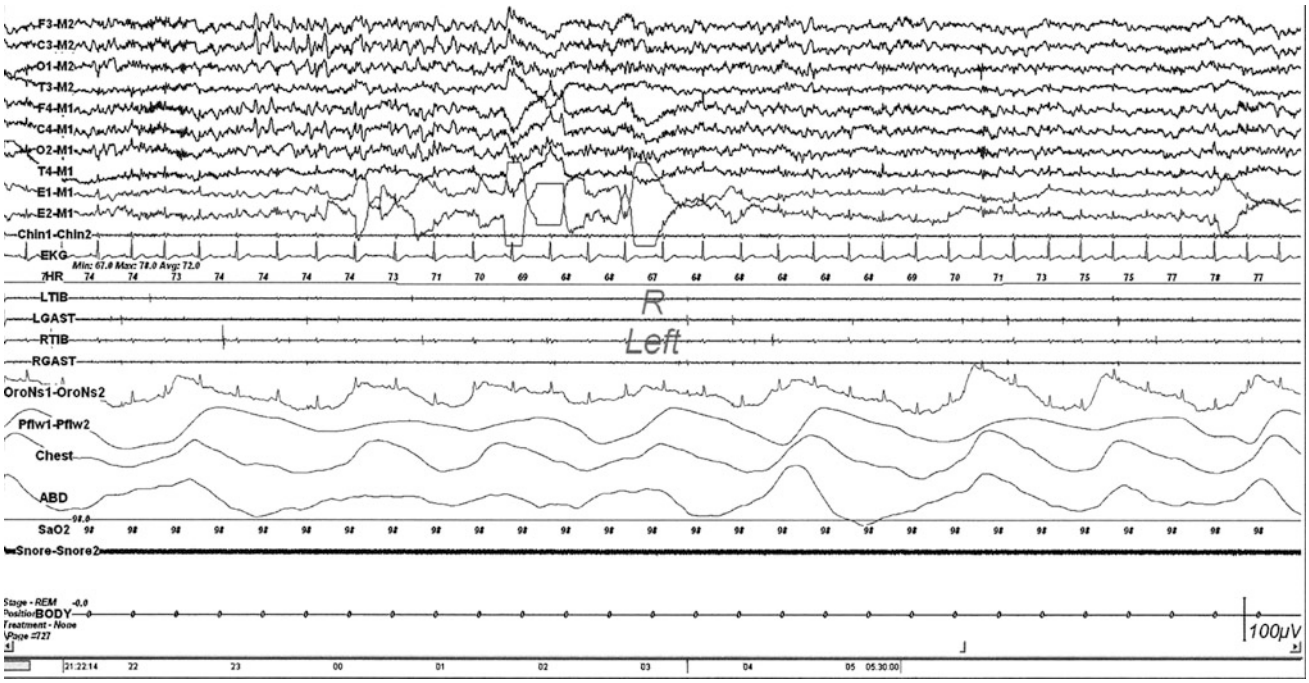

Fig. 2.2 Polysomnographic recording shows rapid eye movement (REM) sleep in an adult. EEG (top 8 channels) shows mixed-frequency theta, low-amplitude beta, and a small amount of alpha activity. Note the characteristic sawtooth waves (seen prominently in channels, 1, 2, 5, and 6 from the *top*) of REM sleep preceding bursts of REMs in the electrooculograms (E1-M1; E2-M2). Chin EMG shows marked hypotonia, whereas TIB and GAST EMG channels show very low-amplitude phasic myoclonic bursts. Reprinted from Chap. 2, 3rd edition

- Saw tooth waves in the EEG
- Alpha bursts in the EEG during REM sleep
- Phasic increase in brain intracellular firing rates during REM sleep
- Penile erections in men and clitoral tumescence in women in REM sleep
- Phasic increase in myocardial oxygen demand in REM sleep
- Phasic vivid dreaming in REM sleep
- Phasic suppression of REM muscle atonia
- Phasic pupillary dilation and constriction
- Phasic fractionations of diaphragmatic activity (pauses of 40–80 ms occurring in clusters) correlating with PGO waves which are phasic events of REM sleep

In summary, during normal sleep in adults, there is an orderly progression from wakefulness to sleep onset to NREM and then to REM sleep. Relaxed wakefulness is characterized by behavioral state of quietness and physiological state of alpha and beta frequency in the EEG, WEMs, and increased muscle tone. NREM sleep is characterized by progressively decreased responsiveness to external stimulation accompanied by SEMs, followed by electroencephalographic slow-wave activity associated with spindle and K-complexes, and decreased muscle tone. REMs markedly reduced or absent muscle tone and low voltage fast electroencephalographic activity mixed with distinctive saw tooth waves and PIPs characterize REM sleep.

The R–K system addresses normal adult sleep and macrostructure of sleep. In patients with sleep disorders such as sleep apnea, parasomnias, or sleep-related seizures, it may be difficult to score sleep according to R–K criteria. Furthermore, the R–K staging system does not address the microstructure of sleep. The recent AASM sleep scoring criteria with a brief reference to R and K system have been outlined in Chap. 24. The macrostructure of sleep is summarized in Box 2.2. There are several endogenous and exogenous factors, which will modify sleep macrostructure (Box 2.3).

Box 2.2: Sleep Macrostructure

Sleep Microstructure—Sleep microstructure includes momentary dynamic phenomena such as arousals, which have been operationally defined by the Task Force of the American Sleep Disorders Association (now called American Academy of Sleep Medicine) [44] which has remained essentially unchanged in the recent AASM scoring manual, [15] and the cyclic alternating pattern (CAP), which has been defined and described in various publications by Terzano and co-investigators [45–47]. Other components of microstructure include K-complexes and sleep spindles (Box 2.4).

Box 2.4: Sleep Microstructure

Arousals
Cyclic alternating pattern
Sleep spindles
K-complexes

Arousals are transient phenomena resulting in fragmented sleep without behavioral awakening. An arousal is scored during sleep stages N1, N2, N3 (or REM sleep) if there is an abrupt shift in EEG frequency lasting from 3 to 14 s (Fig. 2.3) and including alpha, beta, or theta activities but not spindles or delta waves. Before an arousal can be scored, the subject must be asleep for 10 consecutive seconds. In REM sleep, arousals are scored only when accompanied by concurrent increase in segmental EMG amplitude. K-complexes, delta waves, artifacts, and only increased segmental EMG activities are not counted as arousals unless these are accompanied by EEG frequency shifts. Arousals can be expressed as number per hour of sleep (an arousal index), and up to 10 arousal index can be considered normal.

The Cyclic Alternating Pattern—The CAP (Fig. 2.4) indicates sleep instability, whereas frequent arousals with or without stage shifts signify sleep fragmentation [47]. A fragmentation index (number of arousals and stage shifts per hour) can also be calculated to indicate sleep instability. Sleep microstructure is best understood by the CAP, wherein an EEG pattern that repeats in a cyclical manner is noted mainly during NREM sleep. This is a promising technique in evaluating both normal and abnormal sleep, as well as in

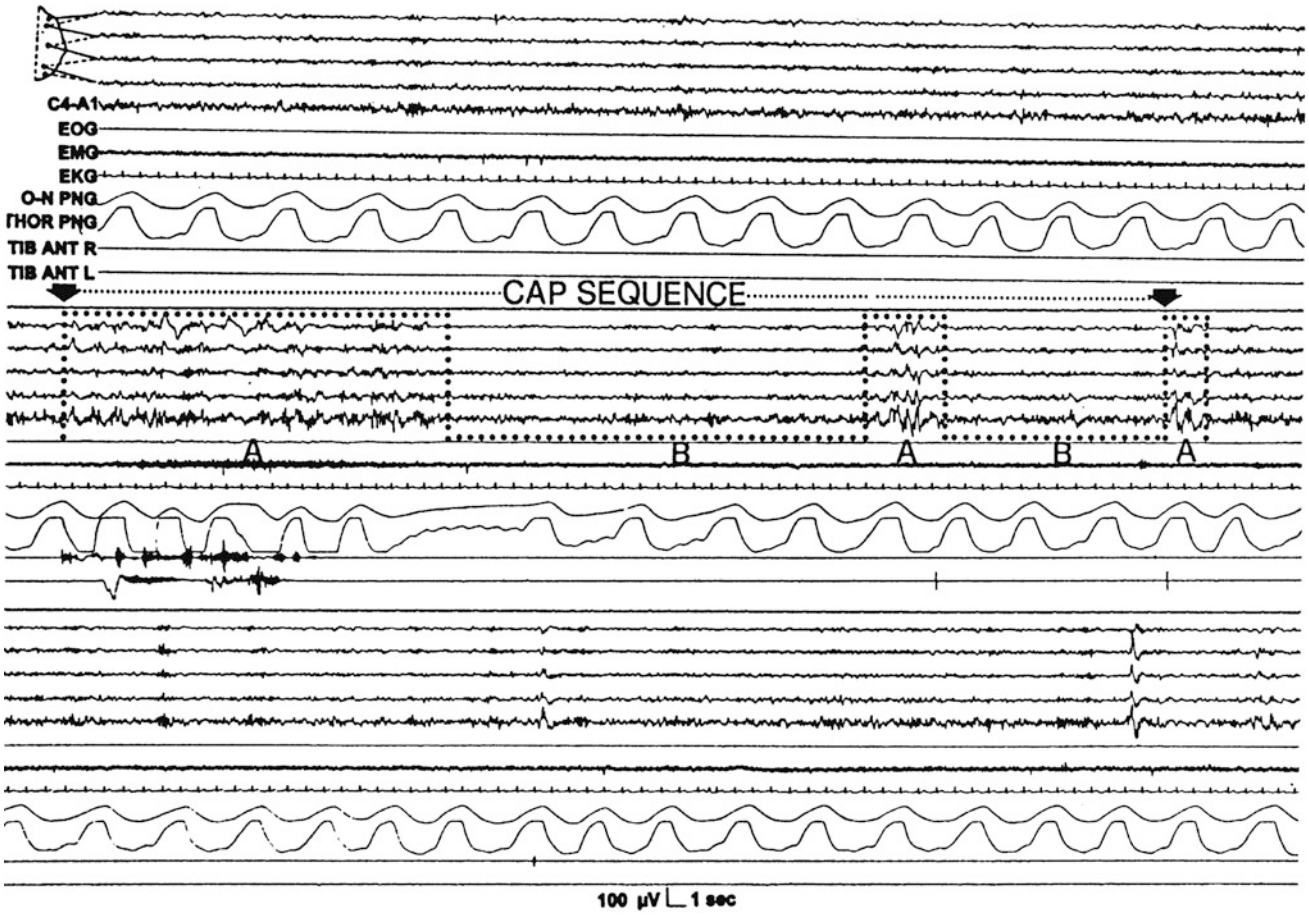

Fig. 2.4 Polysomnographic recording showing consecutive stretches of non-cyclic alternating pattern (non-CAP) (*top*), cyclic alternating pattern (CAP) (*middle*), and non-CAP (*bottom*). The CAP sequence, confined between the two *black arrows*, shows three phase As and two phase Bs, which illustrate the minimal requirements for the definition of a CAP sequence (at least three phase As in succession). Electroencephalographic derivation (top 5 channels in *top* panel): FP2-F4, F4-C4, C4-P4, P4-02, and C4-A1. Similar electroencephalographic derivation is used for the *middle* and *lower* panels. From Terzano et al. [48]. Reprinted from Chap. 2, 3rd edition

understanding the neurophysiologic and neurochemical basis of sleep. A CAP cycle [48] consists of an unstable phase (Phase A) and relatively stable phase (Phase B) each lasting between 2 and 60 s. Phase A of CAP is marked by an increase in EEG potentials with contributions from both synchronous high amplitude and slow, and desynchronized fast rhythms in the EEG recording standing out from a relatively low-amplitude slow background. The A phase is associated with an increase in heart rate, respiration, blood pressure, and muscle tone. CAP rate (total CAP time during NREM sleep) and arousals both increase in older individuals and in a variety of sleep disorders including both diurnal and nocturnal movement disorders. Non-CAP (sleep period without CAP) is thought to indicate a state of sustained stability.

In summary, sleep macrostructure is based on cyclic patterns of NREM and REM states, whereas sleep microstructure mainly consists of arousals, periods of CAP, and periods without CAP. An understanding of sleep macrostructure and microstructure is important because emergence of abnormal motor activity during sleep may be related to disturbed macrostructure and microstructure of sleep.

The Ontogeny of Sleep

Evolution of EEG and sleep states (see also Chap. 52) from the fetus, preterm, and term infant, early childhood, adolescence to adulthood follows in an orderly manner depending upon the maturation of the central nervous system (CNS) [49–52]. Neurological, environmental, and genetic factors as well as comorbid medical or neurological conditions will have significant effects on such ontogenetic changes. Sleep requirements change dramatically from infancy to old age. Newborns have a polyphasic sleep pattern, with 16 h of sleep per day. This sleep requirement decreases to approximately 10 h per day by 3–5 years of age. In preschool children, sleep assumes a biphasic pattern.

Adults exhibit a monophasic sleep pattern, with an average duration from 7.5 to 8 h per night. This returns to a biphasic pattern in old age.

Upon falling asleep, a newborn baby goes immediately into REM sleep, or active sleep, which is accompanied by restless movements of the arms, legs, and facial muscles. In premature babies, it is often difficult to differentiate REM sleep from wakefulness. Sleep spindles appear from 6 to 8 weeks and are well formed by 3 months (may be asynchronous during the first year and by age 2 are synchronous). K-complexes are seen at 6 months but begin to appear at over 4 months. Hypnagogic hypersynchrony characterized by transient bursts of high amplitude waves in the slower frequencies appears at 5–6 months and is prominent at one year. By 3 months of age, the NREM/REM cyclic pattern of adult sleep is established. However, the REM/NREM cycle duration is shorter in infants, lasting for approximately 45–50 mins and increasing to 60–70 mins by 5–10 years and the normal adult cyclic pattern of 90–100 mins by age of 10 years. A weak circadian rhythm is probably present at birth, but by 6–8 weeks, it is established. Gradually, the nighttime sleep increases and daytime sleep decreases and the number of naps decreases. By 8 months, the majority take two naps (late morning and early afternoon). The first 3 months is a critical period of CNS reorganization, and striking changes occur in many physiological responses. In newborns, total sleep time is about 16 h. The total sleep time decreases to 14 h at 4 months and to 13 h at 6–8 months. By 3–6 months, major concentration of sleep occurs at night.

Sleep onset in the newborn occurs through REM sleep. During the first three months, sleep onset REM begins to change. In the newborn, active sleep (REM) occurs 50 % of the total sleep time. This decreases during the first 6 months of age. By 9–12 months, REM sleep occupies 30–35 % of sleep and by 5–6 years, REM sleep decreases to adult levels of 20–25 %. The napping frequency continues to decline, and by age 4–6 years, most children stop daytime naps. Nighttime sleep patterns become regular gradually, and by age 6, nighttime sleep is consolidated with few awakenings. At 9–10 years of age, most children sleep for 10 h at night. Pre-adolescents are highly alert during the day with multiple sleep latency test (MSLT) showing a mean sleep latency of 17–18 min. In summary, the multiphasic sleep pattern of newborns and infants gradually changes to biphasic sleep in preschool children, and finally to monophasic sleep in adults [49, 50]. Sleep reverts to biphasic pattern in the elderly.

There are two other important changes that occur in the sleep pattern in old age: repeated awakenings throughout the night, including early morning awakenings that prematurely terminate the night sleep, and a marked reduction of the amplitude of the slow waves resulting in a decreased percentage of slow-wave sleep (SWS) in this age group. The

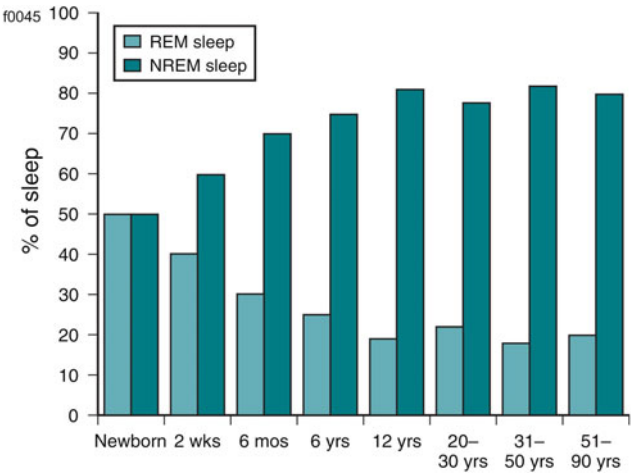

Fig. 2.5 Graphic representation of percentages of REM and NREM sleep at different ages. Note the dramatic changes in REM sleep in the early years. Adapted from Roffwarg et al. [49]. Reprinted from Chap. 2, 3rd edition

percentage of REM sleep in normal elderly individuals remains relatively constant, and the total duration of sleep time within 24 h is also no different from that of young adults; however, elderly individuals often nap during the daytime compensating for lost sleep during the night. Figure 2.5 shows schematically the evolution of sleep step distribution in newborns, infants, children, adults, and elderly adults. Night sleep histograms of children, young adults, and of elderly adults are shown in Fig. 2.6.

The significant evolutionary changes in the respiratory and cardiovascular functions [51, 53]. Respiratory controllers are immature and not fully developed at birth. Respiratory mechanics and upper airway anatomy are different in newborns than in adults contributing to breathing problems, particularly during sleep in newborn infants. Brief periods of respiratory pauses or apneas lasting for 3 s or longer, periodic breathing and irregular breathing may be noted in newborns, especially during active (REM) sleep. According to the National Institutes of Health, Consensus Development Conference on Infantile Apnea, [54] the term periodic breathing refers to respiratory pauses of at least 3 s with less than 20 s of normal breathing in between the pauses. Cheyne–Stokes breathing is periodic waxing and waning of respiration accompanied by central apneas and may be noted in preterm infants. Periodic breathing and occasional central apneas of up to 15 s duration in newborns may be noted without any clinical relevance unless accompanied by bradycardia or cyanosis. These breathing events gradually disappear during the first few weeks of life. The respiratory rate also gradually slows during the first few years of life. Another important finding in the newborn, particularly during active sleep is paradoxical inward motion of the rib cage. This occurs because of

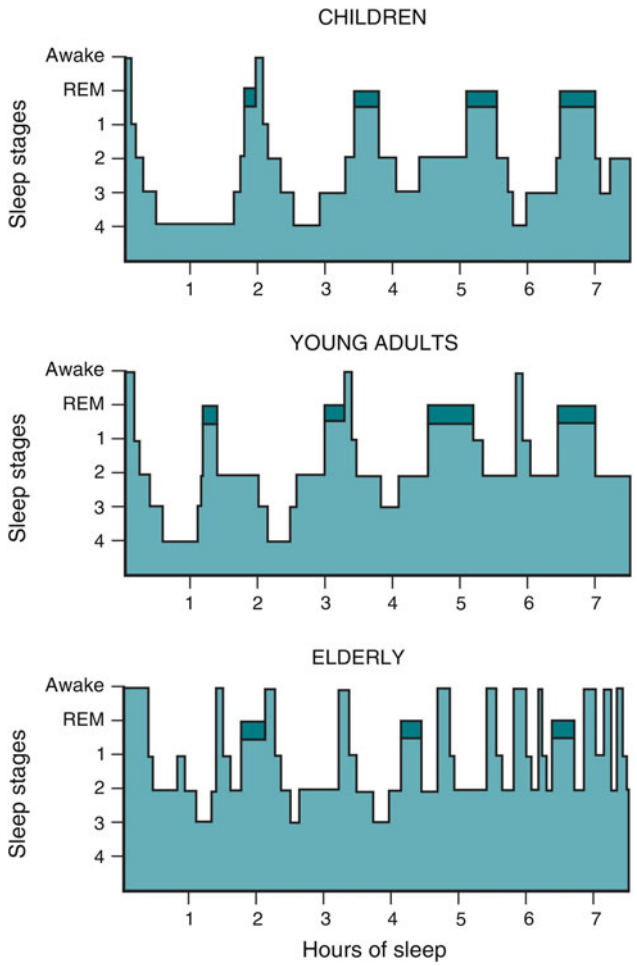

Fig. 2.6 Night sleep histogram from a child, a young adult, and an elderly person. Note significant reduction of stage 4 NREM sleep as one grows older. From Kales and Kales [238]. Reprinted from Chap. 2, 3rd edition

high compliance of the rib cage in newborns, circular rather than elliptical thorax and decreased tone of the intercostal and accessory muscles of respiration. This paradoxical breathing causes hypoxia and reduced diaphragmatic efficiency. Similar breathing in adults occurs during diaphragmatic weakness. At term, posterior cricoarytenoyd muscles which assist in maintaining upper airway patency are not adequately coordinated with diaphragmatic activity causing a few periods of obstructive apneas especially during active sleep. Ventilatory responses to hypoxia are also different in newborns than in adults. In quiet sleep, hypoxia stimulates breathing as in adults, but in active sleep after the initial period of stimulation, there is ventilatory depression. Laryngeal stimulation in adults causes arousal, but in infants, this may cause an apnea. Breathing becomes regular, and the respiratory control is adequately developed by the end of the first year. Changes in cardiovascular function indicate changes in the autonomic nervous system (ANS) during infancy and early childhood. There is greater parasympathetic control for children than infants (as assessed by heart rate low-frequency [LF] and high-frequency [HF] analysis (see also Chap. 11): 0.15–0.5 Hz [HF] indicates parasympathetic and 0.04–0.15 Hz [LF] indicates sympathetic activity). The better parasympathetic control for children than infants indicates ANS maturity. Respiratory heart rate modulation is variable in newborns as assessed by LF and HF heart rate spectral analysis. In active sleep, most of the power is in LF. In older infants and children, there is significant respiratory heart rate modulation termed normal sinus arrhythmia. Respiratory rate during quiet sleep decreases, and the respiratory variability decreases with age.

Sleep Habits

Sleep specialists sometimes divide people into two groups: "evening types" (owls) and "morning types" (larks). The morning types wake up early feeling rested and refreshed and work efficiently in the morning. These people get tired and go to bed early in the evening. In contrast, evening types have difficulty getting up early and they feel tired in the morning; they feel fresh and energetic toward the end of the day. These people perform best in the evening. They go to sleep late at night and wake up late in the morning. The body temperature rhythm takes on different curves in these two types of people. The body temperature reaches the evening peak an hour earlier in morning types than in evening types. What determines a morning or evening type is not known, but heredity may play a role. Katzenberg et al. [55] using the 19-item Horne–Ostberg questionnaire to determine morningness/eveningness in human circadian rhythms discovered a clock gene polymorphism associated with human diurnal preference. One of two H clock alleles (3111C) is associated with eveningness. These findings have been contradicted by later studies [56]. There is a third type (intermediate type) not conforming to either morning or evening type [57].

Sleep Need and Requirement

Sleep requirement or sleep need is defined as the optimum amount of sleep required to remain alert and fully awake and to function adequately throughout the day. Sleep debt is defined as the difference between the ideal sleep requirement and the actual duration of sleep obtained. There are two divergent views: Harrison and Horner [58] concluded that society is not sleep deprived, whereas Bonnet and Arand [59] stated that modern society is chronically sleep deprived. Between 1910 and 1963, there was a mean reduction of 1.5 h of sleep in adolescents aged 8–17 years [60].

However, there may be a significant sampling error in this survey. A study by Bliwise and associates [61] in healthy adults aged 50–65 years showed a reduction of about one hour of sleep between 1959 and 1980 surveys.

It has been traditionally stated that women need more sleep than men, but this has been questioned in a recent field study [62]. There is also a general perception based on questionnaire, actigraphy, and PSG studies that sleep duration decreases with increasing age [63, 64]. This relationship, however, remains controversial. Older adults take naps, and these naps may compensate for nighttime sleep duration curtailment. Sleep is regulated by homeostasis (increasing sleep drive during continued wakefulness) and circadian factors (the sleep drive varying with time of the day). The influence of these factors is reduced in older adults but is still present. Older adults are also phase advanced (e.g., internal clock set earlier yielding early bedtime and early morning awakenings).

Sleep requirement for an average adult is approximately 7½–8 h regardless of environmental or cultural differences [65]. Most probably whether a person is a long or a short sleeper and sleep need are determined by heredity rather than by different personality traits or other psychological factors. Sleep behavior is regulated by genetics. Sleep duration is influenced by the gene DEC2, mutation of which in some people may reduce sleep duration. Social (e.g., occupational) or biological (e.g., illness) factors may also play a role. Sleep need is genetically determined, but its physiologic mechanism is unknown. Slow-wave activity (SWA) in sleep EEG depends on sleep need and homeostatic drive. Adenosine, a peptide, seems to have a direct role in homeostasis. Prolonged wakefulness causes increased accumulation of adenosine which decreases during sleep. SWA increases after sleep loss. Long sleepers spend more time asleep but have less SWS [66] and more stage 2 NREM sleep than do short sleepers [67]. An early important epidemiological study [68] found that the chances of death from coronary arterial disease, cancer, or stroke are greater for adults who sleep less than 4 h or more than 9 h when compared to those who sleep an average of 7½–8 h. There have been some more recent studies by Kripke et al. [69] and others [70–72] confirming these observations. In later studies, other factors such as sleeping medications may have confounded these issues. There is no clear-cut conclusion yet.

There is controversy whether a person can extend sleep beyond the average requirement. Early studies by Taub and Berger [73, 74] showed that sleep extension beyond the average hours may cause exhaustion and irritability with detriment of sleep efficiency. The authors refer to this as the "Rip Van Winkle" effect [74]. Sleep extension studies in the past reported conflicting results regarding MSLT scores, vigilance, and mood ratings [75]. When subjects are challenged to maximum sleep extension, there is substantial improvement in daytime alertness, reaction time, and mood [75]. Most individuals carry a large sleep debt and as extra sleep reduces carryover sleep debt, it is then no longer possible to obtain extra sleep [76].

Sleep and Dreams

Freud [77] called dreams the "Royal Road to the Unconscious" in his seminal book, The Interpretation of Dreams, published in 1900. The Freudian theory postulated that repressed feelings are psychologically suppressed or hidden in the unconscious mind and often manifested in dreams. Sometimes those feelings are expressed as mental disorders or other psychologically determined physical ailments, according to this psychoanalytic theory. In Freud's view, most of the repressed feelings are determined by repressed sexual desires and appear in dreams or symbols representing sexual organs. In recent times, Freudian theory has fallen in disrepute. The modern sleep scientists try to interpret dreams in anatomic and physiologic terms. Nevertheless, we still cannot precisely define what is "dream" and why we dream. The field of dream research took a new direction since the existence of REM sleep was first observed by Aserinsky and Kleitman [11] in 1953. It is postulated that approximately 80 % of dreams occur during REM sleep and 20 % occur during NREM sleep [78]. It is easier to recall REM dreams than NREM dreams. It is also easier to recall dreams if awakened immediately after the onset of REM dreams rather than trying to remember them the next morning upon getting out of bed. REM dreams are often vivid, highly emotionally charged, unrealistic, complex, and bizarre. In contrast, dream recall which sometimes may partially occur upon awakening from the NREM dream state is more realistic. People are generally oriented when awakening from REM sleep but are somewhat disoriented and confused when awakened from NREM sleep. Most of all, dreams take place in natural color, rather than black and white. In our dreams, we employ all five senses. In general, we use mostly the visual sensations, followed by auditory sensation. Tactile, smell, and taste sensation are represented least. Dreams can be pleasant, unpleasant, frightening, or sad. They generally reflect one's day-to-day activities. Fear, anxiety, and apprehension are incorporated into our dreams. In addition, stressful events of past or present may occupy our dreams. The dream scenes or events are rarely rational but often occur in an irrational manner with rapid change of scene, place, or people or a bizarre mixture of these elements. Sometimes, lucid dreams may arise in which the dreamer seems to realize vividly that he or she is actually dreaming [79].

The neurobiologic significance of dreams remains unknown. Sleep scientists try to explain dreams in the terms

of anatomical and physiological interpretation of REM sleep. During this state, the synapses, nerve cells, and nerve fibers connecting various groups of nerve cells in the brain become activated. This activation begins in the brainstem, and the cerebral hemisphere then synthesizes these signals and creates colorful or black and white images giving rise to dreams. Similarly, signals sometimes become converted into auditory, tactile, or other sensations to cause dream imagery. Why the nerve circuits are stimulated to cause dreaming is not clearly understood. Some suggestions to explain significance of dreams include activation of the neural networks in the brain, [80] restructuring and reinterpretation of data stored in memory [81]. This resembles Jouvet's hypothesis of a relationship between REM sleep and recently acquired information [82]. According to molecular biologist and Nobel laureate Crick and Mitchison [83], the function of dreaming is to unlearn, that is, to remove unnecessary and useless information from the brain. Some have also suggested that memory consolidation takes place during the dream stage of sleep (see Chap. 13). In addition, stories abound regarding artists, writers, and scientists who develop innovative ideas about their art, literature, and scientific projects during dreams. Dream-enacting behavior associated with abnormal movement during sleep (REM behavior disorder) and frightening dreams called nightmares or dream anxiety attacks constitute two important REM parasomnias.

Phylogeny of Sleep

Studies have been conducted to find out whether, like humans, other mammals have sleep stages [1, 84–87]. The EEG recordings of mammals show similarities to those of humans. Both REM and NREM sleep stages can be differentiated by EEG, EMG, and EOG in animals. Dolphins and whales are the only groups of mammals showing no REM sleep on recordings [1, 88, 89]. Although initially thought to have no REM sleep, [90] some recent evidence suggests that Australian spiny anteaters (the monotremes, or egg-laying mammals, *echidna*) do have REM sleep [91–93]. Siegel and colleagues [94] suggest that the echidna combines REM and NREM aspects of sleep in a single sleep state. These authors further suggest that REM and NREM sleep evolved from a single, phylogenetically older sleep state.

Like humans, mammals can be short or long sleepers. There are considerable similarities between sleep duration and length of sleep cycles in small and large animals. Small animals with a high metabolic rate have a shorter life span and sleep longer than larger animals with lower metabolic rates [95]. Smaller animals also have a shorter REM–NREM cycle than larger animals. The larger the animal, the less it sleeps; e.g., elephants sleep 4–5 h and giraffes sleep even less than that.

A striking finding in dolphins is that during sleep, half the brain shows the characteristic EEG features of sleep while the other half shows the EEG features of waking [96]. Each sleep episode lasts approximately 30–60 mins; then, the roles of the two halves of the brain reverse. Similar unihemispheric sleep episodes with eye closure contralateral to the sleeping hemisphere are known to occur in the pilot whale and porpoise [35]. It is of interest to note that there are indications from computerized coherence analysis of such interhemispheric SWS asymmetry even in human with severe OSA during apneic arousals [97, 98].

Both vertebrates and invertebrates display sleep and wakefulness [99]. Most animals show the basic rest–activity rhythms during a 24-h period. There is behavioral and EEG evidence of sleep in birds but the avian REM–NREM cycles are very short [99, 100]. Although birds are thought to have evolved from reptiles, the question of the existence of REM sleep in reptiles remains somewhat controversial [99]. The absence of REM sleep in reptiles and the presence of NREM and REM sleep in both birds and mammals would be in favor of REM sleep being a more recent development in the phylogenetic history of land-dwelling organisms [99]. Sleep has also been noted in invertebrates, such as insects, scorpions, and worms, based on behavioral criteria [100].

In conclusion, the purpose of studying the phylogeny of sleep is to understand the neurophysiologic and neuroanatomic correlates of sleep as one ascends the ladder of phylogeny from inframammalian to mammalian species. Tobler [35] concluded that sleep is homeostatically regulated, in a strikingly similar manner, in a broad range of mammalian species. These similarities in sleep and its regulation among mammals suggest common underlying mechanisms that have been preserved in the evolutionary process.

Circadian Sleep–Wake Rhythm

The existence of circadian rhythms has been recognized since the eighteenth century, when the French astronomer de Mairan [101] noted a 24-hr rhythm in heliotrope plants. The plants closed their leaves at sunset and opened them at sunrise, even when they were kept in darkness, shielded from direct sunlight. The discovery of 24-h rhythm in the movements of plant leaves suggested to de Mairan an "internal clock" in the plant. Experiments by chronobiologists Pittendrigh [102] and Aschoff [103] in 1960 clearly proved the existence of 24-h rhythms in animals.

The term *circadian rhythm*, coined by chronobiologist Halberg [104], is derived from the Latin circa, which means *about*, and *dian*, which means *day*. Experimental isolation from all environmental time cues (German *Zeitgebers*) has clearly demonstrated the existence of a circadian rhythm in humans independent of environmental stimuli [105, 106].

Earlier investigators suggested that the circadian cycle is closer to 25 h than 24 h of a day–night cycle; [1, 107–109] however, recent research points to a cycle near 24 h (approximately 24.2 h). Ordinarily, environmental cues of light and darkness synchronize or entrain the rhythms to the night–day cycle; however, the existence of environment-independent, autonomous rhythm suggests that the human body also has an internal biological clock [1, 105–108].

The experiments in rats in 1972 by Stephan and Zucker [110] and Moore and Eichler [111] clearly identified the site of the biological clock, located in the paired suprachiasmatic nucleus in the hypothalamus, above the optic chiasm. Experimental stimulation, ablation, and lesion of these nuclei altered circadian rhythms. The existence of a circadian pacemaker in the suprachiasmatic nuclei (SCN) in humans was confirmed by Lydic and colleagues [112]. There has been clear demonstration of the neuroanatomic connection between the retina and the suprachiasmatic nuclei—the retinohypothalamic pathway [113]—that sends the environmental cues of light to the SCN. The SCN serves as a pacemaker, and the neurons in the SCN are responsible for generating the circadian rhythms [106, 114–117]. The master circadian clock in the SCN receives afferent information from the retinohypothalamic tract which sends signals to multiple synaptic pathways in other parts of the hypothalamus, plus superior cervical ganglion and pineal gland where melatonin is released. The SCN contains melatonin receptors, and there is a feedback loop from the pineal gland to the SCN. Several neurotransmitters have been located within terminals of the SCN afferents and interneurons, including serotonin, neuropeptide Y, vasopressin, vasoactive intestinal peptide, and γ-aminobutyric acid [106, 116, 118].

Time isolation experiments have clearly shown the presence of daily rhythms coordinated by the master clock, the SCN in many physiological processes such as the sleep–wake cycle, body temperature, and neuroendocrine secretion. Body temperature rhythm is sinusoidal, whereas cortisol and growth hormone secretion rhythms are pulsatile. It is well known that plasma levels of prolactin, growth hormone, and testosterone are all increased during sleep at night (see Chap. 11). Melatonin, the hormone synthesized by the pineal gland (see Chap. 11), is secreted maximally during night and may be an important modulator of human circadian rhythm entrainment by the light–dark cycle. Sleep decreases body temperature, whereas activity and wakefulness increase it. It should be noted that internal desynchronization occurs during free-running experiments, and the rhythm of body temperature dissociates from the sleep rhythm as a result of that desynchronization [2, 106–108] (see Fig. 11.10). This raises the question of whether there is more than one circadian (or internal) clock or circadian oscillator [1]. The existence of two oscillators was postulated by Kronauer and colleagues [119]. They suggested that a 25-h rhythm exists for temperature, cortisol, and REM sleep and that the second oscillator is somewhat labile and consists of the sleep–wake rhythm. Some authors, [120] however, have suggested that one oscillator could explain both phenomena. Recent development in circadian rhythm research has clearly shown the existence of multiple circadian oscillators (peripheral clocks) functioning independently from the SCN [121–124] (Fig. 2.7).

The molecular basis of the mammalian circadian clock has been the focus of much recent circadian rhythm research [125–128] (see Chap. 6). The paired SCN are controlled by a total of 8 or more genes (e.g., Clock, Bmal, Per, Cry, and Tim), and their protein products and regulatory enzymes (e.g., casein kinase 1 epsilon and casein kinase 2 delta), and this knowledge is still evolving. By employing "forward genetics" approach, remarkable progress has been made in a few years in identifying key components of the circadian clock in both the fruit flies (Drosophila) and mammals [125–127]. It has been established that the circadian clock gene of sleep–wake cycle is independent of other circadian rhythm functions. There is clear anatomical and physiological evidence to suggest a close interaction between the SCN and the regions regulating sleep–wake states [128, 129]. There are projections from SCN to wake promoting hypocretin (orexin) neurons (indirectly via dorsomedial hypothalamus) and locus coeruleus as well as to sleep-promoting neurons in ventrolateral and median preoptic neurons. Physiological evidence of increased firing rates in single neuron recordings from the appropriate regions during wakefulness or REM sleep and decreased neuronal firing rates during NREM sleep complement anatomical evidence of such interaction between SCN and sleep–wake regulating systems [129, 130]. Based on the studies in mice (e.g., knockout mice lacking core clock genes and mice with mutant clock genes), it has also been suggested that circadian clock genes may affect sleep regulation and sleep homeostasis independent of circadian rhythm generation in other process [131].

Molecular mechanisms applying gene sequencing techniques have been found to play a critical role in uncovering the importance of clock genes, at least in two human circadian rhythm sleep disorders. Mutation of hPer 2 gene (a human homologue of period gene in Drosophila) causing advancing of the clock (alteration of the circadian timing of sleep propensity) and polymorphism in some familial advanced sleep phase state (ASPS) [132–134] and polymorphism in hPer 3 genes in some subjects with delayed sleep phase state (DSPS) [135, 136] suggest genetic control of the circadian timing of the sleep–wake rhythm. Kolker et al. [137, 138] have shown reduced 24-h expression of BMAL1 and clock genes in the SCN of old golden hamsters pointing to a possible role for the molecular mechanism in understanding age-related changes in the circadian clock.

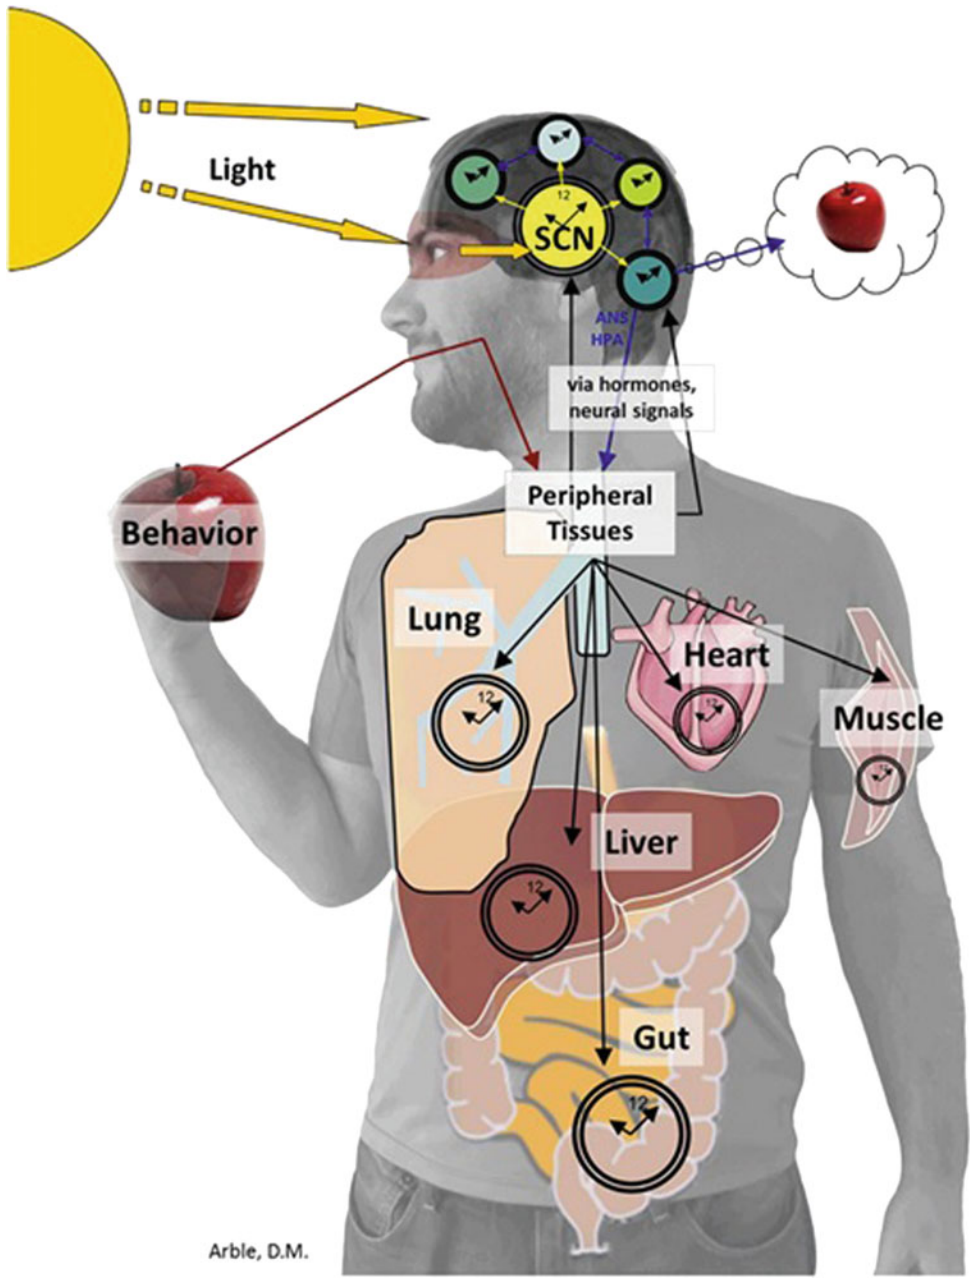

Fig. 2.7 The retinal ganglion cells transmit information about "time of day" via the retinohypothalamic tract to the suprachiasmatic nuclei (SCN), which conveys timing information to the brain including the paraventricular (PVN), arcuate (ARC) nuclei subparaventricular zone (SPZ), medial preoptic area (MPOA), intergeniculate leaflet (IGL), and paraventricular nucleus of the thalamus. The SCN also relays timing cues to peripheral tissues (peripheral oscillators) via the autonomic nervous system and hormones, which together organize complex behaviors. Reproduced with permission from Arble and Sandoval [239]

Kondratov et al. [139] reported that mice deficient in the circadian transcription factor BMAL1 have reduced life span and display a premature aging phenotype. Later, Antoch et al. [140] corroborated these findings by showing that clock mutant mice respond to low-dose irradiation by accelerating this aging process and developing phenotype that are reminiscent of those in BMAL1-deficient mice. It is important to be aware of circadian rhythms, because several other sleep disturbances are related to alteration in them, such as those associated with shift work and jet lag.

Chronobiology, Chronopharmacology, and Chronotherapy

Sleep specialists are becoming aware of the importance of chronobiology, chronopharmacology, and chronotherapy; [141–147] however, studies are spares in these fields. *Chronobiology* refers to the study of the body's biological responses to time-related events. All biological functions of the cells, organs, and the entire body have circadian (approximately 24 h), ultradian (<24 h), or infradian (>24 h) rhythms. It is important, therefore, to understand how the body responds to treatment at different times throughout the circadian cycle and that circadian timing may alter the pathophysiologic responses in various disease states (e.g., exacerbation of bronchial asthma at night and a high incidence of stroke late at night and myocardial infarction early in the morning; see Chap. 47).

Biological responses to medications may also depend on the circadian timing of administration of the drugs. Potential differences of responses of antibiotics to bacteria, or of cancer cells to chemotherapy or radiotherapy, depending on the time of administration, illustrate the importance of chronopharmacology, which refers to pharmacokinetic or pharacodynamic interactions in relation to the timing of the day.

Circadian rhythms can be manipulated to treat certain disorders, a technique called *chronotherapy*. Examples of this are phase advance or phase delay of sleep rhythms and application of bright light at certain periods of the evening and morning.

Cytokines, Immune System, and Sleep Factors

Cytokines are proteins produced by leukocytes and other cells functioning as intercellular mediators that may play an important role in immune and sleep regulation [148–156] (see also Chap. 12). Several cytokines such as interleukin (IL), interferon alpha (IF-α), and tumor necrosis factor (TNF) have been shown to promote sleep. There are other sleep-promoting substances called sleep factors which increase in concentration during prolonged wakefulness or during infection and enhance sleep. These other factors include delta sleep-inducing peptides, muramyl peptides, cholecystokinin, arginine vasotocin, vasoactive intestinal peptide, growth hormone-releasing hormone (GHRH), somatostatin, prostaglandin D_2 nitric oxide (NO), and adenosine. The role of these various sleep factors in maintaining homeostasis has not been clearly established [148]. It has been shown that adenosine in the basal forebrain can fulfill the major criteria for the neural sleep factor that mediates these somnogenic effects of prolonged wakefulness by acting through A1 and A2a receptors [157, 158].

The cytokines play a role in the cellular and immune changes noted during sleep deprivation [148, 149, 159–163]. The precise nature of the immune response after sleep deprivation has, however, remained controversial, and the results of studies on the subject have been inconsistent. These inconsistencies may reflect different stress reactions of subjects and different circadian factors (e.g., timing of drawing of blood for estimation of plasma levels) [148, 159, 164].

Infection (bacterial, viral, and fungal) enhances NREM sleep but suppresses REM sleep. It has been postulated that sleep acts as a host defense against infection and facilitates the healing process [148, 159, 163, 165–168]. It is also believed that sleep deprivation may increase vulnerability to infection [169]. The results of experiments with animals suggest that sleep deprivation alters immune function [1, 159, 160, 165]. Sleep thus has a profound impact on the immune system. It has been shown [170] that following sleep deprivation (e.g., sleeping four hours per night for four nights), there was a delay in immune response 10 days after flu vaccination.

There is evidence that cytokines play an important role in the pathogenesis of excessive daytime sleepiness in a variety of sleep disorders and in sleep deprivation [170–173]. Sleep deprivation causing excessive sleepiness has been associated with increased production of proinflammatory cytokines IL-6 and TNF-α [172, 173]. Viral or bacterial infections causing excessive somnolence and increased NREM sleep are associated with increased production of TNF-α and IL-B [174–176]. In other inflammatory disorders such as HIV infection and rheumatoid arthritis, increased sleepiness and disturbed sleep are associated with increased amount of circulating TNF-α [177–180]. Several authors suggested that excessive sleepiness, in OSAS, narcolepsy, insomnia, or idiopathic hypersomnia may be mediated by cytokines such as IL-6 and TNF-α [181–187]. In a recent review, Kapsimalis et al. [170] concluded that cytokines are mediators of sleepiness and implicated in the pathogenesis of symptoms of OSAS, narcolepsy, sleep deprivation, and insomnia and indirectly play an important role in the pathogenesis of the cardiovascular complications of OSAS.

Theories of the Function of Sleep

The function of sleep remains the greatest biologic mystery of all times. Several theories of the function of sleep have been proposed (Box 2.5). None of the theories are satisfactory to explain the exact biologic functions of sleep. Sleep deprivation experiments in animals have clearly shown that sleep is necessary for survival, but from a practical point of view, complete sleep deprivation for a prolonged period cannot be conducted in humans. Sleep deprivation studies in humans have shown an impairment of performance which demonstrates the need for sleep (see also Chap. 3). The

performance impairment of prolonged sleep deprivation results from a decreased motivation and frequent "micro-sleep." Overall, human sleep deprivation experiments have proven that sleep deprivation causes sleepiness and impairment of performance, vigilance, attention, concentration, and memory. Sleep deprivation may also cause some metabolic, hormonal, and immunologic affects. Sleep deprivation causes immune suppression, and even partial sleep deprivation reduces cellular immune responses. Studies by Van Cauter's group [188, 189] include a clearly documented elevation of cortisol level following even partial sleep loss suggesting an alteration in the hypothalamic–pituitary–adrenal (HPA) axis function. This has been confirmed even in chronic sleep deprivation which causes impairment of glucose tolerance. Glucose intolerance may contribute to memory impairment as a result of decreased hippocampal function. Chronic sleep deprivation may also cause a detriment of thyrotropin concentration, increased evening cortisol level, and sympathetic hyperactivity which may serve as risk factors for obesity, hypertension, and diabetes mellitus. It should, however, be noted that in all of these sleep deprivation experiments, stress has been a confounding factor, raising a question about whether all these undesirable consequences relate to sleep loss only or a combination of stress and sleeplessness.

Box 2.5: Theories of Sleep Function

- Restorative theory
- Energy conservation theory
- Adaptive theory
- Instinctive theory
- Memory consolidation and reinforcement theory
- Synaptic and neuronal network integrity theory
- Thermoregulatory theory
- Immune and endocrine regulation
- Metabolic homeostasis theory

Restorative Theory

Proponents of the restorative theory ascribe body tissue restoration to NREM sleep and brain tissue restoration to REM sleep [190–193]. The findings of increased secretion of anabolic hormones [194–196] (e.g., growth hormone, prolactin, testosterone, luteinizing hormone) and decreased levels of catabolic hormones [197] (e.g., cortisol) during sleep, along with the subjective feeling of being refreshed after sleep, may support such a contention. Increased SWS (rebound) after sleep deprivation [1] further supports the role of NREM sleep as restorative. The critical role of REM sleep for the development of the CNS of young organisms is cited as evidence of restoration of brain functions by REM sleep [198]. Several studies of brain basal metabolism suggest an enhanced synthesis of macromolecules such as nucleic acids and proteins in the brain during sleep, [199] but the data remain scarce and controversial. Protein synthesis in the brain is increased during SWS [200]. Confirmation of such cerebral anabolic processes would provide an outstanding argument in favor of the restorative theory of sleep. Recent work in animals suggests formation of new neurons during sleep in adult animals and this neurogenesis in dentate gyrus may be blocked after total sleep deprivation [201].

Energy Conservation Theory

Zepelin and Rechtschaffen [95] found that animals with a high metabolic rate sleep longer than those with a slower metabolism, suggesting that energy is conserved during sleep. There is an inverse relationship between body mass and metabolic rate. Small animals (e.g., rats and opossum) with high metabolic rate sleep for 18 h per day, whereas large animals (e.g., elephants and giraffes) with low metabolic rates sleep only for 3–4 h. It has been suggested that high metabolic rates cause increased oxidative stress and injury to self-leading to the hypothesis [202] that higher metabolic rates in the brain require longer sleep time to counteract the cell damage by free radicals, and facilitate synthesis of molecules protecting brain cells from this oxidative stress. During NREM sleep, brain energy metabolism and cerebral blood flow decrease, whereas during REM sleep, the level of metabolism is similar to that of wakefulness and the cerebral blood flow increases. In summary, sleep-related reduction in general metabolism including metabolic heat production, lowering of core body temperature, and certain behavioral signs (e.g., immobile posture minimizing heat exchange) conserve energy. Although these findings might suggest that NREM sleep helps conserve energy, the fact that only 120 calories are conserved in 8 h of sleep makes the energy conservation theory less than satisfactory. Considering that humans spend one-third of their lives sleeping, [203] one would expect far more calories to be conserved during an 8-h period if energy conservation was the function of sleep.

Adaptive Theory

In both animals and humans, sleep is an adaptive behavior that allows the creature to survive under a variety of environmental conditions [204, 205].

Instinctive Theory

The instinctive theory views sleep as an instinct [190, 206], which relates to the theory of adaptation and energy conservation.

Memory Consolidation and Reinforcement Theory

The sleep–memory consolidation hypothesis is a hotly debated issue with both proponents and opponents with proponents

outnumbering the opponents. In fact, McGaugh et al. [207] earlier suggested that sleep- and waking-related fluctuations of hormones and neurotransmitters may modulate memory processes. Crick and Mitchison [83] suggested that REM sleep removes undesirable data from the memory. In a later report, these authors hypothesized that the facts that REM deprivation produces a large rebound and that REM sleep occurs in almost all mammals make it probable that REM sleep has some important biological function [208].

The theory that memory reinforcement and consolidation take place during REM sleep has been strengthened by scientific data provided by Karni et al. [209]. These authors conducted selective REM and SWS deprivation in six young adults. They found that perceptual learning during REM deprivation was significantly less compared with perceptual learning during SWS deprivation. In addition, SWS deprivation had a significant detrimental effect on a task that was already learned. These data suggest that REM deprivation affected the consolidation of the recent perceptual experience, thus supporting the theory of long-term consolidation during REM sleep. Recent studies by Stickgold and Walker [210] and Walker and Stickgold [211] strongly supported the theory of sleep–memory consolidation (see Chap. 13). There is further suggestion by Hu et al. [212] that the facilitation of memory for emotionally salient information may preferentially develop during sleep. Stickgold's group concluded that unique neurobiological processes within sleep actively promote declarative memories [213]. Several studies in the past decade have provided evidence to support the role of sleep in sleep-dependent memory processing which include memory encoding, memory consolidation and reconsolidation, and brain plasticity (see review by Kalia) [214]. Hornung et al. [215] using a paired associate word list to test declarative memory and mirror-tracking tasks to test procedural learning in 107 healthy older adults aged 60–82 years concluded that REM sleep plays a role in procedural memory consolidation. Walker's group [216] concluded after sleep deprivation experiments that sleep before learning is critical for human memory consolidation. Born et al. [217] concluded that hippocampus-dependent memories (declarative memories) benefit primarily from SWS. They further suggested that the different patterns of neurotransmitters and neurohormone secretion between sleep stages may be responsible for this function. Backhaus and Junghanns [218] randomly assigned 34 young healthy subjects to a nap or wake condition of about 45 mins in the early afternoon after learning procedural and declarative memory tasks. They noted that naps significantly improved procedural but not declarative memory, and therefore, a short nap is favorable for consolidation of procedural memory. Goder et al. [219] tested the role of different aspects of sleep for memory performance in 42 consecutive patients with non-restorative sleep. They used Rey–Osterrieth Complex Figure Test and the paired associative word list for declarative memory function and mirror-tracking tasks for procedural learning assessment. The results supported the contention that visual declarative memory performance is significantly associated with total sleep time, sleep efficiency, duration of NREM sleep, and the number of NREM–REM sleep cycles but not with specific measures of REM sleep or slow-wave sleep. In contrast to all these studies, Vertes and Siegel [220–223] took the opposing position contending that REM sleep is not involved in memory consolidation or at least not in humans citing several lines of evidence. Vertes and Siegal [220] cited the work of Smith et al. [224, 225] that REM sleep is not involved with memory consolidation. Schabus et al. [226] agreed that declarative material learning is not affected by sleep. In their study, subjects showed no difference in the percentage of word pairs correctly recalled before and after 8 h of sleep. The strongest evidence cited by Vertes and Siegel [220] includes examples of individuals with brain stem lesions with elimination of REM sleep [227] or those on antidepressant medications suppressing REM sleep exhibiting no apparent cognitive deficits. Vertes and Siegel [220] concluded that REM sleep is not involved in declarative memory and REM sleep is not critical for cognitive processing in sleep.

In summary, based on recent studies in our understanding of molecular mechanisms of memory, it can be stated reasonably that sleep strengthens new memories, i.e., sleep can rescue memories that are lost during wakefulness requiring synthesis of new proteins and ribonucleic acid (RNA) by the neurons. Memory consolidation and reconsolidation require both NREM (sleep spindles and SWS) and REM sleep.

Synaptic and Neuronal Network Integrity Theory

There is a new theory emerging that suggests the primary function of sleep is the maintenance of synaptic and neuronal network integrity [203, 228–230]. According to this theory, sleep is important for the maintenance of synapses that have been insufficiently stimulated during wakefulness. Intermittent stimulation of the neural network is necessary to preserve CNS function. This theory further suggests that NREM and REM sleep serve the same function of synaptic reorganization [228]. This emerging concept of the "dynamic stabilization" (i.e., repetitive activations of brain synapses and neural circuitry) theory of sleep suggests that REM sleep maintains motor circuits, whereas NREM sleep maintains nonmotor activities [228, 230]. Gene expression [231] studies using the DNA microarray technique identified sleep- and wakefulness-related genes (brain transcripts) subserving different functions (e.g., energy metabolism, synaptic excitation, long-term potentiation, and response to cellular stress during wakefulness; and protein synthesis, memory consolidation, and synaptic downscaling during sleep).

Thermoregulatory Function Theory

The thermoregulatory function theory is based on the observation that thermoregulatory homeostasis is maintained during sleep, whereas severe thermoregulatory abnormalities follow total sleep deprivation [232]. The preoptic anterior hypothalamic neurons participate in thermoregulation and NREM sleep (see also Chap. 11). These two processes are closely linked by preoptic anterior hypothalamic neurons but are clearly separate. Thermoregulation is maintained during NREM but suspended during REM sleep. Thermoregulatory responses such as shivering, piloerection, panting, and sweating are impaired during REM sleep. There is a loss of thermosensitivity in the preoptic anterior hypothalamic neurons during REM sleep.

Role of Sleep in Immune and Endocrinal Regulation

This has been briefly outlined above

Metabolic Homeostasis Theory

Recent discovery of a new metabolic waste clearing pathway (equivalent to the lymphatic system in the body) in the CNS of mice directs our attention to a new understanding of the function of sleep. This also is beginning to answer a long-standing question of mechanism of clearing of metabolic byproducts of the brain in the absence of a lymphatic system. This pathway was termed "the glymphatic system" by the original researchers led by Nedergaard [233–235] because of its dependence on glial cells (astrocytes) performing a "lymphatic"-like cleansing of the brain interstitial fluid in the perivascular space between the brain blood vessels and leptomeningeal sheathes surrounding these vessels. These researchers have shown that this extracellular space expanded by about 60 % along with shrinkage of the glial cells in the sleeping brain as compared with that in the waking brain to promote clearance of interstitial waste products [234] (Fig. 2.8). Sleep, therefore, restores the function of the brain by promoting glymphatic clearance of neural metabolic waste products accumulated in the waking brain. The investigators have further shown the ability of this system to remove misfolded or aggregated proteins by experimental injection of labeled beta amyloid proteins into the brains of sleeping and awake mice [236, 237]. Cerebrospinal fluid cleared these proteins outside of the cells twice as fast during sleep as during wakefulness. These findings may revolutionize our understanding of sleep dysfunction in many neurodegenerative diseases resulting from proteinopathies (e.g., Alzheimer's disease, Parkinson's disease, and others). Once these findings are replicated in humans using sophisticated neuroimaging techniques, this discovery will electrify the scientific world of sleep toward drug development to prevent or halt the progression of these neurodegenerative diseases.

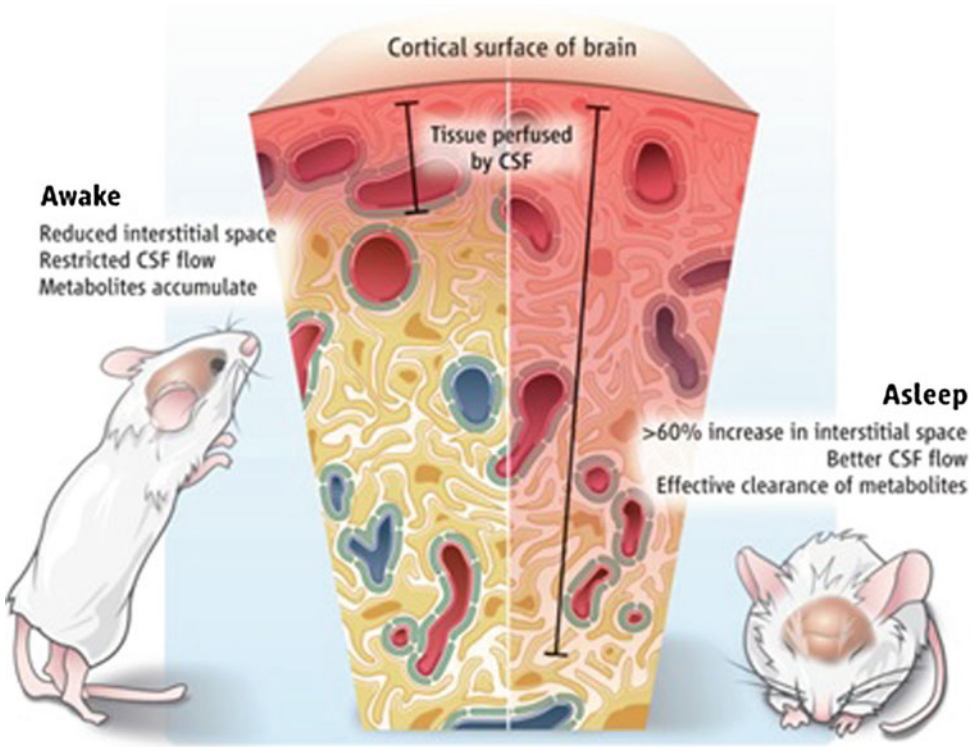

Fig. 2.8 Physiological differences in cerebrospinal fluid (CSF) flow between the awake and the sleeping states in mice. The tissues perfused by CSF including blood vessels are indicated in *red* (arteries) and *blue* (veins). The interstitial space in the mouse cerebral cortex, through which cerebrospinal fluid moves, increases from 14 % in the awake to 23 % in the sleeping animal, an increase that allows the faster clearance of metabolic waste products. Reproduced with permission from Herculano-Houzel [240]

Sleep Deprivation and Excessive Daytime Sleepiness

3

Sudhansu Chokroverty

Circadian Rhythm and Homeostasis

Sleep and wakefulness are controlled by both homeostatic and circadian factors. The duration of prior wakefulness determines the propensity to sleepiness (homeostatic factor) [1], whereas circadian factors [2] determine the timing, duration, and characteristics of sleep. There are two types of sleepiness: physiologic and subjective [3]. Physiologic sleepiness is the body's propensity to sleepiness. There are two highly vulnerable periods of sleepiness: 2:00–6:00 A.M. (particularly 3:00–5:00 A.M.) and 2:00–6:00 P.M. (especially 3:00–5:00 P.M.). The propensity to physiologic sleepiness (e.g., mid-afternoon and early morning hours) depends on circadian and homeostatic factors [4]. The highest number of sleep-related accidents has been observed during these periods. Subjective sleepiness is the individual's perception of sleepiness; it depends on several external factors, such as a stimulating environment and ingestion of coffee and other caffeinated beverages. Homeostasis refers to a prior period of wakefulness and sleep debt. After a prolonged period of wakefulness, there is an increasing tendency to sleep. The recovery from sleep debt is aided by an additional amount of sleep, but this recovery is not linear. Thus, an exact number of hours of sleep are not needed to repay a sleep debt; rather, the body needs an adequate amount of slow-wave sleep (SWS) for restoration. The circadian factor determines the body's propensity to maximal sleepiness (e.g., between 3:00 and 5:00 A.M.). The second period of maximal sleepiness (3:00–5:00 P.M.) is not as strong as the first. Sleep/wakefulness and the circadian pacemaker have a reciprocal relationship; the biological clock can affect sleep and wakefulness, and sleep and wakefulness can affect the clock. The neurologic basis of this interaction is, however, unknown. In this chapter, I briefly review experimental sleep deprivation, the population at risk of sleep deprivation, and the causes and consequences of excessive sleepiness (Box 3.1).

Sleep Deprivation and Sleepiness

Many Americans (e.g., doctors, nurses, firefighters, interstate truck drivers, police officers, overnight train drivers and engineers) work irregular sleep–wake schedules and alternating shifts, making them chronically sleep deprived [5, 6]. A survey study [5] found that, compared with the population at the turn of the century (1910–1911), American adolescents aged 8–17 years in 1963 were sleeping 1.5 h less per 24-h period. This does not mean we need less sleep today but that people are sleep deprived. That there may, however, be a sampling error in these surveys (e.g., approximately 2000 people were surveyed in 1910–1911, vs. 311 in the later survey). A study by Bliwise et al. [7] in healthy adults aged 50–65 years showed a reduction of about 1 h of sleep per 24 h between 1959 and 1980 surveys. Factors that have been suggested to be responsible for this reduction of total sleep include environmental and cultural changes, such as increased environmental light, increased industrialization, growing numbers of people doing shift work, and the advent of television and radio. A review of the epidemiologic study by Partinen [8] estimated a prevalence of excessive sleepiness in Westerners at an average of 5–15 % of the total population. In contrast, Harrison and Horne [9] argued that most people are not chronically sleep deprived but simply choose not to sleep as much as they could.

What are the consequences of sleep deprivation? This question has been explored in studies of total, partial, and selective sleep deprivation (e.g., SWS or rapid eye movement [REM] sleep deprivation). These studies have conclusively proved that sleep deprivation causes sleepiness; decrement of performance, vigilance, attention, and concentration; and

Box 3.1 Causes of excessive daytime sleepiness

Physiologic causes
Sleep deprivation and sleepiness related to lifestyle and irregular sleep–wake schedule
Pathologic causes
Primary sleep disorders
Obstructive sleep apnea syndrome
Central sleep apnea syndrome with or without Cheyne–Stokes breathing
Sleep-related hypoventilation disorders
Sleep-related hypoxemia disorder
Circadian rhythm sleep disorders
Jet lag
Delayed sleep phase syndrome
Irregular sleep–wake pattern
Shift work sleep disorder
Non-24-h sleep–wake disorders
Central disorders of hypersomnolence
Narcolepsy (type 1 and type 2)
Idiopathic hypersomnolence
Kleine–Levin syndrome
Hypersomnia due to a medical disorder
Hypersomnia associated with a psychiatric disorder
Insufficient sleep syndrome
Medication-related hypersomnia
Benzodiazepines
Nonbenzodiazepine hypnotics (e.g., phenobarbital, zolpidem)
Sedative antidepressants (e.g., tricyclics, trazodone)
Antipsychotics
Nonbenzodiazepine anxiolytics (e.g., buspirone)
Antihistamines
Narcotic analgesics, including tramadol (Ultram)
Toxin and alcohol-induced hypersomnolence
General medical disorders
Hepatic failure
Renal failure
Respiratory failure
Electrolyte disturbances
Cardiac failure
Severe anemia
Endocrine causes
Hypothyroidism
Acromegaly
Diabetes mellitus
Hypoglycemia
Hyperglycemia
Psychiatric or psychological causes
Depression
Psychogenic unresponsiveness or sleepiness
Neurologic causes
Brain tumors or vascular lesions affecting the thalamus, hypothalamus, or brain stem
Post-traumatic hypersomnolence
Multiple sclerosis
Encephalitis lethargica and other encephalitides and encephalopathies, including Wernicke's encephalopathy
Cerebral trypanosomiasis (African sleeping sickness)
Neurodegenerative disorders
Alzheimer's disease
Parkinson's disease
Multiple system atrophy
Myotonic dystrophy and other neuromuscular disorders causing sleepiness secondary to sleep apnea
Miscellaneous
Periodic limb movements disorder
Restless legs syndrome
Insufficient sleep syndrome
Inadequate sleep hygiene

increased reaction time. The performance decrement resulting from sleep deprivation may be related to periods of microsleep. *Microsleep* is defined as transient physiologic sleep (i.e., 3- to 14-second electroencephalographic patterns change from those of wakefulness to those of stage I nonrapid eye movement [NREM] sleep) with or without rolling eye movements and behavioral sleep (e.g., drooping or heaviness of the eyelids, slight sagging and nodding of the head).

The most common cause of excessive daytime sleepiness (EDS) today is sleep deprivation. In the survey by Partinen [8], up to one-third of young adults have EDS secondary to chronic partial sleep deprivation, and approximately 7 % of middle-aged individuals have EDS secondary to sleep disorders and 2 % secondary to shift work. Sleep deprivation poses danger to the individuals experiencing it as well as to others, making people prone to accidents in the work place, particularly in industrial and transportation work. The incidence of automobile crashes increases with driver fatigue and sleepiness. Fatigue resulting from sleep deprivation may have been responsible for many major national and international catastrophes [10]. Although both sleep deprivation (SD) and sleep fragmentation (SF) may cause EDS, they are two different phenomena [11]. SD (total, partial, selective) determines sleep duration, whereas SF denotes an interruption of normal continuity of sleep with frequent and transient arousals (e.g., OSAS, RLS/WED-PLMS).

Sleep Deprivation Experiments

Although neither humans nor animals can do without sleep, the amount of sleep necessary to individual people or species varies widely. We know that a lack of sleep leads to sleepiness, but we do not know the exact functions of sleep. Sleep deprivation experiments in animals have clearly shown that sleep is necessary for survival. The experiments of Rechtschaffen et al. [12] with rats using the carousel device have provided evidence for the necessity of sleep. All rats deprived of sleep for 10–30 days died after having lost weight, despite increases in their food intake. The rats also lost temperature control. Rats deprived only of REM sleep lived longer. Complete sleep deprivation experiments for prolonged periods (weeks to months) cannot be conducted in humans for obvious ethical reasons.

Total Sleep Deprivation

One of the early sleep deprivation experiments in humans was conducted in 1896 by Patrick and Gilbert [13] who studied the effects of a 90-h period of sleep deprivation on three healthy young men. One reported sensory illusions, which disappeared completely when, at the end of the experiment, he was allowed to sleep for 10 h. All subjects had difficulty staying awake, but felt totally fresh and rested after they were allowed to sleep.

A spectacular experiment in the last century was conducted in 1965. A 17-year-old California college student named Randy Gardner tried to set a new world record for staying awake. Dement [14] observed him during the later part of the experiment. Gardner stayed awake for 264 h and 12 min and then slept for 14 h and 40 min. He was recovered fully when he awoke. The conclusion drawn from the experiment is that it is possible to deprive people of sleep for a prolonged period without causing serious mental impairment. An important observation is the loss of performance with long sleep deprivation, which is due to loss of motivation and the frequent occurrence of microsleep.

In another experiment, Johnson and MacLeod [15] showed that it is possible to intentionally reduce total sleeping time by 1–2 h without suffering any adverse effects. The experiments by Carskadon and Dement [16, 17] showed that sleep deprivation increases the tendency to sleep during the day. This has been conclusively proved using the Multiple Sleep Latency Test with subjects [17, 18].

During the recovery sleep period after sleep deprivation, the percentage of SWS (stages 3 and 4 NREM sleep using Rechtschaffen–Kales scoring criteria) increases considerably. Similarly, after a long period of sleep deprivation, the REM sleep percentage increases during recovery sleep. (This increase has not been demonstrated after a short period of sleep deprivation, that is, up to 4 days.) These experiments suggest that different mechanisms regulate NREM and REM sleep [19].

Partial Sleep Deprivation

Measurements of mood and performance after partial sleep deprivation (e.g., restricting sleep to 4.5–5.5 h for 2–3 months) showed only minimal deficits in performance, which may have been related to decreased motivation. Later, studies have conclusively proven that total and partial sleep deprivation produce deleterious effects in humans (see under summary).

Selective REM Sleep Deprivation

Dement [20] performed REM sleep deprivation experiments (by awakening the subject for 5 min at the moment the polysomnographic recording demonstrated onset of REM sleep). Polysomnography results showed increased REM pressure (i.e., earlier and more frequent onset of REM sleep during successive nights) and REM rebound (i.e., quantitative increase of REM percentage during recovery nights). These findings were subsequently replicated by Borbely [19] and others [21, 22], but Dement's third observation—a psychotic reaction following REM deprivation—could not be replicated in subsequent investigations [21].

Stage 4 Sleep Deprivation

Agnew et al. [23] reported that, after stage 4 NREM sleep deprivation for 2 consecutive nights, there was an increase in stage 4 sleep during the recovery night. Two important points were raised by this group's later experiments: (1) REM rebound was more significant than stage 4 rebound during recovery nights, and (2) it was more difficult to deprive a person of stage 4 sleep than of REM sleep [22].

Summary

The effects of total sleep deprivation, as well as of REM sleep deprivation, are similar in animals and humans, suggesting that the sleep stages and the fundamental regulatory mechanisms for controlling sleep are the same in all mammals. These experiments and later human studies have proven conclusively that sleep deprivation causes sleepiness and impairment of performance, vigilance, attention, and

concentration, causing serious consequences involving many body systems as well as affecting short- and long-term memories [24–27]. One problem with these SD experiments is the introduction of the confounding factor of stress, and therefore, these experiments may not ideally reproduce the human sleep deprivation conditions.

Consequences of EDS Resulting from Sleep Deprivation or Sleep Restriction

EDS adversely affects performance and productivity at work and school, higher cerebral functions, and quality of life and social interactions and increases morbidity and mortality [24–37].

Performance and Productivity at Work or School

Impaired performance and reduced productivity at work for shift workers; reduced performance in class for school and college students; and impaired job performance in patients with narcolepsy, sleep apnea, circadian rhythm disorders, and chronic insomnia are well-known adverse effects of sleep deprivation and sleepiness. Sleepiness and associated morbidity are worse in night-shift workers, older workers, and female shift workers.

Higher Cerebral Functions

Sleepiness interferes with higher cerebral functions, causing impairment of short-term memory, concentration, attention, cognition, and intellectual performance. Psychometric tests [3, 25] have documented increased reaction time in patients with excessive sleepiness. These individuals make increasing numbers of errors, and they need increasing time to reach the target in reaction time tests [3, 25]. Sleepiness can also impair perceptual skills and new learning. Insufficient sleep and excessive sleepiness may cause irritability, anxiety, and depression. There is a U-shaped relationship between sleep duration and depression similar to that between sleep duration and mortality [38]. Both short (<6 h) and long (>8 h) sleep durations are associated with depression. Learning disabilities and cognitive impairment with impaired vigilance also have been described [36]. This adverse impact of sleep deprivation on cognition may lead to increased number of failures to carry out intended actions causing serious consequences for safety in critical situations [39].

Quality of Life and Social Interaction

People complaining of EDS are often under severe psychological stress. They are often lonely and perceived as dull, lazy, and downright stupid. Excessive sleepiness may cause severe marital and social problems. Narcoleptics with EDS often have serious difficulty with interpersonal relationships, as well as impaired health-related quality of life, and are misunderstood because of the symptoms [40]. Shift workers constitute approximately 20–25 % of the workforce in America (i.e., approximately 20 million). The majority of them have difficulty with sleeping and sleepiness as a result of insufficient sleep and circadian dysrhythmia. Many of them have an impaired quality of life, marital discord, and gastrointestinal problems.

Increased Morbidity and Mortality

Short-term Consequences

Persistent daytime sleepiness causes individuals to have an increased likelihood of accidents. A study by the US National Transportation Safety Board (NTSB) found that the most probable cause of fatal truck accidents was sleepiness-related fatigue [41]. In another study by the NTSB [42], 58 % of the heavy-truck accidents were fatigue related and 18 % of the drivers admitted having fallen asleep at the wheel. The NTSB also reported sleepiness- and fatigue-related motor coach [43, 44] and railroad [45] accidents. New York State police estimated that 30 % of all fatal crashes along the New York throughway occurred because the driver fell asleep at the wheel. Approximately 1 million crashes annually (one-sixth of all crashes) are thought to be produced by driver inattention or lapses [46, 47]. Sleep deprivation and fatigue make such lapses more likely to occur. Truck drivers are especially susceptible to fatigue-related crashes [41, 42, 48–51]. Many truckers drive during the night while they are the sleepiest. Truckers may also have a high prevalence of sleep apnea [52]. The US Department of Transportation estimated that 200,000 automobile accidents each year may be related to sleepiness. Nearly one-third of all trucking accidents that are fatal to the driver are related to sleepiness and fatigue [53]. A general population study done by Hays et al. [54] involving 3962 elderly individuals reported an increased mortality risk of 1.73 in those with EDS, defined by napping most of the time. The presence of sleep disorders (see section "Primary Sleep Disorders Associated with EDS" later in this chapter) increases the risk of crashes. Individuals with untreated

insomnia, sleep apnea, or narcolepsy and shift workers—all of whom may suffer from excessive sleepiness—have more automobile crashes than other drivers [55].

A telephone survey [56] of a random sample of New York State licensed drivers by the State University of New York found that 54.6 % of the drivers had driven while drowsy within the past year, 1.9 % had crashed while drowsy, and 2.8 % had crashed when they fell asleep. Young male drivers are especially susceptible to crashes caused by falling asleep, as documented in a study in North Carolina [57] in 1990, 1991, and 1992 (e.g., in 55 % of the 4333 crashes, the drivers were predominantly male and 25 years of age or younger). Surveys in Europe also noted an association between crashes and long-distance automobile and truck driving [50, 58–61]. A 1991 Gallup organization [62] national survey found that individuals with chronic insomnia reported 2.5 times as many fatigue-related automobile accidents as did those without insomnia. The same 1991 Gallup survey found serious morbidity associated with untreated sleep complaints, as well as impaired ability to concentrate and accomplish daily tasks, and impaired memory and interpersonal discourse. In a 1999 Gallup Poll [63], 52 % of all adults surveyed said that, in the past year, they had driven a car or other vehicle while feeling drowsy, 31 % of adults admitted dozing off while at the wheel of a car or other vehicle, and 4 % reported having had an automobile accident because of tiredness during driving. A number of national and international catastrophes [10] involving industrial operations, nuclear power plants, and all modes of transportation have been related to sleepiness and fatigue, including the Exxon Valdez oil spill in Alaska; the nuclear disaster at Chernobyl in the former Soviet Union; the near-nuclear disaster at 3-Mile Island in Pennsylvania; the gas leak disaster in Bhopal, India, resulting in 25,000 deaths; and the Challenger space shuttle disaster in 1987.

Long-term Consequences

In addition to these short-term consequences, sleep deprivation or restriction causes a variety of long-term adverse consequences affecting several body systems and thus increasing the morbidity and mortality [24–37, 64].

Sleep Deprivation and Obesity

The prevalence of obesity in adults in the United States was 15 % in 1970 and increased to 31 % in 2001 [65]. In children, the figures for obesity were 5 % in 1970 and went up to 15 % in 2001. In the Zurich study [66], 496 Swiss adults followed for 13 years showed a body mass index (BMI) of 21.8 at age 27 that increased to 23.3 at the age of 40, with concurrent decrease in sleep duration from 7.7 to 7.3 h in women and 7.1 to 6.9 h in men. This longitudinal study confirms the cross-sectional studies in adults [67] and children [68]. In the Wisconsin sleep cohort study [69] (a population-based longitudinal study) using 1024 volunteers, short sleep was associated with reduced leptin and elevated ghrelin contributing to increased appetite, causing increased BMI. Several other more recent studies using various approaches have also documented the association of obesity or weight gain with short sleep duration [29, 30, 70–72]. In the study by Altman et al. [72], sleep duration of less than five hours was associated with an additional BMI point of 2.7 and this strong association was not accounted for perceived insufficient sleep. A large-scale prospective study found that the incidence of obesity at one-year follow-up was higher among Japanese men sleeping five hours or less compared with those sleeping seven hours [28].

Sleep Duration and Hypothalamo-pituitary Hormones

Elevated evening cortisol levels, reduced glucose tolerance, and altered growth hormone secretion after experimental acute sleep restriction by Spiegel et al. [73, 74] suggest that participation of the hypothalamic–pituitary axis may contribute toward obesity after sleep deprivation by leading to increased hunger and appetite. There is epidemiologic evidence of reduced sleep duration associated with reduced leptin (a hormone in adipocytes stimulating the satiety center in the hypothalamus), increased ghrelin (an appetite stimulant gastric peptide), and increased BMI [75, 76]. Spiegel et al. [73] in studies using sleep restriction (4 h per night for 6 nights) and sleep extension (12 h per night for 6 nights) experiments in healthy young adults found increased evening cortisol, increased sympathetic activation, decreased thyrotropin activity, and reduced glucose tolerance in the sleep-restricted group. Rogers et al. [77] found similar elevation of evening cortisol levels following chronic sleep restriction. In recurrent partial sleep restriction studies in young adults, the following endocrine and metabolic alterations have been documented [78]: (1) decreased glucose tolerance and insulin sensitivity and (2) decreased levels of the anorexigenic hormone leptin and increased levels of the orexigenic peptide ghrelin. A combination of these findings caused increased hunger and appetite leading to weight gain. Because of these changes, short sleep duration is a risk factor for diabetes and obesity.

Several epidemiologic studies have shown an association between sleep duration and type 2 diabetes mellitus [79]. Ayas et al. [80] found an association between long sleep duration (>9 h) and diabetes mellitus. Yaggi et al. [81] reported an association between diabetes and both short (<5 h) and long (>8 h) sleep duration. Several other reviews [82–85] including some recent studies [29, 30, 32, 83, 86–90] supported a link between sleep duration, particularly short sleep duration and diabetes mellitus. Buxton and

Marcelli [29] used the 2004–2005 National Health Interview Survey (NHIS), and Shankar et al. [30] used the 2008 Behavioral Risk Factor Surveillance System (BRFSS) to find a positive correlation between short sleep duration and diabetes. Hancox and Landhuis [90] from a study conducted in New Zealand found an association between short sleep duration and prediabetes as well as an association between HgA1C and sleep duration.

Sleep Duration and Mortality

Epidemiologic studies by Kripke et al. [91, 92] and Hublin et al. [93] showed increased mortality in short sleepers (also in relatively long sleepers). There is a U-shaped association between sleep duration (both long and short) and mortality [27, 38, 94–96]. The earliest study was by Hammond in 1964 [97]. Another significant early study by Kripke et al. [91, 92] in 1979 found that the chances of death from coronary artery disease, cancer, or stroke are greater for adults who sleep less than 4 h or more than 9 h when compared to those who sleep an average of 7½–8 h. The latest studies by Kripke et al. in 2002 [98] confirmed the earlier observations and documented an increased mortality in those sleeping less than 7 h and those sleeping more than 7½ h. Other factors, such as sleeping medication, may have confounded these issues. In more recent studies, Gallicchio and Kalesan [95] conducted meta-analysis using 23 studies from 2007 to 2009 and Cappuccio et al. [27] using 16 studies from 1993 to 2009 a relationship between sleep duration (both long and short) and all-cause mortality emerged. There is, however, insufficient evidence to make a definite conclusion about sleep duration and mortality. The underlying etiologic factors remain to be determined. One possibility is a common pathway of increased risk of cardiometabolic disease [24].

Sleep Duration and Abnormal Physiologic Changes

Several studies documented abnormal physiologic changes after sleep restriction as follows: reduced glucose tolerance [73], increased blood pressure [99], sympathetic activation [100], reduced leptin levels [101], and increased inflammatory markers (e.g., an increased C-reactive protein, an inflammatory myocardial risk after sleep loss) [102].

Sleep Restriction and Immune Responses

Limited studies in the literature suggest the following responses following sleep restriction: (1) decreased antibody production following influenza vaccination in the first 10 days [103]; (2) decreased febrile response to endotoxin (*Escherichia coli*) challenge [104]; and (3) increased inflammatory cytokines [105] (e.g., interleukin-6 and tumor necrosis factor-α), which may lead to insulin resistance, cardiovascular disease, and osteoporosis.

Sleep Restriction and Cardiovascular Disease

Studies by Mallon et al. [106] in 2002 addressed the question of sleep duration and cardiovascular disease. They did not find increased risk of cardiovascular disease-related mortality associated with sleep duration, but found an association between difficulty falling asleep and coronary arterial disease mortality. However, several other more recent studies found a relationship between increased risk of cardiovascular disease and sleep duration [29, 72, 99, 107–109]. In a 12-year prospective study covering 20,432 men and women with no prior history of cardiovascular disease investigators from the Netherlands [108] observed that short sleepers (≤ 6 h) had higher risk of cardiovascular disease than those sleeping 7–8 h. These findings agree with the observations made by Altman et al. [72], Buxton and Marcelli [29], Cappuccio et al. [109].

Kripke et al. [98] and Newman et al. [107] in their studies concluded that daytime sleepiness and reduced sleep duration predict mortality and cardiovascular disease in older adults. What is the mechanism of increased cardiovascular risk after chronic sleep deprivation? This is not exactly known but may be related to increased C-reactive protein, an inflammatory marker found after sleep loss. In many of the sleep restriction experiments in humans, however, an added stress may have acted as a confounding factor, and therefore, some of the conclusions about sleep restriction regarding mortality, cardiovascular disease, diabetes mellitus, and endocrine changes may have been somewhat flawed.

Summary

Sleep restriction and sleep deprivation are associated with short-term (e.g., increased traffic accidents, EDS, daytime cognitive dysfunction as revealed by reduced vigilance test and working memory) and long-term (e.g., obesity, cardiovascular morbidity and mortality, memory impairment) adverse effects. Thus, chronic sleep deprivation caused either by lifestyle changes or by primary sleep disorders (e.g., obstructive sleep apnea syndrome [OSAS], chronic insomnia) is a novel risk factor for obesity and insulin-resistant type 2 diabetes mellitus.

Causes of Excessive Daytime Sleepiness

Excessive sleepiness may result from both physiologic and pathologic causes (Box 3.1), the latter of which include neurologic and general medical disorders as well as primary sleep disorders and medications and alcohol [110].

Physiologic Causes of Sleepiness

Sleep deprivation and sleepiness because of lifestyle and habits of going to sleep and waking up at irregular hours can be considered to result from disruption of the normal circadian and homeostatic physiology. Groups who are excessively sleepy because of lifestyle and inadequate sleep include young adults and elderly individuals, workers at irregular shifts, healthcare professionals (e.g., doctors, particularly the house staff, and nurses), firefighters, police officers, train drivers, pilots and flight attendants, commercial truck drivers, and those individuals with competitive drives to move ahead in life, sacrificing hours of sleep and accumulating sleep debt. In 2009, the Institute of Medicine (IOM) issued a report on "Resident Duty Hours" focusing on their working hours which predispose them to health and safety issues [111]. Based on this report, the Accreditation Council for Graduate Medical Education (ACGME) implemented new work hours schedule in 2010 which went into effect in July 2011 [112]. Among young adults, high school and college students are particularly at risk for sleep deprivation and sleepiness. The reasons for excessive sleepiness in adolescents and young adults include both biological and psychosocial factors. Some of the causes for later bedtimes in these groups include social interactions with peers, homework in the evening, sports, employment or other extracurricular activities, early wake-up times to start school, and academic obligations requiring additional school or college work at night. Biological factors may play a role but are not well studied. For example, teenagers may need extra hours of sleep. Also, the circadian timing system may change with sleep phase delay in teenagers.

Pathologic Causes of Sleepiness

Neurologic Causes of EDS

Tumors and vascular lesions affecting the ascending reticular-activating arousal system (ARAS) and its projections to the posterior hypothalamus and thalamus lead to daytime sleepiness. Such lesions often cause coma rather than just sleepiness. Brain tumors (e.g., astrocytomas, suprasellar cysts, metastases, lymphomas, and hamartomas affecting the posterior hypothalamus; pineal tumors; astrocytomas of the upper brain stem) may produce excessive sleepiness. Prolonged hypersomnia may be associated with tumors in the region of the third ventricle. Symptomatic narcolepsy resulting from craniopharyngioma and other tumors of the hypothalamic and pituitary regions has been described [113]. Cataplexy associated with sleepiness, sleep paralysis, and hypnagogic hallucinations has been described in patients with rostral brain stem gliomas with or without infiltration of the walls of the third ventricle. Narcolepsy–cataplexy syndrome also has been described in a human leukocyte antigen DR2-negative patient with a pontine lesion documented by magnetic resonance imaging.

Other neurologic causes of EDS include bilateral paramedian thalamic infarcts [114], post-traumatic hypersomnolence, and multiple sclerosis. Narcolepsy–cataplexy syndrome has been described in occasional patients with multiple sclerosis and arteriovenous malformations in the diencephalons [113, 115].

EDS has been described in association with encephalitis lethargica and other encephalitides as well as encephalopathies, including Wernicke's encephalopathy. It was noted that the lesions of encephalitis lethargica described by von Economo [116] in the beginning of the last century, which severely affected the posterior hypothalamic region, were associated with the clinical manifestation of extreme somnolence. These lesions apparently interrupted the posterior hypothalamic histaminergic system as well as the ARAS projecting to the posterior hypothalamus. Encephalitis lethargica is now extinct. Cerebral sarcoidosis involving the hypothalamus may cause symptomatic narcolepsy [117]. Whipple's disease [118] of the nervous system involving the hypothalamus may occasionally cause hypersomnolence. Cerebral trypanosomiasis [119], or African sleeping sickness, is transmitted to humans by tsetse flies: *Trypanosoma gambiense* causes Gambian or West African sleeping sickness, and *Trypanosoma rhodesiense* causes Rhodesian or East African sleeping sickness.

Certain neurodegenerative diseases such as Alzheimer's disease, Parkinson's disease, and multiple system atrophy also may cause EDS [120, 121]. The causes of EDS in Alzheimer's disease include degeneration of the suprachiasmatic nucleus resulting in circadian dysrhythmia, associated sleep apnea/hypopnea, and periodic limb movements in sleep. In Parkinson's disease, excessive sleepiness may be due to the associated periodic limb movements in sleep, sleep apnea, and depression. EDS in multiple system atrophy associated with cerebellar parkinsonism or parkinsonian cerebellar syndrome and progressive autonomic deficit (Shy–Drager syndrome) may be caused by the frequent association with sleep-related respiratory dysrhythmias and possible degeneration of the ARAS [122].

Sleep disorders are being increasingly recognized as a feature of Parkinson's disease and other parkinsonian disorders. Although some studies have attributed the excessive daytime drowsiness and irresistible sleep episodes ("sleep attacks") to antiparkinsonian medications [123], sleep disturbances are also an integral part of Parkinson's disease [124]. In one study of 303 patients with Parkinson's disease, 22.6 % reported falling asleep while driving [123]. Several studies also reported a relatively high prevalence (20.8–21.9 %) of symptoms of restless legs syndrome in patients with Parkinson's disease [125, 126]. There is also

increasing awareness about the relationship between parkinsonian disorders and REM sleep behavior disorder, which may be the presenting feature of Parkinson's disease, multiple system atrophy, and other parkinsonian disorders [127–137].

The relationship between hypocretin and sleep disorders associated with Parkinson's disease is currently being explored [138].

Myotonic dystrophy (types 1 and 2) and other neuromuscular disorders may cause EDS due to associated sleep apnea/hypopnea syndrome and hypoventilation [139–141]. In addition, in myotonic dystrophy, there may be involvement of the ARAS as part of the multisystem membrane defects noted in this disease.

EDS Associated with General Medical Disorders

Several systemic diseases such as hepatic, renal, or respiratory failure and electrolyte disturbances may cause metabolic encephalopathies that result in EDS. Patients with severe EDS drift into a coma. The other medical causes for EDS include congestive heart failure and severe anemia. Hypothyroidism and acromegaly also may cause EDS due to the associated sleep apnea syndrome. Hypoglycemic episodes in diabetes mellitus and severe hyperglycemia are additional causes of EDS.

Primary Sleep Disorders Associated with EDS

A number of primary sleep disorders cause excessive sleepiness (see Box 3.1). The most common cause of EDS in the general population is insufficient sleep syndrome associated with sleep deprivation. The next most common cause is OSAS; narcolepsy and idiopathic hypersomnolence are other common causes of EDS. Most patients with EDS referred to the sleep laboratory have OSAS. Other causes of EDS include circadian rhythm sleep disorders, restless legs syndrome-periodic limb movements in sleep, some cases of chronic insomnia, and inadequate sleep hygiene.

Substance-induced Hypersomnia Associated with EDS

Many sedatives and hypnotics cause EDS. In addition to the benzodiazepine and nonbenzodiazepine hypnotics and sedative antidepressants (e.g., tricyclic antidepressants and trazodone) as well as nonbenzodiazepine neuroleptics (e.g., buspirone), antihistamines, antipsychotics, and narcotic analgesics (including tramadol [Ultram]) cause EDS (see Chaps. 37 and 55).

Toxin and alcohol-related hypersomnolence can occur as well [142]. Many industrial toxins such as heavy metals and organic toxins (e.g., mercury, lead, arsenic, copper) may cause EDS. These may sometimes also cause insomnia. Individuals working in industrial settings using toxic chemicals routinely are at risk. These toxins may also cause systemic disturbances such as alteration of renal, liver, and hematologic function. There may be an impairment of nerve conduction. Chronic use of alcohol at bedtime may produce alcohol-dependent sleep disorder. Usually this causes insomnia, but sometimes the patients may have excessive sleepiness in the daytime. Many of these patients suffer from chronic alcoholism. Acute ingestion of alcohol causes transient sleepiness.

Effects of Sleep Deprivation and Sleepiness on Society and Driving

4

Michael A. Grandner and Raza Mian

Introduction

Sleep deprivation has been identified by the Institute of Medicine as "an unmet public health problem [1]." Sleep deprivation among medical residents was featured in a second Institute of Medicine report [2] that eventually led to changes in rules governing medical residencies. Increasing the proportion of the population that achieves adequate sleep has become a national health priority, featured as a goal in the Healthy People 2020 initiative [3]. The joint task force of the American Academy of Sleep Medicine and the Sleep Research Society identified critical research goals and listed as first the goal to better understand the public health implications of sleep deficiency and circadian disruption [4]. Taken together, these and other initiatives show that the public health relevance of sleep loss is recognized, if not completely understood. There has been a dramatic increase in attention to this area, and there has been much that has been learned regarding the implications of sleep for public health. This review aims to briefly describe a way to conceptualize sleep from a public health perspective using a social–ecological approach. Then, the chapter will briefly outline some of the literature linking sleep to health outcomes of societal relevance and how sleep loss may play a role in segments of society along age, gender, race/ethnicity, relationship status, and occupational lines. Then, there is a brief discussion of the role of sleep loss in driving accidents and a section for conclusions and future directions.

Conceptualizing the Effects of Sleep in the Context of Society

As research has increasingly focused on the role of healthy sleep in the general population, it may be useful to conceptualize the role of sleep in health, taking into account the contextual factors from which sleep arises. One such conceptualization, introduced by Grandner, Hale, Moore, and Patel, is the social–ecological model of sleep and health [5]. This model is built on the social–ecological framework originally proposed by Bronfenbrenner in the 1970s [6].

Briefly, this framework describes how an individual's behavior with respect to health exists in the context of that individual, but also in relation to various social systems. Bronfenbrenner proposed that the individual exists in the context of a "microsystem," a social layer with which the individual is in direct contact. This includes the individual's family, school, and church. These are systems that the individual is a part of and are represented by one-on-one interactions. The next level up is the "mesosystem" which refers to connections that link aspects if the microsystem together, such as factors that connect a person's family to their job. The "exosystem" is the next layer of abstraction and refers to the systems that the individual does not interact with but affects the microsystem/mesosystem. For example, this could be a spouse's work schedule, which affects the individual indirectly. Beyond the exosystem is the "macrosystem" which refers to more abstract systems within which the other systems are a part. For example, this could represent societal norms, laws, and the global environment. See Fig. 4.1 for a general schematic of this framework.

The social–ecological model of sleep and health is based on this approach. The model, presented in Fig. 4.2, conceptualizes sleep in the context of both upstream and downstream factors. Downstream of sleep duration and quality lies adverse health outcomes of poor sleep. These may include weight gain/obesity, metabolic dysregulation, cardiovascular disease, inflammation, psychological disturbances, stress, and performance deficits. It is hypothesized

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_4

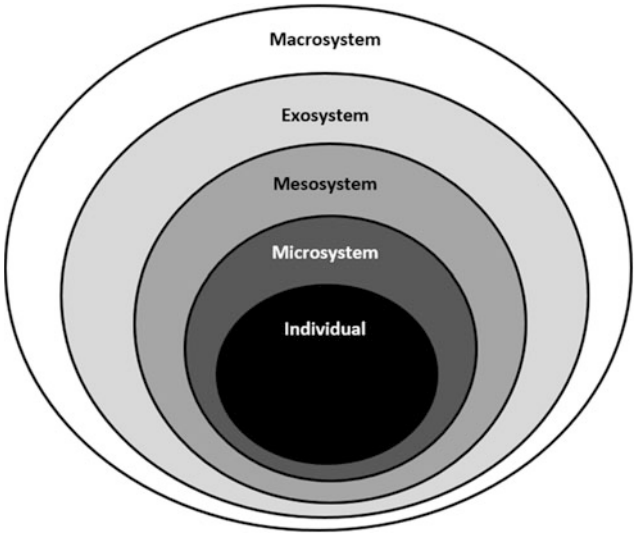

Fig. 4.1 Social–ecological framework

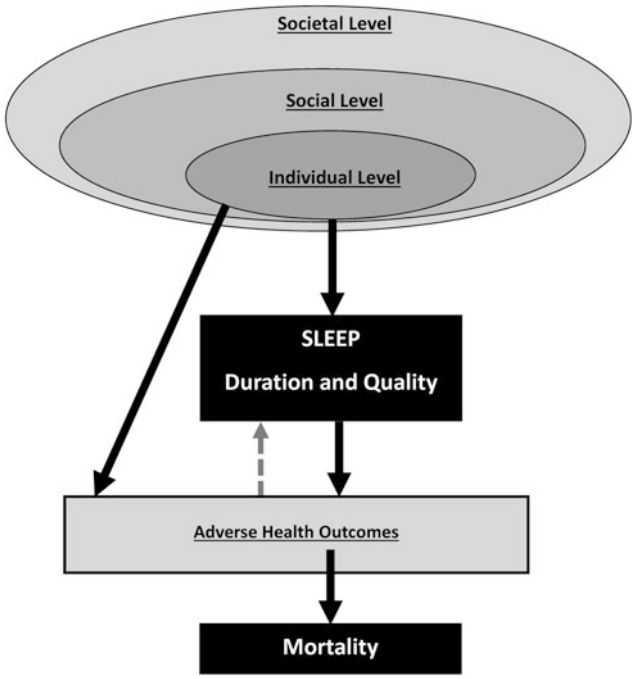

Fig. 4.2 Social–ecological model of sleep and health. Adapted from Grandner, Hale, Moore, and Patel

that these, in aggregate, not only exacerbate each other but eventually contribute to overall morbidity and eventually mortality risk. Upstream of sleep lies the portion of the model that borrows heavily from the social–ecological framework. The model posits that sleep, as experienced by an individual, is best conceptualized in the context of three levels. First is the individual level. These are the individual's own genetics, health, beliefs, choices, etc. These are the proximal causes of sleep experienced by that individual. Beyond the individual level, though, is the social level. This level, which borrows aspects of the microsystem, exosystem, and mesosystem, represents the immediate context of that individual. Factors at this level include neighborhood, culture, social networks, friends, and other systems that exist outside of the individual but to which the individual belongs. Two factors specifically stand out at this level and bridge most directly to the individual level. These include work/school and family/home. These two domains are hypothesized to exert the most influence (above individual-level factors) on sleep at the individual level. The third level is the societal level, within which the social level is situated. This borrows elements of the exosystem and macrosystem. Factors at this level represent structures that the elements at the social level are a part of, but exist outside of those factors. For example, factors at the societal level that influence sleep may include globalization, 24/7 society, public policy, and national geography.

Taken together, this model spells out the role of sleep on health, taking into account the individual and the social–environmental context. This way of thinking may be particularly useful about sleep. For example, when conceptualizing healthy sleep duration and quality, it is difficult to form a comprehensive understanding without taking into account work, family, and other contextual factors.

Health Effects of Sleep Deprivation

Sleep deprivation, whether in the laboratory or in "real-world" settings, is associated with a myriad of adverse outcomes. Any comprehensive summary would be beyond the scope of any single chapter. Of the outcomes that have been studied, effects can be generally conceptualized as neurocognitive (including stress, emotional processing, decision making, attention, and memory) and/or cardiometabolic (including obesity, cardiovascular disease, and diabetes).

Sleep-deprived persons report increased stress, and it is believed that both sleep loss and stress impact mood and emotion. Minkel et al. [7] compared stress handling in sleep-deprived participants with rested controls and reported greater subjective stress, anxiety, and anger in sleep-deprived participants than in rested controls following exposure to a low-stressor condition. High-stressor conditions did not produce varied response. Sleep deprivation may thus lower the psychological threshold for perception of stress from cognitive demands but does not selectively increase response magnitude to high stress performance demands [7]. In an earlier study, the same group had demonstrated that sleep-deprived healthy adults have less emotional expressiveness, especially in response to positive stimuli [8].

Van der Helm et al. investigated the impact of sleep deprivation on the ability to recognize the intensity of human facial emotions [9] in 37 healthy participants and randomly assigned them to total sleep-deprived (TSD) and sleep control (SC) group. This study found that sleep deprivation selectively impairs the accurate judgment of human facial emotions, especially threat relevant (anger) and reward relevant (happy) categories. This study suggests that sleep loss impairs discrete affective neural systems, disrupting the identification of salient affective social cues [9].

Many studies have examined the relationship between habitual short sleep duration and cardiometabolic disease [10, 11]. For example, a number of studies have found associations with obesity [10, 12–14], cardiovascular disease [10, 12, 15–18], stroke [12, 19], and diabetes [11, 12, 20–25]. Proposed mechanisms for these relationships include behavioral and physiological factors. Regarding behavioral factors, short sleep has been associated with overall unhealthy lifestyle choices [26–29] that could predispose to these conditions. Regarding physiological factors, four potential mechanistic pathways linking short sleep to cardiometabolic disease have been identified, representing metabolic, inflammatory, and sympathetic.

The metabolic pathway is represented by studies that have focused on food intake, insulin/glucose function, and secretion of hormones that play important roles in hunger and satiety [30]. Several studies have examined the role of sleep in food intake [31]. Overall, studies of laboratory samples have shown that acute sleep deprivation associated with an increase in energy intake of about 500 kcal per day [32–35]. In particular, the increase in energy intake seems largely confined to after dinner [34, 35]. Some studies have shown that acute sleep deprivation is associated with decreased leptin secretion and elevated ghrelin secretion. Leptin is a hormone secreted by adipose tissue and can be used as a marker of adiposity [36–38]. Some population-level studies have found that short sleepers secrete less leptin [39–44]. But this is complicated by the finding that short sleepers are more likely to be obese, thereby secreting more leptin due to more adipose tissue. This may explain why some studies have shown that short sleepers secrete more leptin overall [45, 46]. Ghrelin, a complement to leptin, is a hormone secreted by the stomach and tends to signal hunger [47–51]. Studies in the population have shown mixed results, perhaps due to a lack of sampling across the day and night [40, 41, 44, 52, 53]. The leptin/ghrelin system represents one aspect of the proposed metabolic pathway. The other main component is the insulin/glucose system. Studies in the laboratory show that acute sleep deprivation leads to temporary insulin resistance [54–60]. In addition, population-level studies have shown that habitual short sleepers are more likely to have diabetes, even using objective criteria including impaired fasting glucose [61].

The inflammatory pathway may also be relevant for the development of cardiometabolic disease. Inflammatory process contributes to all stages of cardiovascular disease, from the development of atherosclerostic plaques in the vascular wall to end-stage thrombotic complications [62]. Several studies have shown that acute sleep deprivation results in a pro-inflammatory state; in particular, studies have shown that sleep deprivation is associated with elevated levels of tumor necrosis factor alpha (TNF-α) [63, 64], interleukin-6 (IL-6) [63, 65, 66], and C-reactive protein (CRP) [66, 67]. Population-level studies have also shown short sleep to be associated with elevated TNF-α [68], IL-6 [69, 70], and CRP [15, 71].

The role of the sympathetic nervous system in the development of cardiovascular disease is well described [72, 73]. One of the primary mechanisms is through the hypothalamic–pituitary–adrenal (HPA) axis, which represents the regulatory/secretory system that induces the release of corticosteroids such as cortisol and catecholamines such as epinephrine (EPI) and norepinephrine (NE). For example, this is key in regulation of blood pressure [74, 75]. Several studies have shown that short sleep is associated with increased blood pressure [76, 77], and this may be reflected in 24-h blood pressure variability [78], which may represent downstream effects of HPA axis activation. A recent study showed that one of the mechanisms by which sleep deprivation disrupts insulin signaling is via alterations in protein kinase B phosphorylation in adipocytes [58]; it should be noted that the primary upstream signal for this process is sympathetic nervous system. In addition, several studies have shown that insufficient sleep is associated with increased HPA axis activity [79–84].

For example, Robertson and colleagues showed that even minor reductions in sleep duration lead to changes in insulin sensitivity, body weight, and other metabolic parameters which vary during the exposure period [85]. Further, short sleep duration is a significant independent risk factor for hypertension [86] and diabetes [87], perhaps because short sleepers demonstrate elevated ghrelin, and reduced leptin, which are likely to increase appetite, thus possibly explaining weight gain associated with short sleep duration [41].

Other systems have been implicated as well. For example, Specker and colleagues investigated the effect of chronic sleep deprivation on bones in 1146 individuals by performing bone measurements on distal radius, spine, and hip [88]. The study then compared bone measurements between sleep-deprived and sleep adequate individuals after controlling covariates. The study found that sleep-deprived women had lower bone mineral density than sleep adequate women

and sleep-deprived men had lower levels of torsional bending strength, relative to than sleep adequate men.

Effects Across Age Groups

Sleep deprivation has implications across the age spectrum. For example, sleep-deprived adults manifest symptoms including daytime sleepiness, psychomotor slowing to impaired cognition, and memory. In contrast, children are more likely to present with emotional and behavioral symptoms, including aggressive and delinquent behaviors, attention and social problems, anxiety/depression, and hyperactivity. A number of studies have tried to elucidate the impact of sleep deprivation on children. Fallone and colleagues studied children aged 6–12 years and found a direct effect on academic performance and attention problems associated with reduced in sleep opportunity, even among students that had no prior history of behavioral or academic problems [89]. Touchettte and colleagues found that patterns of persistent short sleep duration or tendency for short sleep duration in childhood (2.5–6 years) predict high hyperactivity and impulsivity scores and poor performance on neurodevelopmental tasks at time of school entry (ages 5–6 years) [90]. A subsequent study aimed at investigating risk factors associated with short nighttime sleep duration and hyperactivity between ages 1.5 and 5 years using a large database of 2057 children found that children with high hyperactivity scores had a higher risk of short nocturnal sleep time (OR 5.1, 95 % CI [3.2–7.9]) than risk of finding high hyperactivity scores in short sleepers (OR 4.2, 95 % CI [2.7–6.6]). This, it may be the case that it is more plausible that hyperactivity may interfere with nighttime sleep duration rather than short sleep resulting in higher hyperactivity scores. Risk factors for having short sleep duration and high hyperactivity scores included male sex, low household income, lower maternal education and a pattern of receiving comfort outside the bed during nocturnal wakings at 1.5 years of age.

The trajectories of sleep problems between ages 4 and 16 years of age also correlate with general executive function at age 16 years [91]. Individuals whose sleep problems decrease more across time show better general executive control in late adolescence [91]. These findings suggest a probable critical period during childhood when disruptions to the stabilization and consolidation of sleep could very well result in the development of hyperactivity.

Other problems in children have been well documented. For example, the association between autism spectrum disorders (ASDs), attention deficit hyperactivity disorders (ADHDs), and disordered sleep has been commonly reported. Corkum and colleagues reported sleep problems in 25–50 % of children with ADHD [92]. Sleep problems are endemic to children with ASDs with a prevalence ranging from 40 to 86 % [93–96]. The prevalence of sleep disorders among children with ASD is higher than children with other development delays [97, 98] and is unrelated to intellectual quotient [99] or age [100]. In addition to these behavioral issues, several studies have documented poor health outcomes in sleep-deprived children, including metabolic syndrome [101] and visceral adiposity [102].

Questions regarding healthy adolescent sleep date back to 1975, when Webb and Agnew [103, 104] showed that on average, young people between the ages of 8 and 17 were getting 1.5 h less sleep per night than their counterparts did in 1910 and 1911. Since then, various studies and surveys have reported some degree of disrupted or deficient sleep in adolescents. According to the National Sleep Foundation, teens need between 8.5 and 9.25 h of sleep per night, with some laboratory data indicating that 9.2 h is optimal; thus, sleep deprivation can be defined as anything under about nine hours per night. Yet experts generally agree that most adolescents achieve less sleep. After analyzing data from a 2007 Youth Risk Behavior Survey data of US high school students, McKnight-Eily and colleagues found that nearly 70 % reported getting less than eight hours of sleep on school nights [105]. Emphasizing the value of awareness of the impact of sleep insufficiency, the authors agreed with other experts that chronic sleep deprivation in adolescents stems from "social, employment, recreational, and academic pressures as well as biologic changes" in the sleep–wake cycle.

Sleep needs do not markedly decline after puberty, perhaps because of the increased metabolic expenditures associated with growth during adolescence [106]. Yet Wolfson and colleagues, in a study of 3120 American high school students, reported a reduction in total sleep time of 40–50 min and a decline in the average amount of sleep on school nights from about 7.7 h for younger students to about seven hours for older ones [107]. The same study found that 26 % reported that they "usually" sleep less than 6.5 h per night [107]. The sleep loss was due to increasingly later bedtimes, while rise times were reported to be more consistent across ages (likely due to standard school start times). Not surprisingly, in surveys, 13–24 % of adolescents have reported falling asleep in class at least once [107]. Although one recent study concluded that US children and adolescents do get between nine and 10 h per night, as recommended, [108], an accompanying editorial cautioned, "We are still far from understanding what a 'normal,' 'ideal,' or 'adequate' sleep duration is for an individual child to promote optimal health and functioning." [109]

Sleep time restores the neurocognitive functioning of brain [110, 111]. Curcio et al. [112] asserted that insufficient sleep in adolescence impairs behavioral, physiological, and neurocognitive processes vital for learning capacity and

academic performance. Several studies involving actual manipulation of sleep in teenagers and college students have documented the effects of lack of sleep on cognitive functioning, showing impairment of psychomotor abilities, increase in sleepiness, poor memory and computational speed, reduced cognitive achievement, reduced awareness of cognitive impairments, and impaired performance on verbal creativity and abstract thinking [112]. Although the relationship between compromised neurobehavioral functioning and insufficient or disrupted sleep has been well studied in adults, relevant literature on children and adolescents is limited. That said, sleep disruptions in adolescents have also been associated with memory and attention deficits and declines in academic performance [107, 113]. McKnight-Eily and colleagues found that insufficient sleep was associated with many high-risk behaviors; for example, sleep-deprived teens were more likely to engage in physical fighting; seriously consider suicide; and use cigarettes, alcohol, and marijuana [105].

The response to a life stressor may be different among sleep-deprived adolescents. Talbot et al. investigated the impact of sleep deprivation in adolescents and adults on affective functioning and found that participants reported a greater increase in anxiety during a catastrophizing task when sleep deprived than when rested [114]. Further, chronic sleep restriction among adolescents may increase suicidal risk. Lee et al. [115] recruited 8530 students to investigate the association between behaviorally induced insufficient sleep and suicidality. They reported that adolescents with behaviorally induced insufficient sleep syndrome (BISS) had higher SSI score than those who slept 7 h or more on weekdays. They also found that weekend oversleep was associated with suicidality independently of depression, daytime sleepiness, snoring, and insomnia.

Effects Across Racial/Ethnic Groups

Several studies have attempted to understand whether habitual sleep patterns differ according to race/ethnicity group. Ruiter and colleagues [116] conducted a meta-analysis that found that Blacks/African-Americans obtained approximately 28 min less polysomnographic sleep than Whites; they also obtained less slow-wave sleep. These findings are consistent with those of other studies, who found that Blacks/African-Americans obtained less slow-wave sleep [117–121] and had a poorer sleep efficiency [119, 121] than non-Hispanic Whites. This suggests that, on average, for Blacks/African-Americans, sleep is less deep and less restful. Similarly, this meta-analysis evaluated 6 studies of subjective sleep duration [116] that found a similar pattern, with Blacks/African-Americans reporting less sleep on average than Whites (15.1 min less, $p < 0.05$) [116]. A few studies compared sleep among racial/ethnic groups using wrist actigraphy. Several studies reported significantly shorter mean sleep duration and poorer sleep quality for minorities compared to Whites [122–124]. Many of these effects persist after adjustments for socioeconomic factors.

Another approach that has been taken is to evaluate whether people of various groups are more or less likely to report sleep duration by category (usually short or long, relative to normative [7–8 h]). Hale and Do [125] found that, relative to non-Hispanic White Americans, Blacks/African-Americans, non-Mexican Hispanics, and those in the "Other" category were more likely to be short sleepers. Regarding long sleep duration, the only group that was more likely than non-Hispanic Whites to be long sleepers (9 or more hours) was Blacks/African-Americans. Similarly, Nunes and colleagues found that Blacks/African-Americans were less likely to report sleep of 7–8 h, versus non-Hispanic Whites, with increased likelihood of both short and long sleep [126] and Stamatakis and colleagues [127] found that African-Americans were about twice as likely to be short sleepers, and those in the "Other" category were approximately 50 % more likely.

In a more recent study, Whinnery and colleagues examined nationally representative data from the 2007–2008 National Health and Nutrition Examination Survey [128]. The sleep duration categories examined were very short sleep (less than 5 h), short sleep (5–6 h), and long sleep (9 or more hours), compared to normal sleep duration (7–8 h). Those who identified as Black/African-American were approximately 3 and a half times as likely to be a very short sleeper; similarly, non-Mexican Hispanics/Latinos were approximately 3.5 times as likely and Asians/Others were approximately 5 times as likely to be a very short sleeper. Regarding short sleep, those who identified as Black/African-American were about twice as likely to be short sleepers, and those who identified as Asian/Other were approximately 2 and a half times as likely. Mexican–Americans were 60 % less likely to be long sleepers.

This study also examined the degree to which these relationships are attenuated by other factors, including age, sex, relationship status, primary language spoken at home, immigration status, education, income, access to health insurance, home ownership, and food security. Self-identified Blacks/African-Americans were approximately 2.5 times as likely to be very short sleepers and approximately twice as likely to be short sleepers. Mexican–Americans were approximately 60 % less likely to be long sleepers. Non-Mexican Hispanics/Latinos were approximately 2.7

times as likely to be very short sleepers, and Asians/Others were approximately 4 times as likely to be very short sleepers and twice as likely to be short sleepers [128].

It is possible that sleep plays an important role in health disparities. Knutson and colleagues [129] found that racial differences in 5-year change in blood pressure were mediated by differences in sleep duration. In another study, Grandner and colleagues [15] found that the relationship between sleep duration and C-reactive protein (a cardiovascular risk marker) differed by race. Grandner and colleagues also examined whether the relationship between sleep duration and cardiometabolic disease risk depended on race/ethnicity [61]. For all outcomes (self-reported and objectively determined hypertension, hyperlipidemia, diabetes, and obesity), race/ethnicity by sleep duration interactions was significant (all $p < 0.0001$). <Query ID="Q2" Text="The significance of symbol P has been represented by both P and p, and needs to be consistent throughout the text. Please check and amend as necessary".–> When the sample was stratified by self-identified race/ethnicity, different patterns emerged.

Effects for Men and Women

Though the response to altered sleep homeostasis is uniform in general, variation based on gender has been studied across different age groups. In a study aimed at examining gender differences in sleep habits in 11–13 year olds, Natal et al. [130] studied a cohort of 200 students based on a questionnaire. The authors found that girls displayed longer sleep duration over the weekend in comparison with boys.

Arber et al. [131] studied gender and socioeconomic patterning of self-reported sleep problems in Britain using the British Psychiatric Morbidity Survey 2000. The authors report that women reported significantly more sleep problems than men, as did the divorced and widowed compared with married respondents. After adjusting for socioeconomic characteristics, the sleep problems were halved, suggesting a major role for socioeconomic status in these gender differences.

Rodriguez-Munoz et al. [132] studied 240 physicians in Madrid with the aim to assess insomnia and sleep quality in primary care physicians. The study reported a higher frequency of insomnia among women (23 %) compared to men (9.6 %). This relationship between gender and insomnia remained significant even after controlling sociodemographic variables. In terms of sleep quality, as defined by Pittsburgh Sleep Quality Index (PSQI) score of 5 or more than 5, the study reported women scored significantly higher than men on global sleep quality. Sleep problems were more prevalent among women than men (40 vs. 25.3 %).

Goel et al. [133] studied gender differences in polysomnographic sleep in 31 young men and women over a three consecutive overnight sessions in a sleep laboratory. They concluded that women have better sleep quality (shorter sleep onset latency, higher sleep efficiency) compared with men. Yet women of all adult age groups have been found to report more sleep problems, such as inadequate sleep duration and insomnia [134, 135].

Similarly, the susceptibility to various sleep disorders and their consequences differ among men and women. Morrish et al. [136] compared the mortality risk of men and women who were diagnosed with obstructive sleep apnea and were receiving treatment with CPAP between 1995 and 1998 by reviewing hospital records of 292 men and 47 women. Eighty percent of men died compared to 23 % of women ($p = 0.003$). There was a 3.44 greater mortality risk of women diagnosed with OSA and treated with CPAP, mostly due to greater comorbidity. Also, Johnson et al. [137] studied 1014 adolescents from a random sample of an urban health maintenance organization population and found no difference in risk of insomnia in prepubertal girls compared with boys—but the onset of menses in girls conferred a 2.75-fold increased risk of insomnia.

Effects According to Relationship Status

Sleep and spousal relationship/cohabitational status have been a topic of much recent interest. Various studies have tried to decipher the exact nature of such relationship. Troxel et al. [138] conducted an observational longitudinal study aimed at finding associations between marital status and cohabitation history and sleep in midlife women. The authors reported that at the time of the study, partnered women had better sleep quality than unpartnered women; however, with covariate adjustment, most of these associations become nonexistent. Additionally, the prior history showed advantages in sleep for women who were consistently partnered versus women who weren't consistently partnered. This association persisted even after covariate adjustment.

Research suggests that divorced individuals, particularly women, have higher rates of sleep disturbances as compared to married individuals [139]. However, all marriages and marital relations are not equal. So does marital quality translate into better sleep? This was explained by Troxel et al. [140] in a multi-site, multiethnic, community-based study that examined the association between marital happiness and self-reported sleep disturbances in a sample of 2148 midlife women drawn from the Study of Women's Health Across the Nation (SWAN). The Dyadic Adjustment Scale was used to assess marital happiness, and sleep disturbance was assessed using 4 items from the Women's Health Initiative Insomnia Rating Scale (WHIIRS). After controlling for relevant covariates, maritally happy women reported fewer sleep disturbances, with the association evident among Caucasian women and to a lesser extent among

African-American women. In an earlier study, Troxel et al. in 2007 [141] had found that women with bed partners display better sleep efficiency and that married women have shorter sleep latencies as compared with never-married women.

Effects Across Different Occupations

A number of epidemiological studies have suggested [142] an association between shift work and various health problems, such as heart disease [143], ischemic stroke [144], depression [145], metabolic syndrome [146], gastrointestinal ulcers [147], cancer, [148, 149] obesity [150], gastrointestinal dysfunction [147], reproductive problems [151], and some of the adverse pregnancy outcomes [152]. Evidence for the strength of causality of shift work per se for some of these health consequences has been challenged [143]. Translating these studies to predict individual risk of these consequences is required.

Shift work is a stressor that may result in the expression of physiological and psychological vulnerabilities specific to the individual. These vulnerabilities are likely associated with the individuals' genetic and environmental risk of impairment, disability, or disease expression. Further prospective research studies have been sought to clarify the strength of the association between shift work and chronic disease [142]. Furthermore, additional research on the mechanisms underlying reported increased health risks is needed. Among the variety of possible mechanisms and plausible explanations for such an association, which includes vulnerability to circadian rhythm disorder, reduced circadian amplitude, light exposure at night, food intake at inappropriate internal biological times, misalignment of circadian clocks in brain and peripheral tissues, and interactions among the above and with individual differences in disease risk, deficient and discrepant sleep lies at the forefront. Sleepiness, fatigue, cognitive impairment, and impaired sleep have been reported as the immediate consequences of shift work that impact workers simultaneously [153, 154].

Sleepiness and fatigue may reach clinically significant levels thoroughly effecting job performance and predisposing to accidents. Involuntary sleep episodes are more common during the night shift. Risks of errors and accidents appear to be higher among shift workers. Nearly a threefold increased risk of occupational accidents has been reported in shift workers compared with day workers, with increased risk of accidents reported in healthcare workers, police, and commercial drivers, and in all shift workers on the job and during the commute home. The risk of vehicle, aviation, and industrial accidents is highest at night, especially in the early-morning hours.

Shift workers may also underestimate their level of cognitive impairment, providing false confidence as demonstrated by findings of cumulative impairment in performance with little change in subjective alertness during circadian misalignment. Johnson et al. [155] in a study examined how sleep deprivation influenced psychomotor performance of a sample of 289 nurses who worked the night shift. Fifty six percent of the sample was sleep deprived, and a significant inverse relationship between psychomotor performance and hours of sleep was found.

Impact on Driving Accidents

Acute sleepiness in car drivers significantly increases the risk of a crash in which a car occupant is injured or killed. Reductions in road traffic injuries may be achieved if fewer people drive when they are sleepy or have been deprived of sleep or drive between 2 a.m. and 5 a.m. Connor et al. [156] examined the contribution of driver sleepiness to the causes of car crash injuries and assessed the risk of serious injury to car occupants in a case–control study. They reported a strong association between measures of acute sleepiness and the risk of an injury crash. Increased risk was associated with drivers who identified themselves as sleepy (Stanford sleepiness score 4–7 v 1–3; OR 8.2, 95 % CI 3.4–19.7); with drivers who reported 5 h or less of sleep in the previous 24 h compared with more than 5 h (OR 2.7, CI 1.4–5.4); and with driving between 2 a.m. and 5 a.m. compared with other times of day (OR 5.6, 1.4–22.7). No increase in risk was associated with measures of chronic sleepiness. The population attributable risk of driving with one or more of the acute sleepiness risk factors was 19 % (15–25 %).

Howard et al. studied the cumulative effect of extended wakefulness and low-dose alcohol on simulated driving and vigilance and found that both had significantly bad effects on reaction time and concentration lapse, as well as variation in lane position and speed, with extended wakefulness (18–21 h) combined with low-dose alcohol (0.03 % BAC) resulted in greater variation in more lapses ($t = -2.75$, $P < 0.05$) and greater variation in lane position ($t = -3.94$, $P < 0.01$) and speed ($t = -2.79$, $P < 0.05$) than did a BAC of 0.05 % in a rested state. Thus, avoiding alcohol even in lesser concentration after prolonged wakefulness may reduce accident risk.

The risk of human error-related accidents has been reported to increase with sleep deprivation [157]. The overall prevalence of insufficient sleep in adults has been estimated at 20 % [158]. The most common measure in population-based studies is daytime sleepiness. Breslau et al. in a study to determine the prevalence of daytime sleepiness, using interviews over 5.5 years to follow 1007 randomly selected young adults age 21–30 years, was performed in

southeast Michigan [159]. They found the average nocturnal sleep time during weekdays was 6.7 h and on weekends was 7.4 h. Daytime sleepiness was inversely proportional to hours slept, and difficulty falling asleep was more prevalent in single adults with a full-time job.

Studies in young adults indicate that 8–9 h of extended nocturnal sleep is needed to resolve sleepiness caused by decreased sleep time [160, 161]. The apparent chronic partial sleep deprivation of the young adults surveyed in 1997 complements statistics that find young drivers, especially males, at much higher risk of drowsy driving and sleep-related crashes [162]. Accidents related to sleep deprivation have been estimated to have an annual economic impact of $43 to $56 billion [163]. Motor vehicle accidents related to fatigue, drowsy driving, and falling asleep at the wheel are particularly common but often underestimated [164, 165]. Increased time awake, nocturnal circadian phase, reduced sleep duration, prolonged driving duration, and use of soporific medications have all been found to contribute to the occurrence of drowsy driving and fatigue-related motor vehicle crashes [162, 166, 167]. Studies of shift workers, truck drivers [168–170], medical residents [171, 172], and airline pilots [173–176] show an increased risk of crashes or near misses due to sleep deprivation. Sleepiness-related motor vehicle crashes have a fatality rate and injury severity level similar to alcohol-related crashes [162]. Sleep deprivation has been shown to produce psychomotor impairments equivalent to those induced by alcohol consumption at or above the legal limit [177]. For example, in a study of simulated driving performance, impairments in lane-keeping ability after a night without sleep were equivalent to those observed at blood alcohol content (BAC) of 0.07 % [178]. Similarly, a study of professional truck drivers found that deficits in performance accuracy and reaction time at 28 h of sleep deprivation were equivalent to those found after alcohol intoxication (BAC at 0.1 %) [179]. It appears that as continuous daytime waking exceeds 16 h, psychomotor performance deficits increase to levels equivalent to BACs between 0.05 and 0.1 % [177, 179]. Sleep deprivation poses a risk to safe operation in all modes of transportation and to performance in other safety-sensitive activities.

A recent study by Maia and colleagues sheds some light on the potential for sleep deprivation to be involved in driving accidents in the general population [180]. It should be noted that there are no published reports linking objective habitual sleep data to actual driving records. But data from the Behavioral Risk Factor Surveillance System examined drowsy driving behaviors in a population sample. The study by Maia and colleagues found that increased rates of drowsy driving were seen among those reportedly getting 6 h of sleep (per 24 h) or less. This study also allowed for the analysis of an important potential mediating factor: perceived sleep insufficiency. This survey also included an item evaluating how many days in the past month the respondent did not feel that they got enough rest or sleep. It was hypothesized that when the analysis was constrained to only examine individuals who said that they were always fully rested (i.e., 0 nights of insufficient sleep), that these effects would be mitigated. However, the opposite was true. Even in those who felt fully rested, those reporting habitual sleep duration of 6 h or less were approximately 3 times as likely to also endorse reports of drowsy driving. Thus, drowsy driving is not only more common among those who sleep 6 h or less on average, but this risk is not mitigated by feeling fully rested. This is in line with laboratory research studies, which have shown that subjective levels of impairment are not well correlated with objective levels and often underestimate impairment [181].

Conclusions and Future Directions

Sleep deprivation remains an important, unmet public health problem. The effects of sleep deprivation and sleepiness (which often results) are wide ranging. The review in this chapter is only a brief overview of some of the important findings in this area. Individuals who are sleep deprived are more likely to be in poor health demonstrate neurocognitive deficits, have decreased longevity, and experience problems in many functional domains. One of the most salient of these is in driving accidents, many of which are at least partially caused by sleep deprivation. These are issues of not only public health, but also public safety [182] and economic productivity [183]. The consequences of sleep loss are felt across the population. Across the age spectrum, there are unique issues that face children, adolescents, adults, and the elderly [184, 185]. Unique problems also exist for both men and women [186, 187]. The effects of sleep loss may particularly be salient for racial/ethnic minorities, who may be at greater risk of sleep problems [128, 188]. And the social role of sleep is one that is being explored in both quantitative [189–191] and qualitative [192] domains.

The social–ecological model of sleep and health has emerged as a useful framework for conceptualizing the role of sleep at the nexus of physiology and the social environment. It conceptualizes downstream adverse effects of insufficient sleep duration and/or inadequate sleep quality as interconnected risk factors that eventually reduce longevity. And it conceptualizes sleep in the context of individual-level factors, which are embedded within social-level factors, which themselves are embedded within societal-level factors [5].

Still, there are many unanswered questions. The downstream mechanistic pathways linking sleep and important outcomes still need to be clarified. The potentially interactive roles of insufficient sleep duration and inadequate sleep

quality need to be discerned. Further, important social–environmental modifiers of these pathways such as race/ethnicity will aid in the understanding of why certain groups are at increased risk. These and other questions can be addressed, but will require innovative thinking that bridges the population-level experimental studies.

Neurobiology of REM Sleep, NREM Sleep Homeostasis, and Gamma Band Oscillations

5

James T. McKenna, Mark R. Zielinski, and Robert W. McCarley

Introduction

In modern times, sleep disturbance and disorders are an extremely relevant public health issue [1, 2]. Sleep disturbance due to vocational demands contributes to decreased work performance, as well as increased accident rates and health costs. Sleep disorders including insomnia, narcolepsy, restless leg syndrome, and sleep apnea impact much of the population. Understanding the basic neural mechanisms and circuitry involved in the regulation of vigilance states [wake, non-rapid eye movement (NREM) sleep, and rapid eye movement (REM) sleep] has led to the development of pharmacological and behavioral treatments for sleep pathologies. Scientific investigations conducted in the last century have begun to describe molecular, cellular, and complex neural systems responsible for regulating the vigilance states. Much of what we know is due to investigations in animals employing cortical electroencephalogram (EEG) recordings, as well as pharmacological, electrophysiological, optogenetic, and molecular techniques. Furthermore, advances in neuroimaging, in addition to cortical EEG recording, have accelerated the investigation of sleep pathologies in clinical settings.

In this chapter, we present an overview of the circuitry and physiology involved in vigilance state regulation. Each of the three vigilance states is reviewed, focusing on investigations describing electrophysiological characteristics, relevant brain nuclei/regions, neuroanatomical interconnections, and neurotransmitters. We pay particular attention to the role of NREM sleep in homeostasis and review the two-process model of sleep regulation, in which sleep is influenced by both homeostatic (Process S) and circadian (Process C) processes. Herein, we review recent interest in the gamma band oscillation (i.e., ~40 Hz EEG frequency range), a particular high-frequency cortical oscillatory potential seen largely during wake and REM sleep, which plays a major role in attention and memory processing.

Wakefulness

EEG Profile of Wakefulness

In the 1920–1930s, the EEG profile of wakefulness and sleep was first described as changes of electrical cortical amplitude and frequency reflected in wakefulness or sleep [3–5]. Wake characteristics in the EEG largely include low-voltage, high (fast) -frequency activity indicative of cortical activation (Fig. 5.1). Wakefulness is also associated with relatively high muscle tone and movement assessed by electromyogram (EMG) recordings, and eye movements revealed by the electrooculogram (EOG). Wake-indicative cortical activation in humans consists of predominant frequency wave bands in the alpha (8–13 Hz), beta (>13–20 Hz), and gamma (usual EEG frequency around 40 Hz) range. Theta field oscillations in the 4 ≤ 8 Hz range are also seen in the cortical EEG during wake, usually accompanying movement, attention, and cognitive processing.

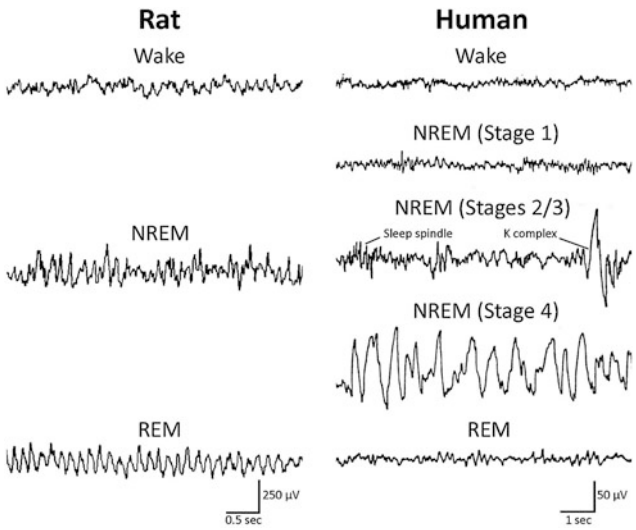

Fig. 5.1 Electroencephalographic (EEG) recordings of vigilance states (wake, NREM sleep, and REM sleep) in the rat and human. Wake in both species is characterized by cortical activation, of largely low-amplitude/fast-frequency activity. NREM sleep in the rodent is usually not differentiated between stages and exhibits large-amplitude delta (1–4 Hz) EEG activity. NREM sleep in humans is classified into 4 stages. In the first stage, the EEG frequency begins to slow, exhibiting alpha and theta activity. Both sleep spindles (7–14 Hz) and K-complexes are seen in NREM stage 2, as EEG amplitude increases and frequency further slows. In NREM sleep stage 4, also known as slow wave sleep, strong delta (1–4 Hz) activity of large amplitude is seen. During REM sleep, the EEG returns to a profile similar to wakefulness, with low-amplitude and high-frequency activity. In the rodent, the EEG exhibits strong theta (5–8 Hz) activity, most likely generated by the hippocampus. Human EEG recordings adapted [366]

Recent Neuroscience Technologies for Sleep Investigations

In recent years, new technologies in the field of neuroscience have been developed that are excelling our understanding of sleep and sleep-related disorders. The advent of optogenetic technologies now allows neurotransmitter-specific excitation and inhibition of neuronal populations [6, 7]. Light-activated ion channels (opsins) packaged in viruses (e.g., adeno-associated) are first intracerebrally injected in mice expressing Cre in specific populations of neurons. The neurotransmitter-select neuronal population of interest may then be excited or inhibited by means of light stimulation at the scale of millisecond precision. An alternative novel technique is the pharmacogenetic excitation or inhibition of select neuronal populations by means of Designer Receptors Exclusively Activated by Designer Drugs (DREADDs), in which cell type-specific expression of G-protein coupled receptors may be excited or inhibited by means of injection of select ligands such as inert clozapine-*N*-oxide [8, 9]. Cellular activation employing this technique, though, does not allow such precise temporal resolution as with optogenetics.

Gamma Band Oscillations (GBO)

Recent evidence points to the importance of GBO in the activated cortical EEG. During wake, the cortical EEG exhibits a predominance of low-amplitude beta (15–30 Hz) and gamma (30–120 Hz) cortical EEG activities. Neural signal transmission is enhanced as GBO occur, produced by the synchronized firing of cortical neuronal populations, providing a mechanism for coding information [10–12]. GBO abnormalities are symptomatic in various pathologies including schizophrenia, autism, and sleep disorders, and a strong association has been established between GBO and attention, perception, and memory [10, 13–15]. Moreover, GBO are enhanced after sleep deprivation largely in the prefrontal and frontal cortices of humans, suggesting an important sleep-related role of gamma rhythms [16].

Neural Mechanisms of GBO

Gamma rhythms are generated locally in the cortex by neural networks in which gamma-aminobutyric acid (GABA)ergic cortical interneurons containing the calcium binding protein parvalbumin (PV) interact with glutamatergic pyramidal cells (Fig. 5.2). Rhythmic fast-spiking inhibition of pyramidal cells produces GBO in the cortical EEG, and GBO frequency is set by the rate of depolarization and hyperpolarization of cortical PV and pyramidal neurons [17]. Electrophysiological investigations have shown that cortical PV neurons fire in phase with cortical EEG field oscillatory activity, especially GBO [18, 19]. GABA-A receptor antagonists applied to the hippocampal and cortical slice block GBO [20, 21]. Optogenetic excitation of cortical PV interneurons promoted GBO, and inhibition reduced GBO [13, 15, 22]. In magnetic resonance spectroscopy neuroimaging studies, cortical GABA levels increased during performance of a GBO-eliciting visual task [23, 24].

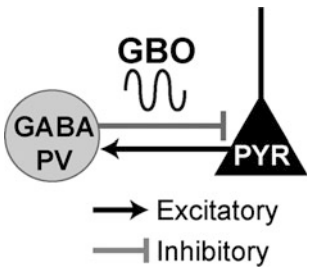

Fig. 5.2 Cortical circuitry generating gamma band oscillations (*GBO*). GBO are generated in the cortex by rhythmic fast-spiking GABAergic, parvalbumin (*PV*) cortical interneuronal inhibition of glutamatergic pyramidal cells. Returning glutamatergic projections excite PV GABAergic interneurons, enhancing oscillatory activity. Interneuronal–interneuronal mutual inhibitory connections between PV neurons, as well as electrical synapses and gap junctions, further promote synchrony (not illustrated)

Gamma band oscillations rhythmic activity is influenced by glutamatergic input from pyramidal cells back to GABA/PV neurons, as well as GABA/PV interneuronal–interneuronal interactions. Furthermore, synchronous PV rhythmic activity is promoted by gap junctions between cortical PV interneurons [25, 26]. In vitro investigations were able to elicit gamma oscillations in cortical slices, indicating that gamma oscillations are generated locally within the cortex [21, 27], and in vivo investigations also indicated that gamma oscillations are locally generated [28].

GBO During Wake

Many investigations indicate that synchronization of GBO between cortical subregions during wake provides a neural mechanism for intracortical communication [29–35]. The amplitude and synchrony of GBO correlated with the challenge/level of difficulty in a working memory task [36]. Recently, a strong correlation has been established between functional magnetic resonance imaging (fMRI) blood oxygen level-dependent (BOLD) signals and local GBO oscillatory activity [37, 38]. Although the temporal resolution of the BOLD signal is too slow to demonstrate GBO, these studies suggest that during select tasks that involve GBO, co-activation of cortical subregions occurs, possibly by means of direct anatomical connections, as well as synchronization by slower hippocampal and cortical oscillations, including theta and delta activity (also referred to as slow wave activity) [17].

Early Investigations of Wake-Regulating Neural Circuitry

During the 1920s, a worldwide epidemic of encephalitic lethargica led to many patients suffering from hypersomnia (i.e., excessive sleepiness). Von Economo analyzed the postmortem tissue of these patients and reported pathological damage in brain tissue located just posterior to the hypothalamus, at the junction of the mesencephalon and diencephalon [39]. A smaller subpopulation of encephalitic lethargica patients exhibited excessive wake, producing profound insomnia, and neurodegeneration was particularly noted in the hypothalamus. It was therefore concluded that an ascending system that involved subcortical projections to the cortex was involved in promotion of wake, and a sleep-inducing brain region resided in the hypothalamus. Later studies confirmed that these same brain regions play a role in the neural circuitry of the ascending reticular activating system (ARAS), reviewed below.

Frederick Bremer in the 1930s performed transection studies in the cat to identify brain regions that promote wakefulness [40, 41]. In one investigation, a particular transection/cut was made in the lower part of the medulla, termed *encéphale isolé*, which did not affect the cortical EEG profile. In another preparation, called *cerveau isolé*, a transection was made at the intercollicular region of the midbrain, rendering the animal in a sleep-like state. These findings suggest that the transition to and maintenance of sleep involve a disconnection of subcortical and cortical brain regions.

Moruzzi and Magoun demonstrated that stimulation of the brainstem reticular formation was very effective in eliciting a cortical EEG profile indicative of wake [42]. The concept of the ascending reticular activating system (ARAS) (Fig. 5.3) was then developed, describing the ascending circuitry originating in the reticular formation that is responsible for wakefulness [43–45]. The ARAS includes a dorsal and ventral pathway, both of which originate in the reticular formation, particularly the rostral pontis oralis (RPO). The dorsal pathway involves reticular formation input to thalamic nuclei that, in turn, strongly project to much of the cortex. Most of the ascending projections for this pathway are excitatory/glutamatergic, including reticular formation input to the thalamus and thalamocortical projections. The ventral pathway again involves projections originating in the reticular formation, now projecting to regions in the hypothalamus, namely the basal forebrain. The basal forebrain in turn sends direct connections to the cortex, again promoting wake. A number of studies have described strong input from the basal forebrain to widespread regions of the cortex, including cholinergic, GABAergic, and, to a lesser extent, glutamatergic basal forebrain input [43–45]. In addition, the medial septum/vertical limb of the diagonal band of Broca of the basal forebrain sends GABAergic and cholinergic input to the hippocampus. GABAergic input paces theta frequency oscillatory activity, seen during wake-related movement and select memory processing, as well as throughout REM sleep [46–48]. The ventral pathway involves glutamatergic output from the reticular formation, as well as basal forebrain glutamatergic projections terminating on the cortex. In addition, a multitude of other neurotransmitters, including acetylcholine, serotonin, noradrenaline, and the neuropeptide orexin, are involved.

Wake-Promoting Neurotransmitters

Acetylcholine

The excitatory neurotransmitter acetylcholine is localized in two essential brain nuclei significantly involved in wake promotion. The first brain region is located in the midbrain tegmentum, including the laterodorsal tegmental (LDT) and pedunculopontine (PPT) tegmental nuclei. The second region is the basal forebrain and includes the medial septum/vertical limb of the diagonal band of Broca,

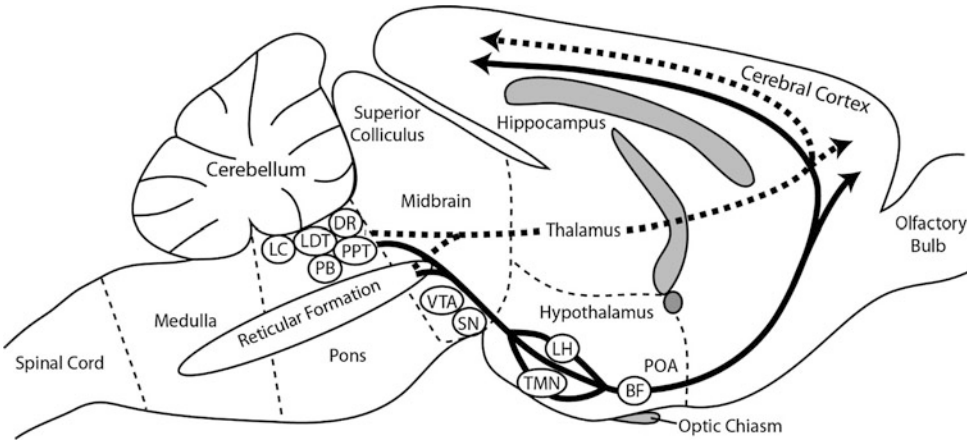

Fig. 5.3 Ascending reticular activating system (*ARAS*) promotes wakefulness. The dorsal pathway (*dashed*) originates in the reticular formation and neighboring dorsal raphe (*DR*), locus coeruleus (*LC*), parabrachial (*PB*), and laterodorsal (*LDT*) and pedunculopontine (*PPT*) tegmental nuclei. These regions project to thalamic nuclei that in turn send widespread projections to the cortex. The ventral pathway (*solid*) also originates in these same pontine and midbrain nuclei, which project directly to the basal forebrain (*BF*) of the hypothalamus, as well as indirectly through the lateral hypothalamic (*LH*) and tuberomammillary (*TMN*) nuclei. BF in turn projects diffusively to the cortex, promoting wakefulness. *POA* preoptic area; *SN* substantia nigra; *VTA* ventral tegmental area

horizontal limb of the diagonal band, magnocellular preoptic nucleus, substantia innominata, and nucleus basalis. Neurochemical measurement revealed increased levels of acetylcholine in the thalamus and cortex during both wake and REM sleep [49–52].

Electrophysiological recordings have revealed a significant association of basal forebrain neuronal activity with cortical activation [44, 45]. Investigations employing post hoc juxtacellular labeling and single unit recording in the head-restrained rat demonstrated that basal forebrain cholinergic neuronal activity was significantly elevated during wake and REM sleep, when compared to NREM sleep [53–56]. Due to optogenetic excitation of basal forebrain cholinergic neurons, there was an increase in transitions from NREM sleep to wake or REM sleep, overall amounts of wake increased, and stimulation during wake and REM sleep sustained cortical activation [57, 58], although recent optogenetic studies indicate that the wake-promoting effect of basal forebrain cholinergic neurons is less potent than that of basal forebrain GABAergic PV populations (see below).

Labeling of c-Fos, an immediate early gene, and its related protein in the brain is a useful tool to document neuronal activation associated with calcium influx [59, 60]. c-Fos activation was documented in basal forebrain cholinergic neurons immediately after the animal was sleep deprived, indicating that these neurons were indeed activated by sleep deprivation [61–63]. Furthermore, the amount of c-Fos activation correlated with the amount of wake observed in the preceding hour before sacrifice [61, 62]. Specific lesions of basal forebrain cholinergic neurons employing the neurotoxin saporin decreased wakefulness and cortical activation [45, 64–68]. Although various wake EEG indices were affected following basal forebrain lesions, wake state total amounts remained intact. Presumed GABAergic and glutamatergic cell populations in the basal forebrain remain following cholinergic-specific lesioning, suggesting that non-cholinergic basal forebrain neurons may also play a role in promotion of wake. Furthermore, alternative ascending systems that do not involve the basal forebrain also promote wake, such as the dorsal ARAS pathway.

LDT/PPT cholinergic neurons send extensive projections to the basal forebrain, thalamus, and cortex, providing multiple routes to influence cortical activation. Numerous electrophysiological studies have shown tegmental neuronal firing in relation to wake and REM sleep [45, 69, 70]. In a recent study employing juxtacellular labeling and single unit recordings, identified cholinergic LDT/PPT neurons exhibited increased firing in relation to cortical EEG during wake and REM sleep [71].

Serotonin

Most of all nuclei in the ARAS receive a serotonergic innervation originating in select brainstem/midbrain raphe nuclei, particularly the dorsal and median raphe [72–75]. Due to the variety of serotonergic receptors (14 subtypes at last count), the role of serotonin in the ARAS is quite complicated. Early work by Jouvet and colleagues reported that depletion of serotonin by means of *p*-chlorophenylalanine (PCPA) produced insomnia, leading to the initial proposal that serotonin is sleep promoting [76, 77]. Later investigations revealed that such serotonergic depletion also influenced body temperature and movement, hence promoting insomnia. Still later investigations concluded that serotonin acts to promote wake and inhibit REM sleep (our

current understanding). Brainstem dorsal raphe neurons are most active during wake, significantly decrease their activity during NREM sleep, and largely cease activity during REM sleep [78, 79]. Notably, juxtacellular labeling and single unit recordings revealed that most dorsal raphe neurons fire during wake, yet a smaller population were sleep active [80, 81], demonstrating the complex heterogeneity of serotonergic cell populations. Optogenetic cell-specific activation of dorsal raphe serotonergic neurons promoted wakefulness, at the expense of NREM sleep amounts [82].

Numerous pharmacological and genetic knockout investigations have also suggested a role of serotonin in wake promotion. Neurochemical measurement revealed that serotonin levels were highest during wake in the dorsal raphe, as well as many of its efferent targets including the anterior hypothalamus, basal forebrain/preoptic region, hippocampus, and frontal cortex [83–87]. Nevertheless, some studies were unable to demonstrate changes in serotonergic levels in brain regions including the cortex and hippocampus during sleep deprivation, again illustrating the complexity of the serotonin system in sleep regulation [87, 88].

Infusion of 8-hydroxy-2-dipropylaminotetralin hydrobromide (8-OH-DPAT), a largely selective 5-hydroxytryptamine (5HT)-1A receptor agonist, into the dorsal raphe nucleus promoted REM sleep, by means of activation of the 5HT-1A autoreceptor on these serotonergic neurons [89, 90]. Similar to these findings, 8-OH-DPAT activation of the 5HT-1A autoreceptor in the median raphe nucleus promoted hippocampal theta activity [91, 92], providing a mechanism by which the serotonergic median raphe may suppress theta activity indicative of REM sleep. Neonatal treatment of mice with the selective serotonin reuptake inhibitor escitalopram induced depression and anxiety-like behavior, as well as increased REM sleep [93]. The serotonin transporter knockout mouse expressed depression-like behavior, and levels of both REM sleep and serotonin were elevated [94–97]. Although these findings seem to contradict the proposed role of serotonin as a wake-promoting neurotransmitter, REM sleep promotion in the knockout mouse may be due to a down regulation of 5HT-1A receptors on cholinergic neurons in response to the increase in serotonergic tone. Neonatal introduction of compounds that block the 5HT-1A receptor in the serotonin knockout mouse reversed both behavioral and cortical abnormalities, including REM sleep stabilization [98].

Noradrenaline

Noradrenergic brain regions, particularly the brainstem locus coeruleus (LC), also play a major role in promoting wakefulness. The LC sends projections to a number of ARAS-related nuclei, including the basal forebrain, midline thalamus, and cortex [72, 73, 99–101]. Noradrenaline may act as an excitatory or inhibitory neurotransmitter, depending on the type of postsynaptic noradrenergic receptor. The majority of ARAS-related noradrenergic projections are excitatory, acting on α1 receptors [45, 102–105]. Noradrenergic projections to the sleep-related preoptic hypothalamic region, some cholinergic tegmental neurons, and the LC itself act on α2 receptors [106, 107]. LC neurons are most active during wakefulness, and largely cease activity during NREM and REM sleep [108–110]. Non-specific lesions of LC do not drastically alter vigilance states, though [111–115], suggesting that the LC may not be sufficient to alone produce wake, but still influences cortical activation. Recent studies suggest that stress-induced noradrenergic activation may contribute to insomnia, further suggesting that noradrenaline acts to promote wakefulness [116, 117]. Recently, cell-specific optogenetic excitation of noradrenergic LC neurons promoted NREM sleep to wake transitions, overall amounts of wakefulness, and locomotion [118]. Furthermore, optogenetic inhibition of these same neurons decreased amounts of wake and promoted the slow wave activity indicative of NREM sleep. Pharmacogenetic excitation of noradrenergic LC neurons by means of Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) produced cortical activation during isoflurane general anesthesia, as slow wave activity was reduced [119], again implicating noradrenergic systems as a major player in arousal.

Dopamine

Dopaminergic neurons, located in specific brain nuclei including the substantia nigra (SN) and ventral tegmental area (VTA), project to the basal forebrain and the cortex, and returning projections from a number of ARAS-related nuclei have been described [120–122]. Midbrain dopaminergic neuronal burst firing is associated with locomotion, select cognitive functioning, and reward [123–127]. Although single unit recordings were not able to directly correlate SN or VTA unit firing with changes in vigilance state [128], dopaminergic neuronal activity fluctuated across vigilance states, as burst firing increased in frequency during wake [122, 129–131]. Another population of dopaminergic neurons in the ventral periaqueductal gray expressed c-Fos immediately following sleep deprivation, indicating neuronal activation during wake, and these activated neurons were found to project to a number of forebrain ARAS-related nuclei [132]. Of note, treatment of narcolepsy with dopamine-stimulating compounds has proven somewhat successful, allowing stabilization of the vigilance state profile [133, 134].

Histamine

Histaminergic neurons located in the bilateral tuberomammillary nuclei of the hypothalamus (TMN) also play a role in

promotion of wake. Notably, first-generation antihistamines have a sedating effect, acting as antagonists on H1 receptors located on a number of wake-promoting nuclei [135]. Histaminergic TMN neurons project to a number of ARAS-related nuclei, including direct projections to the cortex [136–139]. Histaminergic neurons demonstrate a discharge profile similar to noradrenergic neurons, highly increased activity during wake and significantly decreased activity during sleep [140–142]. Levels of histamine in the posterior hypothalamus were highest during wake and decreased during both sleep states [143]. Both non-specific and histamine-specific lesions of TMN, as well as chemical manipulations, suggest that TMN histamine neurons are indeed wake promoting [141, 144]. Additionally, brain mast cells, which produce approximately 50% of brain histamine, are also implicated in promoting wakefulness [145].

Orexin

Recent investigations within the last 2 decades have described a specific population of neurons that express the neuropeptide orexin (also called hypocretin) in the perifornical (near fornix) region of the posterior hypothalamus. Neuroanatomical investigations revealed strong orexinergic input to ARAS wake-promoting nuclei [146, 147]. Orexinergic neurons fire most during wake, decrease activity during NREM sleep, and are largely silent during REM sleep, except for activation during occasional muscle twitching [148]. Levels of orexin are highest during wake in the lateral hypothalamus [149], and c-Fos studies revealed activation of orexinergic LH neurons immediately following sleep deprivation [150].

Optogenetic cell-specific stimulation of orexinergic neurons produced an increase in NREM–wake and REM–wake transitions [151]. Furthermore, these neurons preferentially fired at frequencies of 5–30 Hz, resembling the firing pattern recorded in orexinergic neurons during cortical activation. Optogenetic stimulation of noradrenergic LC neurons produced NREM sleep to wake transitions of a very short latency ($\sim$5 s) compared to orexinergic stimulation ($\sim$10–30 s), leading to the proposal that LC may be a primary effector of arousal [152]. Pharmacogenetic excitation of orexinergic neurons by means of DREADDs produced neuronal activation, reflected by c-Fos protein labeling, as well as increased time in wake at the expense of both NREM and REM sleep amounts [153]. Also, inhibition of orexinergic neurons with DREADDs decreased wake and elevated total amounts of NREM sleep.

Symptoms of the sleep disorder narcolepsy include hypersomnia, hallucinations, cataplexy, sleep-onset REM sleep, and sleep paralysis. Investigations in the narcoleptic canine model described a deficit in the orexin type 2 receptor [154]. Also, wake was significantly decreased in orexin knockout mice in which the orexin precursor prepro-orexin was deleted [155]. In these animals, the number of transitions between vigilance states was significantly increased, similar to that seen in narcoleptic patients [155]. Orexin-specific lesioning and genetic disruption studies produced a number of symptoms in animals similar to that seen in the narcoleptic, including increased state transitions and intrusion of REM sleep-like characteristics into wake [156–159]. Analysis of postmortem brain tissue collected from narcoleptics demonstrated a significant loss of orexin neurons [160, 161], and low cerebrospinal fluid levels of orexin were reported in cataplectic and narcoleptic patients [162, 163]. Recent investigations have attempted to reverse the neurodegeneration of orexin neurons in LH by means of systemic administration, gene transfer, and cell transplantation of orexin [164–169]. Furthermore, treatment of human narcoleptics with orexin improves a number of symptoms, including sleep abnormalities [169, 170].

Investigations in the narcoleptic canine model suggest that noradrenergic and serotonergic cell populations may play more of a role in the maintenance of muscle tone during wake, and histamine in maintenance of cortical activation. Cataplexy, such as seen during narcolepsy, involves a sudden loss of muscle tone, although consciousness remains. During cataplectic attacks in the dog, noradrenergic and serotonergic cell populations largely ceased firing, but histaminergic neurons remained active [142]. Histamine may therefore play a unique role in promoting wake, particularly cortical activation. Abnormalities in histamine levels in the CSF of narcoleptic patients have been reported [171, 172]. Notably, postmortem analysis of human narcoleptic tissue revealed a significant increase in the number of TMN histamine neurons [173].

Treatment of narcolepsy includes stimulant-like compounds, including dopamine reuptake inhibitors, which improve the sleep profile of the narcoleptic patient, and adrenergic, dopaminergic, and serotonergic reuptake inhibitors are effective in the treatment of cataplexy symptoms [45, 133, 134, 174]. Sodium oxybate has been shown to improve the sleep/wake profile and some cataplectic symptoms in narcoleptic patients [175–177]. Also, orexinergic antagonists are being pursued as a treatment for insomnia [178–180].

Gamma-Aminobutyric Acid (GABA) and Glutamate

In addition to sleep promotion, GABAergic neurons in the cortex and select subcortical regions, such as the basal forebrain, also play a role in the promotion of wake. GABAergic PV neurons play a necessary role in the generation and maintenance of cortical GBO, by means of interaction with cortical pyramidal neurons (reviewed above). Select basal forebrain cortically projecting GABA neurons have been shown to fire in relation to cortical GBO activity [56], and caudal basal forebrain lesions with ibotenic acid, presumably targeting GABAergic neurons, reduced cortical activation and

GBO [65]. A number of wake-promoting neurotransmitters, including those reviewed here, excite basal forebrain GABA neurons, which in turn may activate arousal systems that generate both cortical GBO and hippocampal theta rhythms [56]. Optogenetic excitation of basal forebrain GABAergic/PV neurons entrained GBO in the mouse [181]. In particular, 40 Hz optical stimulation of basal forebrain PV neurons increased cortical GBO. Thus, the basal forebrain and particularly its PV neuronal projecting population play a role in both promoting cortical GBO, as well as fine tuning the pattern of cortical activity during wakefulness.

As previously mentioned, both the dorsal and ventral pathways of the ARAS include glutamatergic excitatory projections. The dorsal pathway includes glutamatergic input from the reticular formation to the thalamus, as well as glutamatergic thalamocortical projections. The ventral pathway of the ARAS includes glutamatergic input from the parabrachial nucleus and reticular formation to the basal forebrain, and basal forebrain projections to the cortex include cholinergic, GABAergic, and, to a lesser extent, glutamatergic input.

Subcortical Modulation of GBO

Although GBO are generated locally in the cortex, subcortical input to the cortex influences GBO, beyond basal forebrain PV influence. Electrical stimulation of the brainstem reticular formation, and its presumed glutamatergic input to the hypothalamus and thalamus, promoted GBO, demonstrating that central activation of ARAS provides a mechanism of synchronization of different cortical subregions [182, 183]. Cholinergic brain nuclei of the ARAS promote high-frequency cortical oscillatory activity including GBO during wake and REM sleep [184–189]. Electrical stimulation of cholinergic brainstem tegmental neurons enhanced thalamocortical cell firing at gamma frequency, as well as the cortical GBO itself [190]. Lesions of basal forebrain cholinergic neurons attenuated high-frequency EEG activity, including GBO, particularly when lesions included the caudal basal forebrain cholinergic cell population [65, 68, 191–194]. Serotonin acts to inhibit cholinergic neurons in both the basal forebrain and tegmental zones [187, 195, 196], attenuating high-frequency beta and gamma activities [188].

NREM Sleep

EEG Profile of NREM Sleep

The cortical EEG profile of NREM sleep includes higher-voltage (amplitude) field oscillations, compared to wake, as well as a slowing of oscillatory activity frequency (Fig. 5.1). Human NREM sleep has been traditionally scored as four stages based on the Rechtschaffen and Kales (R and K) criteria [197]. More recently, the American Academy of Sleep Medicine suggested that NREM sleep may be classified in three stages [198]. N1, NREM sleep stage 1, includes a predominance of theta (4 < 8 Hz) and alpha (8–13 Hz) activity. N2, NREM sleep stage 2, includes both sleep spindles (described below) and K-complexes. K-complexes are brief high-voltage spikes of around 110 μV, and last approximately 0.5 s. They are unique to NREM stage 2 and are a combination of neocortical slow oscillations and spindles [44]. N3 includes that previously described by R and K criteria as stages 3 and 4. This stage is "deeper" NREM sleep, characterized by a predominance of slow delta frequency (1 < 4 Hz) oscillations, and therefore also called "slow wave activity" (SWA). Furthermore, throughout NREM sleep a neocortical slow oscillation (0.5–1 Hz) occurs, which plays a role in thalamic and intracortical synchronization, particularly synchronizing sleep spindles [44, 199–201]. During NREM sleep, EMG recordings exhibit lower muscle tone and little movement, and eye movement is usually absent. In rodent studies, stages of NREM sleep are usually not differentiated.

Sleep Spindles

Sleep spindles are most prominent in human NREM stage 2 [44, 45]. These spindles in humans are of the frequency of 11–16 Hz, lasting around 1 s, and are generated by interplay between the thalamic reticular nucleus (TRN) and thalamocortical neurons. Cortical EEG recordings in the mouse revealed an increase in cortical oscillatory activity of ~11 Hz during early NREM sleep, and also prominent during NREM–REM sleep transitions [202–204]. Sleep spindles promote the deafferentation of thalamocortical input to the cortex that is seen during NREM sleep, and GABAergic TRN neuronal activity particularly paces these oscillations [205, 206]. Optogenetic excitation of TRN GABAergic neurons induced burst firing in thalamocortical neurons, as well as produced cortical spindle activity [204] and increased the duration of NREM sleep [207]. LDT/PPT cholinergic input acts, in part, to inhibit TRN activity, thereby desynchronizing the TRN-thalamocortical oscillatory network and promoting wake and cortical activation [45, 206]. Moreover, basal forebrain neurons project to the TRN, particularly its rostral aspect [208], and chemical lesions in the basal forebrain attenuated spindle activity [209].

Sleep spindles are of current interest since they are markedly reduced in schizophrenia [210, 211]. Therefore, spindle activity is probably the most reliable biological marker for this disorder in sleep. Treatment with eszopiclone, a hypnotic with GABA-α2 receptor agonistic activity,

lessened the sleep spindle deficit seen in schizophrenics, as well as improved memory consolidation [212]. During NREM sleep, cortical slow wave activity coordinates the timing of hippocampal ripples as well as prefrontal spindle activity. In a rat model of schizophrenia, fragmented NREM sleep and impaired slow wave propagation was noted, as well as attenuated prefrontal spindle activity, suggesting that NREM sleep abnormalities such as seen in schizophrenia may produce a decoupling of hippocampal and neocortical activity [213].

Delta Slow Wave Activity (1 < 4 Hz)

As previously mentioned, NREM deep stage activity is indicated by cortical EEG oscillations predominantly in the delta frequency of 1 < 4 Hz, referred to as slow wave activity (SWA). Delta activity occurs as thalamocortical neurons are hyperpolarized. Phasic input to these hyperpolarized thalamocortical neurons produces a low-threshold calcium spike, on which sodium-mediated spikes occur (low-threshold burst). Another subsequent hyperpolarization then occurs, generating the delta frequency oscillation. Blocking thalamic input to the neocortex decreased sleep spindle activity and the frequency of NREM sleep SWA [214]. SWA is also blocked by cholinergic, serotonergic, and noradrenergic excitatory input to either thalamocortical or cortical neurons [45]. Recent investigations indicate that SWA originates locally in individual cortices during sleep [201, 215–217]. For example, individual cortical regions exhibit SWA during sleep deprivation/forced wakefulness, although other cortical subregions exhibited cortical EEG activity indicative of wake [216]. As sleep deprivation progressed, more cortical subregions exhibited sleep-like SWA, indicating an increased homeostatic response to extended wakefulness.

GBO During NREM Sleep

Slow oscillations seen during NREM sleep, including the slow 0.5 Hz wave and delta activity, may underlie limited GBO activity in NREM, activity that is much less than in wakefulness and REM sleep. Recent investigations have investigated high-frequency changes in the human cortical EEG during both NREM and REM sleep [218–221]. The up state of SWA is caused, in part, by prolonged cortical pyramidal depolarizations, and associated GBO were recorded in association with these up states, localized largely in the frontal cortex [200, 218, 219, 222]. This up state is followed by a down state, produced by extended hyperpolarization of pyramidal neurons due to GABAergic interneuronal inhibition. In one investigation, GBO were reported to be associated with this down state, specifically seen in temporal cortical regions [218].

NREM Sleep-Active Neurotransmitters: GABA and Galanin

Sleep-active GABAergic neuronal subpopulations are located in the preoptic nuclei of the hypothalamus. Lesioning and electrophysiological studies suggest that a proportion of neurons in the basal forebrain and the neighboring preoptic region promote NREM sleep [45, 223, 224]. c-Fos protein was expressed in preoptic GABAergic neurons, including the ventrolateral (VLPO) and median preoptic (MnPN) nuclei, during natural sleep and after recovery from sleep deprivation, when sleep was particularly enhanced [225, 226]. The VLPO is uniquely positioned to affect ARAS-related nuclei, for it receives input from a number of excitatory wake-related nuclei [227], and reciprocally projects to many of these same nuclei using GABA and galanin as inhibitory neurotransmitters [228]. Specific lesions to the core of VLPO produce largely NREM sleep disturbances [229]. Select basal forebrain/preoptic neurons increased firing during NREM sleep, and juxtacellular labeling and single unit recording techniques revealed that many of these neurons were GABAergic [54]. MnPN neurons fired immediately preceding entrance into NREM sleep, and continued throughout NREM sleep, and VLPO neurons were active largely during NREM sleep [223, 224, 230].

Evidence indicates that cortical neuronal nitric oxide synthase (nNOS) neurons modulate SWA. nNOS knockout mice exhibited disrupted NREM sleep and decreased amounts of SWA after sleep deprivation [231]. In addition, mice injected centrally with the nNOS antagonist 3-bromo-7-nitroindazole have reduced SWA compared to vehicle injections [232]. Recently, cortical GABAergic neurons that co-express nNOS and the neurokinin 1 receptor (i.e., the primary receptor for the pro-inflammatory molecule substance P) were activated during recovery sleep after sleep deprivation, assessed with c-Fos immunoreactivity [231, 233–236]. The activation of these cortical neurons is associated with changes in SWA and likely play a role in regulating SWA.

As mentioned, the VLPO is reciprocally connected with a number of ARAS-related nuclei [237]. Saper and colleagues proposed that this circuitry was reminiscent of a “flip-flop” switch as described in electrical engineering [238], depicted in Fig. 5.4. One exception of this mutual inhibition between wake and sleep-active nuclei is that histamine does not directly affect VLPO activity [239]. TMN histamine may inhibit VLPO indirectly, though, considering TMN histamine neurons are largely GABAergic. As shown in Fig. 5.4, orexin acts to switch the “flip-flop” between wake and NREM sleep states. Abnormalities in orexinergic circuitry would lead to abnormal vigilance state regulation,

which is similar to that seen in narcolepsy. Of note, orexin knockout mice exhibit excessive vigilance state changes [158]. Orexin therefore is an essential player in vigilance state regulation, promoting transitions between wake and sleep in the "flip-flop" model. Recent optogenetic investigations suggest that LC noradrenergic neurons may be a primary effector of arousal, transferring orexinergic LH activity [152].

The Circadian Drive to Sleep

The two-process model of sleep regulation was first proposed by Borbély and colleagues [240], involving both a homeostatic (process S, reviewed later) and circadian (process C) component. Circadian rhythms of behavior follow an approximate 24-h periodicity, and both endogenous internal and exogenous environmental oscillators influence vigilance state regulation. Such environmental cues are termed "zeitgebers" and include light and food. The interactions of both process S and C produce a distinct pattern of daily wakefulness and nocturnal sleep in humans [241–243].

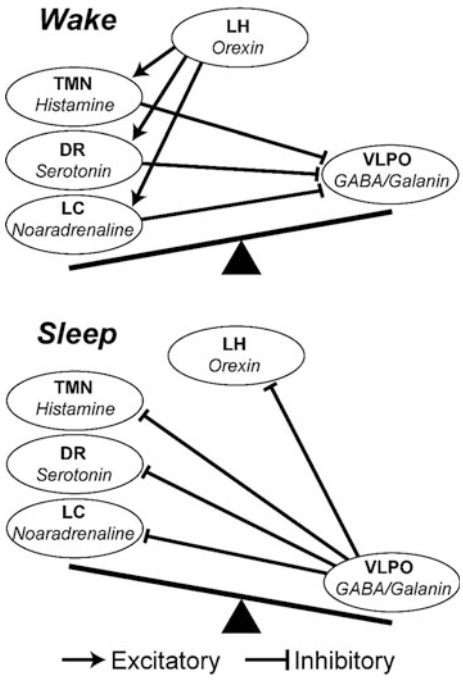

Fig. 5.4 "Flip-flop" switch model of sleep/wake transitions [238]. Histaminergic neurons of the tuberomammillary nucleus (*TMN*), serotonergic neurons of the dorsal raphe nucleus (*DR*), and noradrenergic neurons of the locus coeruleus (*LC*) promote wakefulness and inhibit ventrolateral preoptic (*VLPO*) sleep-active neurons. Lateral hypothalamus (*LH*) orexinergic neurons excite wake-active neurons, stabilizing the wake state. During sleep, GABAergic/galaninergic VLPO GABAergic/galaninergic neurons inhibit the wake-promoting nuclei, including LH. Mutual inhibition between these wake- and sleep-promoting nuclei produces vigilance state transitions

Overviews of circadian rhythmicity and its influence on behavior are beyond the scope of this chapter and available elsewhere [242–244].

A major internal oscillator of circadian rhythmicity is the suprachiasmatic nucleus of the hypothalamus (SCN). The SCN is the primary internal biological clock that influences sleep/wake regulation [243–245]. c-Fos neuronal activation studies and electrophysiological recordings indicate that SCN activity is highest during the inactive period of animals [243, 246]. Lesion studies of SCN produced disrupted rhythmicity of behavior, including vigilance states, as well as hormonal secretions. Notably, although vigilance state regulation was disrupted in SCN-lesioned animals, total amounts of sleep/wake over 24 h remained unchanged.

NREM Sleep Homeostasis

As posited in the two-process model of sleep regulation, sleep is influenced by both process S, the homeostatic drive to sleep based on SWA, and process C, the circadian drive to sleep [240]. Process S is an increase in the propensity to sleep due to the previous time spent awake. That is, the longer an animal (or person) stays awake, neural mechanisms act to increase the drive for sleep. Numerous studies have demonstrated that, as wake is extended with techniques such as acute sleep deprivation/fragmentation, the homeostat is pushed, and the intensity of NREM sleep, measured as SWA, is significantly increased, evident in the recovery period following sleep disturbance. Recent investigations suggest that SWA and sleep are regulated independently [247]. Some experimental sleep disruption protocols model the sleep restriction experienced by many individuals, in which only short amounts of sleep per day are allowed. SWA in the recovery period following multiple days of sleep restriction did not lead to enhancement of SWA in the rat [233, 248–250], yet functional detriments such as impaired cognition persisted [251]. Therefore, chronic sleep loss conditions appear to exhibit a compensatory allostatic response not applicable to the two-process model [249, 250].

Metabolic Homeostasis

Adenosine Triphosphate. One proposed hypothesis of sleep regulation is that sleep allows the replenishment of energy stores diminished during wake [252, 253]. Evidence indicates that adenosine triphosphate (ATP) is released into the extracellular space with increased waking activity and functions to enhance sleep [254]. The purine adenosine is the product of ATP degradation by enzymes including 5′-ectonucleotidase, which occurs as energy stores are used in cellular metabolism [255, 256]. Mice lacking 5′-ectonucleotidase have an attenuated NREM sleep response to sleep deprivation [257]. ATP levels were shown to increase in the

first few hours of NREM sleep, further supporting the relevance of the energy hypothesis; moreover, the increased ATP was associated with a reduction in phosphorylated adenosine monophosphate kinase and hence a favoring of anabolic processes [258].

Adenosine. Adenosine acts as a somnogenic neurotransmitter, promoting sleep by means of interaction with adenosine-specific receptors located in various brain regions [255, 256, 259, 260]. As an organism stays awake, adenosine levels increase, acting on adenosine receptors to inhibit wake-active nuclei of the ARAS, namely the basal forebrain and the cortex. Levels of extracellular adenosine increased selectively in the basal forebrain and the cortex as the sleep homeostat is pushed by means of either sleep deprivation or fragmentation [61, 261–264]. Adenosine diurnally fluctuates, as level rise during the dark (active) period in the rodent, and decrease as the light (inactive) period progresses [263–265]. In epileptic human subjects, indwelling microdialysis sampling in the cortex, hippocampus, and amygdala demonstrated a diurnal fluctuation, as extracellular adenosine levels were elevated during the active day [266].

Administration of adenosine or adenosine agonists into the basal forebrain diminished wake and promoted sleep, and adenosine antagonists increased amounts of wake [255, 256]. Of note, both caffeine and theophylline are adenosine receptor antagonists, explaining the wake-promoting effect of these compounds. Adenosine acts as a somnogen by means of adenosine 1 receptor activation in the basal forebrain [45, 255, 256, 262]. Mice lacking the adenosine 1 receptor gene have a decreased SWA response during the sleep recovery after sleep deprivation, as well as cognitive dysfunction in a working memory task, suggesting that adenosine 1 receptor activation is necessary for sleep homeostasis [267]. Both astrocytes and neurons of the basal forebrain release adenosine and modulate the homeostatic drive for sleep [45, 255, 268]. Recently, NREM sleep has been shown to play a role in metabolic homeostasis by means of a “glymphatic” mechanism [269]. In this study, as natural spontaneous sleep progressed, interstitial space expanded, allowing an increased exchange of cerebrospinal and interstitial fluids. The travel clearance of administered beta amyloid was increased during sleep, suggesting that sleep serves the purpose of removing toxic waste products that accumulate in the brain during wake.

Adenosine also acts as a somnogen in the subarachnoid space just ventral to the basal forebrain and the neighboring preoptic area, including the VLPO, largely by means of adenosine 2A receptor activation that disinhibits VLPO GABAergic/galaninergic sleep-promoting neurons [270]. Prostaglandin 2, another proposed somnogen, was intracerebrally injected into this region, and c-Fos neuronal activation was evident in VLPO neurons [271]. Additionally, NREM sleep amounts were significantly increased after prostaglandin VLPO injections [272], which promoted adenosine release [273].

Nitric oxide. Nitric oxide (NO) production promotes adenosine release during wake, such as seen during sleep deprivation [274, 275]. In vitro administration of NO or NO donors increased adenosine production in the basal forebrain and hippocampus [276, 277], and in vivo intracerebral injection of NO donors into the basal forebrain increased NREM sleep and basal forebrain adenosine release [278]. Therefore, as the sleep homeostat is elevated, levels of inducible NO are enhanced, leading to a release of adenosine in both the basal forebrain and the frontal cortex, in turn inhibiting basal forebrain and cortical wake-active neurons [279, 280.]

Cytokines. Cytokines are humoral factors that regulate both pathologic and normal functions including immune responses and sleep regulation [281–284]. The most well-studied cytokines are the pro-inflammatory molecules interleukin-1 beta (IL-1β) and tumor necrosis factor α (TNF-α), although many cytokines have been implicated in modulating sleep. Pro-inflammatory molecules typically enhance NREM sleep and SWA, while anti-inflammatory molecules attenuate these responses, demonstrated after enhanced waking activity or exposure to pathogens or other related molecules that enhance cytokines. Cytokines are present throughout the body including the brain and are produced by many brain cells types including neurons, microglia, perivascular macrophages, and astrocytes. Plasma and brain mRNA levels of IL-1β and TNF-α are elevated as the homeostatic drive for sleep is increased, such as occurs with sleep deprivation or spontaneous wake progression [285–287]. Administration of either of these cytokines enhances NREM sleep amounts and SWA in animal studies, and IL-1 systemic administration also induced sleep in humans [282–284, 288, 289]. Inhibition of cytokine production or knockout of either the IL-1 type 1 or TNF 55-kDa receptor in mice attenuated NREM sleep responses [290–295]. Extracellular ATP released by either immune cells, neurons or glia acts on the purine type 2 receptor, promoting glial release of both cytokines. In turn, these cytokines alter cell membrane properties allowing increased sensitivity to modulation by adenosine and neurotransmitters [282, 284].

Synaptic Homeostasis

Tononi and colleagues recently suggested that SWA provides a mechanism by which cortical synaptic homeostasis occurs, theorized in their **S**ynaptic **H**omeostasis H**y**pothesis (SHY) [296–298]. As proposed, wakefulness involves strengthening of many synapses as the animal navigates and learns from its environment. These brain mechanisms demand increased metabolism, as energy stores are used. During SWA, synaptic downscaling occurs, as synaptic strength is downregulated and energy reserves restored,

re-normalizing previously active synapses. Upregulation of the mRNA of a number of genes implicated in synaptic strengthening, including brain-derived neurotrophic factor (*bdnf*), neuronal activity-regulated pentraxin (*narp*), and activity-regulated cytoskeleton-associated protein (*arc*), was reported in animals killed immediately following wake, when compared to sleep mRNA profiles [299]. Ex vivo investigations analyzing the prefrontal cortex slice following sleep deprivation showed an increase in miniature excitatory postsynaptic currents (mEPSCs) in pyramidal neurons [300]. Investigations in drosophila demonstrated an increase in synaptic size and strength as flies were kept awake, and downscaling of synapses as sleep was allowed to proceed [301]. Cortical recordings in animals, as well as high-density EEG recordings in humans, demonstrate that the slope and amplitude of SWA diminishes as sleep progresses, which may also reflect synaptic downscaling [302–304].

Although SHY is an intriguing and valuable organizing hypothesis, there are many exceptions [45, 305]. For example, an increase in mEPSCs does not necessarily reflect synaptic strengthening due to neuronal firing. Many studies have shown an increase in synaptic strengthening mechanisms such as long-term potentiation during sleep, evident during NREM sleep spindles and REM sleep theta frequency oscillatory activity [306–312]. Recently, disrupted sleep was found to attenuate NREM branch-specific dendritic spine formation in the motor cortex of mice following motor learning, providing direct evidence that sleep promotes learning-dependent synapse formation [313]. Learning may demand both synaptic strengthening and weakening by such mechanisms as long-term depression, to allow extinction of non-critical forms of information [314, 315]. Also, most of all SHY-related investigations have evaluated synaptic strengthening in cortical regions, but not subcortical circuitry, such as that of the ARAS. Lastly, alternative mechanisms that may produce synaptic strengthening across the sleep/wake cycle, such as circadian fluctuation of temperature and glucocorticoids, need to be investigated [305].

Rem Sleep

EEG Profile of REM Sleep

REM sleep was first documented by Aserinsky and Kleitman in the 1950s [316, 317]. As shown in Fig. 5.1, the EEG profile of REM sleep is strikingly similar to that of wake, exhibiting cortical activation. Because of this similarity, this sleep state is also called "paradoxical sleep." EMG recordings reveal a lack of postural control and little muscle tone compared to wake. EOG recordings capture the rapid lateralized eye movements that define this stage. Also evident during REM sleep are two EEG phenomena: pontine-geniculo-occipital waves, and theta rhythmicity, particularly in the hippocampus. During REM sleep and wake, bursts of GBO are often associated with theta activity in the hippocampus. Parvalbumin neurons in the hippocampus fire at gamma frequencies, and this activity may provide a mechanism for phase locking of GBO in the cortex to theta rhythms [12, 17].

Pontine-Geniculate-Occipital Cortex (PGO) Waves

PGO waves consist of field potential activity in the dorsal pons, lateral geniculate nucleus, and occipital cortex. These waves are recorded in animals immediately preceding transitions into REM sleep, as well as during REM sleep, and the source of activation appears to be in the reticular formation [45]. The dorsolateral pons, brachium conjunctivum, and subcoeruleus/sublaterodorsal tegmental nuclei all appear to be involved in PGO wave generation [318–320]. PET scans and field potential recordings in humans have noted increased activity in the right geniculate and occipital cortex during REM sleep [321, 322], and simultaneous fMRI and EEG recordings revealed REM-related activation in the pontine tegmentum, thalamus, and visual cortex [323].

Theta Rhythmicity During REM Sleep

The hippocampal theta rhythm consists of field oscillatory activity in the frequency range of 5–8 Hz and is seen throughout REM sleep, as well as during select tasks during wake, including attention, spatial navigation, and movement [47, 48, 324]. Theta generation originates in reticular formation sites, particularly the RPO, nucleus gigantocellularis, and pontis caudalis. These neurons fire tonically during theta and project to such regions as the supramammillary nucleus of the hypothalamus (SUM), where the incoming tonic barrage of activity is translated into phasic output that then impinges on such forebrain regions as MS/DBv in the basal forebrain. SUM projections also directly terminate on hippocampal regions [325]. MS/DBv then sends GABAergic and cholinergic projections to the hippocampus, where the field oscillatory theta rhythm is recorded.

REM Sleep-Related Neurotransmitters

Acetylcholine

Transection studies revealed that brain regions anterior to the midbrain and posterior to the medulla were not necessary for REM-related brainstem activity [326, 327], and later lesioning studies determined that in this loci, largely the dorsolateral pons, were nuclei necessary for REM sleep generation including the serotonergic dorsal and median raphe nuclei, noradrenergic LC, and cholinergic LDT/PPT [45, 328]. Unlike the majority of wake-related neurotransmitters, cholinergic neurons are uniquely active during both

wake and REM sleep states. Levels of acetylcholine in the cortex, as well as choline acetyltransferase mRNA in the basal forebrain, are highest during REM sleep, compared to both wake and NREM sleep [52, 329].

Direct reticular formation injections of compounds that enhance cholinergic transmission such as carbachol, muscarinic agonists, or acetylcholinesterase inhibitors induce REM sleep [45]. Early studies using the cholinergic agonist carbachol in the cat demonstrated that reticular formation injections produced a REM-like sleep state [45, 330]. A similar induction of REM sleep can be induced in rats and mice, although the effect is not as robust, possibly due to species differences, difficulty of localization of the agent to the pontine reticular formation in smaller rodent brains, as well as differences in delivery methods [331–333]. Furthermore, non-specific lesioning of LDT/PPT attenuated REM sleep, and the amount of cholinergic cell loss in these tegmental regions strongly correlated with the amount of subsequent REM sleep loss [334]. c-Fos studies also indicate that LDT/PPT neurons are active during REM sleep [335, 336], although some investigators were unable to replicate these findings [114, 337]. Unit recordings reveal that a subpopulation of LDT/PPT neurons fire selectively during wake and/or REM sleep [69, 70, 196], and recent studies employing juxtacellular labeling and recordings demonstrated that many tegmental wake/REM-on cells were indeed cholinergic [71]. Also, cholinergic neurons of the basal forebrain fired in bursts in relation to hippocampal theta activity during both wake and REM sleep, and juxtacellularly identified cholinergic basal forebrain neurons were found to fire maximally during wake and REM sleep [53–56]. Cholinergic-specific lesioning in the basal forebrain produced a reduction in REM sleep individual bout duration, as the amplitude of theta activity was reduced [338]. It is likely that optogenetic and pharmacogenetic studies will greatly enhance our understanding of tegmental cholinergic neurons in REM sleep promotion.

GABA and Glutamate

Select GABAergic/galaninergic neurons in an extended cluster around the VLPO expressed c-Fos specifically during REM sleep, indicating that these neurons are active during REM sleep, and specific lesions to this region also produced REM sleep disturbance [114, 229]. Single unit recordings in the preoptic area revealed that select neurons fire preferentially during REM sleep, further confirming that a subpopulation of neurons in the preoptic region are REM sleep active [223, 224].

An area located near the cholinergic tegmental zone, the sublaterodorsal nucleus (SLD located ventral to the LC), also plays a role in promoting a major characteristic of REM sleep, muscle atonia. This area is called the perilocus coeruleus alpha in the cat, and either SLD or subcoeruleus nucleus in the rodent. Early investigations found that lesions in this region suppressed REM-related muscle atonia. In particular, larger lesions that included SLD, the amygdala and colliculus produced "oneric" dream-like behavior in the cat during REM sleep, including locomotion and head movement [339, 340]. GABAergic neurons in the pontine reticular formation most likely inhibit SLD activity during wake, and these neurons are themselves inhibited during REM sleep by means of tegmental cholinergic input [341–343]. Early work by Magoun and Rhines determined that a region in the ventral medulla in the vicinity of SLD played a role in muscle atonia during REM sleep, and later investigations described projections from SLD to a glycinergic cell population in the ventral medulla, which in turn projects to spinal cord motor neurons involved in postural muscle tone [344, 345]. More recently, Lu and colleagues proposed an alternative pathway, based on c-Fos and neuroanatomical tracer investigations, in which SLD sends a glutamatergic projection directly to GABAergic/glycinergic spinal cord interneurons, which in turn inhibit spinal cord motor neurons [114]. Recently, simultaneous blockade of both GABA-B and glycinergic/GABA-A receptors prevented REM sleep muscle atonia involving the trigeminal motor pool neurons [346, 347]. Therefore, brainstem GABAergic/glycinergic neurons promote atonia by inhibition of these motor neurons, as REM-active glutamatergic neurons excite these same GABAergic/glycinergic cell populations. It remains to be determined if similar mechanisms are at play involving other muscle atonia-related cell populations, such as hypoglossal motoneurons that innervate the genioglossal muscle or spinal cord motor neurons.

Melanin Concentrating Hormone

Interspersed among orexinergic neurons in the lateral hypothalamus are GABAergic neurons that secrete melanin concentrating hormone (MCH), and recent studies suggest that these neurons play a role in sleep regulation [348–351]. MCH acts to inhibit wake-active neuronal cell populations throughout the ARAS, including orexinergic neurons, allowing sleep to be expressed [350, 352, 353]. In turn, a number of wake-related brain nuclei may inhibit MCH activity. MCH neurons are largely inactive during wake, increase firing during NREM sleep, and fire maximally during REM sleep [354]. c-Fos assessed neuronal activation was also elevated in MCH neurons during sleep [355]. Intracerebroventricular injections of MCH significantly increased both NREM and REM sleep, and direct injections of MCH into wake-active nuclei such as RPO, dorsal raphe nucleus, or the basal forebrain promoted REM sleep [350]. MCH neurons act largely on the MCH1 receptor, localized on a number of ARAS-related nuclei. MCH1 receptor suppression by antagonists or genetic knockout produced decreased NREM and REM sleep amounts [349, 356–359].

Additionally, optogenetic stimulation of MCH neurons produced a significant decrease in wake, and excitation applied at the beginning of REM sleep extend REM sleep bout length [360]. Furthermore, optogenetic inhibition decreased REM sleep theta activity, although overall REM sleep amounts and bout lengths were largely unaffected [361].

The Reciprocal Interaction Model of REM Sleep Regulation

McCarley and Hobson introduced the reciprocal interaction model to explain the neural circuitry and neurotransmission involved in transitions to the REM sleep state, as well as the REM oscillator, which is about 90 min in humans and shorter in smaller animals [362]. A further goal was to have the model be mathematically correct in terms of describing these oscillations. Initially the model was purely based on Lotka-Volterra equations, originally proposed to describe predator/prey interactions. An update to the model included a more realistic limit cycle set of equations to account for circadian variation [363]. Other updates have included the growing neurophysiological knowledge of REM sleep control factors, including GABAergic influences on REM sleep regulation [45, 362, 363].

As proposed (Fig. 5.5), cholinergic LDT/PPT neuronal firing increases immediately preceding and during REM sleep. This cholinergic excitation promotes glutamatergic activity in reticular formation regions including the SLD, parabrachial nucleus, and RPO. Cholinergic activation, and excitatory effects on these glutamatergic populations, are responsible for many of the featured REM sleep characteristics reviewed here, including PGO waves, hippocampal theta activity, and muscle atonia. Cholinergic LDT/PPT neurons also inhibit select reticular formation GABAergic cell populations, whose role is to act as REM-off neurons, further promoting REM sleep. Both serotonergic and noradrenergic cell populations are REM-off and wake-on. Their activity during wake decreases significantly as REM sleep approaches due to autoinhibition, and they remain silent until the REM-wake transition [45]. The serotonergic dorsal raphe and noradrenergic LC both project to and inhibit LDT/PPT REM sleep-promoting activity. LDT/PPT cholinergic neurons excite GABAergic reticular formation populations which in turn inhibit both serotonergic and noradrenergic REM-off cell populations.

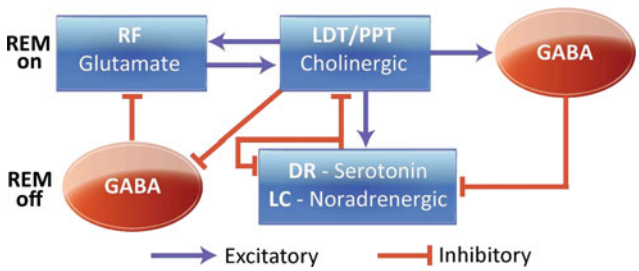

Fig. 5.5 Modified reciprocal interaction model of REM sleep control [362, 363] *Blue nuclei* and *arrows* are excitatory, and *red* inhibitory. Laterodorsal (*LDT*) and pedunculopontine (*PPT*) tegmental REM-on cholinergic activity excites reticular formation (*RF*) glutamatergic REM-on neurons. LDT/PPT REM-on neurons also excite GABAergic REM-on interneurons that act to inhibit dorsal raphe (*DR*) and locus coeruleus (*LC*) REM-off neuronal activity. LDT/PPT REM-on neurons also inhibit GABAergic REM-off interneuronal activity, in turn promoting REM-on RF neurons. As REM sleep progresses, REM-on cells begin to excite REM-off cells, leading to REM sleep cessation

It is important to note that LDT/PPT activity is comprised of both REM-on and wake–REM-on neurons (about 2/3) [69, 70, 364]. To test the hypothesis of differential inhibition of tegmental REM-on populations by aminergic neurons, Thakkar and collaborators developed a novel methodology in freely behaving animals allowing both extracellular single cell recording in PPT and local perfusion of neuropharmacological agents by way of an adjacent microdialysis probe [196]. Discharge activity of REM-on neurons was almost completely suppressed by local microdialysis perfusion of the selective 5-HT1A agonist 8-OH-DPAT, while this agonist had minimal or no effect on the wake/REM-on neurons. These findings suggest that REM sleep ends as the excitatory effects of REM-on neurons cause serotonergic and noradrenergic neurons to resume activity; this in turn, suppresses REM-on neuronal activity. In terms of further evaluation of the cholinergic influences on REM sleep using optogenetic or DREADD technology, it is important to note the presence of both REM-on and wake–REM-on neurons—important in EEG activation in both REM sleep and wake—in the cholinergic population. Activation of the entire population by optogenetic or DREADD experiments may thus fail to produce a clear-cut REM episode. We think early experiments that implicated the brainstem endogenous production of acetylcholine in REM sleep promotion by use of neostigmine are a helpful guide as to cholinergic influences on REM sleep, as microinjection of neostigmine into the pontine reticular formation of cats enhanced desynchronized sleep signs [365].

Summary

This chapter provides an overview of the neurobiology of vigilance state regulation. Over the last 50 years, both clinical and basic investigations have begun to elucidate the neural mechanisms regulating sleep, in part due to the development of exciting new experimental techniques. Increased understanding of these neural mechanisms will aid

the development of pharmacological and behavioral treatment of sleep pathology.

Basic Circadian Timing and Sleep-Wake Regulation

6

Marc Cuesta, Philippe Boudreau, and Diane B. Boivin

Abbreviations

5-HT	5-hydroxytryptamine or serotonin
A1	Adenosine type 1 receptor
A2a	Adenosine type 2a receptor
AA-NAT	Arylalkylamine *N*-acetyltransferase
ACh	Acetylcholine
ACTH	Adrenocorticotropic hormone
AMPA	Alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
ARC	Arcuate nucleus
BDNF	Brain-derived neurotropic factor
BNST	Bed nucleus of the stria terminalis
cAMP	Cyclic adenosine monophosphate
cGMP	Cyclic guanosine monophosphate
CBT	Core body temperature
ccgs	Clock-controlled genes
CR	Constant routine
CRE	Calcium/cAMP response element
CREB	CAMP response element binding
CRH	Corticotropin-releasing hormone
DMH	Dorsomedial nucleus of the hypothalamus
DMV	Dorsal motor nucleus of the vagus
DRN	Dorsal raphe nuclei
EEG	Electroencephalography
EGF	Epidermal growth factor
EMG	Electromyography
ERKs	Extracellular signal-regulated kinases
EOG	Electrooculography
GABA	Gamma-aminobutyric acid
GCs	Glucocorticoids
GHT	Geniculohypothalamic tract
GLU	Glutamate
HB	Habenula
IL-1β	Interleukin-1 beta
IML	Intermediolateral column
IGL	Intergeniculate leaflet
LC	Locus coeruleus
LS	Lateral septum
LDT	Laterodorsal tegmental nucleus
LHA	Lateral hypothalamus area
LPT	Lateral pontine tegmentum
MPO	Medial preoptic area
MRN	Medial raphe nuclei
MT2	Melatonin type 2 receptor
NMDA	*N*-Methyl-D-aspartate
NO	Nitric oxide
NPY	Neuropeptide Y
NREM	Non-rapid eye movement
ORX	Orexin
PACAP	Pituitary adenylate cyclase-activating peptide
PC	Precoeruleus
PPT	Pedunculopontine tegmental nucleus
Process C	Circadian process of sleep-wake regulation
Process S	Homeostatic process of sleep-wake regulation
PSG	Polysomnography
PVN	Paraventricular nucleus of the hypothalamus
PVT	Paraventricular nucleus of the thalamus
RGT	Retinogeniculate tract
RORE	ROR-specific response elements
REM	Rapid eye movement
RHT	Retinohypothalamic tract
SCG	Superior cervical ganglion
SCN	Suprachiasmatic nucleus
SE	Sleep efficiency
SL	Sleep latency
SLD	Sublaterodorsal nucleus
SPZ	Subparaventricular zone
SWA	Slow-wave activity
TMN	Tuberomammillary nucleus
TNF-α	Tumor necrosis factor alpha
TRH	Thyrotropin-releasing hormone
TSH	Thyroid-stimulating hormone

The Circadian Timing System

Origin and Definition of Circadian Rhythms

On Earth, life has evolved under the influence of the cyclic exposure to sunlight and darkness due to the planet's revolution around its axis. As one rotation is achieved in 24 h, most living organisms display rhythmic variations with a similar period for numerous biologic parameters, such as gene and protein production, physiological functions, behaviors, and cognitive processes. It is thought that evolution has led to the development of species that could integrate this rhythmic variation in their functioning allowing them to anticipate environmental changes in order to increase their chances of survival. While the first written description of biologic rhythms was made during the fourth century B.C. by Androsthenes, it is only in 1729 that the French astronomer Jean-Jacques Dortous de Mairan demonstrated that these rhythms are not passive responses to variations of the outside world. By reporting the persistence of daily leaf movements of the sensitive plant *Mimosa pudica* in constant conditions (i.e., constant darkness), he was one of the first to demonstrate their endogenous origin [1].

Today, these intrinsic oscillations, found in humans and in almost all organisms among animals, plants, fungi, and cyanobacteria [2], are known to be driven by the circadian system (from the Latin *circa* and *dies*, meaning "about" and "one day," respectively). In mammals, this system comprises a multitude of oscillatory structures called "clocks" that are found throughout the body and are able to generate circadian rhythms through a hierarchical organization. For a biologic rhythm to be considered as circadian, it has to fulfill the following properties: The rhythm has to be endogenous, meaning that it persists under constant conditions; the rhythm has to be synchronized or entrained by external and internal cues (called *zeitgebers* or ZT from the German, meaning "time-giver"), the most potent being the light/dark cycle; the rhythm has to be temperature-compensated, meaning that a given rhythm remains constant when temperature increases or decreases across a physiological range [3, 4].

Neurolocalization of Circadian Rhythms: The Mammalian Central Clock

In mammals, circadian rhythms are driven by a central or "master" clock enclosed in a well-defined bilateral region of the anterior hypothalamus, namely the suprachiasmatic nuclei (SCN). The first demonstration establishing that the SCNs are essential for the production of circadian rhythms was published in 1972 in two independent studies, in which a bilateral lesion of the SCNs led to the loss of the cortisol secretion rhythm [5], as well as the rest-activity and drinking behavior rhythms [6]. A later study showed that a transplantation of fetal SCN was able to restore behavioral rhythmicity in hamsters bearing SCN lesions [7]. Notably, the period of the restored rhythm was the period expressed by the SCN of the donor. With this elegant demonstration, Ralph and collaborator demonstrated that the SCNs are the primary structures that generate internal circadian rhythmicity.

Anatomically, the SCNs are two nuclei located in the anterior hypothalamus, on top of the optic chiasm, bilateral to the third ventricle [8]. In humans, each SCN contains around 50,000 neurons for an approximate volume of 0.25 mm^3 [9–11] and can be subdivided roughly into "core" and "shell" regions, also described in most mammalian species [8, 12]. While the ventrolateral "core" neurons largely express vasoactive intestinal polypeptide (VIP), the dorsomedial "shell" neurons are rich in arginine vasopressin (AVP), and both neuropeptides co-localize with γ-aminobutyric acid (GABA) and sometimes with glutamate [12]. "Core" neurons primarily receive photic information from the retinohypothalamic tract (RHT) and densely project to the shell. "Core" neurons appear to be essential in the maintenance of internal coupling and the production of a coherent output signal from the SCNs [13]. Both "core" and "shell" regions [14] project mainly to local structures surrounding the SCNs [14, 15] (Fig. 6.1). Numerous other neurotransmitters and neuropeptides have been detected in the SCNs, but their presence and exact localization are species-specific, suggesting that the SCNs organization is more complex than the core-shell subdivision model [16, 17]. Of note, in humans, neurotensin-containing neurons are present in a larger population than that described in monkeys and all other species [17]. Whereas their role is still poorly defined, a loss of neurotensin-containing neurons has been reported in patients suffering from dementia [18, 19] and correlated with dampening in circadian amplitude such that of the core body temperature rhythm (or CBT) [19].

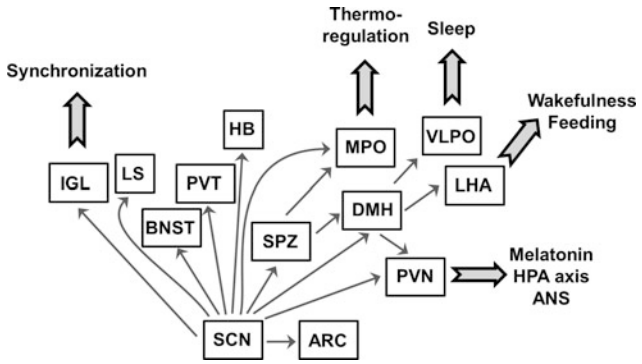

Fig. 6.1 Efferent neural projections from the SCN to different brains regions and their involvement in the regulation of physiological functions. *ARC* arcuate nucleus; *BNST* bed nucleus of the stria terminalis; *DMH* dorsomedial hypothalamus; *HB* habenula; *IGL* intergeniculate leaflet; *LS* lateral septum; *LHA* lateral hypothalamus area; *MPO* medial preoptic area; *PVN* paraventricular nucleus of the hypothalamus; *PVT* paraventricular nucleus of the thalamus; *SCN* suprachiasmatic nuclei; *SPZ* subparaventricular zone; *VLPO* ventrolateral preoptic area

Genesis of Circadian Rhythms: The Mammalian Molecular Clockwork

The molecular mechanisms responsible for the genesis of endogenous circadian rhythms have started to be unfolded in the 1990s. To our knowledge, the first mammalian circadian molecular oscillator model was proposed in 2000 [20], in which the self-sustained rhythmicity is generated by positive and negative components that form feedback core loops with a period of about 24 h (Fig. 6.2; see Table 6.1 for full official/alternative names of the different clock components). Initially, the model was based on reports of behavioral rhythms changes observed in transgenic mice for different "clock" genes. Since 2000, it has been progressively refined with the addition of new components and the development of new transgenic mouse models [3, 21]. Notably, the basic autoregulated feedback core loops have been preserved through evolution and their timing is similar in nocturnal and diurnal species, including humans (for review, see [3]). CLOCK and BMAL1 (two PAS domain helix-loop-helix proteins) represent the positive limb of the loop. In the cytoplasm, CLOCK and BMAL1 translocate to the nucleus where they act as transcription factors on genes containing an E-box (5′-CACGTG-3′) or an E′-box (5′-CACGTT-3′) on their promoter. The genes constituting the negative limb of the loop, namely *Per1/2/3* and *Cry1/2*, contain E-boxes, and their transcription is thus activated by CLOCK/BMAL1. Their protein products, PER and CRY, heterodimerize and bind to CK1ε/δ forming a complex that allows the phosphorylation of PER and CRY. This leads to the translocation of the complex to the nucleus where it accumulates to eventually repress the transcription of several genes, including *Per* and *Cry*. This inhibitory mechanism would be the result of the deacetylation of histones 3/4 following the recruitment of a PTB-associated splicing factor/SIN3-histone deacetylase complex (PSF/Sin3-HDAC complex) by PER/CRY [22].

In addition to this main feedback core loop, interconnected secondary loops and transcription factors have been described, which add supplementary layers of control allowing to fine-tune regulations of the circadian rhythmicity. One of these loops involves the CLOCK/BMAL1 complex, which controls its own production by a regulation of the transcription of other genes containing an E-box, namely *Rev-Erbα/β* and *Rorα/β/γ* (Fig. 6.2). Through a competitive binding on ROR-specific response elements (RORE) present on the *Bmal1* promoter, REV-ERB and ROR proteins can inhibit and activate *Bmal1* transcription, respectively, leading to their cyclic production. Despite this important role, REV-ERB and ROR are not essential to sustain oscillations within the SCN [23]. E-boxes can also be targeted by other transcription factors, such as DEC1/2, which both act to reduce E-box-mediated transcription [24]. Some other second accessory feedback loops involve transcription factors from the proline and acidic amino acid-rich basic leucine zipper family, which can bind to D-boxes (5′-TTATG[T/C]AA-3′) (e.g., DBP and TEF; see Table 6.1) [3].

Transcription factors and transcriptional regulation play a crucial role in the generation of circadian rhythms, but other mechanisms and molecules such as posttranslational modifications, microRNAs, and RNA-binding proteins are also considered important regulatory elements [25, 26]. For instance, the process of elimination of PER and CRY follows a precise timing that is required to end the repression phase and start a new cycle of transcription. Once PER and CRY are targeted by CK1ε/δ and AMPK, respectively, they are polyubiquitylated by β-TRCP1 and FBXL3 (nucleus) or FBXL21 (cytoplasm and nucleus), respectively (proteins that are part of an ubiquitin protein ligase complex, named SKP1-cullin-F-box or SCF ubiquitin ligase complex), which are then degraded by the 26S proteasome (Fig. 6.2). These posttranslational mechanisms allow a control of the stability/degradation rate of the PER and CRY proteins which is crucial to precisely set the period of the central clock [3, 27, 28].

While half of all mammalian genes are expressed rhythmically in at least one tissue [29], it appears that only a small number of genes are truly essential in the genesis of circadian rhythms. All the other rhythmic genes are called clock-controlled genes (ccgs) because they are not involved in the different loops but are regulated by them [30]. Ccgs are considered as the molecular output of the circadian clock. They represent the connection between the feedback core loop and a multitude of cellular and physiological functions, including SCN functions. For example, in the SCN, some of the ccgs, such as the *Avp* gene, are directly under the rhythmic control of CLOCK/BMAL1 via E-boxes [31] and *Avp* is known to be implicated in the circadian regulation of drinking behavior [32]. The rhythmic firing rate of SCN neurons is achieved via the

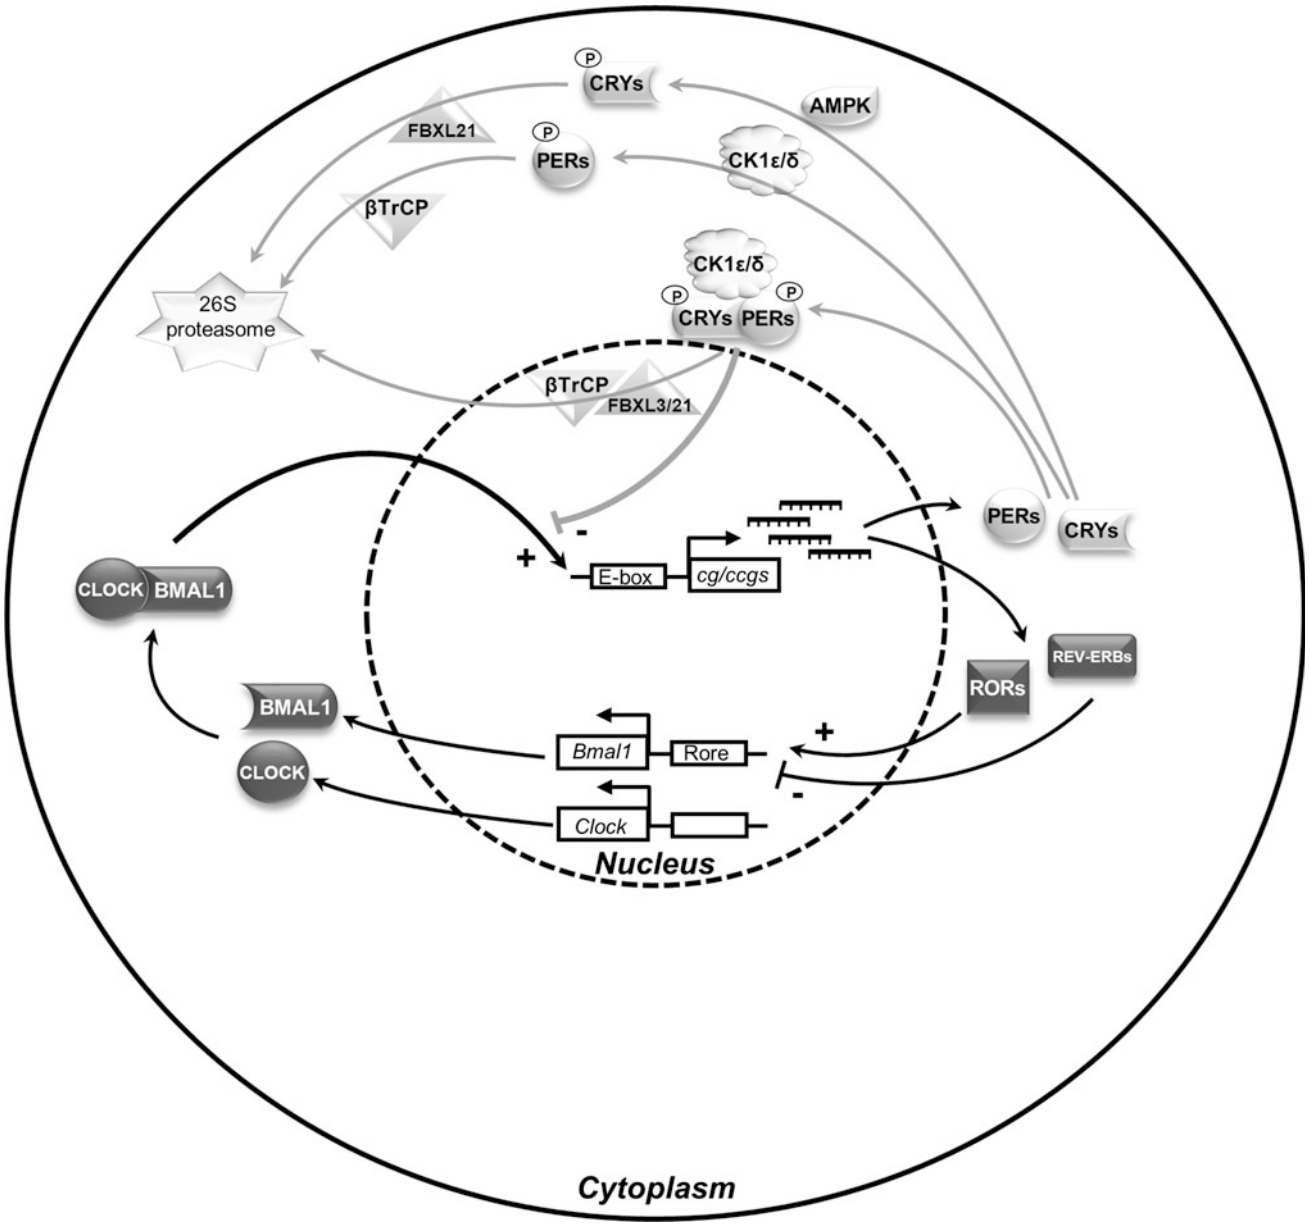

Fig. 6.2 Molecular model of the mammalian cell autonomous oscillator within a SCN cell as described in the text. Genes are represented in *italic* and proteins in CAPITAL. Nomenclature for each element is given in Table 6.1. CLOCK/BMAL1 activates transcription of genes containing an E-Box, including *Per* and *Cry*. PER/CRY, once translated into proteins, inhibit their own transcription. The other actors allow to fine-tune regulations of circadian rhythmicity. *CG* clock gene; *CCGs* clock-controlled genes; *P* phosphate

cyclic regulation of membrane potassium channels, and it is considered as an output of the central clock probably implicating ccgs [33, 34].

Organization of the Circadian System: A Hierarchical Multioscillatory System

For decades, SCN neurons were thought to be the only cells capable of generating self-sustained circadian oscillations explaining why the SCN has been considered as the "master" clock for so long. Today, we know that almost every cell of the body can express the main clock genes in a rhythmic fashion [35], and thus, many brain regions [36–38] and non-neuronal tissues [35, 39–41] can be considered as autonomous clocks, known as peripheral clocks. However, without environmental cues (e.g., in vitro), the oscillations seen in peripheral clocks usually dampen after few days due to a weak coupling between the cells constituting those clocks [42, 43], whereas the SCN can self-sustain

Table 6.1 Non-exhaustive list of core clock genes and associated circadian genes mentioned in the chapter

Gene	Alternative name	Full name
PER1	*PERIOD1*	Period circadian protein homolog 1
PER2	*PERIOD2*	Period circadian protein homolog 2
PER3	*PERIOD3*	Period circadian protein homolog 3
CRY1	–	Cryptochrome 1
CRY2	–	Cryptochrome 2
BMAL1	*ARNTL*; *MOP3*	Brain and muscle aryl hydrocarbon receptor nuclear translocator-like protein 1
CLOCK	–	Circadian locomotor output cycle kaput
NPAS2	*MOP4*	Neuronal PAS domain-containing protein 2
RORα	*RORa*, *NR1F1*	Retinoic acid-related orphan receptor alpha
RORβ	*RORb*, *NR1F2*	Retinoic acid-related orphan receptor beta
RORγ	*RORc*, *NR1F2*	Retinoic acid-related orphan receptor gamma
REV-ERBα	*NR1D1*	Reverse viral erythroblastosis oncogene product alpha
REV-ERBβ	*NR1D2*	Reverse viral erythroblastosis oncogene product beta
CK1δ	*CSNK1d*	Casein kinase I delta
CK1ε	*CSNK1e*	Casein kinase I epsilon
AMPK	–	AMP-activated protein kinase
DBP	–	D-box binding protein
TEF	–	Thyrotroph embryonic factor
B-TRCP1	*BTRC*	Beta-transducin repeat containing protein 1
FBXL3	–	F-box and leucine-rich repeat protein 3
FBXL21	–	F-box and leucine-rich repeat protein 21
DEC1	*BHLHE40*	Differentiated embryo chondrocyte protein 1
DEC2	*BHLHE41*	Differentiated embryo chondrocyte protein 2
AVP	*ADH*	Arginine vasopressin

synchronized rhythms for weeks due to their specific neuronal network. The unique properties of SCN cells are due to their tight coupling elicited through synaptic connections and gap junctions that allow them to remain synchronized with each other even in the absence of a ZT [12].

In peripheral clocks, the molecular mechanisms responsible for the generation of circadian rhythms are similar to those described for the central clock despite the fact that some distinct genetic factors have been described [44, 45]. For instance, in some brain regions including the striatum and the hippocampus, CLOCK is substituted by its analogue NPAS2, while in the liver, both CLOCK and NPAS2 are expressed, but NPAS2 cannot maintain circadian oscillation when CLOCK is missing. Another example defines RORγ as being expressed specifically in peripheral tissues, but with a similar role to this attributed to RORα/β.

In a physiological point of view, these brain- and non-brain tissue-specific clocks, and ultimately, brain and organ functions are likely to be coordinated by the local circadian molecular machinery associated with the integration of systemic synchronizing factors. This dual control leads to the expression of robust circadian oscillations in peripheral clocks. It appears that most of these synchronizing factors primarily originate from the SCNs, although feeding-fasting cycles and temperature variations are known to entrain peripheral clocks [46, 47]. Based on this dual control, the current model of circadian organization in mammals postulates a hierarchical system in which the central clock in the SCNs controls a network of subordinate peripheral clocks throughout the brain and periphery [48]. Despite this apparent organization, it has been demonstrated that some peripheral structures can drive local physiological rhythms independently of the SCNs, such as the retina [41], the olfactory bulb [49], and the adrenal gland [50]. In addition, a line of evidence has shown the existence of two SCN-independent oscillators, namely the food-entrainable oscillator and the methamphetamine-sensitive circadian oscillator [51–57]. These two oscillators are known to control behavioral and hormonal rhythms even in SCN-lesioned animals or in the absence of clock genes, but neither the site nor the mechanisms underlying their functioning have been yet elucidated.

Communication Within the Circadian System: The Neural and Endocrine Pathways

We previously mentioned that neurons from the SCN project mainly to brain regions restricted to hypothalamic nuclei, with the main outputs directed to the subparaventricular zone (SPZ) and the dorsomedial nucleus of the hypothalamus (DMH) (Fig. 6.1) [58]. By projecting to other brain structures, the SPZ and DMH, and the other nuclei can control the rhythmicity of peripheral clocks and their outputs. One of these pathways connects the SCN to the ventrolateral preoptic area (VLPO) via the dorsal SPZ, which is known to control the circadian sleep-wake cycle [59]. Another pathway links the SCN to the medial preoptic area (MPO) through the ventral SPZ regulating the CBT rhythm [59]. In addition, other neuronal pathways areas of particular importance convey information outside of the brain to peripheral tissues. Indeed, using transneuronal retrograde tracers, distinct polysynaptic sympathetic and parasympathetic routes have been identified emerging from the SCN to end up in the liver, kidney, pancreas, bladder, heart, adrenal cortex, spleen, and brown adipose tissues [60–63]. For instance, connections emerging from the SCN reach the adrenal gland via the paraventricular nucleus of the hypothalamus (PVN) and the intermediolateral column (IML) (i.e., sympathetic pathway) and control the rhythm of sensitivity to adrenocorticotropic hormone (ACTH) [64, 65]. Sympathetic projections also control the rhythmicity of melatonin synthesis, a fundamental circadian endocrine factor. To do so, neurons from the IML project to the pineal gland via the superior cervical ganglia (SCG) and regulate in a rhythmic fashion the production of the rate-limiting enzyme arylalkylamine *N*-acetyltransferase (AA-NAT), implicated in melatonin synthesis [66, 67]. The parasympathetic nervous system also conveys rhythmic information via fibers originating in the SCN, which then reach the PVN and the dorsal motor nucleus of the vagus (DMV) allowing for instance a regulation of peripheral clocks found in white adipose tissue and the liver [68, 69]. It seems that through all these innervations, the SCN has the potential to orchestrate the circadian rhythmicity of peripheral oscillators and their metabolic and physiological functions throughout the entire body.

The SCN can also synchronize peripheral oscillators through a rhythmic control of numerous actors of the endocrine system. Among them, few hormones have been well described as regulators of the circadian system. As we previously mentioned, melatonin secretion is regulated by the SCN, and the resulting rhythm of melatonin is known to upregulate some actors of the immune system and to control several seasonal functions [70, 71]. In addition, melatonin would specifically facilitate sleep in humans [70]. Glucocorticoids or GCs (i.e., corticosterone in rats and mice; cortisol in humans) represent another class of hormones that seems essential for the regulation of peripheral clocks. Rhythmic GCs synthesis and secretion are under control of the central clock through direct and indirect projections reaching the PVN. In the PVN, parvocellular neurosecretory cells release corticotropin-releasing hormone (CRH) that controls the release of ACTH from the pituitary gland, itself controlling GCs release by the adrenal glands [50, 72]. The rhythm of GCs is known to regulate the synchronization of many peripheral clocks at both behavioral and molecular levels [45, 72]. The SCN also controls, through the PVN, the release of AVP and thyrotropin-releasing hormone (TRH), the latter stimulating the release of thyroid-stimulating hormone (TSH) and prolactin. Other hormones such as epinephrine and norepinephrine [73], leptin, glucose, and insulin [74] express a circadian rhythm and could constitute endocrine signals by which the central clock synchronizes peripheral oscillators, but further studies are needed to clarify their respective roles.

Synchronization of the Circadian System: External and Internal Factors

In animals, including humans, the endogenous period (or internal day length) of most circadian rhythms is close to, but not exactly, 24 h [75, 76]. To be in phase with the external world, the circadian system is continuously resynchronized to the 24-h terrestrial day through a mechanism called "synchronization" or "entrainment." As a relay between the external environment and the internal functions of the body, the SCN represents the primary structure implicated in this mechanism. Among external factors that influence the circadian system, the 24-h light/dark cycle is the most powerful and the most studied, but it has been demonstrated that variations in environmental temperature or food availability can act as synchronizing factors for the central clock [46, 77, 78]. Notably, a wide range of internal factors that convey physiological information to the central clock are integrated by the SCN in conjunction with light cues and thus participate in the synchronization of the SCN. Some of those internal factors will be described later in this chapter. Of note, in constant conditions, the period of time when nocturnal species are awake is considered as the "subjective" night, while it is named "subjective" day when they are asleep and vice versa for diurnal species.

The Photic Factor: Molecular and Behavioral Effect

In mammals, it has been known for decades that light information is received by image-forming rods and cones' photoreceptors located in the retina, which is then transmitted to the cerebral regions involved in visual processing. While rods and cones are also implicated in the detection of light information that is conveyed to the SCN, a subset of retinal ganglion cells expressing the photopigment

melanopsin (Fig. 6.3) has been described as fundamental for the SCN to be synchronized to the light/dark cycle [79]. Melanopsin cells are present in 0.2–2.5 % of the total number of retinal ganglion cells [79–81] and their maximal photosensitivity occurs in the blue-green light spectrum (~470 nm) [82]. Along with rods and cones, melanopsin cells convey photic information using a direct pathway, the RHT (Fig. 6.3) that has been described in mammals including humans [83–86]. The RHT innervates the ventrolateral "core" region of the SCN and releases glutamate and pituitary adenylate cyclase-activating peptide (PACAP). Moreover, an indirect pathway has been described that connects melanopsin cells to the ventral part of the SCN via the intergeniculate leaflet (IGL), which releases GABA and neuropeptide Y (NPY, Fig. 6.3) [87, 88]. Of note, the IGL is a thalamic structure implicated in the integration of photic and non-photic signals [87–89].

Glutamate released by RHT neuron terminals leads to the activation of multiple signaling pathways in the SCN following activation of *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors [90]. This activation leads to a calcium influx into SCN neurons, which stimulates the synthesis of nitric oxide (NO) [91] known to act differentially depending on the time of day. During the early night, NO induces an activation of ryanodine receptors, which is followed by Ca^{2+} release from the endoplasmic reticulum [92]. During the late night, NO activates guanylate cyclase that stimulates the synthesis of cyclic guanosine monophosphate (cGMP) [92]. A third pathway, implicating cyclic adenosine monophosphate (cAMP) is effective throughout the night [93] and together these three pathways lead to the activation of the protein kinase A and extracellular signal-regulated kinases (ERKs), which phosphorylate cAMP response element binding (CREB) protein [94–96]. In turn, CREB activates *Per1* and *Per2* transcription in the SCN in response to its binding to the cAMP response element (CRE) present on *Per* gene promoters [12, 95–97]. Using alteration of *Per1/2* transcription [98, 99] and *Per1/2* mutant mice [100], these two genes have been attributed a causal role in the mediation of light-induced synchronization of the SCN. Both genes present temporal and spatial differences in their response to the photic factor [101–104]: *Per1* transcription is quickly induced throughout the night in ventral SCN cells; *Per2* expression is induced in the whole SCN, quickly in the early night and slowly or not at all in the late night. Of note, the expression of several other genes and clock genes (i.e., *Bmal1*, *Cry2*, *Rev-erbα*, *Rorβ*, and *c-fos*) is also regulated by light, but their role is less clear [101, 105–110].

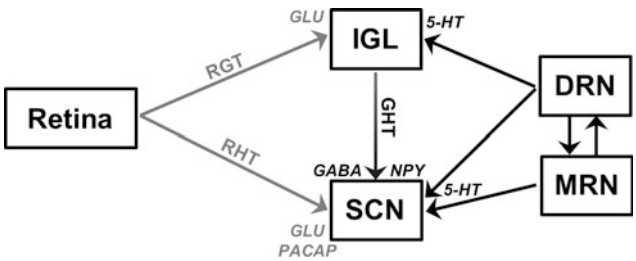

Fig. 6.3 Main afferent neural projections to the SCN, RHT and RGT convey photic cues from the retina to the SCN and the IGL, respectively (*gray arrows*). Non-photic information is conveyed from raphe nuclei (DRN and MRN) to the SCN and the IGL (*black arrows*). The IGL conveys both photic and non-photic cues to the SCN (*black/gray arrow*). Neuropeptides and neurotransmitters are indicated in *italic*. *5-HT* serotonin; *DRN* dorsal raphe nucleus; *IGL* intergeniculate leaflet; *GABA* γ-aminobutyric acid; *GHT* geniculohypothalamic tract; *GLU* glutamate; *MRN* median raphe nucleus; *NPY* neuropeptide Y; *PACAP* pituitary adenylate cyclase-activating peptide; *RGT* retinogeniculate tract; *RHT* retinohypothalamic tract; *SCN* suprachiasmatic nuclei

Thus, from the retina, photic information induces a daily resetting of the central clock by a modulation of the molecular clock leading to changes of the circadian phase of SCN neurons. As SCN neurons form a tightly coupled network, the entire SCN quickly adjusts to a shift of the light/dark cycle. The phase of the SCN can be delayed or advanced by several hours each day in most mammalian species, according to the time of day when the retina receives light [89, 111]. The central clock can then relay photic information to peripheral oscillators through neuronal connections or endocrine signals as previously described, leading to phase adjustments of the circadian rhythms of these oscillators as well as those of their outputs (e.g., locomotor activity, feeding timing, and CBT). For instance, to assess the effects of light on the rhythm of locomotor activity, it is possible to apply discrete light pulses at different time points in animals or humans studied in constant conditions (e.g., constant darkness in rodents and constant routine or CR in humans). Using this method, a phase response curve to light can be defined, which expresses the magnitude of the induced phase shift as a function of the time of light exposure (Fig. 6.4). In both nocturnal and diurnal species, including humans, the phase response curve to light displays a similar pattern with the larger light-induced phase shifts occurring mainly during or close to the subjective night (i.e., active and resting period in nocturnal and diurnal species, respectively) [89, 101, 112–116].

In humans, light exposure in early morning (i.e., after CBT reached its minimal value) is known to phase advance the circadian system [114], while light exposure at night (i.e., before the CBT minimum) results in phase delay of the circadian system. Light intensity [117–119], wavelength [120, 121], and prior light exposure [122] were shown to be important determinants of light-induced phase shifts of the circadian system.

Using a simulated night shift experiment, we recently demonstrated the ability of light to entrain peripheral clocks in humans, through synchronization of the central clock [123].

The Non-photic Factors: Focus on Melatonin, Activity, Sleep and the Serotonergic System

Besides light, many factors can modify the rhythmicity of the circadian system at both molecular and behavioral levels. The most studied non-photic factors cited in this chapter and their effects on clock gene expression in the SCN and the rest-activity cycle are summarized in Table 6.2. This chapter will focus on two categories of non-photic factors, melatonin and factors related to activity, sleep, and the serotonergic system. In animals, food intake represents another well-studied non-photic factor known to synchronize the circadian system. As there have been excellent reviews describing them [55–57], it will not be further discussed here. Many other factors that influence the central clock and/or peripheral clocks have been described (e.g., dark pulses, temperature, GCs, and drug of abuse). Most of these studies have been conducted in nocturnal species and the few results obtained with diurnal species highlight differences between these two types of species that could be relevant to human chronobiology, considering the diurnal nature of human life.

To date, melatonin has been the most studied non-photic synchronizer in humans (for a review, see [124]), and its phase-shifting effects have also been described in several nocturnal and diurnal mammals (Table 6.2). In humans, exogenous melatonin induces phase advances when administered in the late afternoon/evening and phase delays when given in the morning [125, 126]. Similar results have been reported in the evening in nocturnal and diurnal rodents [127, 128]. These effects would be dependent on the

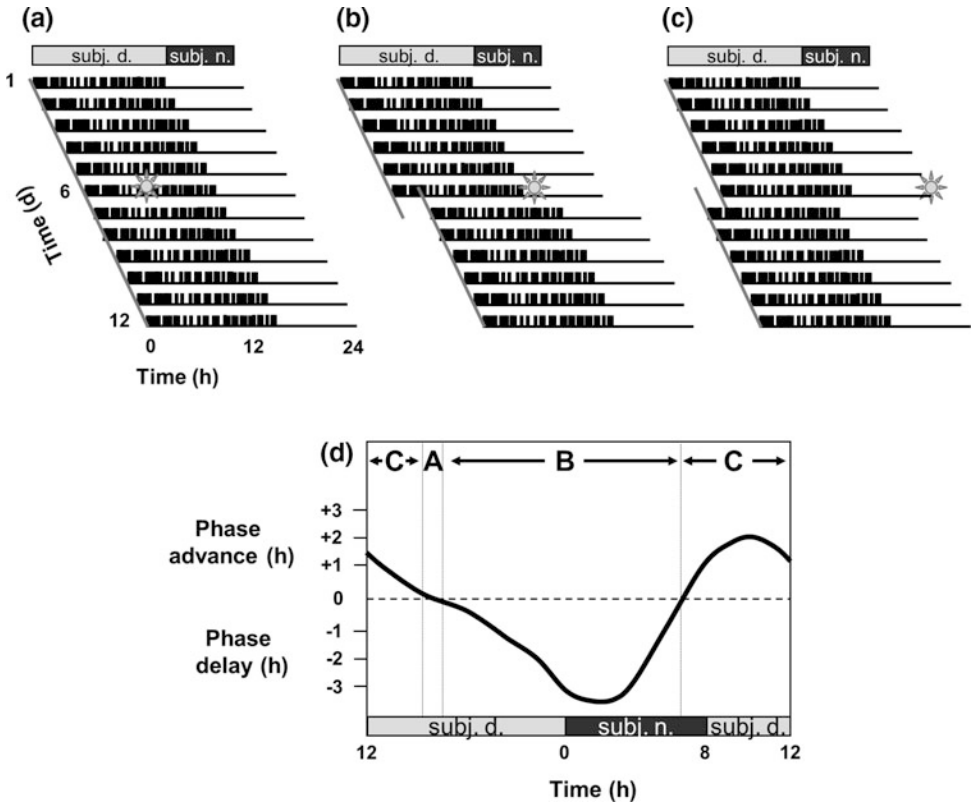

Fig. 6.4 Schematic illustration of light-induced phase shifts of the rest-activity cycle in diurnal humans. Schematic actograms (A, B, C) illustrate the rest-activity rhythm of diurnal humans kept under constant conditions (e.g., constant routine). An actogram is a graph that plots activity levels. In each actogram, twelve successive days are represented from top to bottom, one row corresponding to one day (24-h period). The subjective days (16 h long) and nights (8 h long) are indicated by the *gray* and *black bars*, respectively, at the top of each actogram. In constant conditions, humans express their endogenous period (usually longer than 24 h) explaining why, for a given day, the onset of activity occurs later than the previous day. On the 6th day of recording, a light pulse, represented on the actograms by a *gray* "*sun*," is applied in the middle of the subjective day (*A*), the beginning of the subjective night (*B*), or the end of the subjective night (*C*). In response, the rest-activity rhythm is either not significantly shifted (*A*), phase delayed (*B*), or phase advanced (*C*). Thus, each discrete pulse of light, given at a specific time, leads to various magnitude and direction of shifts. (*D*) represents the phase response curve of the resetting effect of light with by convention phase advance and delays expressed as positive and negative phase shifts, respectively. *subj. n.* subjective night; *subj. d.* subjective day

activation of melatonin type 2 receptor (MT2), which have been found in the SCN of mammals including humans [129–131]. However, *Per* expression is not modified in response to melatonin injections in nocturnal rats [101].

Another well-studied category of non-photic factor comprises behavioral and pharmacological stimuli that are related to levels of activity, sleep deprivation, and the serotonergic system through direct (implicating serotonin or 5-hydroxytryptamine (5-HT) and 5-HT agonists) and indirect (via the IGL and implicating GABA and NPY) connections between the dorsal and median raphe nuclei (DRN and MRN) and the SCN (Fig. 6.3) [132–136]. In nocturnal species, these factors are mainly effective when applied during the middle of the subjective day and they lead to a phase advance of locomotor activity rhythm and a decrease in the expression of *Per1* and/or *Per2* in the SCN [137–142]. Results obtained from diurnal species are limited and provide different results (Table 6.2) [143–148] from those observed in nocturnal species, underlying the differences between these species in terms of sensitivity and responses to non-photic factors. For instance, sustained physical exercise in humans results in a phase delay of the human circadian system when performed at night or in the morning, and a phase advance when exercise is performed in the evening [146, 149–151]. Despite these resetting effects, exercise has been shown to have no effect on the endogenous circadian period of rhythmic parameters in humans [151, 152]. These observations raise an important issue for the development of pharmacological and therapeutic tools that act on the circadian system because they are usually developed and tested in nocturnal species for possible applications to humans.

Of note, this category of activity/serotonin factors highlights the tight connections between the sleep-wake cycle and the circadian system. First, the sleep-wake cycle is closely linked to the activity of 5-HT neurons. For instance, the activity of 5-HT neurons in the cat dorsal raphe is regular and slow during waking episodes [153]. This activity decreases and loses its rhythmicity at the beginning of a sleep episode, until the complete disappearance at the onset of rapid eye movement (REM) sleep episode. Second, 5-HT release in the SCN region occurs during the waking period of nocturnal and diurnal animals and is correlated with the electrical activity of 5-HT neurons [110, 143, 154, 155]. In addition, hyperactivity is known to induce a release of 5-HT into the SCN through fibers originating from the MRN [155], and lesions of 5-HT fibers can block the behavioral phase advances normally present in response to hyperactivity [156]. Third, an induced transient 5-HT deficiency in rats leads to a temporary loss of the circadian rhythms in

Table 6.2 Main behavioral and molecular effects of non-photic factors

Type of factor	Nocturnal species			Diurnal species		
	Timing	Rest-activity rhythm	*Per1/2* expression	Timing	Rest-activity rhythm	*Per1/2* expression
Melatonin	Evening	Phase advance [127]	No effect [101]	*Rodents*: Evening	Phase advance [128]	?
				Humans: Late afternoon/Evening	Phase advance [125, 126]	?
				Humans: Morning	Phase delay [125, 126]	?
Hyperactivity or sustained activity	Midday	Phase advance [137]	Decrease [138]	*Rodents*: Early night	Phase advance [144]	?
				Humans: Evening	Phase advance [146, 149–151]	?
				Humans: Night/morning	Phase delay [146, 149–151]	?
5-HT	Midday	Phase advance [110, 139]	Decrease [139]	*Rodents*: Night	Phase advance [143]	No effect [143]
NPY	Midday	Phase advance [140]	Decrease [141]	?	?	?
GABA	Midday	Phase advance [142, 287]	Decrease [147]	*Rodents*: Midday	Phase delay [147]	Decrease *Per2* [148]

locomotor activity and sleep-wake cycle [157]. Taken together, these results suggest that 5-HT not only promotes wake and inhibits REM sleep [158], but also participates in the circadian regulation of sleep and wake behaviors [157].

The Circadian System in Humans: Specificities and Methods of Investigation

Most of the cellular and molecular data presented in this chapter have been obtained using animal models rather than human subjects, mostly due to the lack of available techniques to measure the intrinsic molecular or electrical activity of the human SCN in vivo and the obvious limited possibilities of human sampling. Nevertheless, laboratories working on human chronobiology typically use robust peripheral output signals primarily regulated by the SCN, thus reflecting the circadian functioning of the central clock. These so-called central circadian markers are derived from physiological measures such as CBT, sleep propensity, or hormone levels such as melatonin and cortisol. Their rhythms are usually defined by their phase, amplitude, and period. The phase represents the time of day when a rhythmic parameter reaches its maximal value (i.e., acrophase or crest time; used for melatonin and cortisol) or its minimal value (i.e., bathyphase or nadir time; used for CBT). The amplitude and period of circadian signals are less commonly reported, though they also provide important information on the state of synchrony/desynchrony between the SCN, peripheral oscillators, and the 24-h environment. In individuals living on regular conditions (entrained to a day-oriented schedule), CBT rhythm typically peaks before habitual bedtime and reaches its minimum values in the second half of the night [159]. Sleep propensity is inversely related to CBT [160]. Melatonin levels start increasing in the evening, reach a peak in the middle of the night, and decrease in the morning with undetectable values occurring during the day [123, 159]. Cortisol secretion peaks just after awakening and slowly decreases through the day to reach its nadir early at night [123]. With the relatively recent discovery of peripheral clocks, markers of those clocks such as clock gene expression (i.e., peripheral markers) have started to be measured in humans as an accessible alternative to central markers. Moreover, they represent a valuable tool to assess the relative synchronization of the different parts of the circadian system. To date, clock gene expression in peripheral oscillators has been measured in different human tissues, including peripheral blood mononuclear cells [159, 161, 162], skin cells [163–165], adipose tissue [166, 167], oral mucosa [163], bone marrow [168], hair follicles [169], and more recently *postmortem* brain regions [38, 170, 171]. Results from these studies indicate that the molecular mechanisms underlying the generation of circadian rhythms are similar in humans and other mammalian species.

In humans, circadian markers can be measured in ambulatory conditions, but they are likely to be masked by behaviors and external stimuli. Negative masking is a process reducing the expression of a circadian pattern [172]. For instance, light exposure at night inhibits the release of melatonin [173]. In contrast, positive masking reflects the expression of a variable in addition to its circadian pattern. In diurnal species, light exposure at night induces a bout of locomotor activity at a time when animals are supposed to sleep [173]. Transient fluctuations in cortisol induced by stress are often high enough to mask the cortisol rhythm [174, 175]. Exercise and feeding have also been described as masking factors that increase the CBT [175, 176]. To precisely describe the circadian profile of a given circadian marker in humans, rigorous protocols need to be used to "unmask" it. Specifically to measure the circadian phase and amplitude, physiological signals have to be measured for at least one complete cycle ($\geq$ 24 h) under constant conditions, such that the influence of the external and internal masking factors (e.g., the sleep-wake cycle, light, food intake, and activity levels) is minimized and/or distributed throughout the day. The most commonly used protocol in human chronobiology, namely the CR (constant routine) [175, 177, 178], is based on this idea and takes place in a laboratory environment of constant dim lighting and ambient temperature. In addition, subjects are requested to stay awake for at least 24 h (up to 72 h), usually in a semirecumbent position to control the level of activity, and meals are replaced by hourly snacks that provide all the essential nutriments needed in a non-circadian rhythmic fashion. Many variations of the CR are in use, with the goal to minimize these masking effects [175]. One of the main issues of the CR is the absence of sleep, especially with protocol >24 h that are known to induce sleep deprivation and negatively affect alertness and performance. As an alternative, a CR protocol with sleep (i.e., constant posture protocol) has been proposed, but by introducing periodic changes in the sleep-wake cycle, parameters such as CBT are affected. Thus, the choice of one or another variant of the CR needs to be based on the type of parameters of interest for a given study. While the CR and its alternatives are very useful to assess the phase and amplitude of central and peripheral circadian markers, other protocols have been developed that focus on other properties of the circadian system. The forced desynchrony protocol induces an internal desynchronization, which is forced by scheduling subjects on sleep-wake regimens that are very different from the classical 24-h rhythm, thus being outside of the range of entrainment of the circadian system (e.g., 28-h day, 20-h day, and 11-h day) [179]. This means that the circadian system cannot be synchronized by the sleep schedule and

instead expresses its own endogenous period. Thus, the phase relationship between the imposed sleep-wake cycle and the circadian system is lost, meaning that the sleep-wake cycle occurs at a variety of circadian phases. This protocol has been very useful to establish the endogenous circadian period of the human central clock and has been used primarily to evaluate circadian and homeostatic influences on observable processes such as sleep, sleep structure, electroencephalographic (EEG) power density in different sleep stages, cognitive performances, mood, and hormonal rhythms (see [179] for references). Other protocols, called multiple naps or ultradian sleep-wake cycle (USW) procedures, have been developed [180–183]. They can be considered as extreme examples of the forced desynchrony protocol. Indeed, in those protocols, the duration of one cycle is usually very short (90 or 120 min) with a wake-sleep ratio that can be of 60/30 min or 60/60 min (the later minimizing the observable sleep restriction). In some extreme cases, the ratio can drop to 15/5 min [184, 185] or 13/7 min [186]. While those protocols do not allow the study of the homeostatic contribution on observable processes, they have the advantage to make possible the examination of the sleep propensity at multiple circadian phases due to the numerous transitions between lights on and lights out.

Circadian Regulation of the Sleep-Wake Cycle

The Sleep-Wake Cycle

As opposed to wakefulness during which functions for survival such as feeding and breeding activities are possible, sleep is a reversible vigilance state characterized by a reduction in voluntary motor functions, sensory perception, and responsiveness and is associated with immobility in a species-specific position. Of note, submitted to the same 24-h light/dark environment, a variety of sleep-wake schedules and sleep durations are observed across species. While some species adopt a diurnal or nocturnal behavior, others are essentially active around dawn and dusk and thus adopt a bimodal behavior [187]. Some species sleep for more than 20 h daily (e.g., cat), while others sleep only for 3 h (e.g., horse) [188]. In humans, sleep is consolidated in a period of approximately 8 h at night, making it one of the most evident behaviors under circadian regulation. It is also interesting to recognize that the sleep-wake cycle can indirectly regulate the circadian system through cyclic exposure to light and darkness. This is especially important in modern society since the development of artificial lighting provides accessible brighter light at night, facilitating nocturnal activities.

Sleep has been historically viewed as a passive behavioral state until the identification of paradoxical sleep by Jouvet et al. [189], also known as REM sleep. With the development of EEG techniques in humans, sleep was subsequently described using standardized terminology and criteria developed by Rechtschaffen and Kales [190], recently updated and simplified by the American Academy of Sleep Medicine [191]. Sleep is generally assessed by polysomnography (PSG), which comprises EEG to measure frontal, central, and occipital cortical activity, electromyography (EMG) to measure muscle activity, and electrooculography (EOG) to measure eye movements. PSG recording is used to classify sleep into two main categories: REM sleep and non-REM (NREM) sleep. NREM sleep can be subsequently subdivided into 3 stages (i.e., stage N1 to N3) marked by progressive slowing and synchronization of electrical cortical activity, as observed on the EEG channels [191]. In healthy individuals, NREM and REM sleep alternate in cycles of approximately 90–110 min and are measured from the end of a REM sleep episode to the end of the subsequent one. The respective proportion of NREM and REM sleep during a sleep period differs between cycles. More N3 sleep (also known as slow-wave sleep) is typically observed in the early night and decreases with time spent asleep. On the other hand, the length of REM sleep bouts during each sleep cycle increases with the amount of time spent asleep. More precisely, the greatest amount of REM sleep is observed in the early morning hours.

The Two-Process Model

Initially proposed by Borbely [192], the two-process model of sleep regulation provides a theoretical framework describing the temporal organization and timing of sleep (Fig. 6.5). The homeostatic process, or Process S, reflects the increased sleep pressure as a function of the amount of time spent awake and its decline as a function of time asleep, similar to an hourglass effect. The circadian process, or Process C, regulates sleep as a function of time of day and depends on the action and timing of the SCN. As a result of the balance between the circadian and homeostatic processes, only a narrow set of sleep-onset times permits a continuous sleep period of about 8 h (i.e., sleep onset ~6 h before CBT minimum) [193–195]. Since its introduction in 1982, other components, such as sleep inertia and a NREM/REM sleep oscillator, have been added to the original two-process model, but the simple conceptual model developed by Alexander Borbely remains the most influential. It has been recently extended to predict alertness and vigilance around the clock [196].

The Homeostatic Process

For a long time, the sleep-wake cycle was considered to be regulated by the accumulation and elimination of a sleep-promoting substance in the organism. To date, many researchers have confirmed the existence of a homeostatic process regulating sleep, but have yet failed to identify a single sleep-related factor. The homeostatic process regulates sleep propensity as a function of the sleep-wake cycle length, independently of the time of day. Specifically, the homeostatic sleep drive or Process S increases when sleep is absent or restricted and conversely declines in response to sleep. Within a sleep period, the EEG slow-wave activity (SWA, 0.5–4.5 Hz) power measured during NREM sleep has been used to quantify Process S. It has been shown to be correlated with the duration of the prior wake period and to decline across the sleep period [197]. In contrast to Process S, the Process C only has a small influence on SWA [195]. The influence of waking on Process S has been estimated by quantifying the level of SWA during naps after various durations of waking [198]. Process S has been modeled by a saturating exponential function throughout the wake period, followed by an exponential decline during sleep [196]. Of note, sleep pressure dissipation during the sleep period is faster than sleep pressure accumulation during the wake period. Furthermore, the decline in Process S following sleep initiation is steeper in the first hours of sleep compared to the last ones. Based on the exponential decline of SWA throughout the sleep period, it has been estimated that after ~4.3 h of sleep, 75 % of the SWA needs would be fulfilled [195].

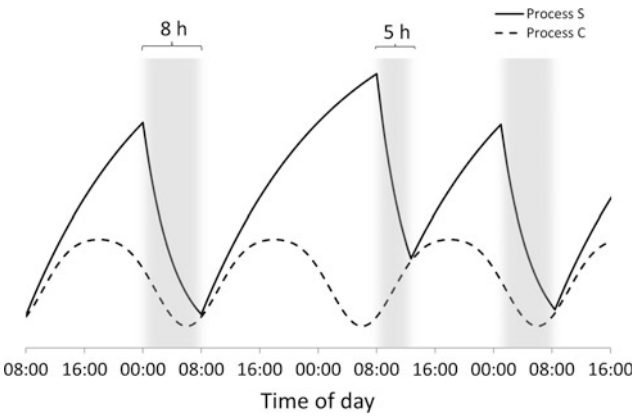

Fig. 6.5 The two-process model of sleep regulation. This model illustrates the interaction between the homeostatic (S) and circadian (C) processes in the control of sleep and waking [288]. Here, Process C represents the circadian variation in the strength of the wake signal, whereas Process S represents the dynamic changes in sleep pressure. During a standard day (e.g., 1st cycle; wakefulness: 08:00–00:00, sleep: 00:00–08:00), Process S (*continuous line*) increases exponentially during the wake period. During that time, Process C sends a wake signal that reaches its peak at the end of the evening. This allows the subject to remain awake for 16 consecutive hours. Sleep (*shaded bars*) is then initiated a few hours after the evening circadian peak of wakefulness. This time also corresponds to the start of the declining limb of the CBT cycle. Process S is at its peak at bedtime and then decreases exponentially throughout the night. At the end of the night, the circadian drive for waking is at its nadir, whereas the circadian drive for sleeping is at its peak. This allows the subject to remain asleep for 8 consecutive hours. When wakefulness is sustained during 24 h and sleep is initiated in the morning (as it is often the case for the first shift of a night shift worker), individuals usually wake up after a reduced amount of sleep. In this case, the present model predicts that about 5 h of consecutive sleep would occur (modified from Daan et al. [288])

Theta power (5–7 Hz) can also be used as an estimate of Process S and parallels sleep propensity during quiet wakefulness [199, 200]. As for SWA, the time course of theta power with time spent awake follows a saturating exponential function [201]. The rise rate of theta power measured during 40 h of sleep deprivation in humans and during enforced wakefulness in rats has been correlated with the SWA power increase observed in the beginning of a recovery sleep period [199, 200].

In the last decade, the synaptic homeostasis hypothesis has been proposed, in which Process S corresponds to the varying synaptic strength or neuroplasticity observed during the sleep-wake cycle [202]. More specifically, this hypothesis states that wakefulness is associated with synaptic potentiation and thus increased energy requirements in several cortical circuits caused by the acquisition of new information during waking. During sleep, the decrease in SWA observed during sleep is presumed to be caused by the progressive downscaling in synaptic strength during the sleep period. In this model, each synapse of a given network would undergo the downscaling process, but the relative weight of each synapse would be conserved, thus resulting in a decrease of energy and space requirement leading to a subsequent increased benefit for memory and learning capacity. Consistent with this hypothesis, it is now admitted that topographical differences exist between EEG derivations when measuring SWA and theta power during sleep and wakefulness, respectively. Indeed, frontal compared to occipital EEG derivations show increased SWA and theta power, especially in response to sleep recovery [203–205]. In addition, the regulation of SWA can be local, restricted to the specific learning cortex regions [203, 204, 206–209]. Brief local sleep can even be identified in local cortical region when rats are submitted to prolonged wakefulness even though the animal remains awake [210].

Some biochemical markers have been found to correlate with Process S and could represent chemical mediators of the homeostatic sleep drive. Such mediators are expected to accumulate during wakefulness and decline with sleep. Among others, adenosine [211], prostaglandin [212], interleukin-1β (IL-1β), tumor necrosis factor alpha (TNF-α), brain-derived neurotropic factor (BDNF), and epidermal growth factor (EGF) [213] have been described, but to date

adenosine represents the most studied candidate in the possible mediation of the homeostatic sleep drive [214]. First, extracellular adenosine accumulation is site specific. With time spent awake, adenosine starts to accumulate in the basal forebrain [211], followed by an increase in the frontal cortex [215]. Then, during sleep recovery, these levels decrease in the cortex and in the basal forebrain. Second, it was shown that sleep is induced by injections of adenosine or adenosine type 1 (A1) receptor agonists in the basal forebrain of cats [211] and by adenosine type 2a (A2a) receptor agonist injections near the VLPO area in rats [216]. This could be due to the fact that adenosine inhibits the release of acetylcholine (ACh) by cortical [217] and basal forebrain [218] neurons via a presynaptic mechanism. Third, caffeine is known to be an adenosine antagonist [219] inducing a reduction of sleepiness and EEG theta activity during wakefulness and a decrease of SWA during subsequent sleep [220]. Finally, in addition to the direct modulation of the frontal cortex activity, inhibition of the basal forebrain by the accumulation of adenosine can in turn promote sleepiness via its projection throughout the cortex. As described in the next section of this chapter, the basal forebrain is indeed part of the ascending arousal pathway regulating sleep.

The Circadian Process

One of the first indications that sleep and sleep propensity are regulated by the circadian system aroused from the work of Nathaniel Kleitman who noticed that staying awake for more than 24 h is usually associated with higher levels of alertness, the next morning in comparison with the levels observed at night [221, 222]. Following that simple but important observation, the circadian rhythmicity of sleep has been extensively studied by placing humans and animals in time-free conditions for several days [89, 223]. As we previously mentioned, without time cues, the circadian endogenous system free-runs with a period close to, but not exactly, 24 h [75, 224, 225]. Under these conditions, sleep propensity is modulated by the slowly shifting (i.e., free-running) rhythm of CBT [223].

The relative contribution of Processes C and S can be better appreciated when participants are studied under a forced desynchrony protocol described earlier in this chapter. Using this experimental paradigm, the main sleep period successively occurs at different circadian phases. Both Processes S and C can thus be mathematically separated and their specific contributions to the various sleep parameters can be observed. With such an approach, it was possible to determine that sleep latency (SL), total sleep time (TST), sleep efficiency (SE), and wake after sleep onset (WASO) have a strong circadian rhythm with increased sleep propensity around the time of CBT minimum [181, 193–195, 226, 227]. In addition, these measurements are influenced by the homeostatic process since sleep consolidation decreases with time spent asleep [194, 195]. The amount of REM sleep and REM sleep latency also follow a strong circadian rhythm with respective maximum and minimum in the morning, approximately 1–2 h following the bathyphase of CBT [181, 194, 195, 226, 227]. Process S can also influence the proportion of REM sleep which increases with time spent asleep. NREM sleep is controlled by the circadian and homeostatic system [195, 226]. The overall proportion of NREM sleep follows a circadian rhythm different from that of REM sleep, with the maximum values observed in the evening and early night [181, 195, 227]. With deeper sleep (i.e., N3 vs N1), there is a shift from an equivalent contribution of Processes S and C in N1, to an almost exclusive contribution of Process S in stage N3 [181, 194, 195, 226].

Subsequently, the introduction of the forced desynchrony protocol confirmed the existence of the circadian regulation of sleep in humans, independently of the homeostatic process. When scheduled to live on a 28- or 20-h rest-activity cycle, most sleep parameters present a circadian rhythm independent of their homeostatic regulation. Thus, this paradigm confirmed that a consolidated 8 h of sleep can only be obtained when sleep is scheduled approximately 6 h before CBT minimum, even though the time spent awake before each sleep period remains about the same [193–195].

The structure responsible for the circadian regulation of sleep was first evidenced following SCN lesions in rodents. In these nocturnal animals, the total duration of sleep over 24 h is similar to wild-type animals, but sleep is randomly distributed in small bouts throughout the 24-h day rather than consolidated bouts mainly during the day [228–231]. SCN-lesioned animals no longer present consolidated rhythms of NREM and REM sleep and display frequent sleep stages transitions and arousals [229, 231, 232]. The sleep recovery process (i.e., increased sleep duration and SWA) is not affected in SCN-lesioned [230] or arrhythmic [233] animals and confirms that Processes C and S arise from different neural substrates.

Although they are independent processes, evidence obtained from the manipulation of the sleep-wake cycle suggests that a higher homeostatic drive can reduce the circadian regulation of sleep. The circadian amplitude of sleep propensity was shown to be reduced in response to chronic sleep deprivation (i.e., 4-h vs. 8-h sleep opportunity per 24 h) in humans [234]. During 6 h of sleep deprivation, the SCN firing activity was reduced to 87 % compared to the baseline levels in rats [235]. During the following 7 h of

recovery sleep after sleep deprivation, the SCN neuronal firing activity during NREM and REM sleep was significantly reduced by about 40 and 30 %, respectively, compared to baseline levels [235]. During NREM sleep, the increase in SWA paralleled the decrease in SCN firing rate, both during normal sleep [236] and during recovery sleep after sleep deprivation [235]. Taken together, these studies suggest that the relative weight of Process C can change with the sleep-wake history, or at least with acute sleep deprivation.

The literature suggests that the SCN has both a sleep- and wake-promoting action depending on circadian phase. First, the majority of SCN-lesioned studies does not show changes in the total amount of sleep or sleep stages throughout 24 h [228–231], although some contradictory evidence has been reported [237, 238]. Furthermore, the proportion of sleep stages throughout the circadian day in SCN-lesioned animals is equivalent to the average 24-h rhythm observed in wild-type animals [228–230], although some evidence suggests that it might be different for REM sleep [231]. It is notable that, even when the homeostatic process is challenged, similar results can be obtained. For example, in the study of Mistlberger et al. [230], wild-type rats were sleep deprived for 24 h. Following this sleep deprivation, the authors analyzed the variation in the amount of sleep and sleep stages over 24 h. Surprisingly, they showed that during the first 12 h following sleep deprivation (corresponding to the habitual active period), the amount of sleep was lower than during the second 12 h (i.e., from 12 to 24 h after sleep deprivation, corresponding to the habitual rest period). In SCN-lesioned rats, when recovery sleep is compared to baseline levels, the proportion of sleep over wakefulness is increased to a constant level during the 24 h following sleep deprivation, with values in between the maximum and minimum levels observed in wild-type rats. This suggests that the SCN restrains sleep propensity during the habitual active period and promotes sleep during the habitual rest period.

Wake Maintenance Zones and Sleep Propensity Zones (The Interaction)

In entrained condition, humans sleep at night and are active during the day. However, when sleep timing was studied in time isolation environments, a bimodal distribution of sleep propensity was observed throughout the 24-h day, with two high sleep propensity and two high alertness zones [239, 240]. A first zone of high sleep propensity is observed at the end of the night, near the CBT minimum. A second peak in sleep propensity is observed in the early afternoon. Of note, in certain countries, naps are commonly taken after lunch and thus during this zone of high sleep propensity. Important, increased drowsiness, errors, and risk of accident have been reported to follow a bimodal patterns with increased levels late at night and in the afternoon [241–243]. Conversely, "wake maintenance zones" (WMZs) are also observed and are characterized by high levels of alertness and difficulty to fall asleep. The first WMZ occurs in the morning, approximately 3–4 h after waking up in the morning [239]. It is usually associated with increased productivity at work and thus represents a profitable timing to plan intellectually demanding tasks. A WMZ is also observed in the evening, approximately 1–2 h before the habitual bedtime. It was indeed shown that in a well-rested individual, advancing bedtime by 1 or 2 h could lead to longer sleep-onset latencies. This is especially important in sleep-onset insomnia patients who often try to advance their bedtime to lengthen their main sleep period, resulting in longer sleep-onset latencies and increased anxiety due to insomnia [244, 245]. These zones are important to consider in our daily schedule to more efficiently plan naps, activities, or when periods of sleep or wakefulness need to be acutely and temporarily displaced. Shifting the sleep-wake schedule, as observed in shift workers or after transmeridian travels, disrupt the normal temporal harmony between Processes C and S, a situation that can lead to reduced sleep duration and quality and lower levels of alertness.

In humans, the interaction between Processes S and C leads to the consolidation of an ~8-h sleep period at night and an ~16-h wake period during the day. In entrained conditions, sleep is initiated in the evening on the decreasing limb of the CBT rhythm, 1–2 h after the evening WMZ. The circadian regulation of distal heat loss, helped by the vasodilation effect of melatonin, is thought to facilitate sleep initiation at the usual bedtime [246]. The following exponential decline in Process S suggests that most of the deep-sleep needs are fulfilled within the first half of the night. Despite the reduced homeostatic need for sleep, the sleep period lasts approximately 8 h because Process C maximally promotes sleep in the second half of the night. Then, after awakening in the morning, sleep propensity is low as a result of the previous time spent asleep.

A phenomenon known as sleep inertia is responsible for the reduced alertness that can be observed in the time period following awakening [247]. Sleep inertia appears to depend on several factors such as sleep stages, time of day and amount of prior sleep deprivation, although its precise duration and severity requires further research [247, 248]. In the late morning, Process S is still low, sleep inertia has dissipated, and Process C starts to promote wakefulness, thus explaining the WMZ observed in the morning. In the afternoon, a zone of higher sleep propensity is observed as a

result of the time spent awake. In the evening, Process C keeps us awake until bedtime by promoting wakefulness maximally during the evening WMZ, even if Process S is elevated (Fig. 6.5).

Brain Regions Implicated in Sleep Regulation

During wakefulness, a series of ascending arousal pathways activate the thalamus and cortex. Two major arousal pathways have been defined. In the first one, cholinergic neurons from the pedunculopontine tegmental nucleus (PPT) and the laterodorsal tegmental nucleus (LDT) activate reticular and relay nuclei of the thalamus to facilitate thalamocortical transmissions. In the second pathway, monoaminergic neurons originating primarily from the locus coeruleus (LC), the ventral periaqueductal gray matter (vPAG), the DRN and MRN, the tuberomammillary nucleus (TMN), the lateral hypothalamus, and the basal forebrain contribute to diffusely activate the cerebral cortex. Sleep occurs when the arousal pathways are directly inhibited by the VLPO via GABAergic and galaninergic neurotransmitters [249]. The VLPO is innervated by inhibitory afferent fibers from nuclei of the arousal ascending pathways. This mutual inhibition between ascending arousal pathways and the sleep-promoting system (i.e., VLPO) can be viewed as a "flip-flop switch" that facilitates sharp transitions between wakefulness and sleep [58]. Orexin (ORX) neurons of the lateral hypothalamus area (LHA) reinforce the wake-promoting system by projecting to the cerebral cortex and to nuclei of both major arousal pathways. The VLPO also projects to ORX neurons and inhibits their action during sleep. Through its massive input to the DMH, the SCN modulates the activity of the VLPO, median preoptic nucleus, and ORX neurons [250]. Therefore, the central circadian clock directly acts as a time-keeping device for the sleep-wake cycle.

Transitions between NREM and REM sleep can be explained in a similar way by mutual inhibition of REM-on and REM-off centers [249, 251]. This switch is composed of the precoeruleus (PC) and sublaterodorsal nucleus (SLD, REM-on) mutually inhibiting the vPAG and lateral pontine tegmentum (LPT, REM-off). Other regulatory areas strengthen this mutual inhibition to facilitate NREM/REM transitions but are not necessarily inhibited by the opposite side of the NREM/REM switch. During REM sleep compared to NREM sleep activity, centers of the ACh arousal pathway including the LDT and PPT (REM-on) increase their activity, while the firing rate in most regions of the monoaminergic pathway completely ceases or decreases. These REM-off regions include the LC, DR/MR, vPAG, and ORX neurons. During both NREM and REM sleep, the VLPO remains active and maintains its inhibition over the monoaminergic arousal pathway.

Intriguingly, sleep centers can also influence the activity of the SCN. Compared to wake and REM sleep, NREM sleep was shown to reduce SCN neuronal activity in rats [236]. Specifically, SCN neuronal firing rate was negatively correlated with the amount of SWA (1–4 Hz) and sigma activity (11–14 Hz), both indicators of sleep homeostasis. This inhibition of SCN activity by SWA was confirmed by selective SWA and REM sleep deprivation experiments. The SCN receives afferent cholinergic projections from the PPT and LDT, serotonergic projections from the DR, and, to a lesser extent, noradrenergic projections from the LC, all implicated in arousal ascending pathways and in the generation of NREM/REM sleep cycling [236, 249, 252]. The presence of afferent neuronal connections to the SCN suggests that the sleep-wake cycle per se could modulate the circadian pacemaker [151].

Chronotype

Although humans are diurnal, individual preferences in the sleep-wake cycle and daytime activity timing are reported and are referred to as chronotype, or morningness-eveningness. Questionnaires have been developed to assess these differences and aim to identify the times of day at which the individual feels better to perform more demanding tasks and to sleep [253, 254]. The chronotype was reported to vary with age [255–257] and gender [258]. Teenager between the ages of 11–18 years tends to progressively delay their bedtime by ~2.5 h [255], a phenomenon that parallels pubertal development [256]. Of note, a progressive change from early to late chronotype has been observed starting at childhood, accelerating during puberty and peaking around the age of 20, with women (~19.5 years) reaching a maximum "eveningness" approximately 1.5 years before men (~21 years) and slowly declining thereafter. Nevertheless, from the age of 20–50 years, men generally present a later chronotype than women, with this sex difference disappearing after the age of 50 [257]. These changes during puberty are associated with a >60 % decrease in SWA and theta power from 9 to 18 years of age [259]. Thus, the homeostatic process is highly affected during adolescence. At that age, adolescents also tend to go to bed and wake up later, reflecting changes in chronotype throughout adolescence [260]. Moreover, later bedtimes could also enhance exposure to light at night and reduce light exposure in the morning and thus entrain the circadian system to a later phase.

Earlier circadian phases of melatonin and CBT have been reported in morning compared to evening chronotypes [261–265]. This difference was also recently reported in peripheral genetic markers, namely in the circadian oscillation of *Per1*, *Per2*, and *Rev-erbα* expression in samples of oral mucosa

[266]. Thus, it suggests that circadian entrainment differs between morning and evening types and influences the timing of their sleep-wake cycle. Of note, a variable-number tandem repeat in the human clock gene *Per3* has been correlated with chronotype, as well as with circadian rhythm sleep disorders [267–269], though not all studies report significant results [270, 271]. The shorter allele of *Per3* ($Per3^{4/4}$ vs. $Per3^{5/5}$) was associated with eveningness, but the acrophase of melatonin, cortisol, and *Per3* mRNA peripheral expression did not differ between carriers of the shorter and longer alleles [272]. Nevertheless, markers of sleep homeostasis were considerably different between *Per3* genotypes: The $Per3^{5/5}$ group was more affected by sleep deprivation, presented more theta and alpha EEG activity during wakefulness, and showed elevated SWA during NREM sleep compared to the $Per3^{4/4}$ group. These results suggest that the homeostatic drive for sleep also influences the timing of the sleep-wake cycle, which underlines the interaction between Processes C and S.

Most of the population is classified as neither morning nor evening type, but a significant proportion can be classified as moderate-to-severe morning or evening type [257, 273]. Patients suffering from delayed or advanced sleep-wake phase disorders can be considered as extreme morning or evening types, although chronotype questionnaires are not sufficient to make a diagnostic [274]. Delayed sleep-wake phase disorder has been associated with circadian gene polymorphism, including *PER3*, *CLOCK*, and *AA-NAT*, a limiting enzyme in melatonin synthesis. An association was also found between the c.3111T/C allele of the *CLOCK* gene and a latter bedtime as well as daytime sleepiness [275]. As for the advanced sleep-wake phase disorder, it has been associated with mutations in the *PER2* and *CK1*δ genes [276, 277] and which highlights the contribution of the circadian system to extreme chronotypes.

Conclusion

Most of us are unaware of the impact of the circadian system in our daily life until our sleep-wake cycle is displaced out of synchrony with this system. Unlike other species, humans can voluntarily and abruptly change their sleep-wake behavior or sustain wakefulness throughout the night, mainly because of social and professional incentives. Abrupt circadian misalignment, as observed in shift workers or in transmeridional travelers, leads to important acute performance and alertness impairments, as well as sleep disturbances [278–281]. Moreover, only a slight delay or advance of the endogenous circadian system relative to the scheduled sleep periods is sufficient to result in clinically relevant sleep-onset and sleep maintenance difficulties. This can lead to chronic sleep disturbances as it has been reported in patients suffering from insomnia, delayed sleep-wake phase disorder, advanced sleep-wake phase disorder, or non-24-h sleep-wake disorder [245]. Long-term exposure to circadian misalignment has been associated with increased risk of several medical conditions, including obesity, metabolic syndrome, diabetes, hypertension, gastrointestinal disorders, endometriosis, adverse pregnancy outcomes, cardiovascular disease, and cancer [282–285]. There is a high prevalence of comorbidity between psychiatric conditions and sleep-wake and circadian rhythm disorders. Interconnections between the circadian, sleep, and mood systems are such that deregulation of one system can lead to deregulation of the others [286]. Different pharmaceutical and non-pharmaceutical interventions have been proposed to treat circadian rhythm disorders including chronotherapy, light therapy, and melatonin and are usually planned based on the phase of the circadian system [245]. Further research is needed to increase the efficiency of these therapies and to develop a better way to assess human circadian rhythms in clinical populations.

Neurotransmitters, Neurochemistry, and the Clinical Pharmacology of Sleep

7

Max Hirshkowitz and Hanul Bhandari

Overview

Physicians practicing sleep medicine use a wide assortment of medications and other substances. Some pharmacologic agents induce sleep; some enhance wakefulness, while others alter the endogenous sleep–wake rhythm. These chemically induced actions may represent a substances' principle therapeutic effect but often the soporific or alerting property occurs as a side effect.

With western societies' ever growing pace and complexity, an individual's alertness or drowsiness level increasingly impacts productivity and safety. Consequently, sleep's mental and physically restorative properties loom ever more important. However, competing daily for time allocation, scheduled sleep time often loses out to work and recreation. Today's pharmacopeia is enormous and continues growing. Attempting to memorize by rote every drug's sleep–wake alterations would be quite a challenge. To facilitate better recall and improve an overall understanding of how medications (and other substances) affect sleep, we organized this chapter according to neurotransmitter systems. Knowing how particular neurotransmitter systems alter sleep and familiarity with the substance's mechanism of action can help the clinician predict the sleep–wake effects. In this chapter, we endeavor to develop *rules of thumb* concerning sleep-related drug effects. Generic medication names are used throughout this chapter; however, because we know many medications by their brand names Table 7.1 is included for cross-reference.

Stimulating Transmitter Systems

Dopamine and Norepinephrine

Pharmacology

Dopamine (DA) and norepinephrine (NE) are monoaminergic neurotransmitters collectively known as catecholamines [1]. In DA neurons, synthesis begins with tyrosine from the blood that is first hydroxylated to dihydroxyphenylalanine (DOPA) and then decarboxylated to DA. The DA is bound into vesicles and if the vesicle fuses with the cell membrane it is released to the synapse [2]. DA can be catabolized intracellularly by monoamine oxidase (MAO) to 3,4-dihydroxy-phenylacetic acid (DOPAC) or extracellularly by catechol-*O*-methyltransferase (COMT) into homovanillic acid (see Fig. 7.1). DA neurons project to many brain areas via several tracts. The largest amount of DA projects via the nigrostriatal tract (from the substantia nigra to the striatum). The tuberoinfundibular tract runs from the hypothalamus's arcuate nucleus to the pituitary stalk. The mesolimbic tract and the mesocortical tract connect ventral tegmentum to limbic areas and to prefrontal area, respectively. Many structures are involved, including hippocampus, amygdala, arcuate nucleus, periventricular hypothalamus, septum, thalamus, and frontal cortex [3]. In noradrenergic neurons, synthesis follows the same course as for dopamine but then in an extra reaction, dopamine beta hydroxylase converts DA to NE. Like DA, the NE is bound into vesicles that will release if fused with the cell membrane (see Fig. 7.2). MAO will catabolize NE to normetanephrine and COMT catabolism will result in homovanillic acid or 3-methoxy-4-hydromandelic acid [4]. NE synthesis occurs in several areas including the locus coeruleus (LC) which projects to the cerebral cortex, hypothalamus, thalamus, and hippocampus. There is a stepwise reduction in LC activity with the highest levels during wakefulness, reduced during NREM sleep, and nearly silent during REM sleep [5].

Pharmacological probes can be used to manipulate dopaminergic neurons to help elucidate the underlying mechanism. The precursor L-DOPA can increase chemical

Table 7.1 Medication classifications and names

Classification	Pharmacological agent (brand name(s))
Amphetamine derivatives	Amphetamine mixed salt (Adderall), dextroamphetamine (Dexedrine, Dextroamphet, Dextrostat, ProCentra), methamphetamine (Desoxyn), lisdexamfetamine (Vyvanse), benzphetamine (Didrex), methylphenidate (Ritalin, Concerta, Metadate, Methylin, Quillivant)
DA precursor	Levodopa (Parcopa, Sinemet, Dopar, Larodopar)
DA agonist	Apomorphine (Apokyn), pramipexole (Mirapex), ropinirole (Requip), rotigotine (Neupro)
Traditional antipsychotics (D_2/D_3 antagonist)	Haloperidol (Haldol), chlorpromazine (Thorazine, Largactil), thioridazine (Mellaril)
Atypical antipsychotics	Amisulpride (Solian), olanzapine (Zyprexa), aripiprazole (Abilify), carpipramine (Pranzinil), asenapine (Saphris), clotiapine (Entumine), clocapramine (Clofekton), iloperidone (Fanapt), clozapine (Clozaril), lurasidone (Latuda), paliperidone (Invega), mosapramine (Cremin), perospirone (Lullan), quetiapine (Seroquel), remoxipride (Roxiam), sertindole (Serdolect), resperidone (Resperdal), sulpiride (Eglonyl, Sulpirid), zotepine (Nipolept), ziprasidone (Geodon, Zeldox)
Adrenergic α_1 agonist	Phenylephrine (AK-Dilate, AK-Nefrin, Efrin)
Adrenergic α_2 agonist	Clonidine (Catapres), guanfacine (Intuniv, Tenex)
Adrenergic α_1 antagonist	Prazosin (Minipress)
Adrenergic α_2 antagonist	Yohimbine (Aphrodyne, Yocon)
Adrenergic β agonist	Albuterol (Proventil, Ventolin, ProAir), terbutaline (Brethine, Bricanyl, Brethaire), isoproterenol (Medihaler-Iso, Isuprel)
NE β antagonist	Propranolol (Inderal)
Tricyclic antidepressant (TCA)	Amitriptyline (Elavil, Tryptanol, Endep, Vanatrip), doxepin (Aponal Adapine, Sinquan, Sinequan), imipramine, clomipramine
SNRIs	Duloxetine (Cymbalta), venlafaxine (Effexor), desvenlafaxine (Pristiq), milnacipran (Savella), atomoxetine (Strattera), reboxetine (Edronax, Prolift)
Atypical antidepressants	Bupropion (Wellbutrin, Zyban), trazodone (Desyrel, Trazorel, Trialodine, Thombran, Trittico, Molipaxin), mirtazapine (Remeron, Zispin), nefazodone (Serzone)
MAO inhibitors	Phenelzine (Nardil), isocarboxazid (Marplan), tranylcypromine (Parnate)
H_1 antagonist	Diphenhydramine (Benadryl), triprolidine (Actidil, Mydil), brompheniramine (Bromfed, Dimetapp, Dimentane, Bromfenex)
H_2 antagonist	Cimetidine (Tagamet), ranitidine (Zantac, Zinetac), astemizole (Hismanal), terfenadine (Seldane, Triuldan, Teldane)
Barbiturates	Barbital (Veronal), phenobarbital (Luminal), pentobarbital (Nembutal)
BZDs	Chlordiazepoxide (Librium), clorazepate (Tranxene), diazepam (Valium), flurazepam (Dalmane), lorazepam (Ativan), oxazepam (Serax), temazepam (Restoril), clonazepam (Klonopin), alprazolam (Xanax), estazolam (ProSom), quezepam (Doral), midazolam (Versed)
BZRAs	Zolpidem (Ambien), zaleplon (Sonata), eszopiclone (Lunesta), zopilcone (Immovane)
Chloral hydrate	Chloral hydrate (Aquachloral, Novo-Chlorhydrate, Somnos, Novtec, Somnote)
Alcohol	Alcohol
AChE inhibitors	Physostigmine (Antilirium, Eserine, Isotopo Ersine), donepezil (Aricept), rivastigmine (Exelon), galantamine (Razadyne)
ACh agonists	Arecholine, nicotine, carbachol (Carbastat, Carboptic, Isotopo Carbachol, Miostat)
Ach antagonists	Scopolamine, atropine
5-HT precursor	L-tryptophan
5-HT_2 antagonist	LSD_{25}
5-HT_{1A} partial agonist	Buspirone (Ansial, Ansiced, Anxiron, Axoren, Bespar, BuSpar, Buspimen, Buspinol, Buspisal, Narol, Spitomin, Sorbon)
5-HT antagonist	Cyproheptadine (Periactin), methysergide (Sansert, Deseril)
SSRIs	Fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), citalopram (Celexa), escitalopram (Lexapro), fluvoxamine (Luvox), dapoxetine (Priligy)
Melatonin	Circadin
Melatonin agonists	Ramelteon (Rozerem), agomelatine (Valdoxan, Melitor, Thymanax)
Orexin antagonist[a]	Almorexant, suvorexant
Unknown	Modafinil (Provigil), armodafinil (Nuvigil), sodium oxybate (Xyrem)

[a]Currently not in the market

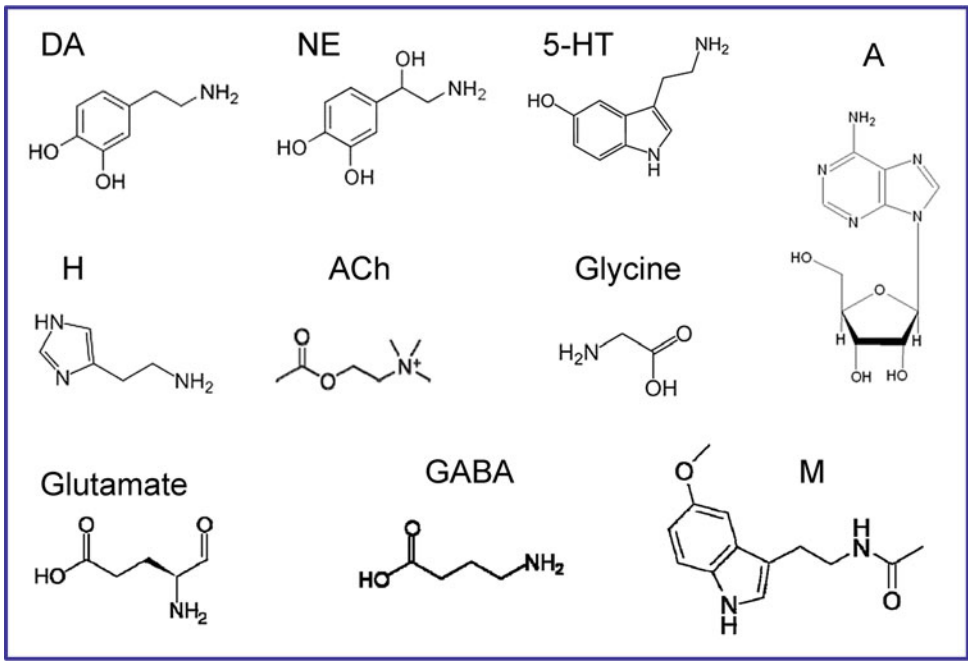

Fig. 7.1 Neurotransmitter diagrams

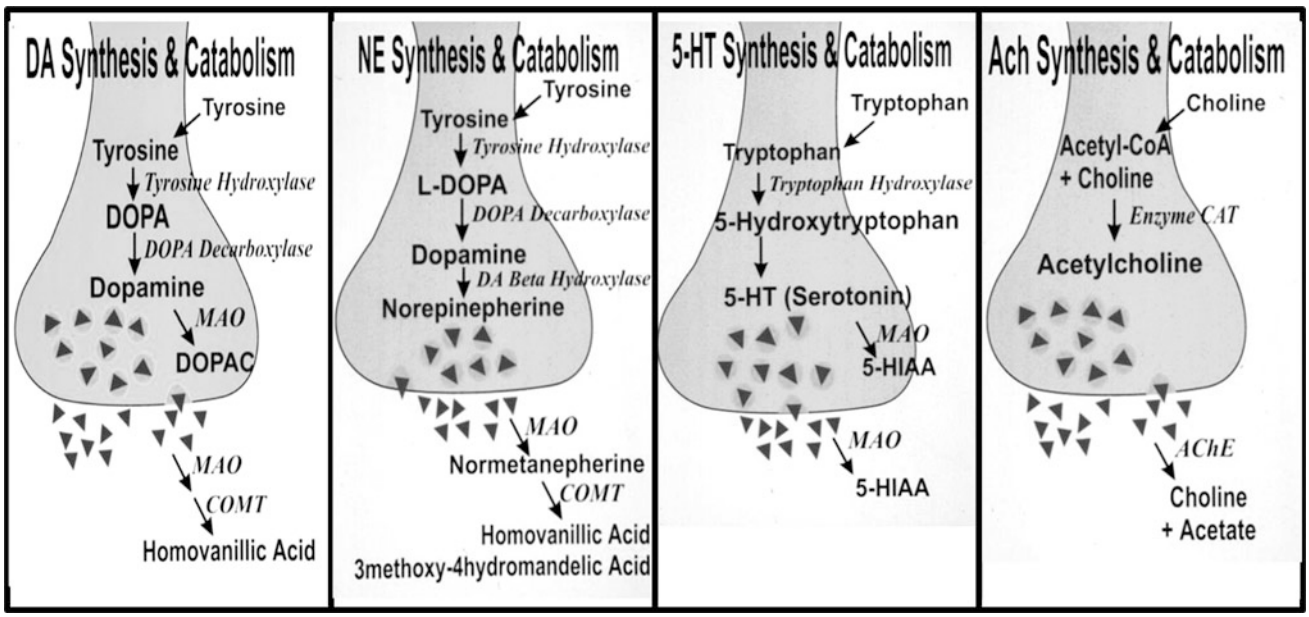

Fig. 7.2 Monoamine and acetylcholine synthesis and catabolism

needed to synthesize DA. By contrast, reuptake into the presynaptic neuron can be inhibited by traditional stimulants (e.g., amphetamines) and cocaine. Postsynaptic receptors can be agonized by apomorphine, pergolide, bromocriptine, pramipexole, rotigotine, and ropinirole. These are G-bound receptors and agonist action differs between drugs. Receptor antagonism can be accomplished with pimozide and any of the traditional neuroleptics (e.g., chlorpromazine, haloperidol, or thioridazine). Intra- and intercellular catabolism can be diminished by monoamine oxidase inhibitors (e.g., phenelzine and tranylcypromine) [6].

NE containing neurons can be chemically probed with a wide variety of compounds. Alpha-methyl-p-tyrosine (AMPT) can retard the synthesis of DA and NE by blocking

the conversion of tyrosine to DOPA. Disulfiram also inhibits NE synthesis by blocking the final step in which DA is converted to NE. Traditional stimulants (e.g., amphetamine) cause vesicles to rupture producing large-scale synaptic release in addition to blocking presynaptic reuptake, thereby greatly increasing synaptic catecholaminergic concentration. This produces excitation and diminishes sleep. Ultimately, the NE or DA that is trapped synaptically gets catabolized resulting in a net depletion of available DA and NE. This "crash" as it is dubbed by stimulant abusers is associated with very profound hypersomnolence. NE reuptake inhibition is also characteristic of tricyclic antidepressants (e.g., imipramine, protriptyline, nortriptyline, and amitriptyline) [7]. However, this property varies widely between compounds. More recently, more specific NE reuptake inhibitors have been developed (e.g., atomoxetine, reboxetine) [8].

Postsynaptically, the central nervous system includes α_1, α_2, and β NE receptors. These receptors can be agonized or antagonized by different pharmacological agents, including phenylephrine (α_1 agonist), prazosin (α_1 antagonist), clonidine (α_2 agonist), yohimbine (α_2 antagonist), and propranolol (β blocker) [9]. More agents are listed in Table 7.1.

Sleep Effects

Dopamine plays an important role in maintaining wakefulness. Consequently, it is not surprising that patients with Parkinson's disease (and related DA deficits) commonly suffer from sleepiness. Some pharmacological agents that increase synaptic availability of NE and DA tend to raise arousal level and decrease REM sleep. This is markedly true of the traditional psychostimulants. These central nervous system stimulants increase arousal level by means of autonomic sympathetic activation (and thereby decrease drowsiness). For many years, these drugs were the mainstay of therapeutics for treating disorders of excessive sleepiness. The older amphetamines formulations of benzedrine, dexedrine, and desoxyn have largely been replaced by mixtures of amphetamine salts (e.g., Adderall®), lysine bound lisdexamfetamine (e.g., Vyvanse®), and the amphetamine congener, methylphenidate. Lisdexamfetamine is a prodrug and was developed in an attempt to decrease abuse potential [10]. Other, dopaminergics with stimulant properties have also been used to treat the sleepiness associated with narcolepsy and idiopathic hypersomnia, including selegiline, pemoline, and mazindol [11]. Pemoline is seldom used today because it was "black boxed" for provoking hepatic failure and jaundice and mazindol was never very popular due to its limited efficacy. Polysomnographic evaluation indicates that compounds in this class generally increase time spent awake and the number of awakenings. They also typically prolong both latency to sleep onset and latency to the first occurrence of REM sleep. In addition to decreasing total sleep time, traditional psychostimulants also suppress REM and slow wave sleep (see Table 7.2). Individuals seeking to extend the duration of their wakefulness period (whether for recreational or vocational purposes) are known to abuse these medications. Trismus (lockjaw), bruxism, and both sleep-related and awake teeth clenching are associated with amphetamine and amphetamine-like stimulants. Thus, teenagers and young adults abusing such substances during all-night dance parties (sometimes called raves) may accessorize their fashion statement with athletic mouth pieces designed to protect the teeth. Most of the formulations also produce significant euphoria, increasing further their potential for abuse. Abused substances include both pharmaceutical and black market products such as homemade methylamphetamine (speed), cocaine, and MDMA (3,4-methylenedioxy-*N*-methylamphetamine, commonly known as Ecstasy, X, or XTC). Methylamphetamine abuse is epidemic. In 2003, more than 10,000 small scale and 130 "superlabs" (capable of producing 10 lb per production cycle) were seized by law enforcement. Moreover, the Drug Enforcement Administration (DEA) has reported that in 2012, 11,210 laboratories producing methylamphetamine were seized.

Dopamine precursors and various DA receptor agonists (D2, D3, and D4), originally designed mainly for treating Parkinson's Disease, are used to treat Restless Legs Syndrome (RLS) and Periodic Limb Movement Disorder (PLMD). This class of drugs includes pramipexole, ropinirole, apomorphine, rotigotine, and bromocriptine. Currently, pramipexole and ropinirole appear to be the medications of choice for treating RLS [12] and both have been approved for this use by the U.S. Food and Drug Administration. At the doses prescribed, these medications are not stimulants. In fact, there have been reports of the opposite, that is, occurrence of sleep attacks. These drugs are also implicated in compulsive disorders (e.g., triggering excessive gambling, eating, and sexual urges). Recently, rotigotine has come into the market for treating RLS transdermally. With a side effect profile much like pramipexole and ropinirole, it provides an alternate route of administration [13]. With respect to RLS and PLMD, medications having the opposite effect, that is, worsening these conditions, include tricyclic antidepressants, selective serotonin reuptake inhibitors, some antiemetics (prochlorperazine and metoclopramide, lithium, some calcium channel blockers (verapamil, nifedipine, and diltiazem), antihistamines, and traditional neuroleptics [14].

Dopamine (D2 and D3) receptor antagonists in the form of traditional neuroleptics reliably produce sedation, increase sleep efficiency, increase slow wave sleep, and usually suppress REM sleep to some degree. This holds true for chlorpromazine, haloperidol, and thioridazine. The newer, non-D2, and non-D3 neuroleptics (clozapine, olanzapine, risperidone, ziprasidone) have variable effects on slow wave sleep with some producing decrease while other (e.g.,

risperidone, olanzapine, and ziprasidone) associated with an increase (perhaps related to its higher affinity 5-HT_2 receptors). These newer atypical antipsychotics do not universally produce sedation [15]. The amount of sedation produced appears to be determined by the combination of the drug's relative potency and its affinity for the histamine-1 (H_1) receptor. For example, clozapine is very sedating and it has high H_1 affinity (32) and low potency (and consequently a need for large doses 50 mg), while olanzapine is less sedating even with an H_1 affinity of 1149 because with its high potency there is need for only a low dose (4 mg). Quetiapine also falls into the low potency (80 mg dose needed) and moderate H_1 affinity (5.2) category and thus is moderately sedating. Like traditional neuroleptics, these newer drugs can increase restless legs and periodic leg movement activity during sleep.

The tricyclic antidepressants (TCAs) comprise a wide range of compounds that share a similar three-ring chemical structure. This group of agents includes imipramine, desipramine, amitriptyline, nortriptyline, clomipramine, trimipramine, doxepin, and protriptyline. Across the board, TCAs increase slow wave sleep (mildly to moderately) and suppress REM sleep (mildly to markedly). This can be seen in Table 7.2. TCAs are generally sedating (with a few exceptions, e.g., protriptyline). The range of sedation varies greatly and is most likely a function of antihistaminergic activity (see section on histamine). Imipramine, the prototypical compound in this class, is regarded as a non-selective NE reuptake inhibitor. In vitro acute biochemical activity studies reveal that it also produces serotonin reuptake inhibition, has high α_1 and muscarinic acetylcholinergic receptor affinity, and binds somewhat to histamine receptors. In sleep medicine, imipramine is best known for its REM suppressing properties and for decades was widely used as an anticataplectic agent for treating patients with narcolepsy. Imipramine's slow wave sleep enhancing and REM sleep suppressing properties are illustrated in Fig. 7.3. In this patient, latency to the first REM sleep episode was almost 3 h, twice as long as normal. No REM sleep episode occurred at the usual 90–120 mins latency from sleep onset (the missing REM sleep episode). Additionally, REM sleep continued to be suppressed later in the night while slow wave sleep appeared to be above normal. The other popular TCA used in this manner is protriptyline. Protriptyline also has the advantage of being non-sedating; however, it can exacerbate erectile problems in men (that in turn can render therapeutic adherence problematic). The REM suppressing properties of TCAs appear to stem from a combination of aminergic (norepinephrine and serotonin) and anti-acetylcholinergic properties. The aminergic properties theoretically provide activation of REM-off systems, while the anticholinergic properties would inhibit REM-on systems. For example, clomipramine, the most REM suppressing TCA, strongly agonizes 5-HT by inhibiting reuptake of serotonin and also has moderate antimuscarinic properties. By contrast, the TCA amitriptyline, another strong REM suppressor, blocks acetylcholine with its very high muscarinic binding affinity but is a weaker serotonin reuptake inhibitor.

Monoamine oxidase inhibitors (MAOIs), as a class, are the strongest suppressors of REM sleep. They, of course, alter catabolism of all biogenic amine neurotransmitters (DA, NE, and serotonin) and like the TCAs; they can be used as antidepressants. It did not go unnoticed that until the atypical antidepressant bupropion was developed, all known antidepressant medications suppressed REM sleep. Furthermore, even instrumentally suppressing REM sleep by awakening sleepers in the laboratory whenever they entered REM sleep improved mood in patients diagnosed with depression [16]. Thus, it was posited that REM sleep promoted depression in some individuals and that REM sleep suppression was necessary and sufficient to achieve an antidepressant effect. The atypical antidepressants (e.g., venlafaxine and trazodone) suppress REM sleep (especially early in the night with some rebound toward morning). However, with the synthesis of bupropion (and afterward nefazodone), the axiom that REM suppression was necessary to achieve an antidepressant property was disproved; neither of these antidepressants suppress REM sleep. Nonetheless, while it may not be necessary to suppress REM sleep, REM suppression remains sufficient to produced antidepressant effects. Also noteworthy is that unlike the TCAs, the atypical antidepressants venlafaxine, nefazodone, bupropion, and trazodone do not increase slow wave sleep.

Histamine

Histamine (H) is an important excitatory neurotransmitter in the central nervous system. Posterior hypothalamus histaminergic neurons are thought to generate wakefulness. In particular, the tuberomammillary nucleus (TMN) is a histamine rich structure thought to play a crucial role in maintaining alertness. TMN may also represent the brain's main source of H. The TMN appears to generate physiologic "normal wakefulness" not associated with over-activation of motor and reward systems. H neuron activity follows a similar stepwise pattern to that of NE, that is, high activity during wakefulness, decreased during NREM sleep, and very low levels during REM sleep. This may help explain why the patients described by von Economo with posterior hypothalamic encephalitic damage were extremely sleepy but those with anterior lesions were not.

Central histaminergic effects are most well recognized for the drowsiness produced by central H_1 antagonists (that are actually inverse agonists) exemplified by action of

Table 7.2 Medication effects on sleep

Classification	Pharmacologic agent	SWS	REM	Wakefulness	Other sleep effects
DA agonists (traditional psychostimulants)	Cocaine, amphetamine	↓↓	↓↓	↑↑↑	Severe hypersomnia and prominent REM sleep rebound after discontinuing it after chronic use, bruxism may occur
DA precursor	Levodopa	↔	↑ (low doses) ↓ (high doses)	↑	Insomnia may be seen at higher doses
DA agonists	Apomorphine, rotigotine, pramipexole, ropinirole	↔	↔	↑	–
Traditional and atypical antipsychotics	Haloperidol, chlorpromazine, thioridazine, risperidal, olanzapine	↑	↑	↓↓↓	Increase PLMs and RLS-like symptoms
Adrenergic α_1 agonist	Phenylephrine	↓	↓	↑	–
Adrenergic α_2 agonist	Clonidine	↑	↓	↓↓	–
Adrenergic α_1 antagonist	Prazosin	↔	↑?	↓	Decreases nightmare distress
Adrenergic α_2 antagonist	Mirtazapine	↔	↔	↓↓	–
Adrenergic β agonist	Isoproterenol, albuterol, terbutaline	↔	↔	↔	–
Adrenergic β antagonist	Propanolol	↓	↓	↑	Can provoke nightmares
SNRIs	Duloxetine	↑	↓	↑	May exacerbate PLMs
	Venlafaxine, desvenlafaxine, milnacipran	↑	↓↓	↑	May exacerbate PLMs
SSRIs	Fluoxetine, citalopram, escitalopram, fluvoxamine, dapoxetine	↓	↓	↑	–
	Paroxetine	↓	↓↓	↑↑	–
	Sertraline	↔	↓↓	↔	–
TCAs	Amitryptiline, nortryptiline, clomipramine	↑	↓↓↓	↓↓↓↓	Increases PLMs and sleep-related movements, may cause RLS-like symptoms
	Doxepin	↑↑	↓↓	↓↓↓↓	
	Clomipramine	↑	↓↓↓↓	↔	
MAO inhibitors	Phenelzine	↓	↓↓↓↓	↑↑	Strong REM sleep suppressors, increase PLMs, prominent REM sleep rebound on discontinuation
	Tranylcypromine	↓	↓↓↓	↑↑↑	
H_1 antagonists	Diphenhydramine, triprolidine, brompheniramine	↑	↓	↓	Upon discontinuation, dream intensity increases
H_2 antagonists	Cimetidine	↑	↑	↓	Interacts with many other medications' metabolisms by cytochrome P_{450} pathway
	Ranitidine	↔	↔	↔	
Barbiturates	Pentobartbital, phenobarbital	↓	↓↓↓	↓↓↓	Severe AEs on withdrawal, overdose leads to respiratory drive suppression
BZDs	Triazolam, diazepam, lorazepam, midazolam	↓↓	↓	↓↓↓	Tolerance and rebound on discontinuation
BZRAs	Zopiclone, zolpidem, eszopoclone, zaleplon	↔	↔	↓↓↓	Low overdose liability, minor AE on withdrawal

(continued)

Table 7.2 (continued)

Classification	Pharmacologic agent	SWS	REM	Wakefulness	Other sleep effects
Chloral hydrate	Chloral hydrate	↔	↔	↓↓↓	–
Alcohol	Ethanol	↔	↓	↓	Increases arousals
AChE inhibitors	Physostigmine, rivastigmine, galantamine, donepezil	↔	↑	↓	Shortens REM sleep latency
Ach agonists	Arecholine	↑	↑	↓	Shortens REM sleep latency, insomnia at higher doses
	Nicotine	↑	↑	↓	Increases SL and WASO
Ach antagonists	Scopolamine, atropine	↓	↓	↑	Increases REM sleep latency
5-HT precursor	L-tryptophan	↑	↓	↔	Increases REM density, decreases SL
5-HT_2 antagonist	LSD_{25}	↔	↑	↑	Increased arousals, decreased REM sleep latency, provoked REMs in SWS
5-HT_{1A} partial agonist	Buspirone	↔	↓	↔	Reportedly a treatment for SSRI-induced bruxism
5-HT antagonist	Cyproheptadine	↑	↑	↔	–

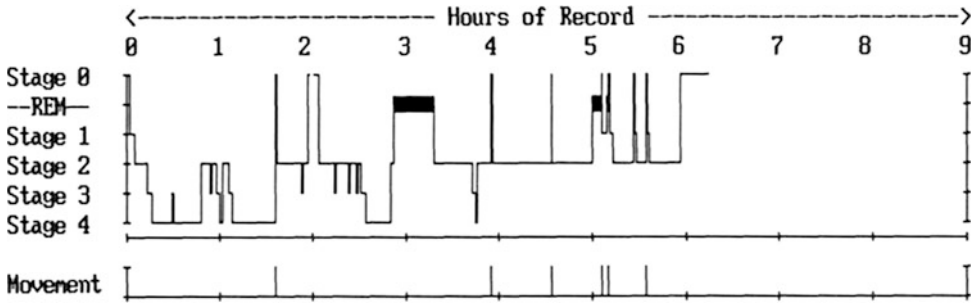

Fig. 7.3 Imipramine and sleep macroarchitecture

diphenhydramine [17]. H_1 antagonists also can decrease REM sleep or REM density. H_2 antagonists have little effect on sleep; however, cimetidine may increase slow wave sleep. Table 7.2 tabulates the main effects of antihistamines on sleep. Sedation that occurs as a side effect of other compounds often has its roots in an antihistaminergic property. Examination of in vitro acute biochemical activity reveals that the sedating TCAs—amitriptyline, trimipramine, and doxepin all have $+++H_1$ receptor affinity [18]. Other sedating medications with known antihistaminergic activity include trazodone, mirtazapine, and quetiapine. Other properties of H_1 receptor blockade are weight gain, hypotension, and potentiating other CNS depressants.

Although not fully understood, the mechanism of action for the wake-promoting medication modafinil is thought to act, in part, via a histaminergic mechanism [19]. However, modafinil also activates glutamatergic circuits and appears to inhibit GABA transmission. Cats administered modafinil show immediate gene product c-fos activation in TMN [20]. Modafinil extends wakefulness and improves performance in normal subjects undergoing sleep deprivation; increases sleep latencies on the multiple sleep latency test (MSLT) in patients with narcolepsy [21] and shift work sleep disorder [22]; increases sleep latency on the maintenance of wakefulness test (MWT) in patients with narcolepsy and sleep apnea (with residual sleepiness) [23–25], but does not alter nocturnal sleep when administered in the morning [26]. The American Academy of Sleep Medicine currently recommends modafinil as the first line treatment for sleepiness associated with narcolepsy [27]. In addition to having an indication for use in narcolepsy, the U.S. Food and Drug Administration (FDA) has also approved modafinil for treating (1) residual sleepiness in patients with sleep apnea who are otherwise well treated with positive airway pressure and (2) sleepiness associated with shift work sleep disorder [28]. In 2007, the dextroenantiomer of modafinil (armodafinil) was also approved for conditions that can be treated with modafinil.

Orexin

Orexins are a pair of excitatory neuropeptide hormones (orexin-A and orexin-B) discovered in 1998 [29, 30]. Produced by a small hypothalamic cell group with widespread projections throughout the brain, orexins appear to promote

wakefulness. Some researchers refer to orexin as hypocretin, because of the locus of origin. These neurons activate structures with other stimulating neurotransmitter systems, including DA, NE, ACh, and H [31].

The discovery of orexin was a major breakthrough for our understanding of narcolepsy. Mutations in genes producing orexin or their receptors were found in narcoleptic mice and dogs. Humans with narcolepsy appear to have an orexin deficit produced by an autoimmune mechanism. Orexin can be detected in cerebrospinal fluid of approximately 90 % of patients with the "narcolepsy-cataplexy syndrome," as it is called in the UK [32]. Direct brain injection of orexin produces wakefulness and can reverse some of the effects of sleep deprivation [33]. A number of orexin agonists (stimulants) and antagonists (sedatives) are being developed. At this point, however, we have little data concerning the effects of orexigenic substances on human sleep. Suvorexant and almorexant are dual orexin receptor antagonists developed to promote sleepiness by reducing wakeful drive [34, 35]. Figure 7.4 illustrates their structure compared to orexin-A and orexin-B. Currently, suvorexant has been approved for medical use.

Glutamate

The brain's most common neurotransmitter is glutamate. The *N*-Methyl-D-Aspartate (NMDA) glutamate receptor is regulated both electrically and chemically. It has binding sites for glutamate, magnesium, glycine, zinc, and phencyclidine. NMDA antagonists include amantadine, dextromethorphan, ketamine, tiletamine, riluzole, memantine, kynurenic acid, and phencyclidine (PCP). PCP (referred to as "angel dust" on the street) can produce hallucinations and psychosis. NMDA receptor agonists include: Aminocyclopropanecarboxylic acid, D-Cycloserine, D-serine, L-alanine, L-aspartate, and Quinolinate. NMDA receptors are concentrated in hippocampus, amygdale, basal ganglia, and cerebral cortex.

Inhibitory Transmitter Systems

GABA

GABA is the main inhibitory neurotransmitter in mammalian central nervous system. It begins as glutamic acid that is catalyzed by GAD to form GABA. $GABA_A$ agonism promotes flux in the chlorine channel. GABA, benzodiazepines, or barbiturates can increase dilation of the ionophore and thereby promote transmission in this inhibitory pathway. Barbiturates, benzodiazepines, benzodiazepine receptor agonists, alcohol, chloral hydrate, steroids, and picotoxins can all affect this system. While there are direct and partial GABA agonists, in sleep medicine practice, the drugs traditionally used to manage the symptoms of insomnia are mainly benzodiazepines (BZDs) and benzodiazepine receptor agonists (BZRAs). GABA neurons are widely distributed in the brain with high concentration in the thalamus.

Chloral hydrate was the first pharmaceutical sleeping pill, developed circa 1860. Chloral hydrate shortens sleep latency and initially increases sleep time. It has been described as

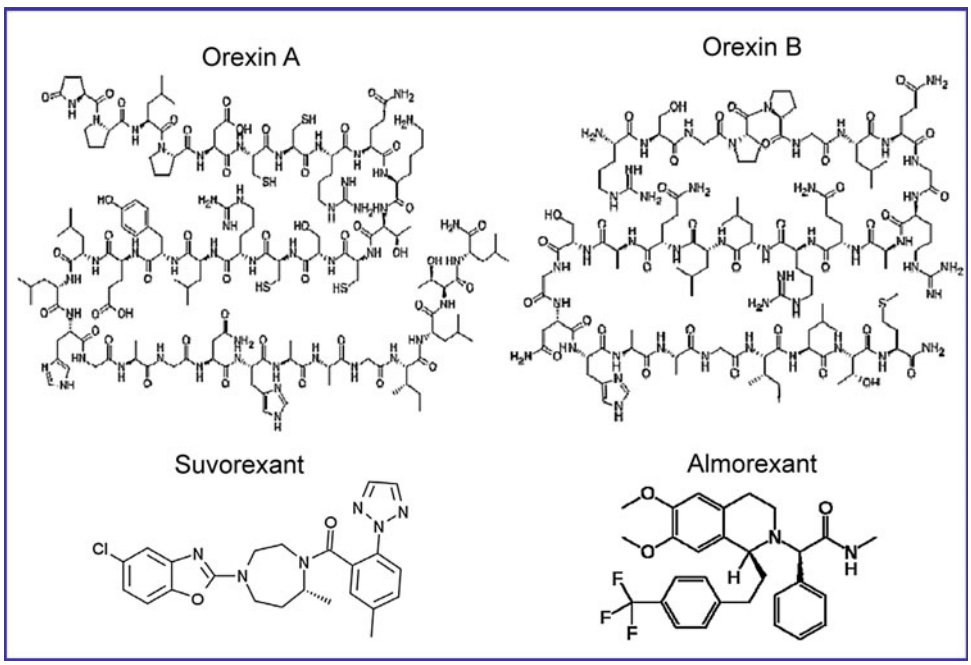

Fig. 7.4 Orexins and dual orexin receptor antagonists

"alcohol in pill form" because after it passes through the gut it forms an alcohol-like compound. Probably best known for its popularization in detective mystery stories by Dashiell Hammett and Raymond Chandler where when mixed with alcohol becomes a "Mickey Finn" and is used to stupefy the gangsters' adversary. Bromides and paraldehydes followed but did not enjoy much success. At the turn of the twentieth century, barbiturates were first synthesized by Adolf von Baeyer and found to be extremely sedating [36]. Polysomnographic studies show that most barbiturates shorten the latency to sleep onset, increase total sleep time and sleep efficiency, decrease wakefulness after sleep onset and the number of awakenings in patients with insomnia. They also tend to decrease REM sleep, perhaps by impairing the muscles that move the eyes and mildly decrease slow wave sleep [37, 38]. Micro-architectural sleep changes included increased β EEG, increased δ spindles, and decreased arousals [39]. Barbiturates, however, are extremely toxic. One popular index for describing toxicity is the ratio of the effective dose found for 50 % of animals tested (ED_{50}) to the lethal dose for 50 % of animals tested (LD_{50}). This ratio provides a safety index with smaller numbers (larger ranges) being less dangerous. For barbiturates, the ratio is only approximately 10:1 (depending of type) meaning that ingesting 10 times the effective dose confers a significant risk of death [40]. Thus, if a prescription provides the patient with 30 pills, it becomes a potential vehicle for committing suicide. 90 % of patients with major depressive disorder have insomnia and 17 % (or more) of patients coming to sleep disorders centers complaining of insomnia have a mood disorder. This circumstance sets the stage for potential tragedy. In the first three-quarters of the twentieth century, many suicides involved barbiturate sleeping pills.

In the 1960s, benzodiazepines (BZD) sleep aids were developed. Compared to barbiturates, BZDs were amazingly safe. In most cases, it was not even possible to determine a lethal dose. Thus, it was joked at the time that the only way a BZD would kill you was if you were run over by the truck delivering them to the pharmacy. However, it soon became apparent that when BZDs were combined with alcohol, this safety was compromised. BZDs have four major characteristics; they are (1) sedating, (2) anxiolytics, (3) myorelaxant, and (4) anticonvulsant [41]. Secondary properties include ataxia, amnesia, and potentiating of alcohol. BZDs proved very effective for treating insomnia: shortening latency to sleep onset, increasing total sleep time, and improving sleep efficiency. They did not suppress REM sleep as much as barbiturates but on average decrease slow wave sleep more than barbiturates. δ spindle activity is increased in a dose–response manner but without dramatic β wave enhancement on the EEG. Figure 7.5 shows polysomnographic tracings from a patient taking temazepam nightly for more than a year. Awakenings and brief arousals are reduced by most BZDs tested [42–44]. Early BZDs tended to be long acting, the champion being flurazepam with its 72–100 h half-life (without counting its active metabolite). In second place, quazepam weighs in with a 27–43 h half-life followed by estazolam with a 10–24 h half-life and temazepam with a 4–18 h half-life [45]. Triazolam was the first short acting BZD for promoting sleep but fell out of favor after high profile reports of amnesia [46] (but all BZDs potentially produce amnesia). Half-life is important for two reasons. First, in combination with the drug's minimal effective dose and the dose administered, it dictates the duration of action (or therapeutic window). If the duration of action extends beyond the individual's sleep episode, there will likely be residual sedation, commonly referred to as "hangover." Secondly, pharmacokinetic *rule-of-thumb* estimates elimination time as 5–6 times the half-life of a compound. It should be realized that the vast majority of medications used in clinical practice are administered according to principles of the infectious disease model. This involves dosing a drug until it reaches therapeutic level and then maintaining it at that level until the bacteria, germ, or microorganism is eradicated. Usually, drug level is maintained for a while longer just to be certain and prevent re-infection. Most psychiatric medication is administered this way but kept at therapeutic level indefinitely (because there was no infection to kill to begin with). By contrast, we desire sleeping pills to work like a switch. One wants to (1) administer the drug, (2) have it rapidly get to therapeutic level, (3) hover there for precisely 7.5 h, and then

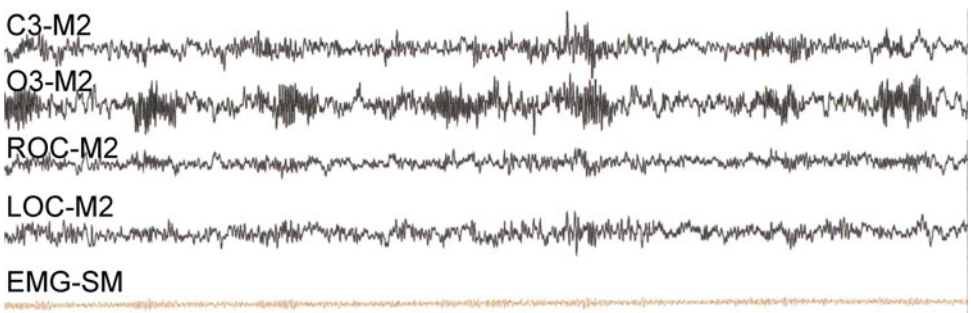

Fig. 7.5 Temazepam and sleep microarchitecture

(4) instantly disappear without a trace. Having drug eliminated fast and completely helps assure there is no hangover, receptors have the maximal time to re-regulate, and there is no cascading drug level produced by adding drug into a system that already has residual drug on board. Of course, pharmacokinetics are not so well behaved. Also, we do not dose patients the way we do laboratory animals; that is, we use fixed doses rather than equivalents in milligrams per kilogram weights. Chances are that there will be undershoot and overshoot with respect to a medication's duration of action compared to the desired therapeutic window. If receptor systems down regulate, adapt, or habituate, then tolerance will more likely to develop in longer acting substances, notwithstanding their potency.

In the 1980s, benzodiazepine receptor agonists (BZRAs), lacking the characteristic benzene ring structure, were developed. These medications boasted generally shorter half-life, little or no alteration of sleep macro-architecture, and greater propensity for increasing sedation than producing anxiolytics, myorelaxant, or anticonvulsant effects [47–49]. At the time, it was speculated that the different characteristics associated with BZD receptor agonism were mediated by subtype receptors. The data from knockout genetic studies in mice and rats confirmed this hunch almost 15 years later [50]. The different BZRAs boast varying degrees of greater affinity to the receptor subtype thought to mediate sedation (α_1) than other receptor subtypes (typically α2). The receptor affinity ratio for currently marketed BZRAs with indication for treating is 2:1 for zopiclone, 10:1 for zolpidem, and 13:1 for zaleplon [51]. Other BZRAs for treating insomnia include variants of these compounds; that is, eszopiclone, the left handed entimer of zopiclone (which turns out to be the active isomer) and zolpidem MR, a multiple release version of zolpidem designed to extend its therapeutic window by 1–2 h. Table 7.2 summarizes characteristics of and differences between barbiturates, BZD, and BZRA sleep-promoting substances.

Adenosine

Kleitman, the dean of American sleep research, postulated that the basic rest activity cycle was governed by the buildup of a "hypnotoxin" during wakefulness that was eliminated during sleep [52]. This general characterization lives on today in our conceptualization of the homeostatic drive for sleep accumulating as "sleep pressure" (or "sleep debt" when unpaid and overdue). There are many possible candidates for a modern-day "hypnotoxins." Perhaps the most obvious candidate is adenosine. Adenosine delivered to the preoptic area and anterior hypothalamus induces NREM sleep. As an animal experiences prolonged wakefulness, basal forebrain adenosine levels rise and they subsequently decline during recovery sleep [53, 54]. Although benzodiazepines ($GABA_A$ receptor agonists) decrease adenosine uptake; caffeine (adenosine antagonist) does not alter benzodiazepine receptor action [55].

Adenosine receptors can be antagonized by the methylxanthines caffeine (found in coffee) and theobromine (found in chocolate). Figure 7.6 shows the chemical structure for adenosine, caffeine, and theobromine. When an individual does not get enough sleep at night to rid the basal forebrain of its adenosine load, morning awakening is usually accompanied by residual sleepiness. Drinking a morning cup (or two) of coffee, or better yet coffee with chocolate in it (mocha java), provides an effective, albeit temporary, antidote. Overall, polysomnographic studies of methylxanthines show decreases in total sleep time, slow wave sleep, and REM sleep [56]. Latency to sleep onset is increased but more important, wake after sleep onset can rise dramatically (see Fig. 7.7).

According to legend, the effect of coffee beans was first noticed by a goat herder from Caffa Ethiopia named Kaldi. He noticed that his goats became hyperactive after eating the red "cherries" from a certain plant when they changed pastures. He tried a few berries himself and became as "hyper" as his herd [57]. The storied origins of chocolate remain even more fanciful; however, chocolate was thought to first be extracted from cocoa in the Amazon circa 2000 BCE. Chocolate became an important part of Mayan culture in the sixth century CE. Subsequently, some 600 years later, the Aztecs attributed creation of the cocoa plant to Quetzalcoatl who smuggled it to earth from paradise when he descended from heaven on a beam of light [58]. It was truly considered the food of the gods.

Glycine

Glycine is the simplest amino acid and can be produced by protein hydrolysis. This sweet tasting compound was first isolated from gelatin in 1820. This central nervous system inhibitory neurotransmitter is particularly important for its role in mediating atonia occurring during REM sleep. Activation of glycine receptors produces inhibitory postsynaptic potentials (IPSP) that decreases spinal alpha and gamma motor neuron activity. Strychnine blocks glycine receptors. Along with glutamate, glycine's co-agonist, it can activate NMDA receptors. Ingesting 3 g glycine before bedtime reportedly improves alertness and subjective feelings after awakening from sleep [59].

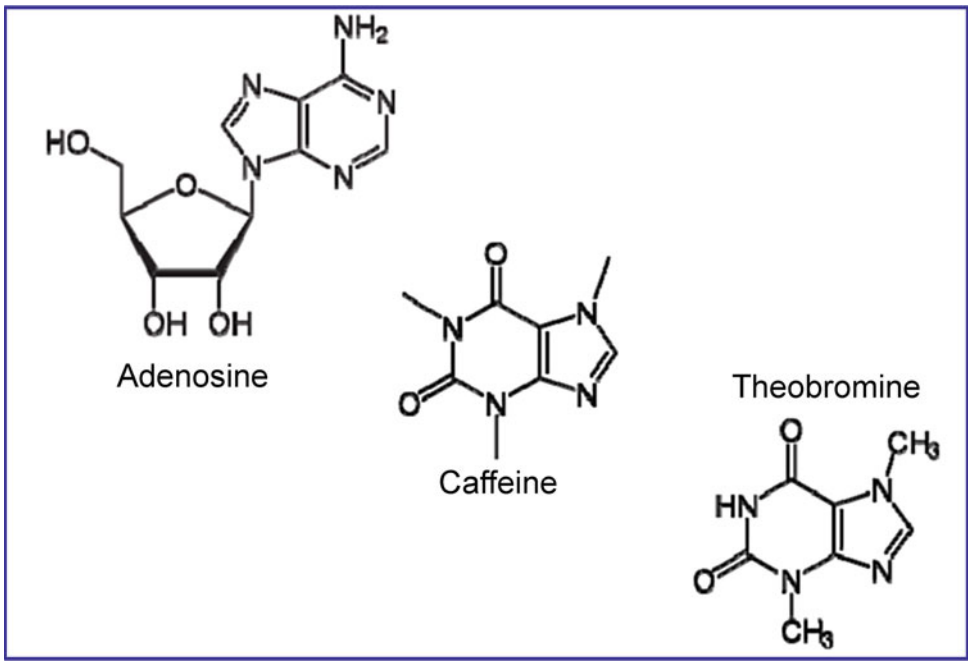

Fig. 7.6 Adenosine, caffeine, and theobromine

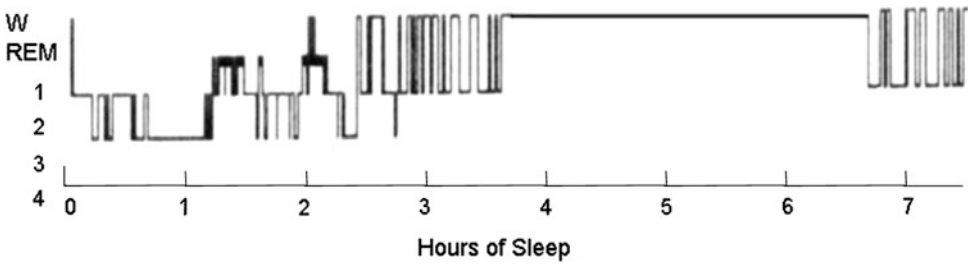

Fig. 7.7 Caffeine and sleep macroarchitecture

Regulating Transmitter Systems

Acetylcholine

Acetylcholine (ACh) begins as circulating choline in the blood. It is taken into presynaptic neurons and is combined with acetyl-CoA to form acetylcholine (reaction catalyzed by CAT). The ACh is then bound into vesicles that are released synaptically upon fusing with the cell wall. Synaptic ACh can be catabolized by acetylcholinesterase (AChE), rendering choline and acetate.

ACh plays a major role in regulating REM sleep [60]. There is a large concentration of ACh in the gigantocellular nucleus of the reticular formation. During the waking state, aminergic neurons are highly active and ACh is implicated in memory processes, as noted in the loss of ACh neurons in the nucleus of Meynert causing Alzheimer's disease. By contrast, during slow wave sleep, cortical activity is greatly reduced. Then, during REM sleep, cortical acetylcholinergic activity returns to high levels [61]. REM sleep "on" neurons are plentiful in the laterodorsal tegmentum and the pedunculopontine tegmentum (LDT/PPT) [62]. Basal forebrain cholinergic neurons project to the hippocampus, amygdala, and cortex. Opposing these cells are the REM sleep "off" cells in the dorsal raphe (a serotonin reservoir) and the locus coeruleus (where most of the brain's NE is synthesized).

Chemical probes of ACh include the agonists–arecholine, nicotine, carbachol, and pilocarpine. Antagonists include scopolamine, atropine, hyoscine, and curare. Agonism can also be achieved by using AChE inhibitors (e.g., physostigmine and donepezil). Table 7.2 shows some of the sleep changes produced by these system probes. In general, AChE inhibitors can increase REM sleep duration, hasten its appearance, or both [63, 64]. ACh agonists enhance REM sleep [65] and antagonists suppress REM sleep and its activity [66]. Administering arecholine or physostigmine intravenously can provoke REM sleep occurrence whereas scopolamine dramatically delays REM sleep onset.

Serotonin

In opposition to acetylcholine, the indoleamine serotonin serves as an inhibitor of REM sleep (see Fig. 7.8). Activation of brainstem raphe nuclei suppresses REM sleep (as does locus coeruleus activation). These biogenic amines are considered REM "off" cells responsible for reciprocal interaction with the LDT/PPT REM "on" cholinergic generators [67]. Nonetheless, serotonin raphe neurons project widely through the brain, including the hippocampus, hypothalamus, thalamus, septum, and cerebral cortex [68]. Brainstem raphe activity is highest during wakefulness, less active during NREM sleep, and nearly silent during REM sleep.

Serotonin begins with tryptophan that is hydroxylated to 5-hydroxytryptophan which is later reduced to 5-hydroxytryptamine (5-HT) which is serotonin. The 5-HT is bound in vesicles and can be released synaptically. Its main catabolite is monamine oxidase that reduces it to 5-hydroxyindolacetic acid. The synthesis of 5-HT can be stimulated by L-tryptophan or inhibited with parachloralphenylalenine (PCPA) [69].

Functional agonism can be achieved by inhibiting the reuptake of synaptic 5-HT into the presynaptic terminal to be rebound in vesicles and ultimately re-used. Many tricyclic antidepressants non-selectively inhibit serotonin reuptake along with having anticholinergic properties that produced undesirable side effects (e.g., dry mouth, ataxia, diplopia, tachycardia, constipation, memory loss, and confusion). The newer selective serotonin reuptake inhibitors (SSRIs) antidepressants quickly became preferred because they required fewer dose adjustments and were less complicated by adverse events. By contrast, serotonin can be antagonized with methysergide and cyproheptadine (which also has antihistaminergic properties). Type-2 receptor antagonism is produced by the hallucinogen lysergic acid diethylamide (LSD_{25}) and presynaptic autoreceptor partial agonism can be achieved with buspirone. Postsynaptic receptors are G-bound proteins, and there is a wide array of them. Table 7.2 describes some of the change in sleep produced by chemically probing the 5-HT system. In addition to a general REM suppressing action of 5-HT agonists [70], these drugs sometimes unhinge the choreography of physiologic changes and activities that make up REM sleep. For example, rapid eye movements characteristically accompany wakefulness and REM sleep. However, it was noted that patients treated with SSRIs would often have rapid eye movements in sleep stages N1, N2, and N3 [71]. The phenomenon was so common it developed the moniker "Prozac Eyes" after the brand name of fluoxetine, the prototypical SSRI (see Fig. 7.9). SSRIs are also reported to decrease the frequency of dream recall but increase the intensity of the dreams that are remembered [72]. The breakdown in coordination of gating mechanism produced by 5-HT alteration extends beyond mere eye movement activity. 5-HT agonists are noted for provoking an iatrogenic form of REM sleep behavior disorder [73], presumably by failing to provoke or sustain striate muscle atonia when dreaming commences. Additionally, SSRIs and TCAs generally increase muscle activity and movements during sleep [74, 75].

Melatonin

Although melatonin (MT) is an endocrine secreted largely by the pineal gland, it is synthesized from 5-HT by pinealocytes. The catalyst NAT (5-HT *N*-acetyl transferase) transforms 5-HT first to *N*-acetyl-5-HT and then to HIOMT (hydroxyindole-O-methyltransferase) and finally to melatonin [76]. MT is released in response to decreasing environmental light and thus synchronizes our physiology with the light–dark cycle. In a sense, it is the "signal of darkness to the brain" [77]. Therefore, if we are rats, our response to rising melatonin would be to become more alert. By

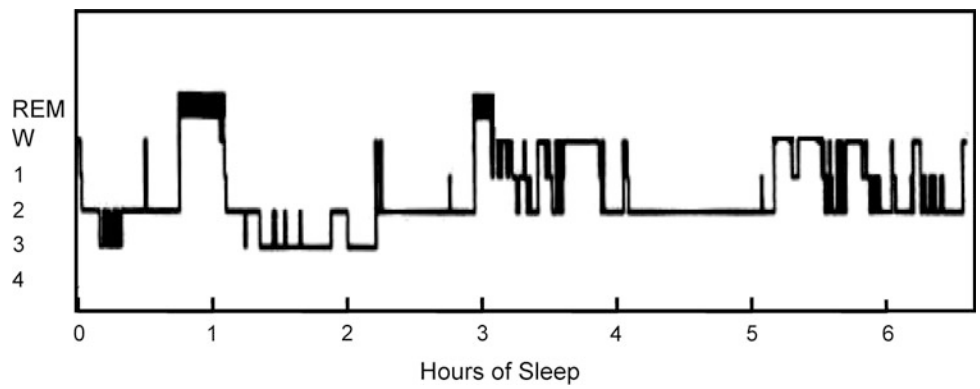

Fig. 7.8 Fluoxetine and sleep macroarchitecture. Note the short REM sleep latency early in the night and SWS dominating the 2nd NREM–REM cycle (typical in depression). As drug becomes active later in night, REM sleep is suppressed and sleep becomes fragmented

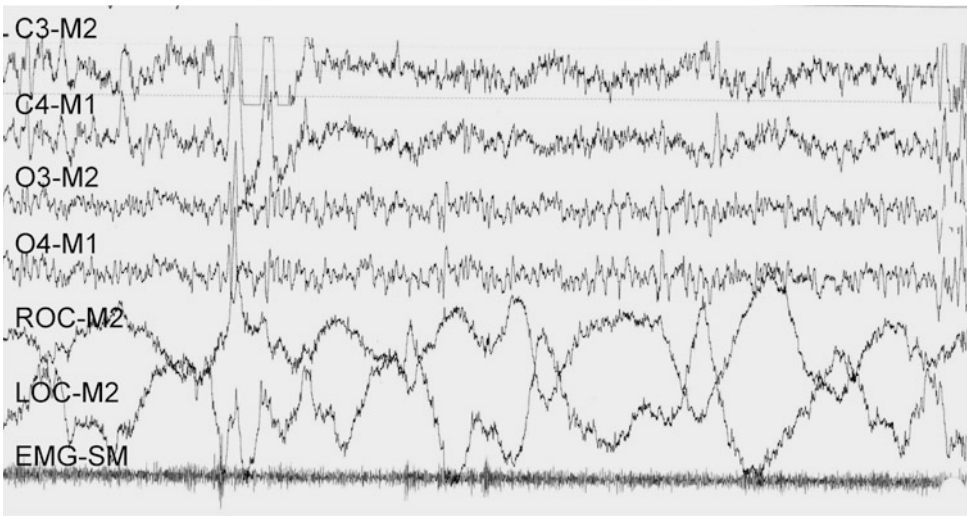

Fig. 7.9 Fluoxetine and sleep microarchitecture

Table 7.3 Clinical pharmacology for sleep disorders

Sleep disorder	Class or disorder	Treatment medication
Insomnia	BZDs	Temazepam, chlordiazepoxide, quazepam, clonazepam, flurazepam, estazolam, triazolam
	BZRAs	Zolpidem, zaleplon, eszopiclone, zopiclone
	Chronobiotics	Ramelteon, agomelatine, melatonin
	Antidepressants	Trazodone, doxepin, amitryptiline, nortryptiline, mirtazapine
	Antipsychotics	Quetiapine, olanzapine
	Orexin antagonists[a]	Suvorexant, almorexant
Narcolepsy	Excessive daytime sleepiness	Modanafil, armodafinil, amphetamine-like agents, SNRIs
	Cataplexy	Sodium oxybate, SSRIs, TCAs
Sleep-disordered breathing	REM sleep suppressants and/or agents to increase airway tone	TCAs, medroxyprogesterone acetate, SSRIs, mirtazapine, theophylline, modafinil, armodafinil, donepezil
PLMD and RLS	Assorted	Iron, pramipexole, rotigotine, ropinirole, levodopa, opiates, BZDs
Parasomnias	Nightmares	Prazosin, quetiapine, olanzapine, gabapentin, mirtazapine
	Terrifying hypnagogia	SSRIs, TCAs, modafinil, armodafinil
	REM sleep behavior disorder	Clonazepam, melatonin, pramipexole
	Sleep-related painful erections	Propanolol, clozapine
	Nocturnal leg cramps	Magnesium citrate
	Sleep-related bruxism	Amitryptiline
	Enuresis	Desmopressin
	Nocturnal paroxysmal dystonia	Anticonvulsants

[a]Amorexant is currently not in the market

contrast, if we are humans (or at least more human than rat), our response to MT would be to become sleepy and get ready to retire for our major sleep period. Presumably, the MT is occupying central MT_1 and MT_2 receptors sites in the suprachiasmatic nucleus (SCN) of the hypothalamus. The SCN is a bilaterally represented structure containing several thousand cells just above the optic chiasm and to either side of the third ventricle. Melatonin decreases the

SCN activating properties that hold homeostatic sleep drive (sleep debt) at bay and thereby result in sleep onset. Thus, melatonin plays a pivotal role in the 2-process model of sleep regulation (sleep drive and circadian rhythm) as described by Borbély [78].

Melatonin can act as a chronobiotic and provide time cues (zeitgabers) [79]. The studies by Sack and colleagues clearly demonstrated this property in blind from birth children [80]. These patients have a chaotic circadian sleep–wake rhythm due to lesions in both visual and retino-hypothalamic tracts. Administering melatonin daily at a set time entrains the sleep–wake cycle remarkably well. Melatonin has also been studied as a potential sleep-promoting substance [81]. It appears to decrease latency to sleep in several published studies. Whether these findings reflect hypnotic or chronobiotic properties is difficult to determine. Melatonin, however, has a very short half-life (approximately 20 min). This may be problematic for exogenously administered melatonin, whereas pineal's continual release renders the short half-life unimportant for naturally occurring endogenous melatonin. Several pharmaceutical companies make or are developing melatonin and melatonin agonists for the treatment of insomnia. Circadin® is a prolonged-release melatonin formulation approved in Europe for treating primary insomnia in patients 55 years and older with poor quality sleep. Ramelteon is a selective melatonin MT_1 and MT_2 agonist with a 2.6 h half-life (and active metabolites) approved in the USA for treating insomnia [82]. In clinical pivotal trials, an 8 mg oral dose of ramelteon taken 30 min before bedtime shortened both objective and self-reported latency to sleep onset in adults with primary insomnia [83]. Similar results were found for individuals age 65 years and older who were diagnosed with insomnia. Agomelatine is a potent melatonin receptor agonist and 5-HT_{2C} antagonist with a 1–2 h half-life. It appears to have antidepressant, anxiolytics, and sleep-promoting properties but has yet to be approved for use to treat insomnia in the American market.

Clinical Pharmacology and Summary

Overall, there appear to be several general observations we can make about drug-related changes in sleep, wakefulness, and sleep architecture. These should not be taken as hard-and-fast rules because there are exceptions. Nonetheless, these general principles may be helpful for predicting how sleep will respond to a substance, given its effects on neurotransmission. The basic 8 rules of thumb are:

1. Catecholamine agonists promote wakefulness and most suppress REM sleep
2. Centrally acting H1 antihistamines are sedating
3. Orexin deficit underlies sleepiness in narcolepsy
4. GABAA agonists and BZD receptor agonists are somnogenic
5. Adenosine antagonists are somnolytic
6. Cholinergic enhancing agents promote REM sleep while anticholinergic agents suppress REM sleep
7. NE and 5-HT agonists suppress REM sleep
8. Melatonin is the signal of darkness in the environment to the brain

Clinically, we capitalize on substance-induced sleep alterations. For example, we use wake-promoting substances to bolster alertness in patients suffering from disorders of excessive somnolence. By contrast, sedating agents are used to treat insomnia. REM sleep suppression represents an approach to treating cataplexy, and chronobiotics may be helpful for individuals with circadian rhythm disorders. Additionally, a variety of medications have therapeutic application that was determined empirically. Table 7.3 shows some of the current therapeutics in sleep medicine clinical practice.

Neurobiology of NREM Sleep and Thermoregulation in Sleep

8

Ronald Szymusiak

Introduction

The regulation of body temperature and sleep interacts in multiple ways. The biological clock in the suprachiasmatic nucleus (SCN) of the hypothalamus determines circadian variations in both core body temperature (CBT) and sleep-wakefulness, and these rhythms are normally coupled [1]. Across mammalian species, whether diurnal or nocturnal, the major sleep period occurs during the circadian phase of lowered CBT and waking behaviors predominate during the elevated phase of the CBT rhythm [2]. The sleep-related fall in the CBT is achieved through organized thermoregulatory adjustments that include reductions in metabolic heat production and increased heat loss to the environment. Homeostatic responses of the thermoregulatory system to heat or cold challenge can be diminished during non-REM sleep compared to waking, and in some species, thermal homeostasis is severely compromised during REM sleep [3, 4].

In addition to sleep-related changes in thermoregulation, manipulation of environmental temperature or body temperatures can alter sleep. Sleep is suppressed in heat or the cold and can be maximized in a thermoneutral or mildly warm environment [4]. Passive whole-body warming and localized increases in brain temperature or peripheral skin temperature (Tsk) have been shown to promote sleep [5–8].

An important concept that has emerged from neurobiological studies is that brain mechanisms that control sleep are anatomically and functionally coupled to thermoregulatory circuits in the brain. Thermoregulatory adjustments occurring around the time of sleep onset in humans, particularly dynamic changes in CBT and distal Tsk, are important determinants of sleep latency, sleep composition, and sleep quality. Therapies that target thermosensitive control of arousal states may have therapeutic potential in treating disorders of initiating and maintaining sleep [2, 9].

Sleep-Related Changes in Body Temperature Regulation

The onset of sleep is associated with a fall in CBT and a readjustment of thermoregulatory control. This coupling between sleep and lowered CBT is most striking in animals like primates (Fig. 8.1), with highly consolidated daily sleep periods [10]. It is also evident in rodents that display both circadian and ultradian rhythms in sleep/wake, with some episodes of sleep normally occurring during the active (nocturnal) phase (Fig. 8.2a).

The sleep-related fall in CBT is an integrated thermoregulatory response, not a passive consequence of behavioral quiescence associated with sleep. The decline in CBT at the transition from waking to sleep persists in humans on a modified constant routine protocol (Fig. 8.3b), in which the level of behavioral activity during the 8-h prior to lights out is kept minimal and constant (Kräuchi et al. 2004) [2].

At the transition from waking to sleep, the thermoregulatory system responds as if the thresholds for inhibition of heat production and for activation of heat loss responses have shifted to lower levels of CBT and/or Tsk. Wake-to-sleep transitions are accompanied by an integrated series of thermoregulatory adjustments, including a reduction in metabolic rate, increased heat loss to the environment through peripheral vasodilation (Fig. 8.3a, b) and, in warm environments, increased evaporative cooling. Body temperature falls to a lower regulated level which is maintained throughout the consolidated sleep period (Fig. 8.1). A simplified way of thinking about these changes is that the body's thermostat has been reset to a lower level during sleep, i.e., a sleep-related lowering of an internal thermal "set point."

With respect to thermoregulatory control, the body can be compartmentalized into a heat producing core and a heat loss regulating shell (Fig. 8.3a). The size of the shell can vary

From Baker et al. [16]

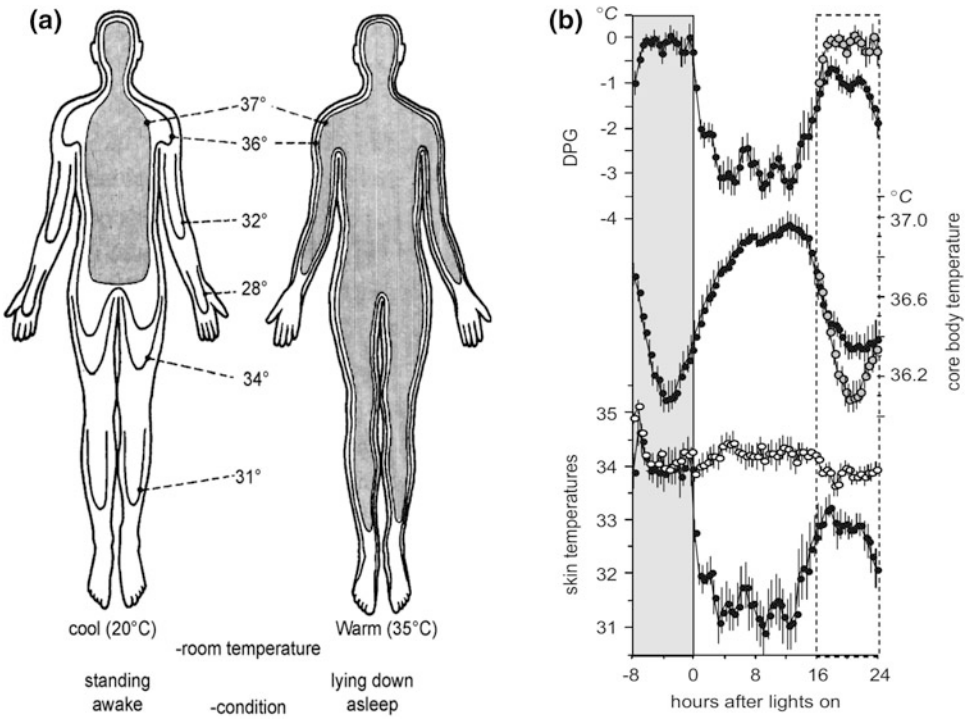

Fig. 8.3 **a** Schematic diagram of a human body indicating the small size of the heat producing core (shown in *gray*) relative to the large size of the heat loss regulating shell (shown in *white*) in a cool (20 °C) environment. During exposure to a warm ambient temperature (35 °C), the core expands significantly as blood flow to the periphery increase to promote facilitate heat loss to the environment. A similar expansion of the core relative to the shell occurs around the time of sleep onset and during the initial non-REM sleep episodes in humans, with the permission from Kräuchi [2]. **b** Dynamics of changes in CBT and Tsk during human sleep. Effects of an 8-h nocturnal sleep period (*shaded area*) on CBT, proximal and distal Tsk and DPG under constant routine conditions. Note the increases in distal Tsk and DPG that coincides with the steep decline in CBT early in the sleep period. The dashed line indicate a 8-h sleep deprivation period when the subjects usually sleep. Data from the 8-h sleep episode are double-plotted on the 8-h sleep deprivation period (gray dots). Modified from Kräuchi [2], with permission

considerably depending on ambient thermal conditions. The shell is large in cool/cold environments when blood flow is diverted away from the limbs to the core to conserve heat (Fig. 8.3a). The shell contracts in warm/hot environment when blood flow to the limbs increases to promote heat loss. The thermoregulatory changes that occur at the wake-to-sleep transition redistribute heat from the core to the shell (Fig. 8.3a), increasing distal Tsk, facilitating heat loss to the environment, and augmenting the decrease in CBT (Fig. 8.3b).

The sleep-related reduction in metabolic heat production and consequent energy savings can be taken as evidence of an energy conservation function of sleep. The sustained lowering of CBT during the sleep episode also has a net energy conserving effect by reducing the CBT-to-ambient temperature gradient which reduces the rate of heat loss to the environment. This latter factor can be important in small mammals with a high surface to volume ratio that have inherently higher rates of environmental heat exchange. Behavioral aspects of sleep onset such as seeking a thermally comfortable nest and adoption of curled heat-conserving postures can also contribute to energy savings by minimizing heat exchange with the environment across an extended period of sleep.

Highly specialized energy conserving adaptations in mammals, such as hibernation and shallow torpor, can be viewed as extreme readjustments in thermoeffector thresholds [11]. Hibernation and torpor are characterized by prolonged and reductions in metabolic activity and body temperature. These events occur seasonally, when thermoregulatory demands are greatest and food availability is low. Bouts of hibernation and torpor are initiated as extensions of sleep episodes, and the dramatic fall in CBT is accompanied by integrated thermoregulatory adjustments similar to those observed during normal sleep [11]. Thermoregulation is not suspended during hibernation or torpor, but the thermoregulatory system behaves as if the thermal set point has been lowered, albeit dramatically so. This is most obvious in shallow torpor, where CBT is maintained well below normal sleeping levels, but significantly above ambient temperature.

Homeostatic responses to thermoregulatory challenges are modulated by arousal state. While CBT is maintained at reduced levels compared to waking during consolidated

sleep episodes, thermoregulatory effector responses persist during non-REM sleep at normal or diminished levels, i.e., the magnitude of effector response to a thermal stimulus may be somewhat reduced compared to waking [12]. During non-REM sleep, there is a reduction in the thresholds and/or gains of autonomic heat and cold defense responses, with an effective expansion of the inter-threshold zone, which is the ambient temperature range between activation of heat production and heat loss responses.

Compared to non-REM sleep, thermoregulatory responses during REM sleep can be severely compromised [4]. This is particularly evident for cold defense responses, where the muscle atonia of REM sleep is incompatible with maintaining heat production via shivering or elevated muscle tone. Partial suppression of heat loss effector responses (e.g., panting) has also been described in REM sleep [13]. As a result of these thermoregulatory changes, animals are more vulnerable to thermal challenges during REM sleep compared to either waking or NREM sleep.

Exposure to hot or cold environments disrupt sleep (see below). This response may be adaptive in minimizing exposure to thermal stress during sleep when homeostatic compensation is weak. Thermal factors have undoubtedly played a role in the evolution of behavioral strategies for species-specific selection of sleeping environments, e.g., nests, sheltered locations, adoption of heat-conserving postures.

The seeming paradox of a sleep-related fall in CBT, combined with the selection of a relatively warm, insulated environment prior to sleep onset can be understood by considering the competing thermoregulatory requirements at work. Lowering metabolic rate and CBT during sleep can yield significant energy conservation benefits. However, diminished thermoregulatory adjustments to heat and cold challenge during sleep dictates that thermal homeostasis can be best achieved over the course of a several hour sleep period by selection of a sleeping environment that poses minimal thermal stress and ultimately maximizes energy conservation.

Interactions Between Circadian Rhythms in Sleep and Body Temperature

In healthy, entrained primates, including humans, habitual sleep onset occurs on the falling phase of the body temperature rhythm, 4–6 h before the CBT minimum (Fig. 8.1 and Fig. 8.3b). The onset of sleep is accompanied by an acceleration in the rate of the decline in CBT. In contrast, morning awakenings occur on the rising phase of the temperature rhythm, 1–3 h after the temperature minimum [2, 14]. The CBT rhythm is dictated by circadian rhythms in heat production and heat loss, with the rhythm in heat production phase advanced with respect to the heat loss rhythm [2]. A CBT rhythm persists during sleep deprivation or during constant routine protocols [15]. Nevertheless, behavioral changes associated with waking and sleep do exert positive and negative masking effects on the circadian temperature rhythms, and the magnitude of the 24 h peak-to-trough difference in body temperature is reduced during sleep deprivation or constant routine.

Circadian rhythms in body temperature and sleep are regulated by the biological clock located in the SCN of the hypothalamus. In experimental animals, lesions of the SCN abolish the 24 h rhythm in both sleep and body temperature [1]. In SCN-damaged rodents, circadian rhythms in sleep and body temperature are eliminated, yet daily total sleep amounts are unchanged. This indicates that the homeostatic regulation of sleep is largely undisturbed by SCN damage. However, the sleep-related fall in CBT persists in rodents with SCN lesions [16]. These animals exhibit ultradian rhythms in body temperature and sleep, and the two variables remain strongly coupled following SCN ablation, i.e., sleep episodes are reliably accompanied by falls in CBT (Fig. 8.2b).

The phase relationship between sleep and body temperature rhythms at sleep onset is an important determinant of subsequent sleep latency, sleep amount, and sleep quality. This has been most convincingly demonstrated in human subjects undergoing internal or forced desynchronization in environments without time cues. During internal desynchronization, sleep and body temperature rhythms free-run with different periods, and eventually, the two rhythms temporally dissociate [15, 17]. In forced desynchrony protocols, subjects adhere to a sleep-wake schedule significantly longer or shorter than 24 h (e.g., 28 or 20 h) and when this is done in the absence of time cues, body temperature and sleep rhythms dissociate as in internal desynchronization [15]. With both methods, over the course of several days the onset of the major sleep period will occur at all phases of the body temperature rhythm. Sleep episodes that are initiated on the falling phase of the temperature rhythm are associated with shorter sleep latencies, longer sleep episode durations, and maximal amounts of Stage N3 [15]. In contrast, sleep episodes initiated on the rising phase of the temperature rhythm are associated with longer sleep latencies, short sleep episode durations, more REM sleep but less Stage N3 sleep [15]. The functional importance of these phase relationships is demonstrated by the fact that, during internal and forced desynchronization, the phase of the CBT rhythm at sleep onset is a better predictor of sleep bout length than is prior time awake.

Collectively, findings indicate that thermoregulatory changes manifested at different phases of the CBT rhythm determine the expression of sleep. Activation of heat loss and suppression of heat production occurring during the falling phase of the temperature rhythm promotes sleep onset, sleep maintenance, and EEG slow-wave activity during sleep. Increased heat

production and heat conservation accompanying the rising phase of the temperature promote waking.

Effects of Environmental and Body Temperature on Sleep

Human and animal studies demonstrate that the temperature of the sleeping environment is an important determinant of sleep amount and sleep quality. In all mammals studied, exposure to moderate hot or cold environments will suppress sleep and/or cause sleep fragmentation [4, 18]. In some species, REM sleep is more easily disrupted by thermal stress than non-REM sleep. In rats, where thermoregulatory responses during REM sleep are absent or weak, REM sleep suppression can occur under conditions of minimal thermal stress and in the absence of any significant change in non-REM sleep amounts [18, 19]. From a thermoregulatory perspective, the REM sleep suppressing effects of heat and cold exposure in these species are adaptive. Increased time spent awake or in non-REM sleep means that a lower threshold and stronger thermoregulatory responses will be evoked to maintain thermal homeostasis.

In contrast to the sleep suppressing effects of moderate-to-severe thermal stress, mild increases in ambient temperature or mild warming of the body can promote sleep. An animal's thermoneutral zone is defined as the range of environmental temperatures at which resting metabolic rate is minimal and constant. Within the thermoneutral zone, minimal effort is required to maintain thermal homeostasis and thermal homeostasis is achieved largely through peripheral vasomotor adjustments that control heat exchange with the environment. Chronic exposure of rats to an environmental temperature that is at the upper end of the thermoneutral zone increases in daily total sleep time over baseline levels [20].

Whole-body warming, achieved by immersion in a hot bath a few hours prior to normal bedtime, promotes sleep in humans [5]. Hot baths prior to bedtime can reduce sleep latency and increase amounts of slow-wave sleep in the first half of the night. The timing of body warming is a critical factor. Optimum sleep-promoting effects of hot bath immersion are achieved 1–2 h prior to bedtime. Hot baths taken early in the day are ineffective. The critical variable in achieving sleep promotion appears to be that CBT remains slightly elevated above normal levels at bedtime, helping to promote a stronger heat loss response at sleep onset.

In rats, similar increases in non-REM sleep and in EEG slow-wave activity are observed following whole-body warming achieved by exposure to an elevated ambient temperature. Sleep is suppressed during initial heat exposure as body temperature increases. The elevations in non-REM sleep time and EEG slow-wave activity are observed during the 2 h after the end of heating as body temperature falls [21]. Collectively, these findings are consistent with the idea that mild activation of thermoregulatory heat defense mechanisms promotes sleep.

Hypothalamic Regulation of Sleep and Body Temperature

Neurons in the preoptic and anterior hypothalamus (POA) are critically involved in thermoregulation [22]. Experimental damage to the POA in animals causes persistent deficits in thermoregulatory defense against heat and cold exposure. Direct infusion of various neurotransmitters or neuromodulators into the POA can alter body temperature and thermoregulatory function.

Specialized temperature-sensing neurons localized in the POA play an important role in body temperature control [22, 23] Warm-sensing neurons (WSNs) are excited by local increases in temperature and inhibited by cooling. Cold-sensing neurons (CSNs) are excited by local decreases in temperature and inhibited by local warming. The functional importance of these temperature-sensing neurons for thermoregulatory control is evidenced by experimental findings that localized warming or cooling of the POA can evoke fully integrated heat defense or cold defense responses that are similar to those evoked by exposing the whole animal to hot or cold environments [22, 23].

POAH temperature-sensing neurons receive inputs from corresponding thermoreceptors in the skin [24]. Inputs from warm sensors in the skin excite POA WSNs (Fig. 8.4). Afferents from peripheral cold sensors activate POA CSNs. Peripheral-to-central thermoreceptor connection is a mechanism by which changes in skin temperature caused by increasing or decreasing ambient temperature can initiate thermoregulatory responses in advance of any alteration in the temperature of the brain or the body core [22, 24].

The level of activation of POA WSNs versus CSNs is an important determinant of the regulated level of body temperature [24]. Preferential excitation of WSNs and inhibition of CSNs will result in reduced metabolic heat production, increased heat loss from the periphery, and the lowering of body temperature to a stable, lower level. Activation of CSNs will have the opposite effect: increased metabolism, heat conservation, and an increase in CBT. Adjustments of thermoregulatory thresholds can arise from changes in thermosensitive neuronal activity evoked by factors such as immune system activation or changes in neurotransmitter/neuromodulator release in the POA. Fever is the prototypical example of an increase in the thermal set point, in which the elevation in CBT is accompanied by an increase in metabolic heat production and reduced heat loss [24, 25]. Exogenous or endogenous substances that evoke fever (e.g.,

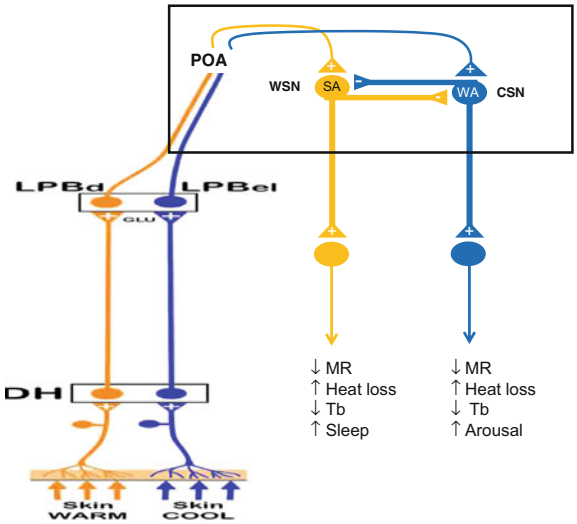

Fig. 8.4 Schematic diagram of the afferent pathways originating in the skin relayed through the dorsal horn of the spinal cord (DH) and lateral parabrachial nucleus in the brainstem (LPB) and converging upon temperature sensitive neurons in the preoptic/anterior hypothalamus (POA). Inputs from peripheral warm receptors excite warm-sensitive neurons (WSN; *orange*) in the POA, a significant subset of which are also sleep-active (SA). Inputs from peripheral cold receptors excite cold sensitive neurons (CSN; *blue*), a majority of which are wake-active (WA). Reciprocal inhibitory connections are thought to exist between WSNs and CSNs. When the population of WSNs in the POA are activated, metabolic rate (MR) decreases, heat loss increases, body temperature (Tb) falls, and sleep propensity is increased. When CSN activity predominates, MR increases, heat is conserved, Tb increases, and EEG and behavioral arousal are enhanced. Activation of sleep-active WSNs through mild–moderate increases in Tb, Tsk, or local POA temperature can all have sleep-promoting effects. In healthy entrained humans, behavioral adjustments (lying down, adjustments of microclimate with bedcovers and/or bed clothing) and physiological changes (melatonin release, decreased sympathetic tone, spontaneous activation of sleep-active WSNs) that occur around habitual bedtime augment the flow of blood to the periphery and increase Tsk and the DPG. This has a feed-forward effect of further activating the central sleep-active WSN population, promoting rapid transitions to stable, deep sleep

lipopolysaccharide, prostaglandin E1) have been shown to excite POA CSNs and to inhibit WSNs. It can be hypothesized that the circadian rhythm in body temperature is driven by changes in the relative activation of warm- versus cold-sensing neurons regulated by output of the SCN, with WSN activity predominating on the descending phase of the rhythm and CSN predominating on the rising phase.

The neural control of sleep and thermoregulation is co-localized in the POA and adjacent brain structures and hypothalamic temperature-sensing neurons participate in sleep regulation [26]. Experimental POA damage that disrupts thermoregulation also causes persistent insomnia, suggesting that thermo- and sleep-regulatory neuronal systems are anatomically related [26, 27]. They appear to be functionally related as well. As summarized in the previous section, local warming or cooling of the POA can evoke robust whole-body heat and cold defense responses. Milder increases in POA temperature, in addition to suppressing metabolic rate and augmenting peripheral vasodilation, reduce sleep latency, promote non-REM sleep, and increase EEG slow-wave activity during non-REM sleep [27]. Local POA cooling has the opposite effects, causing sleep suppression and reduced EEG slow-wave activity during sleep. At the systems level, in can be shown that activation of POA WSNs promotes sleep via inhibition of ascending arousal systems located in the hypothalamus and brainstem. POA warming suppresses waking-related activity of neurons in the basal forebrain, the lateral posterior hypothalamus, the midbrain reticular formation, and the dorsal raphe nucleus [28, 29].

As documented by single neuronal recordings in cats and rats, the majority of POA WSNs exhibit elevation of spontaneous discharge rate during sleep onset and non-REM sleep, compared to waking [30, 31]. The majority of CSNs are maximally activated during waking and exhibit reduced discharge during sleep onset and non-REM sleep. Thus, the changes in POA thermosensitive neuronal activity at sleep onset mimic the pattern expected to accompany a lowering of the thermal set point. This pattern of thermoreceptor activity is consistent with the thermoregulatory responses that normally accompany sleep onset, i.e., reduced metabolic rate and increased heat loss at the periphery (Fig. 8.4).

The ability of local POA warming to evoke non-REM sleep and EEG synchrony indicates that activation of POA WSNs is sufficient for sleep promotion. The sleep- and EEG slow-wave-promoting effects of evening hot bath immersion in humans depend on the residual mild elevation in body

temperature at bedtime, which enhances the activation of WSNs during sleep onset and sleep. Just as changes in Tsk can evoke thermoregulatory responses in anticipation of changes in brain/body temperature, increases in Tsk through application of warming stimuli or increases in peripheral blood flow would excite sleep-active WSN in the POA promoting sleep onset and sleep stability (Fig. 8.4).

Thermoregulatory Control of Human Sleep

Neurobiological studies in experimental animals reveal close anatomical and functional interrelationships between sleep and body temperature control mechanisms in the brain and indicate that activation of hypothalamic neuronal circuits that promote heat loss normally occurs at sleep onset and during non-REM sleep. In humans, the magnitude of the heat loss response around the time of sleep onset is an important determinant of sleep latency, sleep amount, and sleep quality [32–34]. The magnitude of heat loss response in humans can be reliably assessed by quantifying the temperature gradient from distal skin sites (hand and feet) to proximal skin sites (e.g., forehead, stomach, thigh, or some weighted average of several proximal skin sites. A high distal-to-proximal skin temperature gradient (DPG) occurs when Tsk of the feet and hands are warm with respect to proximal sites, indicative of elevated blood flow to distal skin and elevated heat exchange at these sites Fig. 8.3. A low DPG reflects peripheral vasoconstriction and diminished peripheral heat loss. A high DPG is associated with reduced sleep latency, increased Stage N3 sleep, and reduced number of arousals from sleep [2, 34]. The distal-to proximal gradient is also positively correlated with subjective sleepiness after morning awakenings and after awakenings from daytime naps.

It can be hypothesized that thermoregulatory responses that normally accompany sleep onset in humans play a role in reinforcing and consolidating circadian and homeostatic aspects of sleep regulation. In an entrained individual, habitual sleep onset times will occur on the descending phase of the CBT rhythm. Homeostatic sleep drive is also high at this time, because of sustained prior waking. As CBT falls following the nadir of the 24 h rhythm, activation of heat loss mechanisms results in elevated Tsk. Elevations of endogenous melatonin that normally coincide with habitual bedtime in entrained individuals may also promote lowering of the thermal set point and augment peripheral vasodilation [35]. Collectively, these events would result in activation of peripheral warm sensors and excitation of hypothalamic warm-sensing neurons via peripheral-to-central thermosensory pathways (Fig. 8.4). Activation of central warm sensors will increase sleep propensity via suppression of arousal systems and hasten sleep onset, resulting in further increases in peripheral Tsk and heat loss [27]. Thus, thermoregulatory changes have the potential to exert feed-forward excitatory effects on brain mechanisms that control sleep onset and sleep maintenance, leading to more rapid and seamless transitions from waking to consolidated sleep.

Insomnia is the most common sleep complaint, and sleep disturbance is a prominent symptom in several psychiatric and neurological disorders. In many instances, insomnia complaints are accompanied by abnormalities in circadian rhythms, including abnormalities in the CBT rhythm [36]. Sleep onset insomniacs may exhibit a phase delay in the CBT rhythm of >2 h, indicating disturbance of circadian timing or entrainment. This phase delay means that attempts to fall asleep would often be occurring in closer than normal proximity to the CBT peak, and thermoregulatory adjustments that promote sleep might not be as readily evoked. In the elderly, phase delays in the CBT may also be a contributing factor to the increased incidence of insomnia [36, 37]. Although CBT abnormalities in disorders associated with insomnia may be secondary to other underlying pathologies, manipulation of thermoregulatory control, either pharmacologically or behaviorally, in ways that promote heat loss at sleep onset may help to improve sleep amount and sleep quality. Findings confirm the ability of skin warming to facilitate sleep in normal sleepers and in individuals with insomnia and disturbed nocturnal sleep [9, 37, 38].

Phylogeny of Sleep

9

Kristyna M. Hartse

Sleep is a mysterious, intricate biological symphony which is composed and conducted by the genetics, anatomy, physiology, neurochemistry, environment, and psychology of living organisms. The phenomenon of sleep is not a uniquely human experience, and with many variations on a theme, it is ubiquitous throughout the animal kingdom. In order to understand why we sleep and why there are perturbations which result in sleep disorders, it is of importance to study sleep in many different living organisms, including those with a long phylogenetic history, which may shed light on the origins of sleep. However, one might reasonably ask how can the study of sleep in diverse creatures such as insects, reptiles, birds, and dolphins—organisms so unlike ourselves—contribute to our knowledge about human sleep? At first glance the immediate answer would appear to be "not much." However, to entertain the possibility that the study of animal sleep is inconsequential or even irrelevant in understanding human sleep and its disorders would be shortsighted. The identification and study of model organisms such as the fruit fly (*Drosophila melanogaster*), for example, have produced a dramatic explosion in our molecular and genetic knowledge about the mechanisms controlling the expression of sleep. These findings reverberate with new insights across the entire spectrum of sleep disorders medicine. Although the exact functions and purposes of sleep still remain unknown, many pieces of the sleep puzzle derived from phylogenetic studies have laid the foundation for unraveling these mysteries.

Most animal sleep studies have been performed in familiar mammals, and a recent review [1] underlines the fact that primarily mice, rats, cats, and dogs have been used experimentally to construct animal models of human sleep disorders. However, the literature is rich with studies of unusual mammalian and nonmammalian species which, although displaying remarkable variations in environment, evolutionary history, behavior, life span, anatomy, and physiology, exhibit the behavioral characteristics of sleep and provide clues to the origins of sleep. At least from a behavioral standpoint, sleep appears to be a universally conserved phenomenon, and as we shall see, genetic and molecular aspects of sleep have also been conserved. Insects, fish, amphibians, reptiles, and invertebrates as well as mammals including egg laying monotremes (platypus and echidna), marine-dwelling cetaceans (whales, dolphins, porpoises) and pinnipeds (seals), marsupials (kangaroo, possum), and placental mammals all display behavioral sleep. Documentation of distinctive electrophysiology, which can be different from that of mammals, may also accompany behavioral sleep in nonmammals. By studying living organisms with a long history in the fossil record, clues to the role of sleep in species survival as well to the function of sleep might be obtained. There are several recent detailed reviews on behavioral and electrophysiological characteristics of mammalian and nonmammalian sleep [2–6]. Here, we will not recapitulate these details, but rather draw upon relevant studies from the animal literature to explore how clues from phylogenetic studies have contributed to the understanding of human sleep and human sleep disorders.

The Definition of Sleep

The first task in understanding sleep mechanisms is to define sleep. There are two different approaches to this definition, behavioral and electrophysiological. The behavioral definition of sleep is well established, and behavioral criteria have been used to identify sleep in diverse insects, invertebrates, mammalian, and nonmammalian organisms. These criteria include (1) a species specific posture; (2) behavioral quiescence; (3) increased arousal thresholds; (4) state reversibility to distinguish sleep from coma or torpor; and (5) a homeostatic response to sleep deprivation, i.e., an increase in sleep amount following sleep deprivation. In mammals, there are distinctive electrophysiological events which accompany behavioral sleep and which distinguish sleep

from wakefulness. During nonrapid eye movement (NREM) sleep, the EEG is characterized by high amplitude slow waves as well as by other distinctive wave forms such as sleep spindles and K complexes. In humans, NREM sleep has been subdivided into three or four separate sleep stages with specific EEG waveform criteria detailed for each stage [7, 8]. Rapid eye movement (REM) sleep alternates in a cyclical fashion with NREM sleep. REM sleep is characterized by a low amplitude EEG similar to that of waking, skeletal muscle atonia, and rapid eye movements. REM sleep is a period of intense physiological activity in a sleeping organism and other distinctive events during REM sleep include vivid dreaming in humans, increased single neuron firing in the brain, increases in brain temperature, and penile erections. REM sleep is also referred to as paradoxical sleep (PS) recognizing the incongruity of this active physiology in a sleeping organism.

Since there is a close correspondence between the distinctive electrophysiological markers of mammalian sleep and behavior, electrophysiology is generally a more efficient means, rather than continuous visual observation of behavior, in defining mammalian sleep. However, as we shall see, although the behavioral criteria for sleep may be met, the electrophysiological expression of sleep is often different in nonmammalian species.

In comparison with mammals, there are relatively few electrophysiological studies which have been performed during behavioral sleep in nonmammalian organisms. Furthermore, there is controversy as to whether the "true" indicators of electrophysiological sleep are present since nonmammalian electrophysiology is quite different from that of mammals. The high amplitude slow waves defining mammalian NREM sleep have not been reliably observed during nonmammalian behavioral sleep with the exception of birds [9]. Similarly, REM sleep has not been rigorously documented in nonmammals, again with the exception of brief bouts of avian REM sleep usually lasting less than 10 s. In mammals, the thick neocortical layer responsible for generating slow wave activity, is absent in nonmammals, making it unlikely that slow waves can be generated without this anatomical substrate. There are some scattered observational reports of REM sleep in nonmammals, but most studies have not presented rigorous or convincing evidence for REM sleep.

There is, however, a variety of other electrophysiological correlates associated with behavioral sleep in invertebrates and nonmammalian vertebrates. A sampling reveals a decline in local field potentials during behavioral sleep in fruit flies [10, 11], spindle-like activity during quiescence in the frog [12], isolated spikes and spike trains during behavioral quiescence in the octopus [13], spikes during behavioral wakefulness and waves of 15–20 Hz during behavioral sleep in the crayfish [14], and high amplitude spikes during behavioral sleep which disappear with behavioral waking in turtles, tortoises, lizards, and caiman [15–18].

These findings, which are dissimilar to the electrophysiology of mammalian sleep, have prompted debate as to whether the sleep of nonmammalian organisms is the same state as mammalian sleep and whether it is logical or scientifically reasonable to impose the mammalian criteria for sleep on nonmammalian species [19–21]. Other electrophysiological findings which further complicate the picture include reports of high amplitude slow waves characteristic of mammalian NREM sleep occurring during behavioral sleep in young caimans [22], REM sleep in lizards [23], high amplitude slow waves during waking in lizards [24], and high amplitude spikes during reptilian behavioral sleep which appear to be analogous to ventral hippocampus spikes recorded during NREM sleep in mammals [25]. Libourel and Herrel [4] have recently suggested that explanations for these varied findings in reptiles may be the result of differences between natural or seminatural recording conditions and laboratory conditions, differences in habituation to the recording environment, differences in electrophysiological recording techniques, methodological differences in evaluating arousal responses, and differences in electrode placements since no stereotaxic atlases of reptilian brains are available to ensure consistency of electrode placement. This debate surrounding sleep in reptiles is central to the question of whether nonmammalian organisms sleep if they do not exhibit mammalian electrophysiology. Rather than attempt to resolve this issue, examples from phylogenetic sleep studies will be used to evaluate the contribution of phylogeny to human sleep.

Model Organisms in the Study of Sleep

The revolution in our current knowledge about the neurochemical, molecular, and genetic bases for sleep has been propelled forward at an extraordinary rate by the introduction of model organisms, primarily the fruit fly (*Drosophila melanogaster*), and round wormas (*Caenorhabditis elegans*) as well as the zebrafish (*Danio rerio*) (Figs. 9.1, 9.2, 9.3). Compared to mammals, there are a number of features which make these organisms both practical and scientifically desirable for study. There is economic and logistical ease in maintaining large colonies, and a short life span as well as short reproductive cycles allow for the rapid evaluation of experimental manipulations. Increased statistical power can be achieved as the result of a large number of available subjects, and there is the potential for rapid replication of results in genetically identical organisms under similar

conditions. Furthermore, the presence of drosophila appendages such as wings and legs allow for observations of complex behaviors. The most significant scientific advantage is the relatively small number of neurons (approximately 100,000) in the adult drosophila brain as compared to the staggeringly large number of neurons (approximately 86 billion) in the adult human brain [26, 27]. The drosophila genome has been mapped with shared homologues identified in humans [28–31]. In addition, the neurotransmitters which have been demonstrated to play a role in the control of human sleep, including serotonin, dopamine, acetylcholine, GABA, and epinephrine (the equivalent of octopamine in drosophila), and in the case of zebrafish, orexin, are present [32, 33].

A model organism is a model only if, despite strong genetic similarities to humans, there is evidence that behavior meets the criteria for sleep. *Drosophila* quiescence does fulfill the criteria established for behavioral sleep [34, 35]. Behavioral quiescence, a stereotypic posture, elevated arousal thresholds, state reversibility with stimulation, and a homeostatic response to deprivation of rest, i.e., rest increased following the period of rest deprivation are present. This homeostatic response to deprivation is independent of at least one central clock gene, indicating that the homeostatic response is not simply a circadian response rather than a response to rest deprivation. Additional evidence for the similarity between *drosophila* quiescence and human sleep includes a similar response to drugs including caffeine, modafinil, and methamphetamine [36–38]. Antihistamines increase quiescent periods in *drosophila* similar to drowsiness in humans [35]. Finally, there are age-related changes in sleep similar to the changes in sleep amounts across the human life span [35, 39].

Drosophila is the organism which has arguably received the most attention as a model system for the genetic and molecular study of sleep. However, zebrafish (*D. rerio*) also offer similar biological and behavioral properties with respect to sleep for consideration as a model organism [40, 41]. Another proposed model organism is the round worm (*C. elegans*). During lethargus, a quiescent behavioral state which occurs after each of four molts, the behavioral criteria for sleep, including a homeostatic response to rest deprivation and elevated arousal thresholds, are present [42, 43]. There is genetic and molecular conservation between *drosophila* and *C. elegans* [44, 45]. A recent study also provides evidence that quiescence during molts in another worm, the tobacco hornworm (*Manduca sexta*), meets the behavioral criteria for sleep [46]. Thus, these model organisms with their practical and experimental advantages may have the potential to observe, and perhaps unlock, the underlying mechanisms controlling the expression of sleep.

Optimal Sleep and Mortality

> The ill effects of insufficient sleep may be witnessed on some of the principal organic functions, but it is the brain and nervous system that suffer chiefly in the first instance. The consequences of a too protracted vigil are too well known to be mistaken, and many a person is suffering, unconscious of the cause, from the habit of irregular and insufficient sleep.
>
> William A. Hammond, 1866 [47].

The consequences of insufficient sleep have long been a subject of debate and discussion. Still today, some of the most common questions asked of sleep clinicians revolve around sleep quality and sleep amounts: How many hours of sleep per night are necessary for good health, is a lack of

Fig. 9.1 The Fruit Fly (*drosophila melanogaster*)

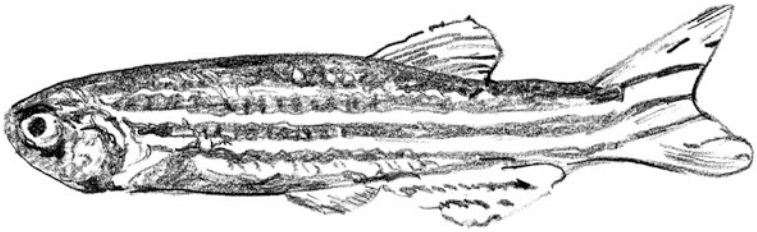

Fig. 9.2 The Zebra Fish (*danio reiro*)

sleep harmful, and will inadequate amounts of sleep or poor quality sleep affect longevity? As we shall see, there are data to suggest that too little or too much sleep may impact health and life span in humans. For example, persistent, but not intermittent, self-reported insomnia is associated with an increased risk of all-cause mortality over a 20-year follow-up period, suggesting that decreased sleep amounts negatively impact life span [48]. In contrast, prolonged sleep amounts have been associated with an increased risk of fatal and nonfatal stroke [49], conversely suggesting that increased sleep amounts negatively impact health. Although studies of sleep in nonhuman organisms reveal significant variations in sleep amounts, there are no data available which shed light on the impact of these variations in promoting species survival and longevity. As we shall see, however, there are examples of "natural" sleeplessness in the animal world, and most importantly the genetic manipulation of model organisms has advanced our knowledge about the mechanisms controlling sleeplessness.

One approach to addressing the question of whether there are optimum amounts of sleep associated with a long life span would be to examine the relationship between sleep amounts and mortality in large populations. A systematic relationship between human sleep and mortality was first described over 30 years ago [50], and since that time a body of epidemiological literature has accumulated which suggests fairly consistently that short and, somewhat inconsistently, that long sleep amounts are associated with increased mortality as well as with diseases such as obesity, diabetes, hypertension, and cardiovascular disease [51–55]. Typically, the best survival curves are associated with about 7 h of sleep per night. Shorter sleep times are variably defined in these studies as 4–6 h per night and long sleep times as more than 8–9 h per night, raising the question of whether the common recommendation of a minimum of 8 h of sleep per night is appropriate [56]. Of note is that in virtually all epidemiological studies, sleep duration was assessed by subjective estimates and not overnight sleep studies utilizing polysomnography, suggesting the possibility of subjective over- and underestimates of sleep duration which could bias results. Also, it cannot be determined in these epidemiological studies whether short and long sleep durations are the direct cause of increased mortality or whether short and long sleep durations are the product of an underlying intervening condition which in turn is responsible for these associations with mortality.

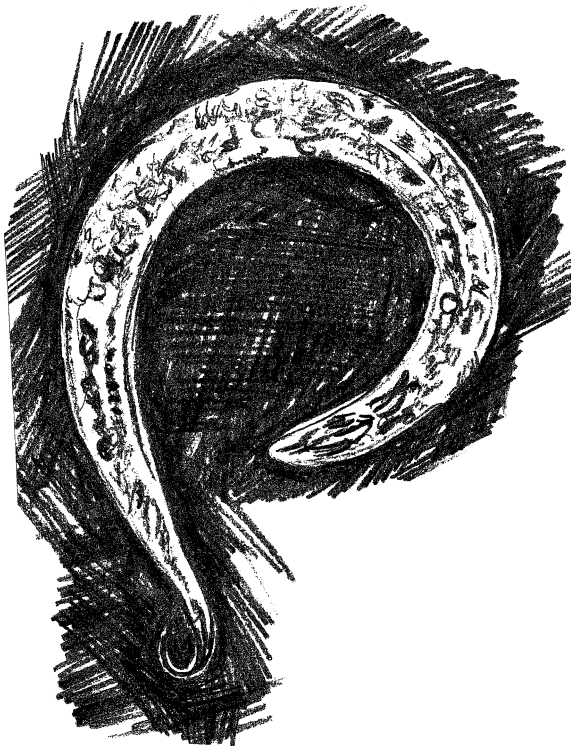

Fig. 9.3 The Round Worm (*caenorhabditis elegans*)

The most extensive and rigorous review of the literature addressing the question of optimal sleep time was recently performed by a panel of sleep experts assembled by the American Academy of Sleep Medicine and the Sleep Research Society [57]. The consensus of the panel was that less than 6 h of sleep is inadequate to support optimal health, but no consensus could be reached about the effects of 9 h or more on optimal health. The final consensus was that 7 h was the minimum amount of daily sleep necessary to support optimal health. However, no consensus could be reached about an upper maximum threshold of sleep for optimal health. This is not surprising. A careful review of the epidemiological studies supporting a relationship between sleep duration and mortality raises the issue of, for example, how

variable methodologies for determining total sleep time may weaken the conclusions which can be drawn from the U-shaped curve characteristic of the relationship between sleep duration and mortality [58]. Also of interest in these considerations of mortality and sleep duration is the demonstration of a dose–response relationship between hypnotic sleep medications typically used to treat short sleep and an increased mortality risk as well as an increased cancer risk for the most frequent users of hypnotics [59]. These findings suggest that intervening variables, inconsistently assessed in epidemiological studies, may contribute substantially to the association between sleep duration and mortality.

Human epidemiological studies, although inviting speculation about the predictive value of sleep amounts in determining life span, do not reveal the biological mechanisms responsible for this relationship. There are age-related changes in *drosophila* sleep similar to the sleep fragmentation and decreased sleep amounts observed in aging humans, suggesting that *drosophila* may shed light on the mechanisms mediating sleep and longevity in humans [39]. Several genetically engineered *drosophila* mutants, including *Minisleep* (*mns*), *Hyperkinetic* (*Hk*), *Sleepless* (*sss*), *and Insomniac* (*inc*), have been developed which have markedly reduced sleep amounts in comparison with wild-type flies [60–62]. Life span in these short sleeping flies is reduced, suggesting that sleep duration has a direct relationship to longevity. Of note is that waking behavior was not impaired in mutant strains. These mutations are mediated by *Shaker*, a gene which encodes for the voltage dependent potassium channel. Another short sleeping mutant, *fumin* (*fmn*), which has a mutation in the dopamine transporter gene (DAT), does not show a reduced life span nor do these flies exhibit a homeostatic response to sleep deprivation [63]. There is substantial evidence from a number of studies to indicate that dopaminergic systems have a major role in the expression of arousal and sleep [36, 64]. Mutations of the *amnesiac* (*amn*) gene, which has a role in the adenylate cyclase/cAMP signaling pathway, are associated with fragmented sleep and, similar to *fmn*, are not associated with a rebound in quiescence following deprivation [65]. Of note is that a high-calorie diet in *fmn* mutants results in further reductions in sleep amounts and reduced longevity, suggesting that accelerated aging and shortened sleep are impacted by increased caloric intake [66]. Also time-restricted feeding with food access limited to 12 h per day in wild-type flies, although not changing caloric intake, is associated with improvements in sleep and ameliorates an age-related cardiac decline [67]. These studies indicate that there are a number of different factors which affect the expression of sleep. Also of interest are mutations in genes which would not seem to play a role in sleep expression such as the fragile X mental retardation gene (*Fmr1*). Overexpression of drosophila *Fmr1* results in shortened sleep, whereas the loss of *Fmr1* is associated with significantly longer sleep amounts as compared to control flies. In neither mutant was there a homeostatic response to sleep deprivation, and of particular interest relevant to the human epidemiological studies is that life span is reduced in both the short and long sleeping *Fmr1* mutants [68]. Finally, it is most likely that there is not a single dedicated "sleep gene," but that other genes more broadly controlling cellular and neuronal functions also control the expression of sleep. An example is the demonstration that decreasing cyclin A, a protein which regulates the progression of cells through the cell cycle, results in decreased total sleep and a decrease in the homeostatic response to sleep deprivation [69]. More recently, a sleep regulating protein *redeye* (*rye*) which interacts with *sss* has been identified in short sleeping mutants and after sleep deprivation in wild-type *drosophila* [70].

The cellular mechanisms controlling sleep in humans are virtually unknown. The complaint of insomnia, difficulty falling and staying asleep typically with resulting daytime fatigue, affects approximately 30 % of the population in varying degrees of severity [71]. Not only physiological factors, but the contribution of psychological factors to this disorder, make it a daunting task to untangle the mechanisms which are involved in the expression of human sleeplessness. There are two disorders characterized by shortened sleep which have been identified in this category of sleep difficulties and which have a known genetic basis. The first is advanced sleep phase syndrome in which affected family members have a mutation of the hPER2 clock gene involved in controlling the timing of sleep. Although the sleep cycle is regular in affected family members, there is a four hour advance of sleep, temperature, and melatonin rhythms in affected as compared to unaffected family members [72]. A second disorder of sleeplessness with a known genetic basis is fatal familial insomnia. This disorder is a rare, inherited, progressive neurodegenerative disease in which there is a progressive inability to sleep eventually culminating in total sleeplessness and death [73]. Autopsy findings reveal selective bilateral neuronal loss and reactive gliosis of the anterior and dorsomedial thalamic nuclei with an accumulation of prion protein. In affected individuals, there is a single mutation on the prion protein gene PRNP at position 178 combined with a mutation at position 129 [74]. Although these are two very specific instances of sleep difficulty, there is, however, evidence to suggest that short sleepers do carry a gene with a specific DEC2 (also known as BhLHE41) mutation. This mutation was identified in a family with two individuals who had lifelong short sleep averaging 6.25 h per day as compared to noncarrier family members who averaged 8.06 h per day [75]. Subsequent work has identified other mutations of BHLHE41 associated with decreased total sleep time and with fewer average

lapses in performance on a psychomotor vigilance task, suggesting resistance to the effects of sleep deprivation [76].

Despite this large body of literature which suggests that sleep and longevity are related, there continues to be no clear answer to the question of whether there is an optimal amount of sleep which can promote maximum longevity in humans. Additionally, understanding the genetic and cellular mechanisms responsible for human sleeplessness is clearly in its infancy. There are, of course, no formulas to translate the equivalency of *drosophila* sleep minutes which can be manipulated by these mechanisms into human sleep hours. As previously noted, at least some of the ambiguity in human studies may be related to subtle differences in survey questioning about sleep amounts which result in subjective under- or overestimation of sleep time [58].

There are also variables identified from *drosophila* studies which may interact with genetics to potentially affect sleep with respect to longevity including social enrichment or isolation, environmental conditions, diet, methods of evaluating quiescence, and climates and altitudes [77–82]. There is also recent evidence that variations in population density during normal *drosophila* larval development affect sleep duration in adults, but not in *amn* mutants, suggesting lifelong cellular changes in sleep controlling mechanisms dating from infancy as the result of environmental exposures [83]. Although not as intensively studied as *drosophila*, other mammals and non-mammals also demonstrate that environment and social experience may affect the expression of sleep. For instance, sleep in honey bees is increased by exposure to the bee colony environment in comparison with isolated bees [84]. Electrophysiological recordings of unrestrained sloths in the rain forest reveal that total sleep time is substantially less than under laboratory conditions [85]. The threat of predation and social status may also play a significant role in determining sleep amounts in mammals [86–88]. In reptiles, young caimans recorded in a colony exhibited differing electrophysiology from caiman recorded in isolation, suggesting that these differences in environment and socialization may have affected the expression of sleep [17, 22].

The most striking example of the evolutionary effects of habitat upon sleeplessness is illustrated by studies in the Mexican cavefish (*Astyanax mexicanus*) [89, 90]. Surface- and cave-dwelling populations of these fish differ remarkably in daily sleep amounts with surface fish averaging over 800 min and three different cave-dwelling populations averaging 110–250 min per day. Blockade of B-adrenergic receptors with propranolol produced dose-dependent increases in cave fish sleep without any effect at any dose on sleep of surface-dwelling fish. Adrenergic antagonists did not affect sleep in surface dwellers, but cavefish sleep increased significantly in response to the B1 antagonist atenolol. The number of catecholamine neurons is conserved in cavefish as opposed to surface-dwelling fish, suggesting that an increase in the adrenergic arousal system in cavefish as compared to surface dwellers has occurred during evolution. Other recent fish studies have examined circadian rhythmicity in aging killifish (*Nothobranchius*) as well as the induction of quiescence by melatonin in the three spot wrasse (*Halichoeres trimaculatus*) [91, 92].

In summary, much of the appeal of the findings from human epidemiological studies resides in the simplicity of the U-shaped curve which suggests that the relationship between longevity and sleep is straightforward. Both short sleep and long sleep are associated with increased mortality. However, as we have seen from the animal literature, these data are fraught with many potentially uncontrolled and confounding genetic, environmental, and ecological factors which have the potential to alter this relationship. An unambiguous answer to the question of how much sleep and under what conditions are necessary for optimal longevity remains unanswered.

Pharmacological Development

A significant advantage of utilizing model organisms to explore the molecular basis of sleep lies in their well-studied genome which is amenable to precise manipulation. Another potentially productive area in which these model organisms may be of substantial benefit is in the area of developing new and focused pharmacological treatments for human diseases, including sleep disorders [30]. For example, approximately 70 % of human genes have at least one zebrafish orthologue, and as a result, zebrafish have been extensively used to develop human disease models [28, 93]. The correspondences between the human genome and the genomes of model systems suggest that model organisms could be instrumental in developing in vivo drug treatments at a molecular level for modifying or treating human sleep disorders. Zebrafish are sensitive to major classes of drugs including anxiolytics, hypnotics, and stimulant among others which could potentially be used to treat disordered sleep [33, 40]. In addition, the cost of screening pharmacologically active compounds is substantially less expensive in an organism such as the zebrafish so that an increased number of compounds can be economically evaluated. New effects and mechanisms of drug action on waking and quiescence produced by similar major neurotransmitter pathways in both zebrafish and mammals, and identification of poorly understood compounds can be rapidly assessed.

Cross-translational studies between model organisms and humans also open new avenues for the discovery of waking and sleep biomarkers which may have practical application. One example is the discovery of salivary amylase as a biomarker for sleepiness and sleep drive in both *drosophila* and humans utilizing cross-translational studies [38, 94]. The

potential applications of such a "sleepiness marker" are far reaching. For example, multiple sleep latency testing (MSLT), a series of daytime nap tests spaced throughout the day according to a standard protocol, is currently the standard electrophysiological assessment tool for objectively evaluating a patient's subjective complaint of sleepiness. The maintenance of wakefulness test (MWT) is used in a similar protocol to evaluate daytime alertness [95]. With further elaboration of the salivary amylase findings, convenient, rapid, cost-effective alternatives to the MSLT and MWT could potentially be developed for objective assessment of sleepiness and alertness in settings where polysomnography is unavailable. Another practical application of these findings may be the assessment of drowsy drivers similar to breathalyzer assessments of alcohol consumption or the assessment of persons such as air traffic controllers, bus drivers, or train conductors whose occupations require a high degree of alertness to ensure public safety.

The utilization of model organisms for development of effective pharmacological treatments and sleep-related biomarkers is still in development. However, as knowledge about sleep mechanisms continues on a rapid, steep trajectory, it is not unreasonable to anticipate that the practical application of this knowledge will also follow.

Sleep Disorders

Narcolepsy

The mechanisms underlying the expression of narcolepsy were virtually completely unknown until the serendipitous discovery by Dr. William Dement of a dog with what appeared to be cataplectic attacks similar to the cataplectic attacks demonstrated by human narcoleptic subjects [96]. Since that time, understanding the etiology of narcolepsy has arguably been primarily the result of discoveries in animal research [97, 98]. The cardinal symptoms of narcolepsy include excessive daytime sleepiness, hypnagogic hallucinations, sleep paralysis, and cataplexy, a sudden loss of muscle tone with strong emotions. Electrophysiologically, narcolepsy is diagnosed by the rapid onset of REM sleep, typically with a latency of less than 15 min as compared to the 60- to approximately 90-min latency to the onset of REM sleep in normal subjects. Narcolepsy, in conjunction with a history of clinical symptoms, is diagnosed by the rapid onset of REM sleep during a protocol of daytime nap testing [95]. Based on epidemiological studies in several countries, the prevalence of narcolepsy has been estimated at between 25 and 50 per 100,000 persons [99]. Of all the sleep disorders, the genetics, neuropharmacology, and molecular mechanisms of narcolepsy appear to be the best understood [100]. The discovery of orexin (hypocretin) deficiency resulting from the loss of orexigenic neurons in narcoleptic dogs, mice, and humans and the close association of the human leukocyte antigen DQB1*0602 and DQA1*0102 in almost all narcoleptics has led to the conclusion that narcolepsy is an autoimmune disease [101]. However, the mechanisms by which orexin is depleted are unknown. Potential environmental triggers for the development of narcolepsy which have been identified include upper airway infections and the H1N1 flu vaccine in genetically susceptible individuals [102, 103].

Gene therapy clinical trials are now being performed for a variety of human diseases including cancer, cardiovascular disease, Parkinson's disease, and cystic fibrosis [104]. Hypothalamic gene replacement therapy in orexin-deficient mice improves sleep quality and the timing of REM sleep, but does not improve cataplexy [105]. Conversely, gene transfer into the zona incerta in orexin-deficient mice improves cataplexy, but not sleep fragmentation [106]. There are no data on gene replacement in narcoleptic humans, but the findings in mice suggest that this approach may be a promising one. As the result of this research in narcolepsy, a new sleeping medication, suvorexant, has been developed as a treatment for insomnia. Suvorexant is a dual orexin 1 and orexin 2 receptor antagonist which dose dependently enhances sleep in humans [107, 108]. Suvorexant was approved for human use by the Food and Drug Administration in August, 2014. Of interest is a detailed account of suvorexant's approval process which appeared in the popular press [109].

A major stumbling block in the use of model organisms to study narcolepsy is the absence of REM sleep. Birds are the only nonmammalian organism to display convincingly behavioral and electrophysiological signs of REM, but avian REM sleep bouts are brief, lasting only a few seconds. Could it be possible that REM sleep is present in *drosophila* or zebrafish and that it has simply been missed? This seems unlikely particularly in light of a recent detailed video analysis of zebrafish eye movements and respiration during sleep which did not uncover any credible evidence for the presence of REM [110]. Additionally, the limited behavioral repertoire of model organisms precludes their usefulness in evaluating, for example, cataplexy or sleep paralysis which are major signs of narcolepsy. The *drosophila* brain does not contain orexin. However, zebrafish have a distribution of orexin expressed in the brain in a fashion similar to that of mammals [111]. Overexpression of orexin in zebrafish results in elevated motor activity, decreases in arousal thresholds, and shortened, disturbed sleep in the dark [111, 112]. During the course of evaluating zebrafish hypocretin receptor mutants, Yokogawa et al. [112] made several interesting observations with respect to sleep. Normal adult zebrafish maintained under constant light conditions have an almost complete suppression of sleep. A homeostatic

rebound response to this sleep deprivation was not observed, and a progressive return to sleep occurred over the course of one to two weeks. Following sleep deprivation in response to electrical stimulation, there was no homeostatic response when animals were released into light, but a homeostatic rebound occurred with release into darkness. Additionally, exposure to light during the last 6 h of the biological night produced a marked suppression of sleep without a homeostatic rebound with release into darkness.

Although the orexigenic substrate of the zebrafish brain parallels that of the mammalian brain, the zebrafish is not a particularly enlightening model organism to elaborate upon mechanisms controlling narcolepsy. None of the model organisms studied to date would appear to serve as a model for narcolepsy. Furthermore, the unusual response of zebrafish sleep to light with sleep suppression and to the absence of a homeostatic response following sleep deprivation suggests that there are components of zebrafish sleep which should not be considered as a model substrate for sleep disorders.

Sleep Apnea

The cardinal symptoms of obstructive sleep apnea (OSA) are well known and unmistakable in their presentation: loud snoring and pauses in respiration terminated by explosive snores, breath holding episodes witnessed by a bed partner, and excessive daytime sleepiness resulting from the arousals terminating often hundreds of respiratory pauses during sleep. Severe OSA is a risk factor for arterial hypertension, heart failure, stroke, pulmonary hypertension, and maternal morbidity [113, 114]. A familial component has been described in several studies [115–117]. There are two reports of a naturally occurring model of sleep apnea in the English bulldog which has a crowded upper airway anatomy similar to sleep apnea patients [118] and in obese miniature pigs [119]. Nonmammalian species have not been observed to have sleep apnea, and model organisms have not been developed for experimental evaluation of this disorder.

The experimental research on sleep apnea has been focused on the induction of sleep apnea in dogs, rats, and mice by artificially occluding the airway and exposure to repetitive hypoxemia [120–123]. The cardiovascular and neurochemical consequences of sleep apnea have been described in these experimental models, but the genetic and cellular components of sleep apnea are not well understood. OSA is a complex disease process with multiple interactive factors including age, weight, gender, arterial and pulmonary hypertension, cardiovascular disease, and metabolic disorders. It is almost certainly the case that there are multiple cellular and genetic components contributing to the expression of OSA. A gene encoding the allele APOEe4 which is essential for cholesterol metabolism and transport has been associated with OSA in adults and children. However, a meta-analysis of studies reporting an association between APOE and sleep apnea concluded that the association is weak [124]. Another meta-analysis of OSA genetic association studies revealed that TNFA rs1800629, which may also be associated with heart disease and heart failure as well as chronic obstructive pulmonary disease, was significantly associated with OSA [125]. These authors concluded that studies examining OSA genetics did not typically provide robust evidence. Thus, the complexity of OSA presents significant challenges in understanding the genetics of this order, and at least at the present time, a model organism with a well-known genome combined with the symptoms of OSA does not appear to be on the horizon.

Restless Legs Syndrome (RLS)

Clinical symptoms of RLS include restless, creeping, crawling, uncomfortable sensations in the legs during sedentary activities with a worsening of these sensations beginning in the evening. They are accompanied by an irresistible urge to move the legs for temporary relief. Typically, there is a worsening of the sensations at sleep onset which results in substantial difficulty falling asleep. Key factors in the expression of RLS are iron deficiency and the involvement of the dopaminergic system in regulating iron metabolism, although the mechanism of this relationship is not clearly understood. Currently, dopamine agonists, such as ropinirole and pramipexole, which enhance brain dopamine, are the treatments of choice for RLS [126]. Prevalence, depending upon the complexity of survey questions, ranges between 9.4 and 15 % querying RLS as a single symptom. This range changes somewhat to 3.9–14.3 % utilizing the criteria of the International Restless Legs Syndrome Study Group [127, 128]. Inclusion of stricter diagnostic criteria such as the frequency and severity of symptoms results in decreased estimates of prevalence.

Genome-wide association studies (GWAS) have opened a new window onto the genetic underpinnings of human RLS. GWAS studies in both European and US populations have identified genomic loci which are associated with restless legs syndrome including *MEIS1, BTBD9*, and *MAP2K5/LBXCOR1* on chromosomes 2p, 6p, and 15q [129–131]. Animal models have been proposed for the study of restless legs syndrome. Mice and rats with lesions of the A-11 dopaminergic nucleus which projects to the spinal cord have demonstrated an increase in locomotor activity [132, 133]. Spontaneously hypertensive rats exhibit increased motor activity, suggesting a possible model for the study of RLS [134]. One study in *C. elegans* demonstrated that the MEIS1 worm orthologue increased ferritin expression and human

cells cultured in iron-deficient conditions revealed decreased MEIS1 expression, lending further support to the role of these genes in iron metabolism [135].

Animal studies are typically the catalyst for human research. However, the discovery of these potential RLS loci via human GWAS provided a reverse "human to animal" stimulus for the development of a *drosophila* RLS model [136]. As described above, the diagnosis of RLS in humans is accompanied by reports of an irresistible urge to move the legs for relief of discomfort. Of course, these sensations cannot be communicated by *drosophila*, but movement can be operationally used to infer the presence of RLS. Genetic alteration of the fly homologue *dBTBD9* which corresponds to human *BTBD9* resulted in fragmented sleep characterized by a decrease in the duration of sleep bouts and an increase in the number of sleep bouts and waking after sleep onset, suggesting the sleep fragmentation of RLS patients. However, sleep duration in flies per 24-h period was not different between mutants and controls. Although flight and negative geotaxis were normal in mutants, when confined to a restricted space flies were hyperlocomotive, reminiscent of the movements experienced by RLS patients during the forced immobility test (FIT) [137]. Uninterrupted bouts of walking were also longer in mutants. Comparing dopamine levels in mutants and controls, mutants revealed a 50 % reduction in dopamine, suggesting a relationship between alterations between *BTBD9* and maintenance of normal dopamine levels. Also of note is that treatment with pramipexole, a dopamine agonist, restored sleep consolidation in mutants to control levels, again suggesting a significant role for dopamine in the expression of RLS. dBTBD9 is also implicated in the regulation of iron metabolism and ferritin homeostasis.

These genetic explorations into the expression of RLS in a model system provide evidence of the complex relationship between specific genes and the role of dopamine in regulating ferritin levels. Ideally, with further studies more effective treatments for RLS will be discovered.

Unusual Sleep Disorders

There is a group of unusual sleep disorders, the parasomnias, in which the distinction between waking and sleep becomes blurred and waking behavior appears to intrude into sleep. Included in this group of disorders are confusional arousals, REM behavior disorder (RBD), sleep walking, and sleep-related eating disorders [138]. Complex vigorous motor activity which can become violent in the case of RBD and loud vocalizations may accompany these disorders. Not a great deal is known about the prevalence of parasomnias, but sleep walking, for example, is relatively common with a lifetime prevalence estimated at 29.2 % [139]. RBD is rarer with a prevalence of 2.01 % and subclinical RBD estimated at 4.95 % in a Korean elderly population [140]. Due to the complexity of behavior in parasomnias, no animal models have been developed to study these disorders, and not surprisingly no naturally occurring animal models of parasomnias have been identified. However, early studies in cats revealed "dream enacting" behavior following pontine tegmental brainstem lesions, reminiscent of the vocalizations and motor movements in RBD [141, 142].

Can sleep and wakefulness be present in the same brain at the same time? This possibility seems counterintuitive to our normal experience since we typically dichotomize states of alertness as being either waking or sleep and the transition between them as drowsiness, often euphemistically described as being half awake or half asleep. The parasomnias suggest that the comingling of sleep and waking in the same neural substrate is possible, and insights from animal studies are of benefit in shedding light on this issue.

There are a number of examples in the animal literature in which "nonquiescent" or literally "motorically active" sleep is present, suggesting that sleep can be compatible with behavior typically present during waking. For example, nocturnal "sleep swimming" fish inhabiting coral reefs in the Red Sea vigorously move the dorsal, pectoral, and caudal fins in fixed body positions at a frequency of strokes approximately twice the rate with daytime swimming outside the coral reef [143]. This behavior may function to aerate the reef and assure healthy corals. Captive dolphin and killer whale neonates and their mothers remain continuously active and do not exhibit signs of behavioral sleep for several months postpartum with gradually increasing periods of behavioral quiescence which eventually return to normal amounts, but do not exceed normal amounts, of behavioral sleep [144, 145]. Dolphins are able to maintain continuous vigilance with accurate echolocation for a testing period of up to 15 days [146]. In the laboratory birds demonstrate marked decreases in EEG defined sleep during the migration season, and data from freely moving swifts equipped with data loggers during a 200-day nonstop flight suggest that sleep occurs during periods of decreased activity during flight [147–149].

There is the possibility that these animals are unique and simply do not sleep. However, this would be contrary to findings from virtually all other living organisms. Alternatively, a variant of sleep may be present which coexists with waking and which allows for sustained vigilance in the presence of physiological sleep. In fact, there is a unique form of sleep, unihemispheric sleep, a state in which one hemisphere of the brain exhibits waking EEG activity simultaneously with sleeping EEG activity in the other hemisphere. Unihemispheric sleep has been recorded in dolphins [150], whales [151], fur seals [152], and birds [9]. Only NREM sleep has been observed in whales and dolphins, whereas in birds and seals REM sleep is present. Of interest is a recent demonstration of decreased orexin bouton density in the cerebral cortex of a porpoise and a whale compared to ten mammalian species [153]. The presence of

unihemispheric sleep offers the significant advantages of an ability for part of the brain to sleep during long-distance migration while maintaining sentinel functions in monitoring the environment [148, 154].

Unihemispheric sleep is clearly an unusual form of physiological sleep. However, there are recent human electrophysiological studies utilizing scalp, intracerebral EEG, and unit recordings which suggest the possibility that there are also coexisting regional differences in human sleep and waking. For example, detailed sleep electrophysiological studies have demonstrated that 85 and 75.8 % of sleep spindles and slow waves, respectively, have been detected in less than half of brain recording sites [155]. This regionality of sleep waveforms, along with the demonstration of unihemispheric sleep in animals, suggests that parasomnias such as sleep walking or RBD may be a manifestation of simultaneously occurring waking and sleep processes. There is also further evidence from intracerebral recordings that motor cortex activation lasting from 5 to more than 60 s can occur simultaneously with an increase in slow wave activity in the dorsolateral prefrontal cortex [156]. Also relevant in this regard is the finding that human sleep spindles recorded in the hippocampus precede the sleep spindles and K complexes characteristic of Stage 2 sleep recorded from neocortical scalp electrodes [157]. Similarly in cats, increases in ventral hippocampus spikes precede the onset of NREM sleep, also suggesting that sleep processes may begin in different brain regions at different times in both animals and humans, strengthening the similarities between these electrophysiological processes [25]. Studies in both the echidna, a primitive egg laying mammal considered the basal stock of living mammals, and the ostrich, a basal bird, demonstrate that elements of both NREM and REM sleep may be simultaneously present during behavioral sleep [158, 159]. Further illustrating the simultaneous presence of different physiological states in humans are data from a single subject with stereotaxically implanted electrodes who experienced confusional nocturnal arousals [160]. During these episodes, there was localized activation of the motor, cingulate, insular, temporopolar, and amygdalar cortices in the presence of slow waves recorded from the frontal and parietal dorsolateral cortices and in the presence of spindles recorded from the hippocampal cortex.

Parasomnias are very poorly understood, and the triggers which initiate waking-like behaviors during sleep are completely unknown. There are no readily available animal preparations in which to study these unusual behaviors. Unihemispheric sleep in marine-dwelling mammals and birds hints that there is a capacity for simultaneous expression of both waking and sleeping electrophysiology in the same brain. However, the mechanisms controlling the expression of unihemispheric sleep may be controlled by different, more orderly processes than the processes which result in the often explosive behavior and vocalizations which accompany many of the human parasomnias. Nonetheless, the parasomnias suggest that sleep and waking may be the manifestation of simultaneous waking and sleep.

Conclusions

Although the behavioral and electrophysiological parameters of sleep have been described in great detail in many living organisms, the cellular origins of sleep are still elusive. Studying living organisms is unlikely to provide a definitive answer to the question of how sleep originated, and the behavioral or cellular origins of sleep cannot be preserved in the fossil record. There is one speculative observation that a dinosaur fossil from the Cretaceous era (between 145 and 65.5 million years ago) has been preserved in an avian-like sleeping posture [161]. Sleep is undoubtedly an ancient behavior which has been conserved through evolution, but the crucial life sustaining functions it serves to maintain its presence in many different species is unclear.

Knowledge about sleep mechanisms has rapidly evolved by utilizing model organisms as the genetic and molecular substrates for the study of mechanisms controlling sleep. Even though there are tremendous benefits to the utilization of these organisms, there are also a number of issues which are raised.

Considerations in the Use of Model Organisms

A major question is whether model organisms can truly serve as models for the exploration of human sleep mechanisms and sleep disorders. As we have seen, there is a remarkable correspondence among the genetic, neurochemical, and cellular operations of model organisms and humans. However, it is obvious that the complexity of human behavior and the unexplored cellular effects of human emotions and psychology upon sleep cannot be unraveled by model organisms. The clinical understanding of human sleep disorders relies not only upon the patient's descriptions and environment, but also on observations of witnesses to the patient's symptoms. For example, can it be assumed that frequent movements of the fruit fly's legs are a model for the uncomfortable sensations described by patients in restless legs syndrome? Thus, even though a model may produce a wealth of information about the "technical" aspects of sleep, this does not ensure that this model is necessarily the model for human discovery. Is human NREM sleep the homologue of behavioral sleep in model organisms? There have been no convincing data which have demonstrated the presence of REM sleep in model organisms, and electrophysiological correlates of human NREM sleep have not been described. This absence of some electrophysiological sleep correlate of behavior is a

significant drawback for an organism modeling human sleep. Also, there have been a large number of studies, particularly in *drosophila*, to suggest that short sleep has adverse effects upon life span. What is the translation factor between old age in "drosophila days" and "human years?" What is the translation factor between short or long drosophila "sleep minutes" and short or long human "sleep hours?" These questions are probably unanswerable. Finally, there are some aspects of sleep in model organisms which are different from human sleep characteristics such as the absence of a homeostatic rebound in sleep following deprivation of quiescence in some mutant flies or the suppression of sleep upon exposure to light and the lack of a subsequent homeostatic response in zebrafish.

These questions should not, of course, discourage the use of model organisms in discovering clues to the cellular and genetic mechanisms of human sleep. There has been a massive increase in understanding the cellular basis of sleep, almost completely unknown just a few years ago, as the result of complex cellular manipulations performed in these organisms. It seems unlikely that model organisms will provide us with a "true" model of sleep disorders such as sleep apnea or narcolepsy, and their major utility may lie in being model organisms for understanding the cellular and genetic basis of sleep.

Besides enlightening our understanding of the cellular mechanisms controlling sleep, another area of interest with respect to the use of model organisms is the demonstration of positive and negative effects of social isolation or enrichment upon sleep. These findings suggest that greater attention should be devoted to exploring the impact of environmental factors in assessing human sleep problems. Furthermore, it would be of interest in these studies to determine in model organisms the effects of, for example, predation or threat on sleep in a controlled environment.

Treatments for Human Sleep Disorders Resulting from the Use of Model Organisms

Ideally, understanding the genetic and cellular mechanisms controlling human sleep would be fruitful in yielding more effective treatments for human sleep problems. There has been one recent addition to the armamentarium of sleeping medications, suvorexant, which was developed directly as the result of research in narcolepsy and the identification of orexigenic neurons in the expression of waking and sleep. The identification of salivary amylase as a marker for sleepiness which arose from cross-translational studies in drosophila and humans may also potentially find a practical use in the more widespread identification of sleepiness. With continued research into the details of sleep mechanisms revealed by the use of model organisms, it is anticipated that these findings will translate into practical applications.

Phylogenetic Studies and Human Sleep

The remarkable diversity in sleep behavior and electrophysiology in nonmammalian organisms has provided an array of clues which sheds light upon the understanding of normal and disturbed human sleep. One of the most interesting examples of diversity in animal sleep is the unihemispheric sleep of cetaceans which challenges the notion that sleep is a global state affecting all areas of the brain in the same manner and at the same time. Organisms which display unusual sleep-related behavior such as sleep swimming fish, cetaceans, and their offspring which do not exhibit behavioral sleep for several continuous months after birth, and the demonstration of prolonged, continuous flight in birds offer hints that there may be clues in nature for at least some human sleep complaints of short sleep. New monitoring techniques such as high-resolution video monitoring, in vivo calcium imaging, and multielectrode recording probes hold promise for more refined analyses of behavior and electrophysiology in nonmammalian species [110, 162, 163]. Additionally, behavioral and electrophysiological studies of animals in their own habitats utilizing new technologies will expand our understanding of the diversity of sleep.

Sleep studies in animals have unquestionably enhanced our appreciation of the behavioral, molecular, and environmental factors which govern the expression of sleep, and, in turn, these studies have provided insight into the factors influencing human sleep and its disorders. The biological symphony of sleep continues to be performed throughout nature, and ongoing scientific exploration on a variety of fronts will only continue to enlighten our understanding of this intricate, universal composition.

Sleep and Anesthesia: Different States with Shared Pathophysiological Traits

10

David Hillman, Roop Kaw, and Ralph Lydic

Introduction

Although sleep and anesthesia are different states of consciousness, data from many laboratories now indicate that examining physiological traits in one state and elucidating the mechanisms that generate them can provide clinically useful insights into traits and underlying mechanisms in the other [1–6]. Breathing disorders are cases in point. Patients prone to upper airway obstruction or hypoventilation during sleep also have these tendencies during anesthesia, and the reverse is also true [7]. In this chapter, we consider similarities and differences between sleep and anesthesia, their neurophysiological bases and the implications for enhancing clinical care.

Sleep is a behavioral state of unconsciousness which is actively generated by the brain. It is an inhomogeneous state occurring in a variety of postures and comprising distinct stages, both of which influence breathing and other physiological functions. The states can be broadly divided into rapid eye movement (REM) sleep (named for the presence of rapid eye movements) and non-rapid eye movement (NREM) sleep. While, relative to wakefulness, muscle activation is diminished during NREM sleep, the changes are profound in REM sleep. A key feature of REM sleep is that spinal alpha motoneurons are hyperpolarized resulting in atonia of antigravity muscles and hypotonia of upper airway and respiratory pump muscles. These changes are fundamental to the vulnerability to upper airway obstruction and hypoventilation that occurs during sleep, particularly REM sleep, in predisposed individuals.

Reconciliation of fossil evidence with molecular clock analyses indicates that mammals first appeared about 60 million years ago [8]. It is notable that all placental, terrestrial mammals exhibit two distinct states of sleep, an evolutionary perspective suggesting that mammalian brains evolved neural networks for generating states of sleep from their earliest origins. In contrast, the history of anesthesia is brief, with the first successful human anesthesia occurring approximately 170 years ago. Anesthetic molecules, therefore, have existed for about three ten thousanths of one percent of mammalian history. The absence of any evolutionary pressure to evolve an anesthesia center in the brain favors the shared circuits hypothesis that anesthetic molecules cause loss of wakefulness by acting on sleep-generating neuronal systems [6, 9, 10].

This is a relatively recent notion as it was believed for much of the twentieth century that anesthetic drugs exerted their action through effects on neuronal cell membranes. This more recent ligand-based theory postulates anesthetic activation of pathways involved in the production of sleep and wakefulness [2, 11–13]. Particular attention has been given to GABA-a-mediated pathways [6]. A parallel advance has come from evidence provided from many sources, suggesting that no single brain region generates states of sleep and wakefulness [3, 14, 15]. Studies of the role of signal transduction pathways in causing states of sleep and anesthesia show that proteins referred to as regulators of G protein signaling (RGS proteins) modulate sleep disruption caused by isoflurane and sevoflurane anesthesia [16].

Human brain imaging data (Fig. 10.1) illustrate the regions and neuronal networks that are altered during states of sleep and wakefulness, as well as during states of anesthesia [17]. While postulation of a sleep center has simplifying appeal, the changes illustrated by Fig. 10.1 and an extensive literature fail to support the primacy of any particular brain center-generating states of anesthesia or sleep [3]. Thus, the notion of sleep centers has been supplanted by a view that future advances will come from a deeper

understanding of network dynamics. This consideration is not limited to sleep neurobiology. For example, efforts to understand respiratory rhythm generation also incorporate network analyses [18].

The construction of mathematical and conceptual models that attempt to describe the generation of sleep or respiratory rhythms also must confront the difficulty in phase switching from sleep to wakefulness or from inspiration to expiration. One promising advance that may help understand phase switching is the discovery of an evolutionarily conserved feature of the central nervous system that functions to resist changes in states of behavioral arousal [4]. Data from fruit fly demonstrate a genetic basis underlying the neural inertia that resists phase switching from one bistable state (wakefulness) to another (anesthesia) [5].

Among vertebrate mammals facets of the shared neurophysiology underlying the generation of sleep and anesthesia may help explain the similar effects that sleep and anesthesia have on other physiological traits, including muscle activation and ventilatory control. The elimination of wakeful cortical influences reduced reflex gain and decreased ventilatory drive seen in both states predisposes to upper airway obstruction and/or hypoventilation, with individuals vulnerable to these problems in one state being at high risk of them in the other. The shared neurophysiology may also help explain other similarities between the states including the suggestion that anesthesia (unmodified by surgery and pain) may have some sleep-like restorative powers, as has been demonstrated in rodents (although not in Drosophila) [19, 20]. Furthermore, better understanding of this shared neurophysiology informs efforts to devise sedative drugs that induce a more sleep-like restorative state, particularly for use in sleep-challenging environments such as ICU. Sleep loss in such circumstances appears to be a significant factor in the production of postoperative delirium, and dexmedetomidine is an example of a drug with sleep-like sedative actions that exhibits promise in managing this difficult syndrome [21].

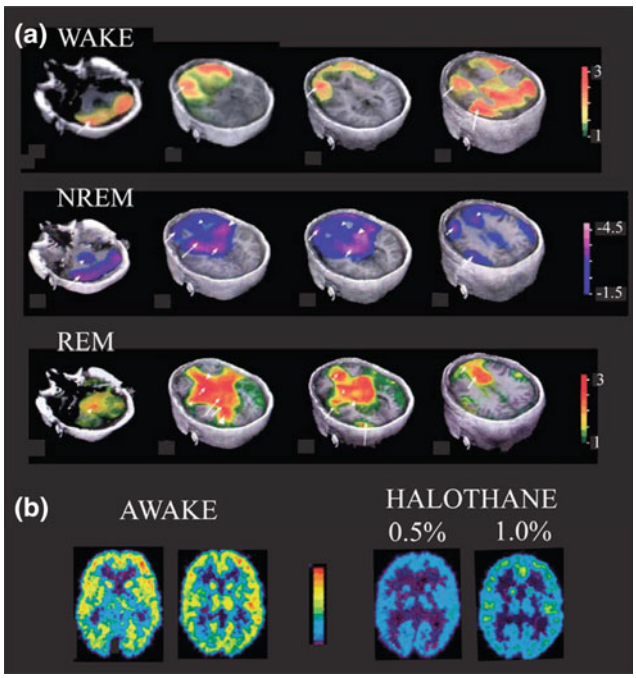

Fig. 10.1 Human brain imaging with positron emission tomography (*PET*) reveals anatomically distributed changes in brain function across states of arousal**. a** PET imaging of cerebral blood flow (*CBF*) in 37 humans during states of wakefulness, NREM sleep and REM sleep. *Yellow* and *red colors* indicate increases in CBF, whereas *blue* and *purple* indicate decreases in CBF. Modified from Braun [65]. **b** PET measures using F-18 fluorodeoxyglucose illustrate widespread changes in brain metabolism caused by halothane anesthesia. Modified from Alkire [66]. These pioneering studies have been supported over the years by additional brain imaging data that demonstrate anatomically distributed changes in brain function across states of arousal rather than selective change in specific brain regions posited as centers for particular states of arousal

While sleep and anesthesia have these shared characteristics, based on activation of shared pathways, their most fundamental differences relate to mode of offset of these effects. Sleep is readily disrupted by environmental stimuli, physiological disturbance or psychological disequilibrium and reverses spontaneously when the need for it has been requited. The capacity to arouse protects the sleeping patient. In contrast, suppression of arousal is a basic aim of general anesthesia. This makes the anesthetized patient highly vulnerable and critically dependent on observation and, where indicated, intervention by others until rousability is reliably restored. As a drug-induced state of unconsciousness anesthesia requires drug elimination for its reversal. The drug-induced stability of the state precludes spontaneous arousal or awakening, or disturbance by psychological factors or environmental stimuli. Unlike sleep, with its variable stages and postures, anesthesia is a relatively homogenous state, although depth varies with anesthetic dose.

Furthermore, while the propensity for sleep increases with increased time awake and is subject to diurnal variation, increasing late at night, anesthesia is largely independent of these homeostatic and circadian influences. Not completely, though, there is some animal evidence for recovery from sleep deprivation during anesthesia and for lower anesthetic drug requirement during circadian periods of high sleep propensity than at less sleep conducive times of the day [19, 22] (Fig. 10.2).

Clinical Correlates: Anesthesia, Sleep and Breathing

(a) Upper Airway Collapsibility

Upper airway obstruction—partial and complete—during anesthesia and sleep is a consequence of the combination of

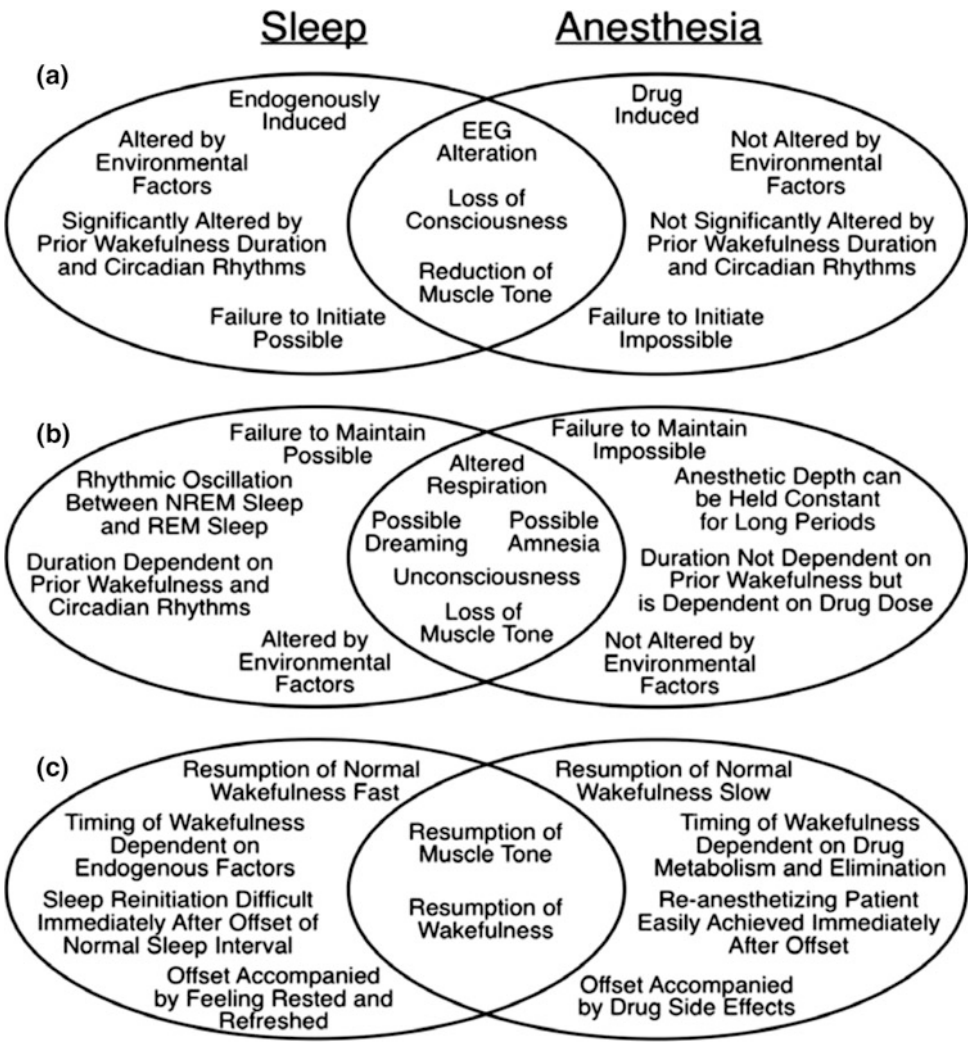

Fig. 10.2 Sleep and anesthesia: similarities and differences. Reproduced from Watson et al. [67], with permission

a narrow, anatomically predisposed airway and the permissive effect of state-related upper airway muscle relaxation, the degree of which varies with anesthetic depth or sleep stage (being most profound in REM sleep). Predisposing features acting to narrow the airway include: skeletal factors that constrict the skeletal confines, such as retrognathia; increased soft tissue around the pharynx, as in obesity and macroglossia; pharyngeal muscle weakness, as seen in many neuromuscular disorders; and as tonsillar and adenoidal hypertrophy. Familial issues also play a part: Some have inherently narrow pharynges. Further, it appears that upper airway neuromotor responses are impaired in OSA patients relative to controls; variability in collapsibility of the upper airway between individuals cannot be explained by structural loads alone [23, 24]. Certain postures also predispose to upper airway obstruction including recumbency, supine position and neck flexion. Alcohol, sedatives and opioids also exacerbate narrowing of the pharyngeal airway through their effects on pharyngeal muscle tone.

There are two main sites for obstruction in the pharynx: the velopharynx (that portion behind the soft palate) and the retrolingual hypopharynx. Indeed, the velopharynx—usually the narrowest segment of the pharynx—appears to be the primary site of obstruction in 80 % of events in both sleep and anesthesia. Increased collapsibility of the upper airway occurs quite abruptly with the encephalographic alpha–theta transition at sleep onset and with loss of consciousness/rousability during anesthetic induction [25, 26]. This emphasizes the importance of conscious state as a determinant of muscle activation.

Predicting those with narrow "difficult" upper airways is a time honored pursuit in anesthesia, mainly in relation to predicting difficult tracheal intubation. "Can't intubate, can't ventilate," where the patient cannot be tracheally intubated or ventilated by bag and mask after induction of anesthesia is a dreaded scenario and identifying patients at risk allows such problems to be circumvented (e.g., by awake intubation) or avoided (e.g., by use of regional anesthetic techniques rather than general anesthesia). Clinical predictors of

difficult intubation include oropharyngeal crowding (the Mallampati score) and a short thyromental distance (signifying micro- or retrognathia) [27]. These have also been found to be of value in predicting those with obstructive sleep apnea (OSA). Indeed, there is a close relationship between difficult intubation and the presence of OSA [28]. Furthermore, the tendencies to upper airway obstruction during anesthesia and during sleep are related [7]. Pharyngeal collapsibility under anesthesia is substantially higher among OSA patients than those without OSA [29]. An airway that proves "difficult" in one state tends to also be difficult during the other.

It follows that where such problems are noted in sleep or anesthesia, then implications for behavior in the other must be considered. For example, difficulty with intubation should prompt the anesthesiologist to consider whether the patient has OSA, as should increased propensity to upper airway obstruction during anesthesia or recovery. Similarly a history of OSA should alert the anesthesiologist of increased difficulty with airway management during anesthesia and increased risk of obstruction in the postoperative period. This risk is compounded by compromise of protective arousal responses by anesthetic, analgesic and sedative drugs during this time.

(b) OSA and Anesthesia

These issues emphasize the importance of identifying at-risk patients preoperatively. There is a growing literature documenting increased risk of perioperative cardiorespiratory complications in patients with OSA [30–32]. Particular risk appears to attend major surgery where there is a need for postoperative opioids and sedatives, presumably because of the depressant effects these can have on protective arousal responses. There is significant variability between individuals in their sensitivity to these depressant effects. Recently, it has been shown that in volunteers at high risk of OSA, nocturnal hypoxemia is associated with greater sensitivity to opioids, suggesting that increased potency of opioid analgesia could be a marker of its propensity to depress respiration during sleep [33].

Identifying OSA and predicting patients those most at risk of perioperative complications ("risk stratification") is a challenge for anesthesiologists. Important factors determining risk are likely to include degree of collapsibility of the relaxed upper airway, susceptibility to the depressant effects of analgesic and sedative drugs, and sensitivity of arousal responses in the case of an obstructive event. There is a general relationship between degree of airway collapsibility and apnea–hypopnea index (AHI), making this (as in sleep medicine) an important metric of severity [34]. However, the safety issues center on capacity to arouse from an obstructive event. The propensity to arousal failure might be better reflected by other metrics such as length of apneas and hypopneas and the degree of associated hypoxemia. Those individuals with lengthy apneas accompanied by deep desaturations on preoperative sleep study are of concern, as these characteristics suggest little tolerance for further depression of arousal [35]. It is notable that (in contrast to multiday surgery) outpatient surgery does not appear to be associated with demonstrable increased risk of postoperative adverse events in OSA patients [36]. This may reflect the fact that such patients, having emerged from anesthesia, are not exposed to the risk of re-suppression of arousal responses through postoperative administration of opioids and sedatives [37].

Obesity is an important OSA consideration in several ways. Besides being a risk factor for OSA, it predisposes to hypoventilation and to disordered gas exchange during sleep and anesthesia. Obesity-related reduction in functional residual capacity (FRC) when recumbent and asleep or anesthetized promotes atelectasis in the dependent regions of the lungs with consequent shunt. The reduction in FRC reduces oxygen stores in the lungs. Both these effects magnify the degree of desaturation observed during an obstructive event of a given duration [38].

Upper airway surgery presents additional risk for patients with OSA, as postoperative edema can temporarily further narrow the airway. Somewhat paradoxically, such problems can be seen in the early postoperative course following palatal surgery to treat snoring and OSA [39]. Children undergoing upper airway surgery for OSA present particular risks based on their small airway dimensions and low lung volumes relative to body size [40].

Because of its potential for perioperative problems and because its presence helps alert the anesthesiologist to the possibility of difficulties with airway maintenance intraoperatively, identifying OSA preoperatively is an important task. A popular tool is the acronymic Stop-BANG questionnaire, which asks 8 questions relating to OSA risk: the presence of loud **S**noring, daytime **T**iredness and lethargy, **O**bserved apneas, history of elevated blood **P**ressure, a **B**ody mass index of greater than 35 kg/m^2, **A**ge greater than 50 years, a **N**eck circumference more than 40 cm and male **G**ender [41, 42]. A positive response to 5 or more of these questions indicates high risk of OSA, while a score of 3–4 indicates intermediate risk. A problem with the questionnaire is that while highly sensitive for the presence of OSA, it is relatively non-specific. This together with a high community prevalence of OSA means that it designates many patients as at risk, with a high rate of false positives. This leaves anesthesiologists with a dilemma: which patients justify extra resources perioperatively? How do they risk stratify? The answers are not yet clear, but factors such as severity of

OSA, inherent arousal thresholds, postoperative opioid and sedative requirements, sensitivity to the depressant effects of these, and presence of comorbidities including obesity and vascular disease are all likely to be influential.

Current guidelines for the perioperative management of OSA are understandably cautious [43]. Some general principles apply (Table 10.1). Circumventing the difficulties associated with general anesthesia and postoperative sedative and analgesic by use of regional anesthetic/analgesic techniques is an attractive option if appropriate for the surgical procedure [44]. Where general anesthesia is required, then use of anesthetic drugs that readily reverse at the end of the procedure and, where possible, use of non-opioid analgesics following it are likely to help. Close observation is required until the patient is sentient and not likely to be exposed to further treatments which have potential to compromise arousal. Availability and use of positive airway pressure (PAP) therapies postoperatively are further tenet. These treatments are much more easily implemented if the patient already has some familiarity with them. This provides a strong rationale for preoperative diagnosis and initiation of treatment where practicable.

(c) Sleep Hypoventilation and Type 2 Respiratory Failure

Besides OSA, another major category of sleep-disordered breathing is (non-obstructive) sleep hypoventilation. The sleep-associated decrease in ventilatory drive, a consequence of the combination of loss of the stimulatory effects of wakefulness and a specific state-related down-regulation of hypercapnic and hypoxic ventilatory responses, ensures that any disorder with the potential for hypoventilation is exacerbated by sleep, particularly REM sleep where ventilatory drive is at its nadir. Such disorders have in common an imbalance between the load on respiratory muscles and their capacity to cope with these loads. Common examples of conditions that increase the load on muscles include obesity and advanced lung diseases such as chronic obstructive pulmonary disease. Conditions that decrease their capacity to cope include a wide variety of neuromuscular disorders affecting the respiratory (and upper airway) muscles, high spinal injuries, diaphragmatic palsy and the inefficiencies associated with the low flat diaphragm of emphysema and use of respiratory depressant drugs. Emphysema is an example of a condition that both loads the muscles (by increasing airway resistance) and decreases their capacity to cope (through the hyperinflation-associated decrease in inspiratory muscle mechanical advantage). Often hypoventilation coexists with upper airway obstruction, as is the case in obesity hypoventilation syndrome and in neuromuscular disorders that involve both upper airway and respiratory pump muscles. Obesity hypoventilation is common in obese patients with OSA: a recent meta-analysis of more than 4000 such patients demonstrated that 19 % of them had daytime hypercapnia, fulfilling the criteria for obesity hypoventilation syndrome [45].

Where there is a gross imbalance between load on respiratory muscles and their capacity to cope, a state of type 2 (hypercapnic) ventilatory failure exists and continuous mechanical ventilatory support is required. In conditions associated with a slow evolution in this imbalance (such as progressive neuromuscular problems or obesity), sleep hypoventilation may precede daytime respiratory failure by months or years [46]. Indeed sleep hypoventilation is both a harbinger of wakeful type 2 respiratory failure and a contributor to its evolution. The hypercapnia and hypoxemia that occur with significant sleep hypoventilation cause a loss of sensitivity to these ventilatory stimulants, through buffering of hypercapnia-associated decreases in extracellular pH levels

Table 10.1 Principles for perioperative management of patients with OSA

Principles for perioperative management of patients with OSA
• Assess risk of OSA preoperatively by systematic enquiry
• When probability of previously undiagnosed OSA is high, refer patients for preoperative sleep evaluation if surgery is elective and there is a likely need for postoperative opioids or sedation
• Where OSA has been previously diagnosed and the patient is compliant with CPAP, ensure it is available for perioperative use
• Where previously diagnosed but not compliant with CPAP, reinstruct in its use
• Avoid sedative premedication
• Use regional anesthesia and analgesia where practicable
• When general anesthesia is used, be prepared for difficult intubation and other difficulties in airway maintenance. Use techniques that allow early return of consciousness
• Minimize postoperative sedation
• Ensure CPAP is available for early postoperative use
• Observe in a high-dependency unit with continuous monitoring of respiratory parameters (oximetry, oro-nasal airflow) until the patient is sentient and able to self-administer CPAP. Patients requiring ongoing opioids or sedation should remain in a high-dependency area until this need abates
• Use lateral positioning, a nasopharyngeal airway, and oxygen therapy where CPAP is refused and upper airway obstruction is problematic
• Consider OSA in patients who encounter difficulties with airway management perioperatively. Inform the patient and refer for investigation for the possibility where clinically indicated

and roll-off of hypoxic responsiveness. Intervention along this evolutionary pathway with bi-level ventilatory assistance, delivered noninvasively during sleep, can prevent or reverse daytime respiratory failure where the imbalance between load and capacity on muscles is of moderate degree [46].

Not surprisingly, given their similar effects on ventilatory drive, the same problems predispose to hypoventilation during anesthesia where spontaneous ventilation is preserved. Despite this, sleep hypoventilation has not yet been seriously examined as a risk factor for postoperative respiratory complications, including respiratory failure. However, a recent retrospective study has shown that most patients with obesity hypoventilation syndrome are unrecognized at the time of elective surgery and that they are at substantially greater risk of respiratory failure after elective surgery than patients with OSA alone (44.4 vs. 2.6 %) [30]. Where postoperative respiratory failure occurs, the possibility of sleep-related hypoventilation should be considered, particularly where predispositions exist and where there is not an acute event (such a pneumonia or pulmonary edema) to explain it. Such patients often require bi-level ventilatory assistance rather than CPAP. An empiric inspiratory PAP of 16–18 cm H_2O and expiratory PAP of 9–10 cm H_2O can be used to initiate therapy to overcome upper airway obstruction and improve ventilation with subsequent titration conducted according to therapeutic response [42].

(d) Periodic Breathing

Besides OSA and sleep hypoventilation, a further form of sleep-disordered breathing is periodic breathing. While this can also be present during wakefulness, it is always worse during, and often confined to, sleep because wakefulness provides its own stimulatory, dampening effect on periodicity [47]. It can take the form of Cheyne–Stokes respiration where there is regular waxing and waning of ventilation, as seen in heart failure and cerebrovascular disease, or ataxic (Biot's) breathing where the waxing/waning pattern is irregular, as seen with chronic opioid use. The combination of periodic breathing and OSA is a form of "complex" sleep apnea. It is notable that untreated OSA aggravates heart failure and so the problems of OSA and periodic breathing may not only coexist, but also be inter-dependent.

At a fundamental level, irregular breathing occurs because of: increased ventilatory responsiveness to hypercapnia or hypoxia (as may occur, for example, following a cerebrovascular accident); loss of dampening effects on changes in blood gas tensions with small changes in ventilation (as may occur in the presence of low lung volume associated with reduced O_2 and CO_2 stores or at altitude); or prolonged delays in feedback between the effects of changes in ventilation and the chemoreceptor responsible for modulating them (as may occur with the increased circulation times of cardiac failure).

This instability in ventilatory drive affects the upper airway muscles as well as the respiratory pump muscles. Hence, periodic breathing and upper airway obstruction frequently coexist. These problems are of relevance to anesthesiology, both as this instability represents a potential for postoperative ventilatory instability and because it alerts to the possibility of an underlying disorder requiring independent evaluation. For example, breathing periodicity during sleep is frequently seen in low cardiac output states with approximately 50 % of those with an ejection fraction of <45 % having this problem [48].

Irregular breathing patterns are also frequently seen with chronic opioid use [49]. While the mechanism for this remains to be fully elucidated, one possibility is that while hypercapnic ventilatory responsiveness is depressed (as it is with acute opioid use), the depression of hypoxic ventilatory responses seen acutely gives way to a long-term increase in hypoxic responsiveness. This has a destabilizing effect on ventilation. The influence of these changes on ventilation during and after anesthesia, particularly if additional opioids are required, remains to be defined, but the underlying instability in breathing pattern generation suggests a potential for postoperative ventilatory problems [50]. Ongoing efforts to understand the mechanisms by which opioids depress breathing aim to localize brain sites and cellular substrates of opiate action. Respiratory depression caused by opiates can be caused, in part, by G protein-gated inwardly rectifying potassium channels (GIRK channels) [51].

Periodic breathing can be addressed using a PAP therapy known as adaptive servo ventilation. This applies increased pressure support during the waning hypoventilatory phase of the periodic breathing, decreasing it during the waxing hyperventilatory phase. Combined with positive end expiratory pressure, this therapy can pneumatically splint the upper airway, provide pressure support and act to dampen the periodicity.

(e) Disordered Gas Exchange

In addition to the problems discussed to this point, which have substantial obstructive and/or hypoventilatory components, gas exchange is also compromised during sleep and anesthesia as a result of recumbency and a state-related decrease in inspiratory muscle activation. These changes lead to a decrease in FRC at sleep onset and with induction of anesthesia [52, 53]. The magnitude of the reduction is variable between individuals, but generally of the order of 20 %. It can be much greater with obesity. In the morbidly obese, FRC can be well below closing volume, the lung volume at and below which airway closure occurs in the

dependent parts of the lung. In the most severe cases, FRC is close to residual volume [54]. Where FRC is less than closing volume, then airway closure (in the dependent parts of the lung) is present for at least part of the breathing cycle. The effect is to cause atelectasis and shunt with hypoxemia a prominent feature. In many cases of morbid obesity, this derangement is present in addition to hypercapnia consequent upon alveolar hypoventilation.

(f) Postoperative Delirium and Cognitive Decline

Sleep and sedative hypnosis have overlapping neuroimaging and EEG signatures. In activating the VLPO and inducing sleep through its alpha-adrenergic inhibition of the locus coeruleus, dexmedetomidine produces an EEG pattern akin to slow wave sleep wave NREM sleep. In contrast, sedatives such as benzodiazepines and low-dose propofol activate GABA receptors with little effect on noradrenergic activity [55]. An accompaniment of this appears to be that these agents create the potential for some persisting connectedness with the environment at low levels of consciousness, predisposing to an acute confusional state akin to delirium. Furthermore, disrupted sleep reduces cognitive reserve, and it appears that sleep disruption or restriction in the immediate perioperative period may precipitate delirium, particularly where cognitive reserves are low [56–58]. Longer-term sleep disruption, as with OSA, could also contribute to such a decline in cognitive reserves, and recent evidence suggests that it is a significant predictor of postoperative delirium [59, 60]. Apart from its capacity to disrupt sleep, OSA could also contribute to postoperative delirium indirectly through its pro-inflammatory tendencies and its relationship to metabolic syndrome. Recent literature points to a higher propensity for decline in cognitive function after non-cardiac surgery among patients with metabolic syndrome [61]. This has also been observed in a rat model of metabolic syndrome and attributed to dysregulation of the inflammatory response to surgery [62]. Data from in vitro studies support the interpretation that brain inflammation can up-regulate $GABA_A$ receptors and increase the sensitivity of some neurons to general anesthetics [63].

The notion that sleep could be an antidote to postoperative delirium is driving the quest for sedative drugs that induce natural or near-natural sleep particularly in sleep-challenging environments (such as critical care units) or circumstances (such as the first few days postoperatively). The concept of curtailing the noradrenergic stimulation has been recently proposed as an important aim in sedation to reduce the connectedness to the environment as in natural sleep. Dexmedetomidine is a promising agent in this respect, although there is evidence that dexmedetomidine-induced sedation differs significantly from sleep [21, 64]. Irrespective of this, sedative interventions cannot be at the cost of impairing arousal responses in those vulnerable to upper airway obstruction where the airway is unprotected.

Conclusions

Sleep and anesthesia are related states. Their shared influences on respiratory and upper airway function suggest that information from one state can be applied to the other and at-risk patients identified. These considerations extend beyond OSA to include sleep hypoventilation, periodic breathing and disordered gas exchange. Sleep disruption can also affect postoperative cognitive function, providing a further reason for identifying and dealing with sleep disorders preoperatively where the opportunity exists. Arousal suppression is a critical difference between the states. Patients with sleep-disordered breathing require close observation and, often, PAP therapies until sentient and no longer at risk of further periods of unconscious sedation.

Physiological Changes of Sleep

11

Sudhansu Chokroverty

In 1958 when sleep medicine was in its infancy without fundamental understanding of the physiology and functions of sleep, Robin [1] stated that "there are a number of physiological differences between the sleeping and the waking state" and he concluded that "the interrelations between sleep and the pathologic physiology of disease constitute a fruitful field for a more complete understanding of many diseases." How right he was as reflected by fruitful research in sleep medicine decades later. A constellation of physiological changes are observed in humans which are distinctly different in three states of our existence (e.g., wakefulness, non-rapid eye movement [NREM] and rapid eye movement [REM] sleep) [2]. These sleep-related changes play an important role in energy conservation, memory consolidation and thermoregulation besides other functions, and are important to understand the pathophysiology of many primary sleep and medical disorders including critically ill patients in the intensive-care units with unstable hemodynamic, respiratory and immune mechanisms. A case in point is the implication of reduced upper airway dilator muscle tone in sleep causing upper airway collapse and obstructive sleep apnea (OSA) in susceptible individuals. In a similar manner stroke, myocardial infarction, cardiac arrhythmias and even sudden cardiac death may be related to profound changes occurring during REM sleep in late night and early morning hours.

Physiological changes are known to occur in both the somatic nervous system and the autonomic nervous system (ANS) during sleep. Important changes in the endocrine system and temperature regulation are also associated with sleep. This chapter provides a review of the physiological changes in the central somatic nervous system and the ANS, including changes in the respiratory, cardiovascular, and neuromuscular systems, and in the gastrointestinal tract during sleep contrasting these changes with the conditions in the waking state. Some attention is also given to thermal and endocrine regulation. For a discussion about cytokines, immune function and sleep factors as they relate to the physiological changes in sleep, the readers are referred to Chaps. 2 and 12. Tables 11.1, 11.2 and 11.3 summarize the physiological changes during wakefulness, NREM and REM) sleep. For a more detailed discussion, readers are referred to excellent reviews by Orem and Barnes [3] and Lydic and Biebuyck [4].

Changes in the Central Somatic Nervous System During Sleep

Sleep is not just a state of rest and repose; many areas of central nervous system (CNS) show excitation during sleep as demonstrated by intracellular electrophysiological studies, C-fos activation shown by immunohistochemical observations and positron emission tomographic (PET) scans of the brain. NREM sleep is characterized by enhanced activity of ventrolateral preoptic and median preoptic neurons in the anterior hypothalamic nuclei and to a certain extent also lower brainstem nucleus tractus solitarius (NTS); in contrast, the wake-promoting neurons in the ascending reticular activating system (ARAS), histaminergic, aminergic and orexinergic neurons as well as most of the cerebral cortical regions are deactivated. During REM sleep, much of the cortical regions are activated along with pontine areas controlling REM sleep coupled with a paralyzed body caused by excitation of motor atonia pathways in the brain stem and spinal cord. The combined alterations in the somatic CNS and the ANS (see further on) are responsible for vast physiological changes in the body systems and organs during sleep.

Table 11.1 Summary of physiological changes in breathing during sleep

Parameters	Wakefulness	NREM sleep	REM sleep
Respiratory rate	Normal	Decreases	Variable, apnea may occur
Minute ventilation	Normal	Decreases	Decreases further
Alveolar ventilation	Normal	Decreases	Decreases further
$PaCO_2$	Normal	Increases slightly	Increases further slightly
PaO_2	Normal	Decreases slightly	Decreases further slightly
SaO_2	Normal	Decreases slightly	Decreases further
Hypoxic ventilatory response	Normal	Decreases	Decreases further
Hypercapnic ventilatory response	Normal	Decreases	Decreases further
Upper airway muscle tone	Normal	Decreases slightly	Decreases markedly or is absent
Upper airway resistance	Normal	Increases	Increases further

Table 11.2 Summary of physiological changes in heart and circulation

Physiological characteristics	NREM	REM
Heart rate	↓	↑↓
• Cardiac output	↓	↓↓
• Systematic arterial BP	↓	↓↑
– Dippers		
– Extreme dippers		
– Non-dippers		
– Reverse dippers		
• Pulmonary arterial BP	↑	↑
• Peripheral vascular resistance	—↓	↓
• Systematic blood flow		
– Cutaneous	—	↓
– Muscular	—	↓
– Mesenteric	—	↑
– Renal	—	↑
• Cerebral blood flow	↓	↑

↓ = Decreased; ↑ = Increased; ↓↑ = Uncertain; — = Unchanged

There are also changes in certain neural reflexes and cortical evoked potentials during sleep. The H-reflex, the electrical counterpart of monosynaptic muscle stretch reflex is decreased in amplitude because of motor neuron hyperpolarization, presynaptic inhibition and disfacilitation of brain stem aminergic and lateral hypothalamic orexinergic neurons projecting to brain stem motor and aminergic neurons as well as ventral horn cells of the spinal cord.

Polysynaptic reflexes which are useful in clinical studies include blink reflex and spinal flexor reflex. Certain components of these reflexes (R2) also decrease or are unobtainable during sleep. Babinski response (extensor plantar-response) which is absent in wakefulness in normal individuals may be elicited in sleep as a result of cerebral cortical inhibition and release of lower centers.

Somatosensory cortical evoked potentials (SEPs) attenuate during sleep, particularly during slow-wave sleep (SWS). Motor evoked potential (MEP) amplitude following magnetic brain stimulation also shows attenuation in all stages of sleep. There is an increased intracortical inhibition of interneurons in NREM sleep and decreased intracortical facilitation in REM sleep as determined by paired brain magnetic stimulation technique [5].

Neuroimaging studies have clearly shown areas of activation and deactivation of various regions of the brain during NREM and REM sleep, emphasizing that sleep is a variable and dynamic state and not simply a passive period in our life (see Chap. 21).

Clinical Relevance: In narcolepsy-cataplexy syndrome during cataplectic episodes, there is marked inhibition of

Table 11.3 Physiological changes during normal wakefulness and sleep in the gastrointestinal system

Physiological characteristics	Wakefulness	Sleep
Swallowing frequency	Normal	Decreased
Salivary flow	Normal	Decreased
Esophageal acid clearance time	Normal	Prolonged
Lower and upper esophageal sphincter pressure	Normal	Decreased
Esophageal peristaltic contractions	Normal	Decreased
Gastric motility	Normal	Decreased
Gastric acid secretion	Depends on food ingestion	Peak Secretion between 10 P.M. and 2 A.M.
Migrating motor complex (MMC) recurs every 90 min)	Normal velocity	Reduced velocity
Colonic motility	Normal	Decreased
Rectal motor activity and anal canal pressure	Normal	Increased periodic activity with retrograde propagation and higher anal canal pressure

monosynaptic reflexes including H-reflex. Blink reflex excitability study during cataplectic episodes may show facilitation of R2 component and impaired habituation suggesting involvement of brain stem interneurons in the pathogenesis of cataplectic motor phenomenon [6]. MEP amplitude during a cataplectic spell showed inconsistent results. One study documented persistence of MEP indicating enhanced cortical excitability [7], but another study [8] showed MEP amplitude attenuation. In RLS patients, spinal flexor reflex study during sleep disclosed hyperexcitability suggesting release of spinal motor centers from supraspinal inhibition [9].

Autonomic Nervous System and Sleep

Central Autonomic Network

The existence of a central autonomic network (CAN) in the brain stem with ascending and descending projections that are often reciprocally connected has been clearly shown by work done in the 1980s and 1990s (Figs. 11.1 and 11.2) [10 –11]. The NTS may be considered a central station in the CAN. The NTS, which is located in the dorsal region of the medulla ventral to the dorsal vagal nucleus, is the single most important structure of the autonomic network and is influenced by higher brain stem, diencephalon, forebrain, and neocortical regions (Fig. 11.3; see also Figs. 11.1 and 11.2). The NTS receives afferent fibers—from the cardiovascular system and the respiratory and gastrointestinal tracts—important for influencing autonomic control of cardiac rhythm and rate, circulation, respiration, and gastrointestinal motility and secretion (Fig. 11.4). Efferent projections arise from the NTS and are sent to the supramedullary structures, including hypothalamic and limbic regions, and to the ventral medulla, which exerts significant control over cardiovascular regulation [12–14]. The ventral medulla sends efferent projections to the intermediolateral neurons of the spinal cord (see Figs. 11.1 and 11.2). Box 11.1 lists afferent and efferent connections of NTS, considered a major central station of the CAN. The final common pathways from the NTS are the vagus nerve and sympathetic fibers, which send projections to the intermediolateral neurons of the spinal cord to orchestrate the CAN for integrating various autonomic functions that maintain internal homeostasis. The NTS also contains the lower brain stem hypnogenic and central respiratory neurons. Dysfunction of the ANS, therefore, may have a serious impact on human sleep and respiration.

Box 11.1. Afferent and Efferent Connections of Central Autonomic Network (CAN)

Nucleus tractus solitarius (NTS), the major central station of the CAN

- Afferents
  - Cardiovascular
  - Respiratory
  - Taste
  - Gastrointestinal
  - Descending projections from cerebrum and upper brain stem
- Efferents
  - Ventral medulla
  - Intermediolateral neurons
  - Inspiratory neurons

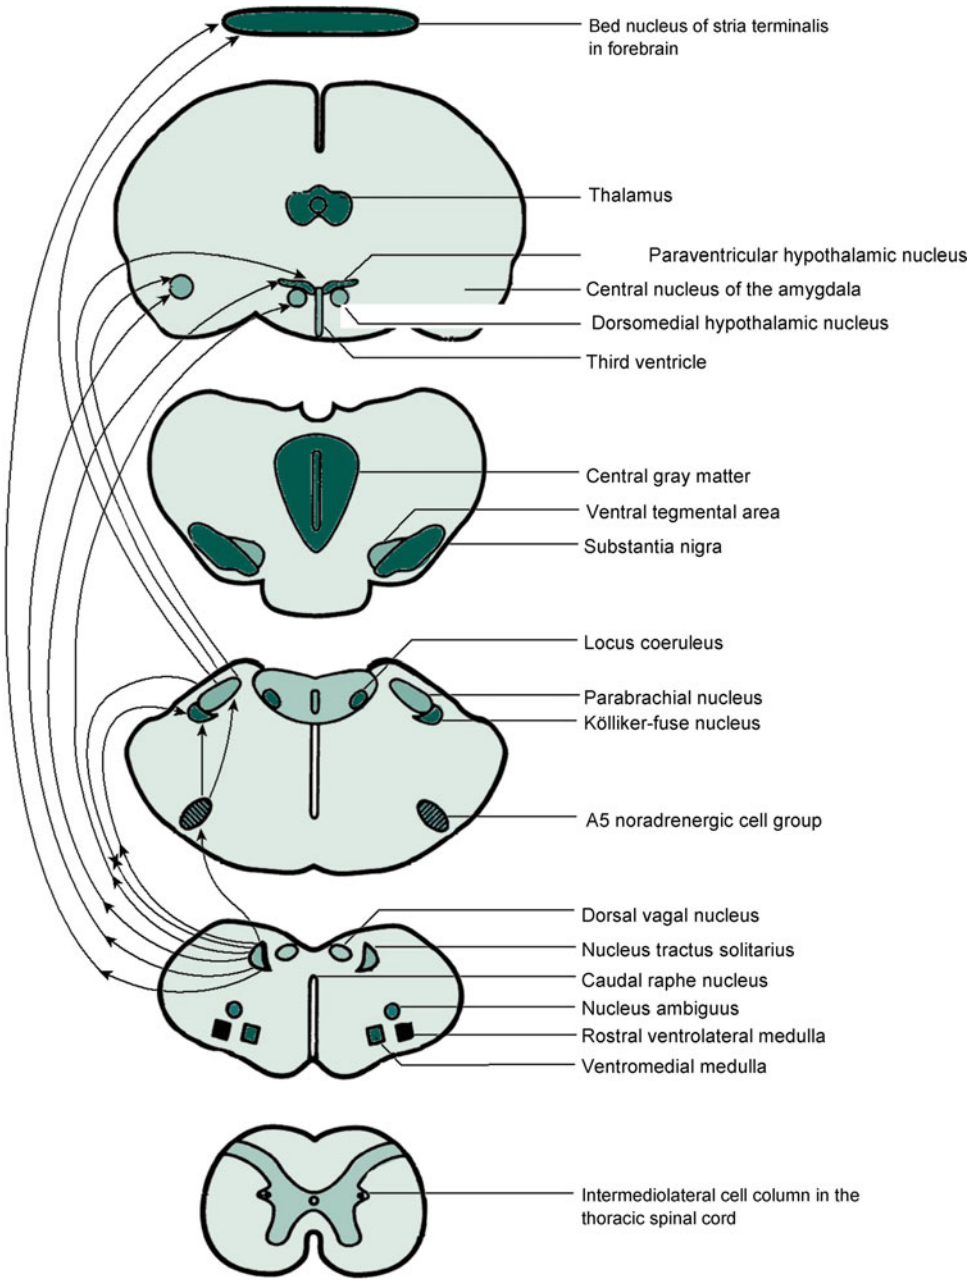

Fig. 11.1 The ascending projections from the central autonomic network (Reprinted with permission from Chokroverty [15])

- Vagal efferents to cardiovascular, respiratory and gastrointestinal systems
- Ascending projections to upper brain stem and cerebrum.

The cardiovascular system and respiration play significant roles in the maintenance of the internal homeostasis in human beings [13– 17]. Cardiovascular control in humans is maintained reflexively, involving peripheral receptors in the heart and blood vessels with afferents to the CNS and efferents to the heart and blood vessels. Sympathetic preganglionic neurons regulating the cardiovascular system are located predominantly (90 %) in the intermediolateral neurons of the thoracic spinal cord, with a small number (10 %) in the adjacent spinal structures. Parasympathetic preganglionic neurons controlling the heart and circulation are located in the nucleus ambiguus as well as in the dorsal

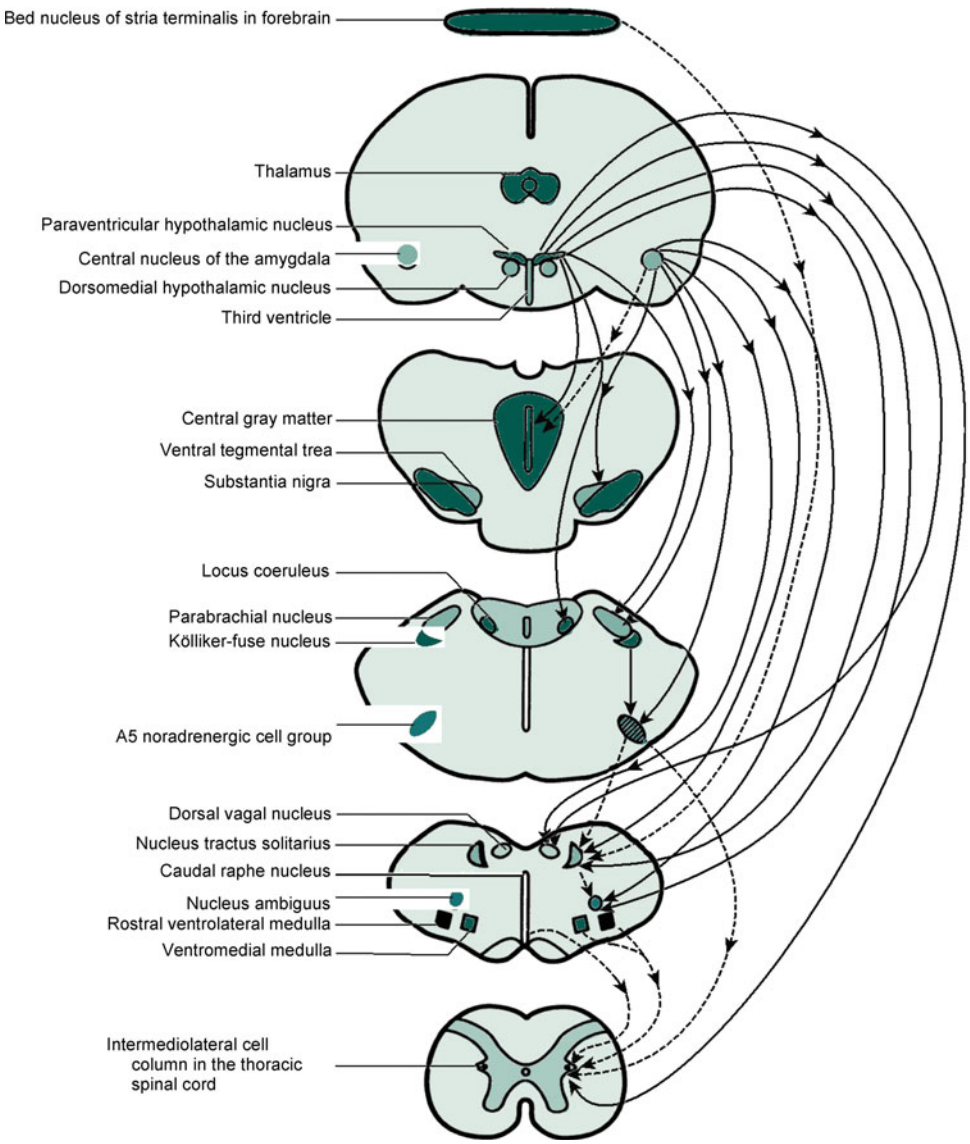

Fig. 11.2 The descending projections from the central autonomic network (Reprinted with permission from Chokroverty [15])

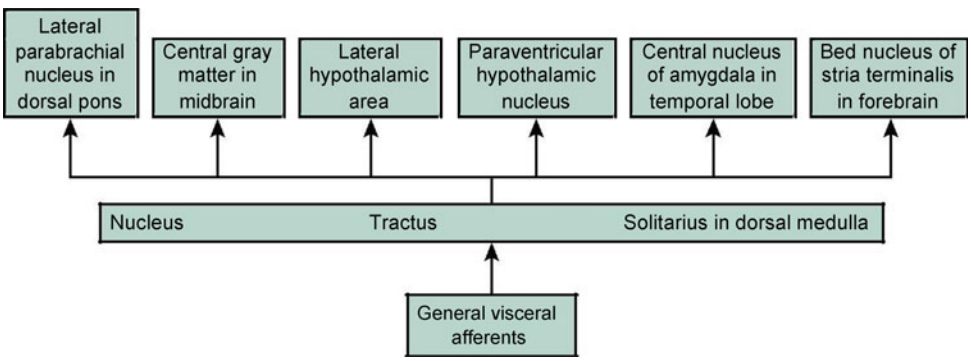

Fig. 11.3 Schematic diagram of central autonomic network: ascending projections from nucleus tractus solitarius (Reproduced with permission from Chokroverty [16])

motor nucleus of the vagus in the medulla. Sympathetic preganglionic neurons in the intermediolateral column of the spinal cord as well as parasympathetic preganglionic neurons in the nucleus ambiguus and dorsal motor nucleus of the vagus are the central determinants of cardiovascular regulation. Both the sympathetic and parasympathetic preganglionic neurons have extensive connections to the CAN, which in turn is influenced by peripheral afferents (Fig. 11.5;

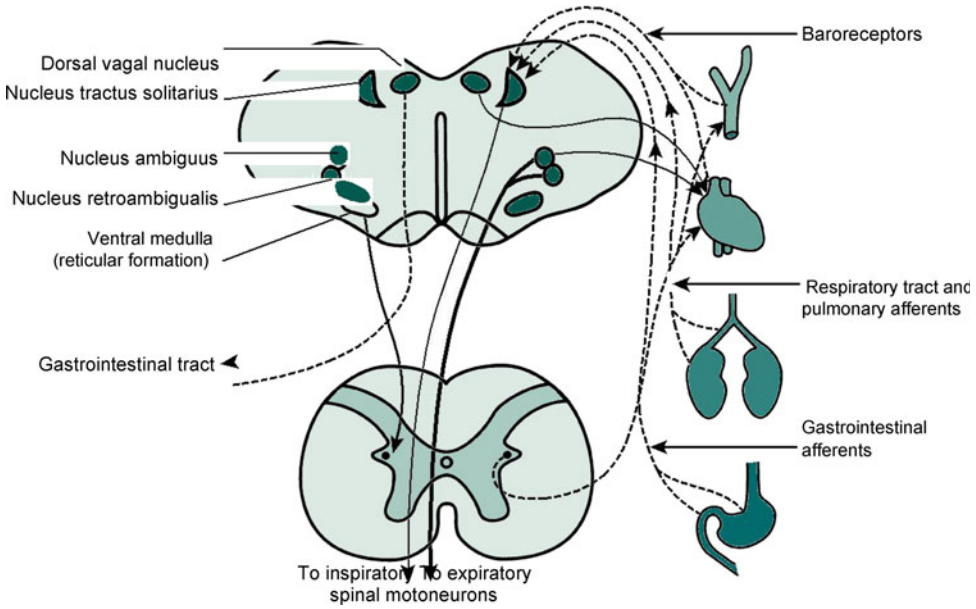

Fig. 11.4 The visceral afferents to and efferents from the nucleus tractus solitarius (Reprinted with permission from Chokroverty [15])

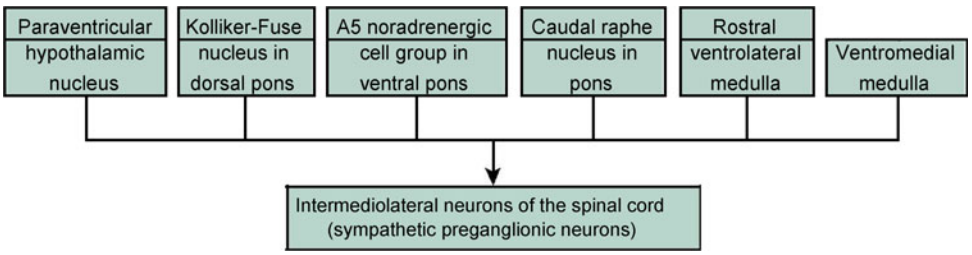

Fig. 11.5 Schematic diagram showing descending hypothalamic and brain stem inputs to intermediolateral neurons in the spinal cord (Reprinted with permission from Chokroverty [15])

see also Figs. 11.1, 11.2, 11.3, 11.4). There is direct projection from the hypothalamic paraventricular nucleus (PVN) to sympathetic preganglionic neurons in the spinal cord (see Figs. 11.2 and 11.5).

Autonomic Changes During Sleep

During sleep in normal individuals, there are profound changes in the functions of the ANS [10, 12, 18–25] (See Box 11.2). Most of the autonomic changes that occur during sleep involve the heart, circulation, respiration, and thermal regulation. There are also pupillary changes. Pupilloconstriction occurs during NREM sleep which persists after preganglionic sympathectomy and is maintained during REM sleep due to tonic parasympathetic drive. Phasic dilation during phasic REM sleep results from central inhibition of parasympathetic outflow to the iris.

Box 11.2. Functional Changes in the AUTONOMIC NERVOUS SYSTEM DURING SLEEP

- NREM Sleep
  - Increased parasympathetic activity
  - Decreased sympathetic activity
  - Decreased low-frequency (LF) components reflecting decreased sympathetic tone but increased high frequency (HF) components reflecting increased respiratory vagal tone
- REM Sleep
  - Further increase in parasympathetic activity

- More marked decrease in sympathetic activity
- Intermittent bursts of sympathetic activity in phasic rapid eye movements
- Profound increase in sympathetic activity in skin and muscle vessels (microneurographic recordings)
- Variable LF and HF with decreased HF and intermittent increment of LF components.

Autonomic functions during wakefulness must be compared to those during sleep to understand ANS changes in sleep [18]. The basic ANS changes during sleep include increased parasympathetic tone and decreased sympathetic activity during NREM sleep accompanied by a reduction of circulating levels of norepinephrine and epinephrine. During REM sleep, there is further increase in parasympathetic tone and further decrease of sympathetic activity; intermittently, however, there is an increase in sympathetic activity during phasic REM sleep resulting in swings in BP and HR causing tachy–brady arrhythmias. The ANS changes during sleep can be assessed by measuring heart rate variability (HRV) [26]. The indices of HRV can be documented by fast Fourier transform showing power in the following bands: HF, LF, very low frequency (VLF), and ultra low frequency (ULF). HF band power ranges from 0.15 to 0.4 Hz. The power in the LF band ranges between 0.04 and 0.15 Hz. The VLF band power ranges from 0.003 to 0.04 Hz, and the power in the ULF band is 0.003 Hz or less. The major contributor of the HF component is the efferent vagal activity. The LF component is thought to be a marker of sympathetic modulation by some authors [27, 28], whereas others [29, 30] considered this to contain both sympathetic and vagal influences. Therefore, the LF/HF ratio is thought to reflect sympathovagal balance [28, 29]. The significance of VLF and ULF components remains uncertain, but these may be markers of humoral and hormonal fluctuations. Both spectral components and direct nerve recordings (see below) show that the HF component predominates during NREM and the LF component predominates during REM sleep. During NREM sleep, the LF component decreases, whereas the HF component increases, reflecting increased vagal tone. In contrast, during REM sleep, extreme variation in LF and HF with increased LF and decreased HF components is noted. The heart rate (HR) changes precede electroencephalographic (EEG) changes during transition of sleep states. HRV is similar in presleep and intrasleep wake periods. It should be further noted that the HF component mainly reflects the respiration–vagal modulation of sinus rhythm, whereas the nonrespiratory LF component reflects the sympathetic modulation of the heart in addition to baroreflex responsiveness to beat-to-beat variations in blood pressure (BP) [31,32]. Power spectrum analysis of normal subjects at sleep onset by Shiner et al. [33] showed that the wake/sleep transition period represents a transitional process between two physiologically different states, with a decrement of LF power and unchanged HF power causing a decrement of the LF/HF ratio reflecting a shift toward parasympathetic predominance. Thus, NREM sleep can be considered as a state of relative cardiorespiratory stability, whereas REM sleep is a state of profound instability with an intense autonomic and respiratory dysregulation. In a recent study, Richard et al. [34] pointed to the effect of gender on autonomic and respiratory responses during sleep. They noted that, in women, there was a greater NREM-to-REM increment in LF, a greater decrement in HF, and a greater increment in LF/HF power. NREM-to-REM excitatory cardiorespiratory responses are, therefore, more marked among women compared to men.

There is also a profound change of sympathetic activity in muscle and skin blood vessels. Microneurographic technique measures peripheral sympathetic nerve activity in the muscle and skin vascular beds. The technique permits direct intraneural recording of efferent sympathetic nerve activity involving the muscle and skin blood vessels by using tungsten microelectrodes [35–39]. Muscle sympathetic nerve activity is reduced by 10–30 % in stages N1 and N2 sleep and by 30–50 % from wakefulness to SWS, but increases to levels above waking values during REM sleep [38]. Although sympathetic nerve activity increases in the skeletal muscle vessels (vasoconstriction) during REM sleep, the sympathetic drive decreases in the splanchnic and renal circulation (vasodilation) [38]. Sympathetic nerve activity is lower during NREM sleep than during wakefulness but increases above the waking level during REM sleep, particularly during phasic REM sleep (Fig. 11.6). During the arousal and appearance of K complexes in NREM sleep, the bursts of sympathetic activity transiently increase.

Clinical Relevance

The implications of changes in the ANS during sleep in humans are profound. Reduced HRV may be noted in patients with myocardial infarction, cardiac transplantation, and diabetic autonomic neuropathy [26, 27, 30, 40, 41]. There is a significant relationship between the ANS and cardiovascular mortality, including sudden cardiac death. Lethal arrhythmias are related to either increased sympathetic activity or decreased vagal activity. HRV (e.g., reduced HRV) is a strong and independent predictor of mortality after acute myocardial infarction. HRV study thus has potential for assessment of ANS fluctuations in patients

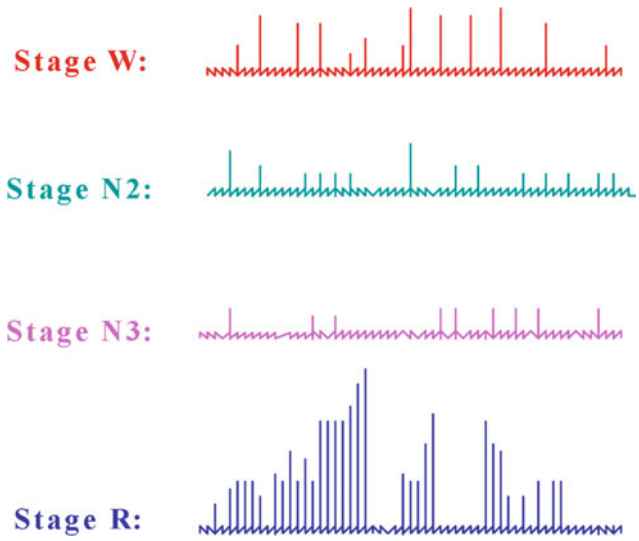

Fig. 11.6 Sympathetic nerve activity (SNA) during wakefulness (W), NREM sleep (Stages N1 an N2) and REM sleep (Stage R) in a normal subject shown schematically. Progressive decrement of SNA from W to Stage N2 and Stage N3 but marked increment in Stage R (Adapted from: Somers et al. [38])

with cardiovascular and noncardiovascular disorders and may help us understand physiological phenomena, disease mechanisms, and effects of medications. Furthermore, disorders of the ANS in humans, such as multiple systems atrophy, familial dysautonomia, and secondary autonomic failure (see Chap. 41), adversely affect respiratory and cardiovascular functions during sleep. A number of human sleep disorders may affect autonomic functions (e.g., obstructive sleep apnea syndrome (OSAS), cluster headache, sleep terrors, REM sleep behavior disorder and narcolepsy [25, 42, 43]). Thus, significant sleep-related changes in the ANS affecting the circulatory, respiratory, gastrointestinal, and urogenital systems have important clinical implications in patients with central or peripheral autonomic failure (e.g., sleep-related respiratory dysrhythmias, cardiac arrhythmias, gastrointestinal dysmotility and urogenital disorders). Thus, there is a bidirectional relationship between the ANS and sleep: autonomic changes can alter sleep regulation and in turn sleep disturbances can affect the ANS.

In patients with OSAS, chronic sympathetic hyperactivity is thought to play a major role in linking OSAS with hypertension, cardiac ischemia, congestive cardiac failure and stroke [41, 42]. A variety of cardiovascular reflex tests measuring HR and BP changes to special maneuvers (e.g., head-up tilt, valsalva maneuver, deep breathing, hand grip, cold face, cold pressor and mental arithmetic tests) can detect integrity of sympathetic and parasympathetic divisions of the ANS as well as baroreflex [23, 43]. Baroreflex is an important mechanism to maintain BP homeostasis [22–25]. Baroreflex function [44, 45] can be evaluated by an indirect technique of baroreflex sensitivity (BRS) which is defined as change in HR per unit change in arterial BP [23, 24]. The slope of the changes in RR interval (or HR) in relation to BP changes determines BRS which indirectly assesses baroreflex function. BRS is increased during NREM sleep as result of resetting of baroreflex function, and this results in slowing of the HR despite a decrement of BP [22, 23, 43, 45].

Other tests to evaluate ANS function included HR spectral analysis of HRV and recording of muscle and skin sympathetic nerve activity (MSNA and SSNA) using tungsten microelectrodes inserted into the peroneal and median nerves [38]. Additionally, imaging studies are available such as MIBG scintigraphy [46] to assess cardiac sympathetic innervation, which is impaired in post ganglionic cardiovascular autonomic disorders.

Respiration and Sleep

Functional Neuroanatomy of Respiration

In order to understand the control of breathing, it is essential to have a basic knowledge about the functions of breathing, the functional anatomy of breath, and control of respiration during wakefulness and asleep. The function of breathing is to maintain an adequate alveolar ventilation and diffusion across the alveolar capillary membranes (i.e., elimination of carbon dioxide [CO_2] to and supply of oxygen [O_2] from the atmospheric air containing 21 % O_2 78 % nitrogen, and 1 % other inert gases), and to maintain arteriolar homeostasis (i.e., normal partial pressure of oxygen [PO_2] and carbon dioxide [PCO_2]). An adequate pulmonary circulation is essential to complete the processes of alveolar ventilation and diffusion. The respiratory system consists of three interrelated and integrated components: central controllers located in the medulla aided by the supramedullary structures, including forebrain, peripheral chemoreceptors, and pulmonary and upper airway receptors; the thoracic bellows, consisting of respiratory and other thoracic muscles and their innervation and bones; and the lungs, including the airways.

In 1812, Legallois [47] discovered that breathing depends on a circumscribed region of the medulla. After an intensive period of research in the nineteenth century on the respiratory centers, in the twentieth century, Lumsden [48, 49], and later Pitts et al. [50], laid the foundation for modern concepts of the central respiratory neuronal networks. Based on

sectioning at different levels of the brain stem of cats, Lumsden [48, 49] proposed pneumotaxic and apneustic centers in the pons and expiratory and gasping centers in the medulla. Later, Pitts' group [50] concluded from experiments with cats that the inspiratory and expiratory centers were located in the medullary reticular formation.

Upper brain stem respiratory neurons are located in the rostral pons, in the region of the parabrachial and Kölliker-Fuse nuclei (pneumotaxic center), and in the dorsolateral region of the lower pons (apneustic center) [51]. These two centers influence the automatic medullary respiratory neurons, which comprise two principal groups [51–59]. The dorsal respiratory group (DRG) located in the NTS is responsible principally, but not exclusively, for inspiration, and the ventral respiratory group (VRG) located in the region of the nucleus ambiguus and retroambigualis is responsible for both inspiration and expiration (Fig. 11.7). The VRG contains the Botzinger complex in the rostral region and the pre-Botzinger region immediately below the Botzinger complex, responsible mainly for the automatic respiratory rhythmicity as these neurons have intrinsic pacemaker activity. These respiratory premotor neurons in the DRG and VRG send axons that decussate below the obex and descend in the reticulospinal tracts in the ventrolateral cervical spinal cord to form synapses with the spinal respiratory motor neurons innervating the various respiratory muscles (see Figs. 11.3 and 11.4). Respiratory central pattern generator (RPG) [60] includes neurons in the dorsolateral pons (e.g., parabrachial [PB], and Kolliker-Fuse [KF] nuclei in this region), NTS and ventrolateral medulla (Ventral respiratory group [VRG]). Box 11.3 summarizes functions of various respiratory neurons [60]. The site of central chemoreceptor zone is not definitely known but most likely located in the retrotrapezoid nucleus (RTN) in the rostral medulla (part of the parafacial nucleus) between the facial nucleus in the lower pons and the ventral surface of the medulla, and contains glutamatergic neurons [61, 62]. RTN neurons innervate also the brainstem area containing the RPG [61]. The neurons in the arcuate nucleus at the ventromedial aspect of the medullary pyramid may also have a role in central chemosensitivity and respiratory frequency [60].

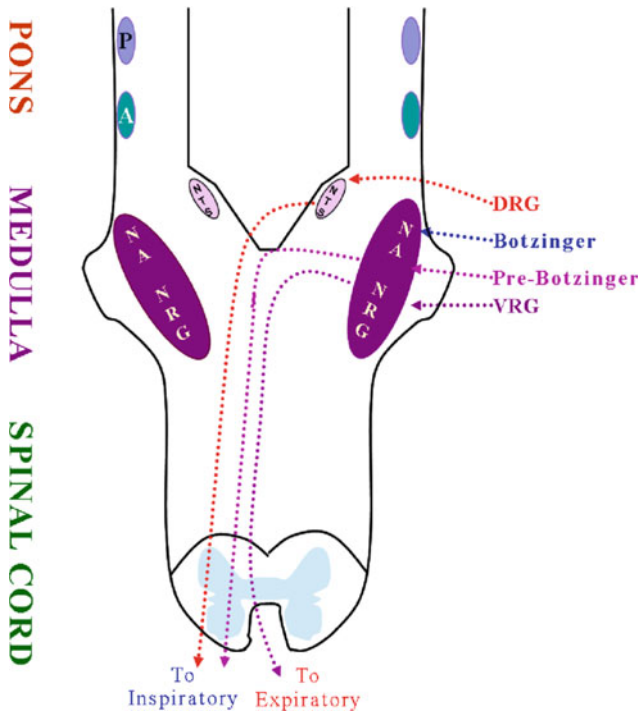

Fig. 11.7 Schematic representation of central respiratory neurons in Pons and Medulla. *DRG* Dorsal respiratory group with projections to contralateral predominantly inspiratory muscles. *VRG* Ventral respiratory group with projections to contralateral inspiratory and expiratory muscles. *P* Pneumotaxic center; *A* Apneustic center. Box 11.3. Functions of Respiratory neurons [60]

- PB and KF nuclei control the phase-switch between inspiration and expiration.
- The NTS is the primary relay station for medullary reflexes controlling respiration.
- The Botzinger complex (in the VRG) contains expiratory neurons.
- The pre-Botzinger complex is responsive for respiratory rhythm generation.
- The rostral VRG contains inspiratory neurons.
- The caudal VRG contains expiratory neurons.
- The DRG contains mainly, but not exclusively inspiratory neurons

PB: parabrachial; KF: Kölliker-Fuse
NTS: nucleus tractus solitarius
VRG: ventral respiratory group
DRG: dorsal respiratory group.

Control of breathing by the medullary respiratory neurons to regulate the rate, rhythm, amplitude, rhythmicity and pattern of breathing, and internal homeostasis depends on a variety of afferent inputs to respiratory neurons in the brainstem. These include the parasympathetic vagal afferents from the peripheral respiratory tracts and receptors, the carotid and aortic body peripheral chemoreceptors (sensing predominantly low O_2 but to an extent also increased CO_2 and H+),

the central chemoreceptors in the medulla sensing alteration in CO_2 or H(+) in the local circulation, the supramedullary structures (e.g., forebrain, midbrain, and pontine regions), and the reticular activating systems [51, 63–66].

Breathing is controlled during wakefulness and sleep by two separate and independent systems [52–57, 67]: the metabolic or automatic [53, 54], and the voluntary or behavioral [67]. Both metabolic and voluntary systems operate during wakefulness, but breathing during sleep is entirely dependent on the inherent rhythmicity of the autonomic (automatic) respiratory control system located in the medulla [55–57]. Voluntary control is mediated through the behavioral system that influences ventilation during wakefulness as well as nonrespiratory functions [68, 69] such as phonation and speech. In addition, the wakefulness stimulus, which is probably derived from the ARAS [70–72], exerts a tonic influence on the brain stem respiratory neurons during wakefulness.

The voluntary control system for breathing originating in the cerebral cortex (forebrain and limbic system) controls respiration during wakefulness and has some nonrespiratory functions [65, 67]. This system descends with the corticobulbar and corticospinal tracts partly to the automatic medullary controlling system and to some degree both terminates and integrates there. However, it primarily descends with the corticospinal tract to the spinal respiratory motor neurons, in the high cervical spinal cord, where the fibers finally integrate with the reticulospinal fibers originating from the automatic medullary respiratory neurons for smooth, coordinated functioning of respiration during wakefulness [53, 54, 57, 73, 74].

There is a close interrelationship between the respiratory [52–54] central autonomic [12, 75, 76], and lower brain stem hypnogenic neurons [77–83] in the pontomedullary region. The hypothalamic and lower brain stem hypnogenic neurons are also connected [84]. Reciprocal connections exist between the hypothalamus, the central nucleus of the amygdala, parabrachial and Kölliker-Fuse nuclei, and the NTS of the medulla (see Figs. 11.1 and 11.2) [75, 11, 73, 15]. In addition, the NTS connects with the nucleus ambiguus and retroambigualis (see Fig. 11.2) [75, 11, 73, 15]. Thus, their anatomic relationships suggest close functional interdependence among the CAN, the respiratory and hypnogenic neurons. In addition, peripheral respiratory receptors (arising from the pulmonary and tracheobronchial tree) and chemoreceptors (peripheral and central) interact with the CAN in the region of the NTS [51–54, 85].

The thoracic bellows component consists of thoracic bones, connective tissue, pleural membranes, the intercostal and other respiratory muscles, and the nerves and blood vessels. Respiratory muscle weakness plays a critical role in causing sleep dysfunction and sleep-disordered breathing in neuromuscular disorders. Box 11.4 lists the respiratory muscles. The main inspiratory muscle is the diaphragm (innervated by the phrenic nerve, formed by motor roots of C3, C4, and C5 anterior horn cells), assisted by the external intercostal muscles (innervated by the thoracic motor roots and nerves), which expand the core of the thoracic cavity and lungs during quiet normal breathing. Expiration is passive, resulting from elastic recoil of the lungs. During forced and effortful breathing (e.g., dyspnea and orthopnea), accessory muscles of respiration assist the breathing. Accessory inspiratory muscles include the sternocleidomastoideus, trapezius, and scalenus (anterior, middle, and posterior) as well as the pectoralis, serratus anterior, and latissimus dorsi. Accessory expiratory muscles consist of internal intercostal and abdominal muscles (e.g., rectus abdominis, external and internal oblique, and transversus abdominis) innervated by thoracic motor roots and nerves. Normally, these three respiratory components (central controllers, chest bellows, and lungs) function smoothly in an automatic manner to permit gas exchange (transfer of O_2 into the blood and elimination of CO_2 into the atmosphere) for ventilation, diffusion, and perfusion. Minute ventilation is defined as the amount of air breathed per minute, which equals about 6 L; about 2 L stay in the anatomic dead space, consisting of the upper airway and the mouth, and 4 L participate in gas exchange in the millions of alveoli constituting alveolar ventilation. Respiratory failure may occur as a result of dysfunction anywhere within these three major components of the respiratory control systems.

Box 11.4 The Respiratory Muscles

Inspiratory Muscles

- Diaphragm
- External intercostal

Accessory Inspiratory Muscles

- Sternocleidomastoideus
- Scalenus (anterior, middle, posterior)
- Pectoralis major
- Pectoralis minor
- Serratus anterior
- Serratus posterior superior
- Latissimus dorsi
- Alae nasi
- Trapezius.

Expiratory Muscles (*silent during quiet breathing but contract during moderately severe airway obstruction or during forceful and increased rate of breathing*)

- Internal intercostal
- Rectus abdominis
- External and internal oblique
- Transversus abdominis.

Control of Ventilation During Wakefulness

The function of ventilation is to maintain arterial homeostasis (i.e., normal partial pressure of oxygen [PO_2] and carbon dioxide [PCO_2]) [86]. The PCO_2 depends predominately on the central chemoreceptors with some influence from the peripheral chemoreceptors, whereas PO_2 depends entirely on the peripheral chemoreceptors. To maintain optimal PO_2 and PCO_2 levels, the metabolic or autonomic respiratory system uses primarily the peripheral and central chemoreceptors but also to some extent the body's metabolism and the intrapulmonary receptors [86]. It is well known that hypoxia and hypercapnia stimulate breathing [87, 88]. Hypoxic ventilatory response is mediated through the carotid body chemoreceptors [89, 90]. Normally, this response represents a hyperbolic curve that shows a sudden increase in ventilation when PO_2 falls below 60 mm Hg [51, 55–57, 86] (Fig. 11.8). Conversely, the hypercapnic [86, 88] ventilatory response is linear (see Fig. 11.8). It is mediated mainly through the medullary chemoreceptors [91] but also to some extent through the carotid body peripheral chemoreceptors [89]. The central respiratory chemosensitivity depends predominantly on an adequate response of chemosensory neurons of the RTN to sensing changes in CO_2 or H(+) in the local circulation [92]. When PCO_2 falls below a certain minimum level, which is called the apnea threshold, ventilation is inhibited [86]. The metabolic rate (e.g., carbon dioxide production [VCO_2] or oxygen consumption [VO_2], particularly VCO_2) affects ventilation in part [86]. During sleep, metabolism slows. The intrapulmonary receptors do not seem to play a major role in normal human ventilation [86]. The Hering-Breuer reflex, important to respiration, depends on pulmonary stretch receptors. Vagal afferent stimulation by increasing lung inflation terminates inspiration.

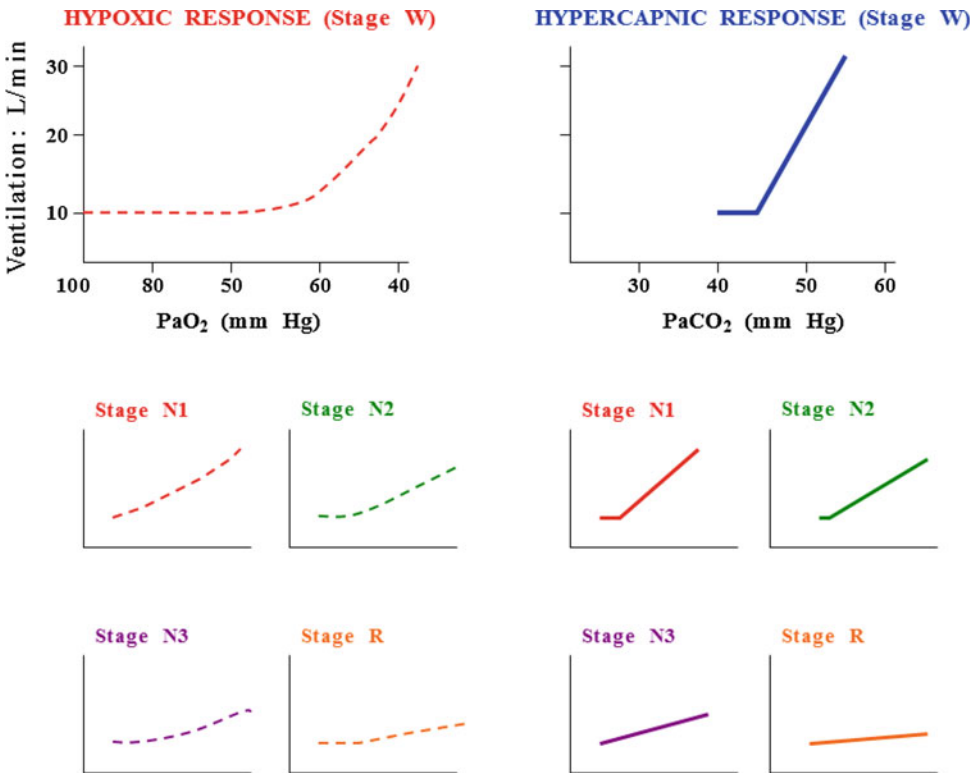

Fig. 11.8 Hypoxic and hypercapnic ventilatory responses during wakefulness, NREM (Stages N1, N2 and N3) and REM (Stage R) sleep in a normal man shown schematically. There is progressive decrement of responses with shift to the right from wakefulness to Stages N1, N2, N3 and REM state (Stage R). (Adapted from References [93, 94]

Control of Ventilation During Sleep

In normal persons, during both REM and NREM sleep, clear alterations are noted in tidal volume, alveolar ventilation, blood gases, respiratory rate and rhythm, chemosensitivity, respiratory muscle tone and upper airway reflexes and resistance [55–57, 65, 67, 95–100].

Changes in Ventilation

During NREM sleep, minute ventilation falls by approximately 0.5–1.5 L/min [86, 92, 96, 97, 101, 102, 103, 104] and this is secondary to reduction in the tidal volume. REM sleep shows a similar reduction of minute ventilation, up to approximately 1.6 L/min [86, 92, 98, 102, 104, 105]. Although there is a discrepancy in the literature regarding REM sleep-related ventilation in humans, it is generally accepted that most reduction occurs during phasic REM sleep.

The following factors, in combination, may be responsible for alveolar hypoventilation during sleep [86, 92]: reduction of VCO_2 and VO_2 during sleep, absence of the tonic influence of the brain stem reticular formation (i.e., absence of the wakefulness stimulus), reduced chemosensitivity (see *Chemosensitivity and Sleep* later), and increased upper airway resistance to airflow resulting from reduced activity of the pharyngeal dilator muscles during sleep [102, 106].

Changes in Blood Gases

As a result of the fall of alveolar ventilation, the PCO_2 rises by 2–8 mm Hg, PO_2 decreases by 3–10 mm Hg, and arterial oxygen saturation (s) decreases by less than 2 % during sleep [96, 98, 99, 107, 108]. These changes occur despite reductions of VO_2 and VCO_2 during sleep [109].

Respiratory Rate and Rhythm

In NREM sleep, the respiratory rate primarily shows a slight decrement, whereas in REM sleep the respiration becomes irregular, especially during phasic REM [86]. There is also waxing and waning of the tidal volume during sleep onset resembling Cheyne-Stokes breathing [95, 98, 109–111] which is related to several factors [86]: sudden loss of wakefulness stimulus, reduced chemosensitivity at sleep onset (see *Chemosensitivity and Sleep* later), and transient arousal. During the deepening stage of NREM sleep, respiration becomes stable and rhythmic and depends entirely on the metabolic controlling system [55–57, 65, 86, 98].

Chemosensitivity and Sleep

A rising arterial PCO_2 and falling arterial PO_2 stimulate ventilation. Hypoxia acts through peripheral chemoreceptors in the carotid bodies, whereas CO_2 acts mainly through the central chemoreceptor in the medulla and also to an extent through the carotid body chemoreceptor.

Hypoxic ventilatory response in humans is decreased in NREM sleep in adult men but not in women, whereas hypoxic ventilatory response during REM sleep is significantly decreased in both men and women (Fig. 11.8) [93, 95, 112–116]. The underlying mechanisms for this gender difference are not clear [117]. This reduction could result from two factors: (1) increased upper airway resistance to airflow during all stages of sleep [102, 106, 118] and (2) decreased chemosensitivity.

Hypercapnic ventilatory response also decreases by approximately 20–50 % during NREM sleep [96, 99, 103, 94, 119] and further during REM sleep (Fig. 11.8) [116, 94, 119]. This results from a combination of two factors: (1) a decreased number of functional medullary respiratory neurons during sleep and (2) increased upper airway resistance [102, 106, 118]. During sleep, the CO_2 response curve shifts to the right so that increasing amounts of PCO_2 are needed to stimulate ventilation [108]. These findings suggest decreased sensitivity of the central chemoreceptors subserving medullary respiratory neurons during sleep. The marked blunting of the hypercapnic ventilatory response during REM sleep could also be related to increasing brain blood flow during this sleep state [107].

Metabolism and Ventilation During Sleep

There is a definite decrease in VCO_2 and VO_2 during sleep [109, 120, 121]. Metabolism slows suddenly at sleep onset and accelerates slowly in the early morning at approximately 5:00 A.M. [109]. During sleep, ventilation falls parallel to metabolism. The rise of PCO_2 during sleep, however, is due to alveolar hypoventilation and is not related to reduced metabolism [86]. The role of the intrapulmonary receptors during normal sleep in humans is unknown [86].

Arousal Responses During Sleep

Hypercapnia is a stronger arousal stimulus than hypoxemia during sleep. An increase in PCO_2 of 6–15 mm Hg causes consistent arousal during sleep [113], whereas SaO_2 would have to decrease to 75 % before arousing a normal person [106, 122].

Laryngeal stimulation normally causes cough reflex response, but this is decreased during both states of sleep and is more markedly decreased during REM than NREM sleep [123]. Thus, clearance of aspirated gastric contents is impaired during sleep. In infants, laryngeal stimulation causes OSA, and this has been postulated as one mechanism for sudden infant death syndrome (SIDS) [124].

Upper Airway Reflexes, Receptors and Resistance

The upper airway reflexes are important in controlling the upper airway resistance and upper airway space. The activity of the upper airway inspiratory dilator muscles reflexively increases at the onset of inspiration due to the negative intrathoracic pressure. These respiratory-related increased pharyngeal muscle activations during inspiration are an attempt to enlarge the upper airway space to resist the sub-atmospheric inspiratory airway collapsing pressure. These upper airway muscles can be considered, in a way, respiratory muscles ("secondary" respiratory muscles) which modulate rather than generate airflow (see Table 11.4). Such reflex responses, however, are decreased during sleep, making the upper airway susceptible to suction collapse. This decreased upper airway reflex response probably results from decrement in the excitability of the upper airway motor neurons. The pressure sensitive upper airway muscle receptors send impulses via the glossopharyngeal (IXth cranial) and vagal (Xth cranial) nerves to respiratory centers in the medulla. The role of the upper airway reflexes in maintaining the upper airway resistance is strengthened by the observation of increased frequency of obstructive apneas and hypopneas in normal subjects during sleep following upper airway anesthesia [125] as well as increased apnea index after upper airway anesthesia in snorers [126]. Patients with OSA, however, do not show an increase in their apnea index after upper airway anesthesia which does not support a role for upper airway reflexes in the pathophysiology of OSAS [127, 128]. Alcohol, benzodiazepines, and age clearly cause a decrement in upper airway reflex response [129–131]. There are two other receptors important for control of ventilation: intrapulmonary stretch receptors sending afferent impulses via the vagus (Xth cranial) nerve to the inspiratory

neurons in the NTS in the medulla responsible for reflex termination of inspiration (Hering-Breuer reflex); and lung parenchymal irritant or J receptors causing increased ventilatory effort associated with pulmonary congestion.

Changes in the Upper Airway and in Intercostal Muscles and Diaphragm Tone

Upper airway resistance increases during sleep as a result of hypotonia of the upper airway dilator muscles [100, 102, 106, 118, 132, 133] (see *Physiologic Changes in the Neuromuscular System* later). There is also hypotonia of the intercostal muscles and atonia during REM sleep. The phasic activities in the diaphragm are maintained, but the tonic activity is reduced during REM sleep [57]. As a result of the supine position and hypotonia of intercostal muscles, the functional residual capacity (FRC) decreases [134, 135]. In most normal individuals, there are circadian changes in airway patency with mild bronchoconstriction during sleep at night [136].

Summary and Conclusions

During wakefulness, both metabolic and voluntary (behavioral) control systems are active. In NREM sleep, the voluntary system is inactive and respiration is entirely dependent on the metabolic controller—behavioral influences and wakefulness stimuli are not controlling respiration. The nature of ventilatory control during REM sleep has not been determined definitively, but most likely the behavioral mechanism is responsible for controlling breathing in REM sleep. Ventilation is unstable during stage N1, stage N2 and REM sleep, and apneas may occur, particularly at sleep onset and during REM sleep. Respiratory homeostasis is thus relatively unprotected during sleep. However, the breathing is more regular and stable during stage N3 (SWS). Following three mechanisms may be responsible for this singly or in combination:

1. Increased genioglossus muscle single motor unit (SMU) activity during SWS compared with stage N1 or stage N2 [137]. This may be related to three possible factors: (a) higher PCO_2 during SWS than stage N2 (this is unlikely but possible); (b) higher upper airway resistance during stage N3 than stages N1 and N2 triggering activation of local mechanoreceptors (variable results in prior studies); and (c) increased central respiratory drive (a theoretical possibility as no prior study is available to prove this).
2. Increased arousal threshold in SWS compared with stages N1 or N2, preventing arousal related instability of breathing [138].
3. Increased phasic upper airway muscle activity in SWS [139].

The major cause of hypoventilation and reduced ventilatory response to chemical stimuli during sleep is increased airway resistance [102, 106, 118, 140]. The increased resistance results from reduced activity of the pharyngeal dilator muscles as well as decreased output from the sleep-related medullary respiratory neurons [141]. The reduction of the medullary respiratory neuronal activity in sleep causes a loss of the tonic and phasic motor output to the upper airway muscles, resulting in an increase in airway resistance. Other factors that contribute to sleep-related hypoventilation include the following [55–57, 65, 86, 142]: reduction of metabolic rate by approximately 10–15 %; absence of wakefulness stimuli; reduced chemosensitivity; increased blood flow to the brain during REM sleep, which may depress central chemoreceptor activity; and functional alterations in the CNS during sleep, such as cerebral cortical suppression due to reticular inhibition and physiological cortical deafferentation (presynaptic and postsynaptic inhibition of the afferent neurons [143]) as well as postsynaptic inhibition of motor neurons during REM sleep (see *Physiologic Changes in the Neuromuscular System* later).

Physiological Changes in the Neuromuscular System

Physiological changes have been noted during sleep in both the somatic nervous system and the ANS that in turn produce changes in the somatic and smooth muscles of the body. This section presents a discussion of the physiological changes noted during sleep in the somatic muscles, including cranial, limb, and respiratory muscles.

Changes in Limb and Cranial Muscles

Alterations of limb and cranial muscle tone are noted during sleep. Muscle tone is maximal during wakefulness, slightly decreased in NREM sleep, and markedly decreased or absent in REM sleep. Electromyography (EMG), particularly of the mentalis or the submental muscles, is necessary to identify REM sleep and is thus important for scoring technique. In addition, transient phasic (myoclonic) bursts are noted during REM sleep. An important EMG characteristic is documentation of periodic limb movements in sleep, which are noted in the majority of patients with restless legs syndrome; patients with a variety of sleep disorders; and normal individuals, most commonly elderly ones.

Upper Airway Muscles and Sleep

Changes occur in the function of the upper airway dilator muscles (Table 11.4) during sleep that have important clinical implications, particularly for patients with sleep apnea syndrome. The upper airway dilator muscles can be considered secondary respiratory muscles which are responsible for modulating and maintaining airflow but not for generating airflow and controlling breathing [144]. These muscles are located in the nose, tongue, soft palate, pharynx, hyoid arch and larynx (Table 11.4). All these upper airway muscles show phasic bursts synchronous with inspiratory intercostal muscles (external intercostal and diaphragmatic activities). The coordinated activity of these upper airway dilator muscles by generating opposing forces to counter the collapse of upper airway (resulting from negative subatmospheric pharyngeal pressure induced by diaphragmatic contraction) maintains upper airway patency [130, 131, 144] for a smooth performance of normal breathing. The upper respiratory tract subserves both respiratory and nonrespiratory functions [145]. In experimental studies in cats, pharyngeal motor neurons in the vagus and glossopharyngeal nerves were found to be located in the medulla, overlapping the medullary respiratory neurons [146]. The experimental study by Bianchi et al. [147] demonstrated that, after changes induced by chemical stimuli (normocapnic hypoxia and normoxic hypercapnia), pharyngeal motor activities are more sensitive than phrenic nerve activation. The influence of sleep on respiratory muscle function has been reviewed by Gothe et al. [148] and Horner [130, 131].

Nasal Muscles

The compressor and dilator naris, and alae nasi muscles are the most rostral part of the upper airway secondary respiratory muscles. EMG recordings have been shown that the phasic inspiratory activation of the alae nasi muscles precedes the onset of airflow and diaphragmatic activation during wakefulness and sleep, and this interval is increased during NREM sleep [144]. This asynchrony in susceptible individuals may contribute to upper airway collapse during sleep [144]. The phasic alae nasi inspiratory activity is maintained, although decreased, during apneic episodes in OSA. Nasal CPAP is shown to reduce EMG muscle tone in the alae nasi suggesting that nasal CPAP may open the upper airway passively [127].

Genioglossus Muscle

This is the principal tongue muscle and has been studied best to show its role in OSA. The genioglossus and geniohyoid muscles are mainly responsible for forward displacement of the tongue (protrusion), whereas three other tongue muscles (Table 11.4) are responsible for backward displacement of the tongue (retrusion). EMG recordings can be obtained by intramuscular electrodes percutaneously via a submental or transoral approach or by submental surface electrodes which may record additional activation from the neighboring muscle (e.g., mylohyoid, anterior belly of the digastric, hyoglossus and geniohyoid) [144]. Genioglossal EMG activities consist of phasic inspiratory bursts and variable tonic discharges [137, 139, 144], which are mildly decreased during NREM sleep but markedly decreased during REM sleep [144–153]. In OSA patients, this sleep-dependent hypotonia of the tongue may be responsible for backward displacement of the tongue partially or completely against the posterior pharyngeal wall causing apnea or hypopnea in an anatomically compromised posterior airway. Thus, the genioglossus muscle plays an important role in upper airway OSAS. In OSA patients, genioglossal muscle tone is increased during wakefulness as a compensatory measure.

Selective reduction of genioglossal or hypoglossal nerve activity (i.e., disproportionately more reduction than the diaphragmatic or phrenic activities) has been noted with alcohol, diazepam, and many anesthetic agents [149]. Conversely, protriptyline and strychnine selectively increase such activity [150].

Palatal Muscles

Levator veli palatini and palatoglossus muscles in humans show phasic inspiratory and tonic expiratory activities [154, 155], but tensor veli palatini muscle shows tonic activity during both inspiration and expiration in wakefulness and sleep [156, 157]. During sleep in normal individuals, palatal muscles (palatoglossus, tensor veli palatini, and levator veli palatini) show decreased tone causing increased upper airway resistance and decreased airway space.

Masseter Muscle

Masseter contraction closes the jaw and elevates the mandible. In sleep apnea patients, masseter activation is present during eupneic episodes but decreased during apneic ones. Masseter EMG activity decreases immediately before the apnea, is absent during the early part of the episode, and increases at the end of the apneic period [158]. Based on experiments using chemical stimuli, Suratt and Hollowell [158] concluded that masseter activity can be increased by hyperoxic hypercapnia and inspiratory resistance loading. It appears that phasic EMG bursts start in the masseter at the same time as in the genioglossus and the diaphragm. Suratt and Hollowell [158] did not find phasic activity in masseter muscle in normal subjects during regular breathing, but

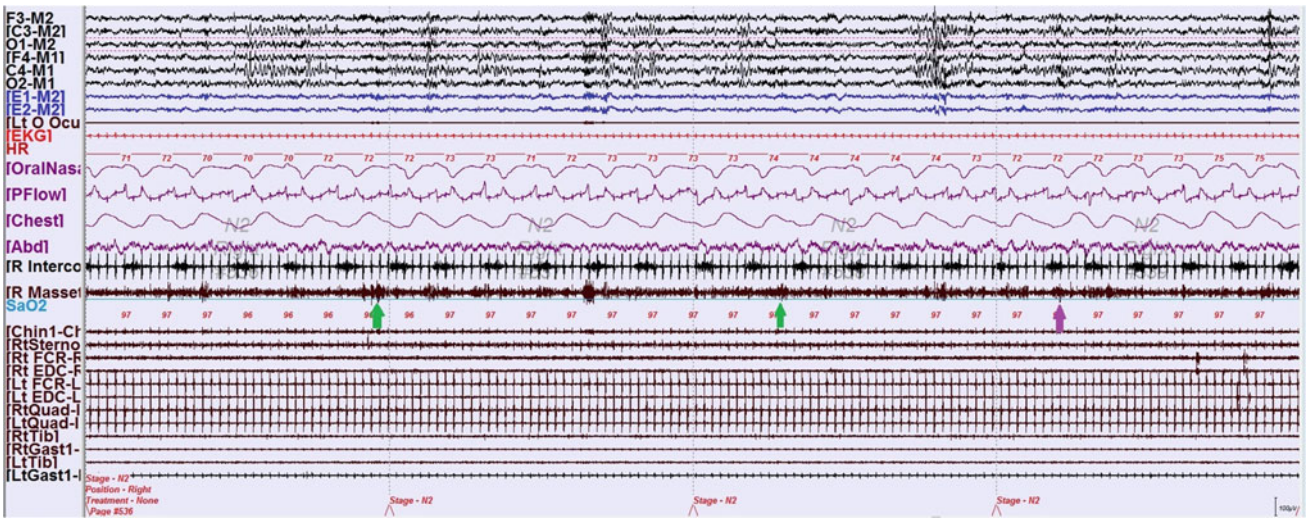

Fig. 11.9 A 120-s epoch from polysomnogram of a year-old healthy subject showing muscle bursts in the surface electromyographic (*EMG*) recording from right (R) masseter muscle during stage N2. EMG bursts are seen during both expiratory (*green arrows*) and inspiratory (*purple arrow*) phases but more frequently seen during expiration. *Top six channels* Electroencephalogram (international nomenclature); *E1-M2* and *E2-M2* Left and right electro-oculogram; *Lt O ocu* left orbicularis oculi; *EKG* Electrocardiogram; *Hr* Heart rate; *Oral Nas* Oronasal thermistor *PFlow* Nasal pressure transducer, *chest and Abd* Chest and abdominal respiratory effort channels; *R Interco* right external intercostal (inspiratory) EMG channel; *R masse* right masseter muscle; SaO_2 arterial oxygen saturation by finger oximetry; *Chin 1-Chin 2* submental EMG; *R sterno* right sternocleidomastoideus EMG; *Rt FCR* right flexor carpi radialis EMG; *Rt EDC* right extensor digitorum communis EMG; *Lt FCR* left flexor carpi radialis EMG; *Rt Quad* right quadriceps EMG; *Lt Quad* left quadriceps; *Rt Tib* right tibialis anterior EMG; *Rt Gast* right gastrocnemius EMG; *Lt Tib* Left tibialis anterior EMG; *Lt Gast* left gastrocnemius EMG

noted such activity during inspiratory stimulation such as inspiratory resistance loading or hypercapnia. In sleep apnea patients, spontaneous phasic masseter activity was noted during regular breathing. Using surface electrodes, the present author has documented phasic respiratory bursts in masseter muscle in normal subjects and those without sleep apnea (Fig. 11.9) [unpublished observation].

Intrinsic Laryngeal Muscle Activity

Intrinsic laryngeal muscles, controlled by the brain stem neuronal mechanism, play an important role in the regulation of breathing [159–161]. In addition, the larynx participates in phonation, deglutition, and airway protection [160]. The posterior cricoarytenoid (PCA) muscle is the main vocal cord abductor. Laryngeal EMG can be performed by placing hooked wire electrodes percutaneously through the cricothyroid membrane [161].

PCA demonstrates phasic inspiratory bursts in normal subjects during wakefulness and NREM sleep [159]. In addition, there is tonic expiratory activity in wakefulness that disappears with NREM sleep. In REM sleep, PCA EMG shows fragmented inspiratory bursts and variable expiratory activity. During isocapnic hypoxia and hyperoxic hypercapnia, normal subjects show increased phasic inspiratory PCA activity but minimal increase in tonic expiratory activity [159].

Hyoid Muscles

Suprahyoid muscles (those inserted superiorly on the hyoid bone) include the geniohyoid, mylohyoid, hyoglossus, stylohyoid, and digastric muscles [162]. Infrahyoid muscles (those that insert inferiorly) include the sternohyoid, omohyoid, sternothyroid and thyrohyoid muscles [162]. The size and shape of the upper airways can be altered by movements of the hyoid bone. Motor neurons supplying these muscles are located in the pons, the medulla, and the upper cervical spinal cord. The hyoid muscles show inspiratory bursts during wakefulness and NREM sleep that are increased by hypercapnia. The relative contribution of hyoid, genioglossus, and other tongue muscles in the maintenance of pharyngeal patency needs to be clarified [162].

It is important to understand central neuronal mechanisms and the contributions of neuromodulators and neurotransmitters involved in sleep-related suppression of pharyngeal muscle activity [130, 131]. This knowledge will help in designing treatment for upper airway OSAS.

Mechanism of Mild Muscle Hypotonia in NREM Sleep

Mild muscle hypotonia in NREM sleep appears to result from a combination of disfacilitation of brain stem motor

neurons controlling muscle tone (e.g., mild reduction of activity of locus ceruleus noradrenergic and midline raphe serotonergic neurons) and slight hyperpolarization of brain stem and spinal motor neurons [163]. In addition, there is a direct cerebral cortical mechanism to explain mild muscle hypotonia in NREM sleep, as evidenced by significant enhancement of intracortical inhibition during slow-wave sleep (SWS) after paired-pulse transcranial magnetic brain stimulation [164]. Intracellular microelectrode recording of motor neurons at the onset of NREM sleep by Chase and collaborators [163] clearly showed either no change in membrane potential or a slight hyperpolarization. It should be remembered that the resting membrane potential is determined by an unequal distribution of ions on the outside and the inside of the membrane and by differential permeabilities of the concentration of the sodium, potassium, and chloride ions.

Mechanism of Muscle Atonia or Hypotonia in REM Sleep (See also Chap. 39)

REM sleep is characterized by almost complete cessation of voluntary muscle tone in the presence of a highly active forebrain (paralyzed body with an activated brain) with inhibition of the mesencephalic locomotor region. This is nature's way of preventing abnormal movements during REM sleep in the presence of highly active cerebral cortex and forebrain regions. The dorsal pontine tegmentum appears to be an important central region responsible for limb muscle atonia in REM sleep [78, 165–167]. Muscle atonia during REM sleep is initiated during activation of a polysynaptic descending pathway from the peri–locus ceruleus alpha in the region of the nucleus pontis oralis to the lateral tegmentoreticular tract, the nucleus gigantocellularis and magnocellularis in the ventral region of the medial medullary reticular formation (the inhibitory region of Magoun and Rhines) [165, 166], and finally, the ventral tegmentoreticular and reticulospinal tracts to the alpha motor neurons causing hyperpolarization and muscle atonia (Fig. 11.3) [167–170]. During REM sleep, an increased number of c-Fos (a nuclear protein synthesized during neuronal activation) labeled cells were detected by immunocytochemical techniques in the inhibitory region of Magoun and Rhines. A key element in the REM sleep-generating mechanism in the pons is the activation of γ-aminobutyric acidergic (GABAergic) neurons located in a subgroup of the pontine reticular formation (sublaterodorsal nucleus [SLD]) as well as GABAergic neurons in the ventrolateral periaqueductal gray region in the mesencephalon [167, 170, 171]. An activation of GABAergic neurons causes excitation or disinhibition of cholinergic neurons, and inhibition of noradrenergic and serotonergic neurons, in the pons. The cholinergic neurons, in turn, excite pontine glutamatergic neurons projecting to the glycinergic premotor neurons in the medullary reticular formation, causing hyperpolarization of the motor neurons and muscle paralysis during REM sleep. This GABAergic mechanism also plays an important role in motor neuron hyperpolarization (see later). Based on more recent study Luppi et al. [171] concluded that REM-on SLD neurons are predominantly glutamatergic. Ventral SLD sends both direct and indirect projections via the ventromedial medulla to brain stem and spinal motoneurons causing hyperpolarization of these neurons using GABA and glycine inhibitory neurotransmitters. During REM sleep, there is also disfacilitation of motor neurons as a result of reduction of the release of midline raphe serotonin and locus ceruleus noradrenaline partially contributing to muscle atonia. Additional contribution to REM atonia comes from lateral hypothalamic hypocretinergic neurons (see further on). Finally, a cerebral cortical mechanism may also contribute to the inhibition of spinal motor neurons in REM sleep, as evidenced by decreased intracortical facilitation in the paired-pulse transcranial magnetic brain stimulation techniques [164].

In summary, there are four fundamental mechanisms responsible for muscle atonia in REM sleep: inhibitory postsynaptic potentials (IPSPs) causing postsynaptic inhibition of motor neurons (major mechanism); disfacilitation (i.e., a reduction of excitation) of presynaptic spinal excitatory neurons; disfacilitation of brain stem and spinal motor neurons controlling muscle tone; and decreased intracortical facilitation (e.g., paired-pulse brain magnetic stimulation technique). During wakefulness and NREM sleep, there are a few spontaneously occurring low-amplitude IPSPs, but during REM sleep, in addition to an increase in these low-amplitude IPSPs, high-amplitude REM sleep-specific IPSPs are noted. These are generated by sleep-specific inhibitory interneurons located mainly in the brain stem (immunocytochemical techniques are used to prove this observation) that send long-projecting axons to the spinal cord and short axons to the brain stem motor neurons [165–170]. As a result of these IPSPs, motor neurons are hyperpolarized by 2–10 mV during REM sleep. Intracellular recordings reveal increased number and appearance of REM sleep-specific IPSPs in the lumbar motor neurons of cats [163, 172–176]. Thus postsynaptic inhibition of motor neurons is responsible for the atonia of somatic muscles, as evidenced by intracellular recordings of spinal motor neurons in chronic spinal preparations of cats. These potentials are derived from inhibitory interneurons, possibly located either in the spinal cord or in the brain stem, from which long axons project to the spinal motor neurons [165, 174, 176]. In addition, there is also postsynaptic inhibition causing a decrease in the Ia monosynaptic excitatory postsynaptic potentials (EPSPs), resulting in motor neuron

hyperpolarization. Lesions of the dorsal pontine tegmentum abolish muscle atonia of REM sleep [173–179]. Similar episodes of REM sleep without muscle atonia have also been observed in cats with localized lesions in the ventromedial medulla [180].

Intermittently during REM sleep, there are excitatory drives causing motor neuron depolarization shifts as a result of EPSPs [163, 173–176]. Muscle movements caused by these excitatory drives during REM sleep are somewhat different from the movements noted during wakefulness. These movements are abrupt, jerky, and purposeless. EPSPs during REM sleep reflect increased rates of firing in the motor facilitatory pathways during REM sleep. Enhanced IPSPs during REM sleep check these facilitatory discharges, thus balancing the motor system during this activated brain state; otherwise the blind, unconscious subject will jump out of bed, as may happen in pathologic conditions such as REM sleep behavior disorders [163, 181]. Facilitatory reticulospinal fibers are responsible for transient EPSP phasic discharges causing muscle twitches in REM sleep. Corticospinal or rubrospinal tracts are not responsible for these twitches because Pompeiano showed in 1967 that destruction of these fibers in cats [182] did not affect these twitches.

What neurotransmitters drive these IPSPs? Glycine, a major inhibitory neurotransmitter, was originally thought to be the only driving force. The elegant work by Chase and Morales [163, 183] suggested that glycine is the main neurotransmitter responsible for motor neuron hyperpolarization and IPSPs. The REM sleep-specific IPSPs are reversed after strychnine (a glycine antagonist) administration by microiontophoretic application into the ventral spinal cord [163]. In contrast, picrotoxins and bicuculline (a GABA A antagonist) did not abolish these IPSPs. Recent evidence, however, suggests an important contribution by GABA in addition to glycine [184–189]. Brooks and Peever [188, 189] have shown in their experimental studies in rats that GABA A, GABA B and glycine receptors play a role in mediating REM muscle atonia. It is notable that, in the experiments by Chase and Morales, although the GABA antagonist picrotoxin did not reverse REM sleep-related IPSPs, it reduced the IPSP duration considerably. According to Nitz and Siegel [190, 191], there is a selective GABAergic inhibition of noradrenergic and serotonergic neurons during REM sleep accounting for cessation of discharge of these aminergic cells. As a result of this cessation, there is disfacilitation of motor neurons. GABA may also have a direct inhibitory effect on interneurons and motor neurons. Experimental studies in rats by Besnard et al. [192] and Kubin [193] also provided evidence of wakefulness-related serotonergic and noradrenergic excitatory drive to hypoglossal neurons and withdrawal (disfacilitation during REM sleep).

What is the role of hypocretin in REM motor atonia? Hypocretinergic neurons located in the lateral hypothalamus play a facilitatory role in the motor system by direct projections to the motor neurons and indirectly through projections to the monoaminergic, and cholinergic neurons [163, 194–197]. Hypocretinergic neurons also project to REM generating reticularis pontis oralis nucleus (REM-on) in the Pons and to REM-off neurons in the Pons to suppress REM sleep [198]. Hcrt neurons facilitate motor activity during wakefulness but enhance motor inhibition during REM sleep. There is withdrawal of Hcrt activation of the locus ceruleus noradrenergic and midline raphe serotonergic neurons during REM sleep, as well as withdrawal of Hcrt activation of the spinal motor neurons causing disfacilitation of these brain stem and spinal motor neurons contributing to muscle atonia.

REM Sleep-Related Alterations in Respiratory Muscle Activity

During REM sleep, activity of upper airway muscles and the diaphragm is reduced. Three types of REM sleep-related alterations in the respiratory muscles have been described [199]:

1. *Atonia* of EMG activity throughout the REM sleep period is found. Somatic muscles characteristically show this response, which is related to glycine as well as GABA-mediated postsynaptic inhibition of motor neurons [163, 173–176, 188, 189, 200].
2. Rhythmic activity of the diaphragm persists in REM sleep, but certain diaphragmatic motor units cease firing. Kline et al. [201] described *intermittent decrement of diaphragmatic activity* during single breaths. Upper airway muscles also show similar changes.
3. *Fractionations of diaphragmatic activity* refer to pauses lasting 40–80 ms and occur in clusters correlated with pontine-geniculate-occipital waves, which are phasic events of REM sleep [202].

What is the mechanism of muscle atonia in the upper airway muscles during REM sleep? Postsynaptic inhibition of motor neurons during REM sleep as described previously is a critical mechanism mediating suppression of hypoglossal motor neurons during REM sleep. Kodama et al. [184], Nitz and Siegel [190, 191] as well as Brooks and Peever [188, 189] suggested that both glycine and GABA play important roles in the regulation of upper airway and postural muscles. A combination of decreased monoamines (e.g., noradrenaline and serotonin) and increased GABA release in the motor neuron pools may be involved in the REM sleep muscle atonia. Fenik et al. [185, 186] as well as

several other authors [192, 193, 203–209] suggested that the suppression of upper airway motor tone, including the genioglossus muscle tone, during REM sleep is caused by withdrawal of excitation mediated by norepinephrine and serotonin. Fenik et al. [185, 186] concluded that suppression of motor activity or muscle atonia of the hypoglossus and other upper airway dilator muscles is caused by all or some of the following mechanisms: the withdrawal of motor neuronal excitation mediated by norepinephrine and serotonin, and increased inhibition mediated by GABA and glycine. In summary, the selective inhibition of monoaminergic and orexinergic (hypocretinergic) systems (disfacilitation) coupled with direct active inhibition of motor neurons by GABA and glycine produces a loss of postural muscle tone.

Summary and Clinical Relevance

There is considerable reduction of the activity of the upper airway dilator muscles during NREM sleep, with further reduction in REM sleep, causing increased upper airway resistance and narrowing of the upper airway space. Increased upper airway resistance, which is noted during sleep in normal individuals, may predispose to upper airway occlusion and OSA in susceptible individuals [100]. The site of the upper airway obstruction in OSA is usually at the level of the soft palate, but in approximately half the patients the obstruction extends caudally to the region of the tongue, with further caudal extension during REM sleep [210–218]. Therefore, decreased tone in the palatal, genioglossal, and other upper airway muscles causing increased upper airway resistance and decreased airway space plays an important contributing role in upper airway obstruction in OSA, particularly because many OSA patients have smaller upper airways than individuals without OSA [210, 219–222]. An understanding of these physiological changes in the genioglossus and other upper airway muscles stimulated successful development of hypoglossal nerve stimulation systems for treatment of OSA patients [223]. As a result of the complex effects of sleep on respiration, there is an overall reduction in ventilation during sleep compared to wakefulness [100]. This may not significantly affect a normal person, but may cause life-threatening hypoxemia and abnormal breathing patterns during sleep in patients with neuromuscular disorders, chronic obstructive pulmonary disease, and bronchial asthma, especially in those with daytime hypoxemia [100]. The chemoreflex control of breathing may vary across patients with OSAS. In patients with an apnea-hypopnea index of greater than 30, Mahmed et al. [224]. have shown a significant overnight increase in chemoreflex sensitivity of 30 %, which is another contributing factor toward destabilization of breathing during sleep in this condition. The circadian changes of mild bronchoconstriction during sleep in normal individuals may be accentuated in patients with asthma, causing a marked decrease in peak flow rate, which may in turn cause severe bronchospasm [100, 127].

In summary, during sleep there is a reduction of metabolism and sympathetic activity as a result of which there is depression of respiration, circulation and other vital functions [225]. Following suggested physiological factors may be responsible for breathing dysfunction in sleep [224, 225]:

1. Reduction of skeletal muscle or upper airway muscle tone;
2. Reduced hypoxic and hypercapnic ventilator response;
3. Loss of the wakefulness stimulus causing functional changes in the CNS and reduced respiratory neuronal drive;
4. Fluctuation of excitatory and inhibitory impulses on breathing during various stages of sleep and transition to sleep;
5. Reduced FRC;
6. Ventilation/perfusion (V/Q) mismatch related to body position.

These physiological mechanisms do not affect normal healthy individuals but may worsen breathing in compromised individuals (e.g., those with narrow upper airway space or altered central ventilator stability [i.e., those with high loop gain]).

Physiological Changes in the Heart and Circulation During Sleep

Physiological changes in the heart during sleep include alterations in HR and cardiac output. Changes in circulation during sleep include changes in BP, peripheral vascular resistance (PVR), and blood flow to various systems and regions [226, 227]. All these cardiovascular hemodynamic changes are controlled by the ANS. Briefly, sympathetic inhibition is associated with a decrease in BP and HR during NREM sleep, whereas in REM sleep, intermittent activation of the sympathetic system accounts for rapid fluctuations in BP and HR [38].

Heart Rate

The HR decreases by 5–8 % during NREM sleep and shows frequent upward and downward swings during REM sleep [18, 20, 227–236]. Bradycardia during NREM sleep results from a tonic increase in parasympathetic activity (sympathectomy has little effect) [18, 230, 231]. Bradycardia

persists during REM sleep and becomes intense owing to tonically reduced sympathetic discharge. Phasic HR changes (bradytachycardia) during REM sleep are due to transient changes in both the cardiac sympathetic and parasympathetic activities. [18, 228–231]. Thus parasympathetic activity predominates during sleep, and an additional decrease with intermittent increase in sympathetic activity is observed during REM sleep.

In several studies, the HRV during sleep stages has been documented after spectral analysis [20, 231–233, 235]. The documentation of the HF component of the electrocardiogram clearly indicates the prevalence of parasympathetic activity during both NREM and REM sleep. These studies also show intermittent increases of LF components in the electrocardiogram, indicating intermittent sympathetic nervous system activation during REM sleep. Studies also show that the HR acceleration occurs at least 10 beats before EEG arousal [231].

The effect of sleep on cardiac rhythm has been studied in healthy individuals using Holter monitor (see Chap. 47).

Cardiac Output

Cardiac output falls progressively during sleep, with the greatest decrement occurring during the last sleep cycle, particularly during the last REM sleep cycle early in the morning [228, 237]. This may help explain why normal individuals and patients with cardiopulmonary disease are most likely to die during the hours of early morning (see Chap. 47). Maximal oxygen desaturation and periodic breathing are also noted at this time.

Systemic Arterial Blood Pressure

BP falls by approximately 5–14 % during NREM sleep and swings up and down during REM sleep with an overall increase by about 5 % above that noted in NREM sleep. There is a sharp rise in BP around the time of awakening [228, 229, 238–240]. These changes are related to alterations in the ANS [18]. Coote [241] concluded that the fall in BP during NREM sleep was secondary to a reduction in cardiac output, whereas the BP changes during REM sleep resulted from alterations in cardiac output and PVR.

Pulmonary Arterial Pressure

Pulmonary arterial pressure rises slightly during sleep. During wakefulness, the mean value is 18/8 mm Hg; that during sleep is 23/12 mm Hg [242].

Baroreflex Function

There is alteration of baroreflex function, measured indirectly by BRS during sleep as described above.

Peripheral Vascular Resistance

During NREM sleep, PVR remains unchanged or may fall slightly, whereas in REM sleep there is a decrease in PVR due to vasodilation, of the Splanchnic vessels [228, 243, 244].

Systemic Blood Flow

Cutaneous, muscular, and mesenteric vascular blood flow shows little change during NREM sleep, but during REM sleep, there is profound vasodilation resulting in increased blood flow in the mesenteric and renal vascular beds [36–39, 228, 244, 245]. However, there is vasoconstriction causing decreased blood flow in the skeletal muscular and cutaneous vascular beds during REM sleep [36–39, 244]. Mullen et al. [246] reported a decrease of plasma renin activity (PRA) in humans during REM sleep, which indirectly suggests increased renal blood flow.

Cerebral Blood Flow

Cerebral blood flow (CBF) and cerebral metabolic rate for glucose and oxygen decrease by 5–23 % during NREM sleep, whereas these values increase to 10 % below up to 41 % above the waking levels during REM sleep [247–255]. These data indirectly suggest [247, 255] that NREM sleep is the state of resting brain with reduced neuronal activity, decreased synaptic transmission, and depressed cerebral metabolism, both glucose and brain oxygen metabolism. CBF is noted to be lower in NREM than in REM sleep, lower at the end of the night compared with that at the beginning of the night, and lower in postsleep wakefulness than presleep wakefulness [255]. Cerebral metabolic rate for oxygen and glucose also decreases in postsleep wakefulness and toward the end of the night compared with the values noted in presleep wakefulness and the beginning of the night [255]. This decreased metabolism, reduced CBF, and reduced anaerobic glycolysis (i.e., there is a greater decrease in glucose utilization compared with oxygen utilization) all support restorative functions of sleep [255].

In the last decade, Maquet and his group (see also Chap. 21) and others[256–274] have made significant contributions using positron emission tomography with [^{15}O]-labeled water or [^{18}F]fluorodeoxyglucose and functional

magnetic resonance imaging (MRI) to understand the functional neuroanatomy in normal human sleep. These studies have shown major differences of brain activation during wakefulness, NREM sleep, and REM sleep. During NREM sleep, there is a global decrease in CBF with a regional decrement of CBF in the dorsal pons, mesencephalon, thalami, basal ganglia, basal forebrain, anterior hypothalamus, prefrontal cortex, anterior cingulate cortex, and precuneus [263–265]. These studies confirmed in humans the existence of brain stem–thalamocortical circuits responsible for the NREM sleep-generating mechanisms and correlate with the electrophysiological findings of hyperpolarization of thalamic neurons with generation of sleep spindles, K complexes, and delta and very slow oscillations [260, 265]. The pattern of deactivation in NREM sleep is not homogeneous. The least active areas in NREM sleep were noted in the dorsolateral prefrontal (DLPF) and orbito-frontoparietal and, less consistently, the temporal and insular regions [257, 260, 264]. The primary cortices are the least deactivated areas [264]. However, recent advances in neuroimaging techniques capturing images with higher spatial and temporal resolution have shown that NREM sleep state may not particularly be a state of brain quiescence. Using simultaneous EEG/ event-related functional magnetic resonance imaging (fMRI), Macquet and his group [274, 275] have detected regionally specific increase in activities during SWS in brain stem, cerebellum, ventral prefrontal cortex, posterior cingulate cortex/precuneus and parahippocampal areas in addition to areas generating fast and slow spindles. These findings suggest that during NREM sleep, brain is actively involved in generating synchronized slow waves and spindles which have important implications for memory processing.

In contrast, REM sleep represents an active brain state with increased neuronal activity and increased metabolism. The largest increases during REM sleep are noted in the hypothalamus and the brain stem structures, and the smallest increases are in the cerebral cortex and white matter. REM sleep is characterized by increased neuronal activity, energy requirements, and CBF with regional activations in the pontine tegmentum, thalamus, amygdala, anterior cingulate cortex, hippocampus, temporal and occipital regions, basal forebrain, cerebellum, and caudate nucleus [274]. In contrast, there is regional deactivation in the DLPF, posterior cingulate gyrus, precuneus, and inferior parietal cortex [256, 264, 266]. REM sleep-related activation of the pontine tegmentum, thalamic nuclei, and basal forebrain supports the REM sleep-generating mechanisms in these regions [270]. An activation of limbic and paralimbic structures including the amygdala, hippocampal formation, and anterior cingulate cortex supports the modulatory role of these structures during REM sleep during generation of pontine-geniculate-occipital waves, a major component of phasic REM sleep and HRV in REM sleep [263], and participation of REM sleep in memory processing. REM sleep also showed regional deactivation in the DLPF, precuneus, posterior cingulate cortex, temporoparietal region, and inferior parietal lobule [256, 264, 273, 274].

In the resting state, there are intense neuronal activities both in wakefulness and sleep that can be detected in fMRI as fluctuations of the blood oxygen level-dependent (BOLD) fMRI. These resting state networks (RSN) in sleep and wakefulness showing spontaneous fluctuating neuronal activities suggest that these RSN play an important role in synaptic homeostasis and brain function [276–278].

There are three mechanisms controlling CBF [279]: cerebral autoregulation, cerebral metabolism, and respiratory blood gases (arterial PO_2 and arterial PCO_2). Cerebral autoregulation is determined by the intrinsic properties of the muscles of the cerebral arterioles. Cerebral autoregulation is normally maintained between the mean systemic arterial pressures of 150 and 60 mm Hg [279]; as the systemic BP falls, cerebral blood vessels dilate in response to changes in transmural pressure, whereas in cases of a rise in BP, the cerebral vessels constrict, thus protecting the brain from fluctuations in systemic BP. This systemic autoregulation may break down in disease states such as stroke, encephalitis, hypertensive crisis, acute head injury, and excessive antihypertensive therapy [279].

There is circadian variation in BP: a reduction during sleep and an increased awakening [280, 281]. Dipping of BP of 10–20 % during sleep compared to mean awake daytime values is physiologic, and these individuals are called "dippers" [280, 281]. There are certain individuals in whom the nocturnal systolic BP during sleep does not fall below 10 % of baseline waking value, and they are known as "nondippers". There are also individuals known as "reverse dippers" ("risers") in whom BP does not drop but actually increases during sleep periods. Those individuals considered "extreme dippers," in whom BP falls excessively, as well as nondippers and reverse dippers, are at higher risk for stroke than dippers [280–283]. Finally, both hypercapnia and hypoxia would cause vasodilation, with hypercapnia causing stronger vasodilation in the cerebral circulation.

Summary and Clinical Implications

These hemodynamic changes in the cardiovascular system result from alterations in the ANS [10, 12, 18, 46, 241]. In general, parasympathetic activity predominates during both NREM and REM sleep and is most predominant during

REM sleep. In addition, there is sympathetic inhibition during REM sleep. The sympathetic activity during REM sleep is decreased in cardiac, renal, and splanchnic vessels but increased in skeletal muscles, owing to an alteration in the brain stem sympathetic controlling mechanism. Furthermore, during phasic REM sleep, BP and HR are unstable owing to phasic vagal inhibition and sympathetic activation resulting from changes in brain stem neural activity. HR and BP therefore fluctuate with up and down swing of the BP and HR during REM sleep. Because of these hemodynamic and sympathetic alterations during REM sleep, which is prominent during the last third of total sleep in the early hours of the morning, increased platelet aggregability, plaque rupture, and coronary arterial spasm could be initiated, possibly triggering thrombotic events causing myocardial infarction, ventricular arrhythmias, or even sudden cardiac death [282–285] (see Chaps. 11 and 47). As stated previously, those patients who are nondippers, extreme dippers, and reverse dippers are at higher risk for cardiovascular or cerebrovascular events causing infarctions and periventricular hyperlucencies on MRI. Meta-analysis of epidemiologic studies provides support to the circadian variation in cardiovascular and cerebrovascular events, with the highest rates of events occurring during the early morning hours [284, 285].

Gastrointestinal Physiology During Sleep

A brief summary of the physiology of the gastrointestinal tract during sleep is given in this section. For a more detailed discussion, readers are referred to the writings of Orr [286–289]. Gastrointestinal changes include alterations in gastric acid secretion, gastric volume and motility, swallowing, and esophageal peristalsis and intestinal motility (Table 11.3).

Studying the physiology of the gastrointestinal system has been difficult traditionally because of the lack of adequate technique. Techniques as well as facilities for making simultaneous polysomnographic (PSG) recordings are now available, allowing study of the alterations in gastrointestinal physiology during different stages of sleep. Before the advent of these techniques, scattered reports generally showed decreased motor and secretory functions during sleep. Subsequent methods have produced better and more consistent results, although findings are still somewhat contradictory overall. There is a dearth of adequate studies using PSG and other modern techniques to understand the physiological alterations of gastrointestinal motility and secretions during sleep. The activity of the gastrointestinal tract is controlled by the ANS and the enteric nervous system which is an intrinsic system within the walls of the visceral organs that work closely with the ANS.

Esophageal Function

There are profound alterations in esophageal function during sleep [289–292]. Gastroesophageal reflux (GER) is the most common upper gastrointestinal problem. GER occurs most commonly postprandially during wakefulness, but also occurs during sleep but is less frequent. The availability of the method to measure GER during sleep by 24-h esophageal pH monitoring [293] has advanced our understanding of esophageal function and swallowing during sleep. Waking reflux events are rapidly cleared within 1–2 min, whereas sleep reflux events persist longer, causing longer acid contact. Sleep alters normal response to acid mucosal contact [294]. During wakefulness GER causes increased salivary flow and increased swallowing with the complaints of heartburn. In contrast, during sleep salivary flow and swallowing are considerably decreased, causing prolongation of acid mucosal contact. This predisposes to development of esophagitis, for which there are two other factors: decreased esophageal peristalsis in sleep, particularly SWS, and proximal migration of gastric contents in the distal part of the esophagus [289]. The refluxed acid contents are harmful not only to the esophagus but also to the tracheobronchial tree [286–289, 295].

There are two esophageal sphincters, the upper esophageal sphincter (UES) and the lower esophageal sphincter (LES), acting as barriers to reflux. The third barrier is the epiglottis [295]. The LES is the primary barrier to GER, and both the UES and the LES act as barriers to pharyngoesophageal reflux [289, 295, 296]. In a recent paper, Eastwood et al. [297] simultaneously monitored the functions of the LES and UES during PSG studies in 10 normal volunteers and found a decrement of UES pressure during SWS, particularly in the expiratory phase of breathing. In contrast to other investigators [289, 295, 298], Eastwood et al. [297] did not find an alteration of LES pressure. UES pressure is generated mainly by the cricopharyngeus and to a certain extent by inferior pharyngeal constrictor muscles. LES pressure is generated by contractions of the esophageal smooth muscles and the diaphragm. Pandolfino et al. [298] studied 15 normal subjects using a solid-state high-resolution manometry recording from the hypopharynx to the stomach with simultaneous measurement of lower esophageal pH. These authors noted that the majority of postprandial transient LES relaxations were associated with brief periods of UES relaxations.

The relationship of GER and sleep is reciprocal: sleep affects GER and GER in turn affects sleep. Sleep-related prolonged esophageal acid clearance and acid-mucosa contact result from several sleep-related physiological alterations, which include decreased salivary production and swallowing as well as decreased conscious perception of

heartburn and arousal, and delayed gastric emptying [286–289]. In normal individuals who experience episodes of GER, there is generally a reduction in LES pressure [286–289, 295, 296]. Lipan et al. [299] postulated that reflux may advance to the laryngopharynx and into the nasopharynx and paranasal sinuses as a result of a laryngopharyngeal reflux. These authors suggested that breakdown of the following barriers to reflux may cause the laryngopharyngeal reflex: the LES and UES, esophageal motility, esophageal acid clearance, and pharyngeal and laryngeal mucosal resistance. This suggestion is in agreement with that of Orr [295].

Gastric Acid Secretion

During wakefulness, gastric acid secretion depends on food ingestion, increased salivation, and the activity of the gastric vagus nerve. Moore and Englert [300] and Orr [289, 295] showed a clear circadian rhythm for gastric acid secretion in humans. Moore and Englert [300] noted peak gastric acid secretion between 10:00 P.M. and 2:00 A.M. in patients with duodenal ulcer. Figure 11.10 (adapted from Moore and Halberg [301]) schematically shows mean 24-h values for gastric acid secretion in patients with peptic ulcer and normal controls. Acid secretion increases in these patients considerably during the day and at night [302, 303]. The importance of vagal stimulation for the control of circadian oscillation of gastric acid secretion has been demonstrated by the absence of circadian rhythm for gastric acid secretion following vagotomy [304].

Several studies have attempted to understand gastric acid secretion during different stages of sleep, but the results have not been consistent because of methodological flaws and cumbersome techniques [289, 290, 301–308]. An important study was made by Orr et al. [308], who examined five duodenal ulcer patients for five consecutive nights using PSG technique and continuous aspiration of gastric contents. They found no relationship between acid secretion and different stages of sleep or REM versus NREM sleep. The most striking finding was failure of inhibition of acid secretion during the first 2 h of sleep, a result that agrees with the previous study by Levin and associates [302].

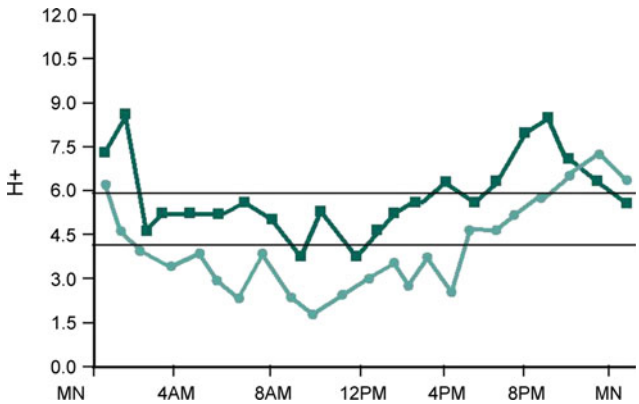

Fig. 11.10 Mean 24-h values for gastric acid secretion from patients with active peptic ulcer disease (*dark blue rectangles*) and normal controls (*light blue circles*) shown schematically. The ordinate shows hydrochloric acid (H^b) secretion in milliequivalents (Adapted from Moore and Halberg [301])

Gastric Motility

Findings regarding gastric motility have been contradictory. Both inhibition and enhancement of gastric motility have been noted during sleep [289–292]. Finch et al. [309] showed that gastroduodenal motility during sleep was related to sleep-stage shifts and body movements. Orr [286, 289] reported that, although no definite statement regarding gastric motility can be made, there seems to be overall inhibition of gastric motor function during sleep.

Intestinal Motility

Although methods are now available to accurately measure intestinal motility, the results of motility studies during sleep are contradictory [286, 288, 289]. A special pattern of motor activity, called *migrating motor complex* (MMC), recurs every 90 min in the stomach and small intestine [310, 311]. This periodicity of the gut motor activity is similar to the cyclic REM-NREM sleep. In fact, a circadian rhythm in the propagation of the MMC has been documented with the slowest velocity occurring during sleep [312–314]. The MMC distribution among REM sleep and NREM sleep stages are random without any consistent relationship, although MMS is modulated by sleep [310]. During both nocturnal and diurnal sleep, MMC cycle length and duration showed a significant reduction [310]. Specifically, the MMC and REM cycles are independent. Consistent abnormalities in the MMC in different bowel diseases have not been documented [289].

Orr [289] summarized the studies from the literature to indicate that there is decreased colonic motility in the transverse, descending, and sigmoid colon. Rao and Welcher [315] observed increased periodic rectal motor activity during sleep; the majority of these contractions are propagated in the retrograde direction and, at the same time, the anal canal pressure is consistently above the pressure of the rectum, thus preventing the passive escape of rectal contents during sleep.

Summary and Clinical Relevance

Patients with peptic ulcer disease may have repeated arousals and awakenings as a result of episodes of nocturnal epigastric pain and failure of inhibition of gastric acid secretion that occurs after sleep onset.

Sleep-related GER, by causing marked prolongation of esophageal acid clearance time, may cause mucosal damage giving rise to esophagitis, laryngopharyngitis, pulmonary aspiration, and exacerbation of bronchial asthma [287, 288, 289, 295, 296]. GER includes esophageal syndrome and extraesophageal complications [316]. Several factors are implicated in the pathogenesis of esophageal syndrome [289, 295]: hiatal hernia, reduced LES pressure, prolonged esophageal acid clearance, and delayed gastric emptying. The UES prevents pharyngoesophageal reflux, and thus loss of UES pressure during sleep makes one vulnerable to reflux of esophageal contents into the pharynx and tracheobronchial tree, which is the most dreaded complication of sleep-related GER. It should be noted that OSAS also predisposes to nocturnal GER disease. Orr et al. [317] have clearly shown that sleep is a significant risk factor for acid migration to the proximal esophagus with prolongation of the acid clearance time, contributing to the extraesophageal complications of reflux such as laryngopharyngitis and pulmonary aspirations.

Patients with functional bowel disorders (e.g., irritable bowel syndrome) have increased sleep complaints, but their sleep architecture does not differ from normal controls [289]. The actual mechanism of sleep disturbance in dysfunctional bowel disorders remains to be determined. Finally, Orr [289] suggested that alterations of the periodic rectal motor contractions and anal canal pressure during sleep in sleeping individuals with diabetes may explain the loss of rectal continence in this condition.

Thermal Regulation in Sleep

Changes in Body Temperature and Circadian Rhythm (See also Chap. 8…)

That body temperature follows a circadian rhythm independent of the sleep–wake rhythm [318] has been demonstrated in experiments involving desynchronization and resynchronization of human circadian rhythms. It has been shown that, when all environmental cues (*zeitgebers*) are removed, the endogenous rhythms are freed from the influence of exogenous rhythms and a free-running rhythm ensues. During this time, it is clear that body temperature has a rhythm independent of the sleep–wake rhythm (Fig. 11.11) [319]. Nevertheless, body temperature has been linked intimately to the sleep–wake cycle [320, 321]. Body temperature begins to fall with the onset of sleep, and the lowest temperature is noted during the third sleep cycle [322].

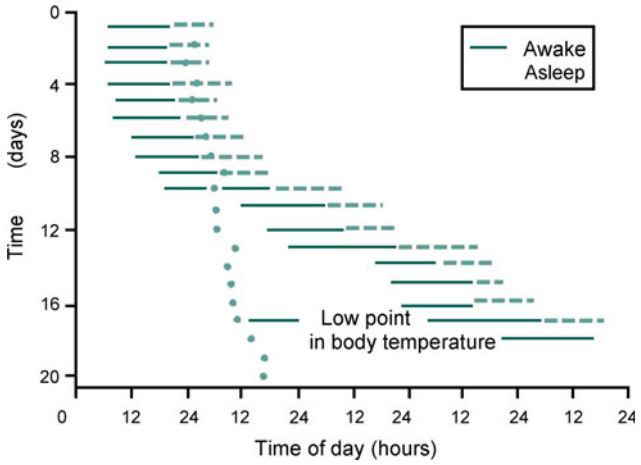

Fig. 11.11 Synchronized (light-entrained) and desynchronized (free-running) rhythms in a person showing dissociation between body temperature and sleep-activity cycles (Reproduced with permission from Aschoff [319])

Role of REM Sleep in Thermal Regulation

During REM sleep, the thermoregulating mechanism appears to be inoperative [320, 323, 324]. Body temperature increases during REM sleep, and cyclic changes in the temperature occur throughout this period. Thermoregulatory responses such as sweating and panting are noted in NREM sleep but are absent in REM sleep; in fact, animals display a state of poikilothermia during REM sleep. However, Bach et al. [321] stated that in contrast to animals, thermoregulation in adult human is not completely abolished during REM sleep but is simply impaired. Brain temperature rises during REM sleep which may be related to all increase in blood supply to the brain causing depression of brain cooling [325]. Szymusiak and McGinty [326] speculated that REM sleep, by elevating brain temperature or by reversing the cooling trend in SWS, prepares the body for behavioral activation. It should be noted that the loss of thermoregulation in REM sleep is not related to inhibition of motor control but is determined by central integration or thermoafferent pathways, or may be due to both mechanisms [320].

Mechanism of Thermoregulation in Sleep

The function of sleep appears to be energy conservation, as evidenced by a reduction in body temperature and metabolism during sleep, especially NREM sleep [322, 323, 327]. Body temperature follows a sinusoidal rhythm with a peak around

9:00 P.M. and a minimum (nadir) around 5:00 A.M. as a result of circadian rhythmicity [328], which is controlled by the master clock in the suprachiasmatic nucleus (SCN). The neural projections from the SCN to the preoptic nucleus of the anterior hypothalamus (POAH) as well as several other brain structures participating in the regulation of sleep and wakefulness are well documented [329]. The circadian system influences core body temperature and the sleep–wake cycle through these connections. At sleep onset, there is a reduction of core body temperature. Exercise or passive body heating causes a rebound stimulating the homeostatic thermostat, permitting peripheral heat loss by vasodilation with a decline in body temperature at sleep onset. Sleep onset latency is shortened, and SWS is increased by peripheral heat loss (e.g., after a hot bath) [330]. This could also be achieved by simply warming the feet [331, 332]. Thermoregulatory effects are also observed after sedative-hypnotic administration. The somnogenic effects of melatonin [333–335] and the benzodiazepines [336–339] are accompanied by a decrease in core body temperature. In contrast, caffeine and amphetamines decrease sleep propensity and increase body temperature [340]. The question is whether sleep onset affects body temperature or body temperature affects sleep onset. The independent circadian rhythm of body temperature appears to be unrelated to a reduction of motor activities at sleep onset [46, 322]. A reduction of body temperature and peripheral heat loss promote sleep onset and amount of SWS; sleep in turn causes a further decrease in body temperature and increases heat loss, thus consolidating sleep. The body temperature and sleep regulation are therefore interrelated. The thermoregulatory changes function as physiological triggers [318] for sleep onset.

Thermosensitive neurons are located mainly in the GABAergic median preoptic nucleus (MnPN) of the anterior hypothalamus (POAH) which received inputs from the skin and thermosensitive neurons in the brain [341]. MnPn and the ventrolateral preoptic (VLPO) nucleus of the POAH are also responsible for generation of NREM sleep [342]. Thus, POAH region is responsible for both the thermoregulation and NREM sleep. Electrical stimulation of the POAH region will cause cutaneous vasodilation, panting, suppression of shivering and decreased body temperature promoting heat dissipation. A POAH lesion suppresses both NREM sleep and thermoregulation. Physical warming [341, 343] or chemical stimulation [344] of the POAH may initiate sleep onset. In the V POAH, warm-sensitive neurons increase firing rates at sleep onset and decrease the rates at sleep offset [345]. An immunocytochemical study by Sherin et al. [346] showed activation of POAH neurons during sleep. These findings provide evidence for a role of temperature in sleep regulation. The conclusive evidence is provided by the observation of increased firing rates of warm-sensitive neurons in the POAH and other brain areas participating in sleep regulation following application of heat to peripheral skin [345, 346], probably through a neural pathway between the peripheral skin and sleep-regulating regions of the brain. Van Someren [347] proposed a thermoregulatory signaling pathway to the circadian system (SCN) promoting circadian regulation of sleep and body temperature. Gilbert et al. [339] suggested a model to show how thermoregulatory changes (e.g., an increase in peripheral temperature and heat loss or a decrease in core body temperature) trigger sleep–wake-promoting areas of the brain directly or via POAH thermosensitive neurons to initiate and consolidate sleep, taking into consideration also the circadian control of sleep and body temperature via the SCN.

MacFadyen et al. [348] observed increased SWS after 2–3 days of fasting in humans, suggesting that the length of hypometabolism helps conserve energy. As stated previously, the POAH neurons participate in both NREM sleep and thermoregulation. McGinty and Szymusiak [349] also cited evidence in support of this hypothesis: POAH warming will facilitate SWS, whereas lesions will suppress it; microinjections of putative sleep factors into the POAH will promote SWS. Szymusiak and McGinty [326, 350] also hypothesized that the neuronal mechanisms in the POAH regions are responsible for both thermoregulation and SWS generation, and that SWS is essentially a thermoregulatory process. Although thermoregulation and sleep are clearly linked, they are also unquestionably separate (Fig. 11.11) [351].

Clinical Relevance

Changes in thermoregulatory function have been noted in some insomniacs and elderly poor sleepers [352–354]. For example, in patients with sleep-onset insomnia [352], the core body temperature rhythm is delayed, suggesting that these people attempt to initiate sleep before the nocturnal dip in body temperature [339]. Similarly, in elderly poor sleepers, there is advancing of the core body temperature rhythm, indicating that these individuals attempt to sleep after the decline in core body temperature [339, 353] or attenuation of the circadian decline in core body temperature [335]. It has been suggested that age-related impairment of the heat loss mechanism or phase advance in body temperature rhythm may partly explain sleep initiation or maintenance difficulty in the elderly [321]. Therefore, thermal manipulation (e.g., behavior to enhance peripheral heat loss) may improve sleep [321, 355]. People with cold feet (e.g., vasospastic syndrome) with impaired heat loss have also prolonged sleep onset latency [339, 356].

Jet lag and shift work may disrupt this linkage of thermoregulation and SWS generation and change the rhythms of sleep and body temperature, which may cause difficulty in

initiating and maintaining sleep and disorganization of sleep architecture and daytime function [320].

Menopausal hot flashes are thought to be a disorder of thermoregulation initiating within the preoptic anterior hypothalamic area. Woodward and Freedman [357] performed 24-h ambulatory recordings of hot flashes and all-night sleep characteristics on 12 postmenopausal women with hot flashes and 7 without hot flashes to determine the effect of hot flashes on sleep patterns. They found that hot flashes were associated with increased stage 4 sleep and that hot flashes occurring in the 2 h before sleep onset were positively correlated with the amount of SWS. They concluded that the central thermoregulatory mechanism underlying hot flashes may affect hypnogenic pathways, inducing sleep and heat loss in the absence of a thermal load in these patients. Menopausal hot flashes (HFs) have a circadian rhythm peaking in the evening around 6:25 PM [358]. HFs can be measured objectively using sternal skin conductance which measures sweating [358]. HFs triggered by a slight rise of core body temperature are manifested by profuse sweating, feeling of intense heat, peripheral vasodilation and sleep disturbances due in part to estrogen depletion [359]. Awakenings and arousals may be triggered by HFs in the first but not the second half of the night because in the second half of the night, REM sleep dominates impairing thermoregulatory mechanism [358].

It has been suggested that environmental temperature and hyperthermia play a role in SIDS [360]. However, multiple factors (e.g., sleep-related respiratory dysrhythmias and CNS disorders, particularly in the region of the arcuate nucleus in the medulla) are implicated in SIDS, and the primary cause of the syndrome remains unknown. Finally, the suggestion that thermoregulatory dysfunction may cause sleep disturbance in patients with depression [361] has no compelling evidence to support it.

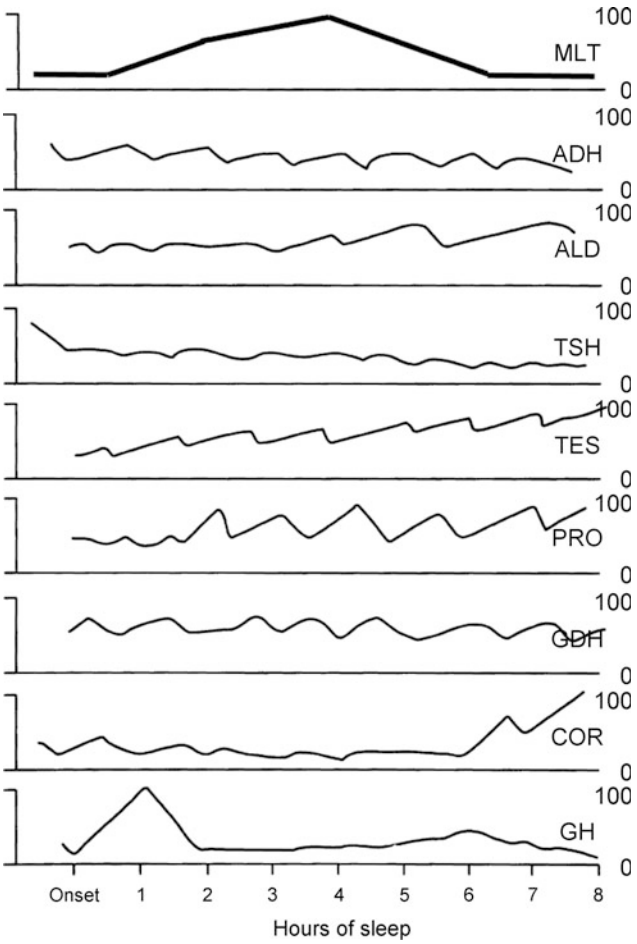

Fig. 11.12 Schematic representation of the plasma levels of hormones in an adult during 8 h of sleep. *Zero* indicates lowest secretory episode and 100 indicates peak. *MLT* melatonin; *ADH* antidiuretic hormone; *ALD* aldosterone; *TSH* thyroid-stimulating hormone; *TES* testosterone; *PRO* prolactin; *GDH* gonadotropic hormone; *COR* cortisol; *GH* growth hormone. (Modified from Rubin [369])

Endocrine Regulation in Sleep

Neuroendocrine secretion appears to be under both circadian control (that is, it shows circadian rhythm in the plasma concentrations of the hormones) and sleep–wake homeostasis. The characteristic pattern of endocrine gland secretion is episodic or pulsatile secretion every 1–2 h, which suggests ultradian rhythmicity. Hormone secretions are thus governed by both the internal biological clock located in the suprachiasmatic nuclei and the stages of sleep. For example, adrenocorticotropic hormone (ACTH), cortisol, and melatonin rhythms are determined by the circadian clock, whereas growth hormone (GH), prolactin, thyroid-stimulating hormone (TSH), and renin rhythms are sleep related. Current evidence indicates that most likely an interaction between the circadian pacemaker and the timing of sleep–wakefulness as well as age, and other diurnal events (e.g., food intake, stress, exercise) determine the daily hormone profiles [362–367]. Changes in the secretion of some major hormones during sleep are described in the following paragraphs. Figure 11.12 shows a schematic of the patterns of neuroendocrine secretion during sleep in an adult human. It is evident from the figure that during the first part of the night the plasma GH level is high and the cortisol level is low, whereas during the later part of the night GH level is low and cortisol level is high, suggesting a reciprocal interaction of the hypothalamic–pituitary–adrenocortical axis and the hypothalamic–pituitary–somatostatin system [368]. Thus there are 24-h oscillations of circulating levels of various endocrine secretions showing a time-of-day dependence [366]. These are driven not only by the endogenous circadian rhythms but also by sleep–wakefulness and behavioral or environmental factors [366].

Growth Hormone

Hypothalamic GH-releasing hormone (GHRH) stimulates release of GH from the anterior pituitary in a pulsatile fashion. In contrast, hypothalamic somatostatin inhibits release of GH [367, 368, 370]. Ghrelin, an appetite-stimulant gastric peptide, also stimulates GH secretion [371]. Sleep, particularly SWS, is associated with increased GH, GHRH, and ghrelin levels. GH secretion occurs shortly after sleep onset during SWS and is inhibited during awakenings and sleep fragmentation. A sexual dimorphism has been noted in GH secretion [365, 366]. Men secrete GH with increased peak amplitude during SWS but also secrete in discrete pulses throughout the day; however, in women, in addition to the GH pulse during first SWS episode, GH is secreted in non-discrete peaks throughout a 24-h cycle. Agents promoting SWS (e.g., γ-hydroxybutyrate) will encourage GH secretion. GH has an anabolic function that is mediated by insulin-like growth factor-I produced in the liver and other organs [368, 370].

Takahashi et al. [372] observed that the plasma concentration of GH peaked 90 min after sleep onset in seven of eight normal subjects and lasted approximately 1.5–2.5 h. The peak is related to SWS (stages 3 and 4 of NREM sleep). Several subsequent reports showed nocturnal peaks of GH in association with SWS [357, 365, 373–379]. Although the major peak in plasma GH occurs during the early part of nocturnal sleep, it has been shown that, in approximately one-fourth of young, healthy men, peaks in circulating GH occur before sleep onset [378]. Sleep deprivation causes suppression of GH secretion, which may be an age-dependent phenomenon that develops during early childhood. The sleep-related release of GH is absent before age 3 months and is reduced in old age [367, 368, 377, 379, 380, 381]. It should be noted that GH secretion is regulated physiologically by opposite actions of GHRH and somatostatin [382]. It has been suggested that somatostatin may induce sleep deterioration in the elderly [382]. Van Cauter and Plat [367, 381] suggested that age-related decrements in GH secretion play a major role in the hyposomatotropism of senescence. The timing of the release of GH shifts if sleep is phase advanced or phase delayed, suggesting a close relationship between episodic GH secretion and sleep [383]. Sadamatsu et al. [384] measured 24-h rhythms of plasma GH, prolactin, and TSH in nine normal adult men by means of serial blood sampling at 30-min intervals. Their findings suggested two mechanisms regulating GH secretion: one that is sleep-independent and has an ultradian rhythm and another that is sleep-dependent.

There is some evidence of possible circadian influences on the regulation of GH secretion from a jet lag study by Goldstein and associates [385] and a study of GH secretory rate in night workers by Weibel et al. [386]. Increased GH secretion has been noted after flights both eastward and westward [385].

The tightly linked normal relationship between GH and SWS is disrupted during sleep disturbances (see later under *Clinical Relevance*). It is notable that such a tight relationship is observed only in humans and baboons, and not in rhesus monkeys and dogs [387], a fact that may relate to the monophasic sleep patterns observed in baboons and humans [369].

An activation of hypothalamic GHRH neurons promotes both the onset of SWS and the peak GH levels, suggesting a direct link between SWS and GH secretion [367, 368, 370, 388]. Furthermore, the GHRH gene is found in the mouse in the same region regulating NREM sleep in the hypothalamus [389]. Experimentally, both intravenous [390] and intranasal [391] administration of GHRH in young men promoted sleep [368]. Many hypothalamic GHRH neurons are thought to be GABAergic [368, 392]. It is notable that POAH GABAergic neurons are important in initiating NREM sleep (see Chaps. 2, 5 and 8), strengthening the link between GHRH and sleep-promoting neurons in the anterior hypothalamus.

Adrenocorticotropic Hormone and Cortisol Secretion

The 24-h ACTH-cortisol rhythm is primarily controlled by circadian rhythmicity but clearly modulated by sleep–wake state. Sleep onset is associated with a decrease in cortisol secretion but with a rapid elevation in the later part of the sleep at night and with subsequent decline throughout the day [280, 362, 365–368, 393–397]. These effects of sleep onset and sleep offset are found to be absent during sleep deprivation. Studies have also shown that awakenings causing sleep interruption will increase the pulsatile cortisol secretion [362]. The inhibitory influence of early nocturnal sleep on ACTH-cortisol levels is most marked during SWS [395]. Some studies [398, 399] have documented both a circadian and an ultradian episodic pattern of secretion for cortisol and ACTH. However, it should be noted that, in contrast to nocturnal sleep, daytime sleep fails to significantly inhibit cortisol secretion; this suggests that sleep does not suppress cortisol release at any point of its circadian rhythm, but only within a limited range of entrainment [400, 401].

In general, the circadian rhythm of cortisol secretion remains undisturbed in disease states such as Cushing's syndrome and narcolepsy [402]. With depression, the earlier occurrence of the lowest point of cortisol levels is thought to indicate a circadian phase advance [403]. The failure of

dexamethasone to suppress cortisol secretion in depressed persons is not necessarily positively correlated with reduced REM latencies noted in depression [404]. Sleep deprivation itself may be responsible for such failure, as is noted in normal individuals [405].

Sleep fragmentation is associated with pulsatile increase in cortisol secretion. Primary insomnia patients had higher mean nocturnal cortisol levels [315, 406]. However, in one report [407], nocturnal cortisol levels did not differ between controls and insomnia patients. Sleep deprivation is also associated with hypercortisolism similar to that noted in normal elderly subjects, accompanied by repeated nocturnal awakenings [408].

Prolactin Secretion

The hormone prolactin, synthesized mainly by the anterior pituitary gland, promotes lactation in women and also participates in multiple metabolic and immune functions. Plasma prolactin concentration has long been known to exhibit a sleep-dependent pattern, with the highest levels occurring during sleep and the lowest during waking [365–368, 402, 409–411]. The plasma prolactin level does not seem to have a definite circadian rhythm; it appears to be linked to sleep [409, 410] but is not related to specific sleep stages [402]. The prolactin level begins to rise approximately 60–90 min after sleep onset and peaks in the early morning hours from approximately 5:00 to 7:00 A.M. [412]. Studies by Mendelson et al. [402, 413], Rubin et al. [414], and Van Cauter et al. [415] showed no relationship between prolactin secretion and NREM–REM cycles. Subsequent studies, however, have clearly shown that prolactin secretion is also driven by a sleep-independent circadian pattern [416, 417]. Waldstreicher et al. [416] studied 12 men and 10 women using a constant routine protocol, during which the subjects remained in semirecumbent wakefulness. The authors clearly documented a robust, sleep-independent, endogenous circadian rhythm of prolactin secretion in humans. The authors hypothesized that the endogenous components of the circadian rhythm of prolactin secretion, along with body temperature, urine production, and cortisol, TSH, and melatonin secretion, are driven by a central circadian pacemaker located in the SCN of the hypothalamus [416].

Prolactin secretion is suppressed by dopamine but stimulated by thyrotropin-releasing hormone [402]. Although prolactin secretion is related to sleep, the secretory pattern of prolactin does not decline with age like that of GH [418]. In women who breastfeed and those with hyperprolactinemia, SWS is increased.

Gonadotropic Hormone (Gonadotropin)

The gonadotropin-releasing hormone (GnRH) produced by the hypothalamus stimulates the anterior pituitary gland to secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH). In men, LH is the stimulus for the secretion of testosterone by the testes, and FSH stimulates spermatogenesis. In women, the ovarian hormones estrogen and progesterone are secreted by the ovaries in response to LH and FSH, which also are responsible for ovarian changes during the menstrual cycle. It has been difficult to study the relationship between FSH and LH plasma levels because of the limitations of assay sensitivity in measurements and the inaccuracies associated with pulsatile secretion of circulating gonadotropin. A clear relationship between FSH and LH plasma levels and the sleep–wake cycle or sleep stages in children or adults has not been found [367]. FSH and LH show a pulsatile pattern of secretion, but there is no clear variation in their diurnal pattern of secretion [365]. In pubertal boys and girls, gonadotropin levels increase during sleep [367, 419–423]. In 62 healthy 6- to 13-year-old girls, Rosenfield et al. [424] observed that plasma LH and FSH levels rose steadily during sleep throughout the prepubertal years. However, these findings are inconsistent in boys [425]. These authors [425] also studied 9- to 15-year-old boys and noted that LH and FSH plasma levels rose steadily during sleep in the late prepubertal years. By using an ultrasensitive immunofluorometric assay to measure plasma LH and deconvolution analysis to depict LH secretory characteristics, it has been possible to show an increase in sleep-associated GnRH and LH secretion during puberty and the prepubertal stage in boys [426]. Nocturnal elevation of gonadotropins is associated with nocturnal rise of testosterone in boys at puberty.

FSH and LH show pulsatile activities throughout the night without showing any relationship to testosterone secretion. During sleep early in puberty [419], however, there is a marked rise of plasma LH concentration, in contrast to testosterone or prolactin. Based on the observation that LH and prolactin secretion precedes testosterone secretion by 60–80 min, Rubin [369] suggested a relationship between these hormones. Some studies in adult men have shown a modest elevation of nocturnal LH and possibly FSH levels [427]. LH and FSH secretion show no distinct circadian rhythms. Plasma testosterone levels rise at sleep onset and continue to rise during sleep at night [428]. The nocturnal rise of testosterone has been found to be linked to REM sleep in some studies [429] as there was attenuation of this nocturnal rise in those who failed to have REM sleep after sleep fragmentation experiments [430]. In older men, the sleep-related rise in testosterone is reduced and the

relationship to REM sleep is lost [431, 432], and the circadian variation of testosterone and LH is reduced [427].

In contrast to normal men, a sleep-related inhibitory effect on LH secretion has been noted in the early parts of the follicular and luteal phases of the menstrual cycle [431–434]. In a more recent study, Klingman et al. [435] noted no circadian rhythm on LH and FSH in women during early follicular phase.

Thyroid-Stimulating Hormone

A distinct circadian rhythm has been established for the secretion of TSH in normal humans [280, 365–367, 398, 435, 436]. There is general agreement that sleep has an inhibitory effect on TSH secretion: TSH levels are low during the daytime, increase rapidly in the early evening, peak shortly before sleep onset, and are followed by a progressive decline during sleep [367, 399, 402, 437]. Sleep deprivation is associated with nocturnal increase in TSH levels [362, 408]; however, during SWS rebound following prior sleep deprivation, there is marked inhibition of nocturnal TSH rise, suggesting that the sleep-associated fall in TSH is related to the SWS stage [438]. The fact that TSH secretion is not suppressed significantly during daytime sleep and the fact that sleep-related inhibition of TSH secretion occurs following nighttime elevation of TSH indicate an interaction between circadian timing and sleep for the control of TSH secretion [362]. TSH is thus controlled by both circadian clock and sleep homeostasis [366, 367]. Exposure to bright light in the early evening can delay the TSH circadian rhythm, whereas exposure late at night or in the early morning can advance it [367, 437].

Melatonin

Melatonin, the hormone of darkness, is synthesized by the pineal gland and released directly into the bloodstream or cerebrospinal fluid [439–447]. The amino acid L-tryptophan, the precursor of melatonin, is converted to 5-hydroxytryptophan by the enzyme tryptophane hydroxylase, followed by decarboxylation to serotonin. The enzymes acetyltransferase and hydroxyindole-*O*-methyltransferase then catalyze serotonin into melatonin (*N*-acetyl-5-methoxytryptamine). It has been clearly shown that the environment light–dark cycle and the SCN act in concert to produce the daily rhythm of melatonin production. Melatonin secretion is controlled by a complex multisynaptic pathway, which can be briefly outlined as follows [439]: impulses from the retinal ganglion cells are transmitted via the retinohypothalamic tract to the SCN, which then sends efferent fibers to the PVN of the hypothalamus and then to the intermediolateral horn cells of the upper thoracic spinal cord, and subsequently to the superior cervical ganglia, which in turn transmit impulses via the postganglionic efferent fibers to the pineal gland. This complex neural pathway is activated during the night, triggering melatonin production, which is suppressed by exposure to bright light. The melatonin circadian rhythm is clearly driven by the circadian rhythm of the SCN through activation of two major melatonin receptors (MT_1 and MT_2) [448–454]. Both receptors are heavily concentrated in the SCN. MT_1 receptors inhibit SCN neuronal activity and MT_2 receptors phase-shift circadian firing rhythms in the SCN. Melatonin begins to rise in the evening on attaining maximum values between 3:00 and 5:00 A.M. and then decreasing to low levels during the day [440–442, 445]. The maximum nocturnal secretion of melatonin has been observed in young children, ages 1–3 years; secretion then begins to fall around puberty and decreases significantly in the elderly [446, 455].

Because of the important effect of melatonin on circadian rhythms and its possible hypnotic effect, there have been a few clinical applications of melatonin that appear promising [448, 449, 452, 456–467]. Placebo-controlled, double-blind studies using a large number of subjects need to be performed, however, before accepting melatonin as a treatment for various sleep disorders. Administration of melatonin has been shown to have some beneficial effects on the symptoms of jet lag [445, 456, 463, 464, 467] and on nighttime alertness and daytime sleep of shift workers [438, 445, 461, 468]. Administration of melatonin has been found to be beneficial in some primary circadian rhythm sleep disorders, such as delayed sleep phase syndrome [456, 469, 470] and non-24-h sleep–wake syndrome [437, 456, 458–460, 471, 472]. In a subgroup of elderly subjects with reduced melatonin secretion at night, beneficial effects of melatonin on sleep disturbances have been noted in those with insomnia [442, 473]. The hypnotic effect of melatonin has been noted in several reports [442, 474–476]. Again, however, placebo-controlled, double-blind studies with large numbers of subjects are needed before considering the clinical applications of melatonin as a hypnotic agent. In conclusion, until further studies are conducted to determine the long-term effects of melatonin, its indiscriminate use (melatonin is available as a nutritional supplement without U. S. Food and Drug Administration control) should be discouraged. Furthermore, melatonin should only be administered to subjects with clearly documented melatonin deficiency [442, 443, 473].

Miscellaneous Hormones

Renin–Angiotensin–Aldosterone System

The renin–angiotensin–aldosterone (RAA) is a complex system [477] is controlled by the ANS, BP variation, serum electrolytes, particularly sodium, and the sleep process.

Renin, an enzyme secreted by the juxtaglomerular cells of the kidneys, acts upon angiotensinogen found in the α_2-globulin fraction of blood to form angiotensin I, which is then converted by a chloride-dependent converting enzyme into angiotensin II; the latter acts upon the zona glomerulosa of the adrenal cortex to stimulate aldosterone secretion. The juxtaglomerular cells act like baroreceptors responding to changes in BP variation during sleep. During NREM sleep, especially SWS, PRA increases, associated with a fall in BP and a reduction of sympathetic activity as indicated by a significant decrement of the LF/HF power ratio in the spectral analysis of electrocardiographic R–R intervals [478]. In contrast, during REM sleep associated with fluctuating BP and intermittently increased sympathetic activity, there is a significant decrement of PRA [246, 477]. Brandenberger et al. [479–481] demonstrated that 24-h variations in PRA are not circadian in nature but are related to sleep processes and are dependent on the regularity and length of the sleep cycles in an ultradian manner. Thus, PRA oscillations are synchronized to the NREM–REM cycles during sleep [481] (Fig. 11.13). Later studies, however, have shown that the RAA system has clear circulation oscillations [280, 482, 483].

During sleep, aldosterone levels are increased compared with levels during wakefulness [484]. Sleep-related aldosterone levels are related to PRA oscillations, whereas during daytime waking periods aldosterone levels parallel cortisol pulses [484]. Some investigators [280], however, noted that the circadian rhythm of aldosterone parallels that of cortisol also at night. Thus, the 24-h aldosterone secretory pattern is influenced by a dual system: renin–angiotensin and ACTH-cortisol. Sleep deprivation modifies the 24-h aldosterone profile by preventing the rise of nocturnal sleep-related aldosterone release, causing an alteration of overnight hydromineral balance [484].

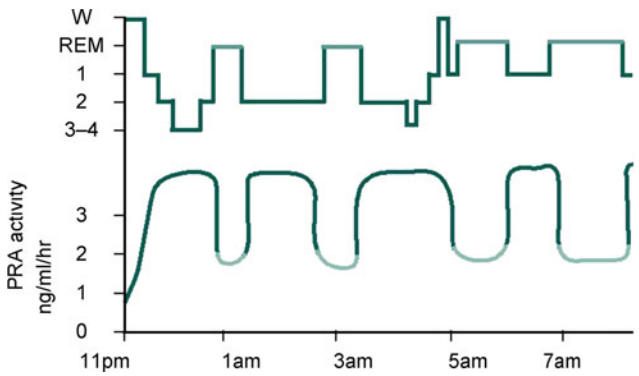

Fig. 11.13 Plasma renin activity profiles schematically shown in a normal subject during sleep at night from 11:00 P.M. to 7:00 A.M.. Note plasma renin activity (PRA) oscillations synchronized to NREM–REM cycling, with the lowest values during REM sleep (Adapted from Brandenberger et al. [481])

Renal Excretion of Water and Electrolytes at Night

In normal persons, nocturnal urine volume and electrolytes decrease owing to decreased glomerular filtration, increased reabsorption of water, increased activation of the RAA system, and decreased sympathetic activity [484, 485]. Antidiuretic hormone (ADH) shows episodic secretion without any relationship to sleep, sleep stages, or circadian system, but the plasma levels of ADH and aldosterone are increased during sleep [370, 414] explaining the reasons for reduced urine production and urinary sodium at night.

Parathyroid Hormone

In normal young men, Chapotot et al. [486] noted a significant increase in levels of plasma parathyroid hormone (PTH or parathormone) during nighttime sleep compared with waking periods but failed to find a significant association with SWS, REM sleep, or plasma ionized calcium and phosphate levels. Their findings demonstrated that the 24-h plasma PTH profile is influenced by sleep processes with a weak circadian component. These findings of Chapotot et al. [486] of a lack of a significant association with sleep stages contradict the earlier observations by Kripke and associates [487] of PTH peaks related to cycles of SWS.

Clinical Relevance

The tightly linked normal relationship between GH and SWS is disrupted during sleep disturbances. For example, in narcolepsy [488], depression of GH secretion is associated with sleep disturbance, and in some cases of insomnia [489], there is a dissociation between SWS and GH secretion. Such dissociation also occurs in old age [377, 465, 466, 490, 491]. These findings suggest that there are independent mechanisms for controlling GH secretion and SWS.

In acromegaly patients, GH secretion remains high throughout sleep and has no relationship to sleep onset or SWS [492, 493]. Diminished, sleep-related secretion of GH is found in both sleep apnea and narcolepsy [494]. In OSAS patients, nocturnal release of GH and prolactin is decreased in untreated apneic subjects but is increased following continuous positive airway pressure (CPAP) treatment [362, 365, 367]. Atrial natriuretic peptide (ANP) is increased in OSAS, resulting in suppression of the RAA system and increased urinary and sodium output [495]. PRA profiles show a flat oscillation in OSAS patients and are normalized after CPAP treatment. The normalization of sodium and urinary output in OSAS patients following CPAP treatment could be related to restoration of normal PRA and aldosterone oscillations as well as decreased release of ANP [495].

The age-related decrease in GH may be related to the reduction of SWS and increased fragmentation of sleep in the elderly. Similarly, decreased prolactin levels in normal elderly subjects may cause increased awakenings and fragmented sleep. The exponential decrease of GH and linear increase in cortisol in old age correlates with age-related decrease in SWS; these changes may impair the anabolic function of sleep in the elderly [362, 365, 367].

Glucose tolerance and thyrotropin concentrations are reduced, whereas evening cortisol concentrations and sympathetic nervous system activity are increased after sleep debt resulting from partial sleep deprivation [365, 367, 408]. Thus, sleep debt has a harmful effect on carbohydrate metabolism and endocrine function. These effects are similar to those noted in normal aging, thus suggesting that sleep debt may increase the severity of age-associated chronic disorders. Age-related sleep fragmentation may also cause increased nocturnal corticotropic activity [363, 365–367, 370]. The pattern of GH secretion associated with clinical depression is contradictory: both impairment and normal sleep-related GH secretion have been noted [402, 489, 496]. GH secretion is somewhat disturbed in alcoholics [497]. Schizophrenia, alcoholism, and depression in adults are associated with impaired sleep-related GH secretion [402]. Whether the impairment is related to an associated decrease in SWS or abnormalities of biogenic amine metabolism in these disorders cannot be stated with certainty. Cushing's syndrome is associated with decreased SWS and GH secretion. Nocturnal GH secretion was found to be higher than normal, and SWS increased, in two patients with thyrotoxicosis [498]. These abnormal findings normalized in response to antithyroid medication.

There is a suggestion that the shift work-related increased incidence of infertility in women may be related to a sleep-related inhibitory effect on gonadotropin release during the follicular phase of the menstrual cycle [499].

Prolonged dyssynchrony or a mismatch between central and peripheral circadian oscillators, and sleep–wake rhythm may impair endocrine homeostasis [366]. Such chronic dyssynchrony as seen in shift work disorder may cause altered immune function, increased tumor growth, increased adiposity, cardiometabolic syndrome (e.g., cardiovascular diseases such as ischemic heart disease) and gastrointestinal disorders [366].

There has been considerable progress in our understanding of how melatonin modulates sleep and circadian phase through activation of the MT_1 and MT_2 melatonin receptors, which inhibit (MT_1 receptors) neuronal activity and phase-shift (MT_2 receptors) circadian firing rhythms in the SCN [448]. This knowledge led to the development and availability of a melatonin receptor agonist (ramelteon) for the treatment of sleep-onset insomnia [454]. Additional melatonin receptor agonists are being developed for treating circadian rhythm disorders and depression. A dysfunction of the multisynaptic pathway from sCN to the pineal gland for melatonin synthesis may abolish melatonin production [439]. Patients with high cervical spinal cord injury affecting this pathway show no circadian rhythm of melatonin, whereas patients with injury below the third thoracic vertebral level sparing this pathway display normal melatonin circadian rhythm.

Sleep and Immune Regulation

12

Norah Simpson, Monika Haack, and Janet M. Mullington

Introduction

While it has long been recognized that inadequate sleep at night is followed by daytime sleepiness, only in the last few decades has sleep deprivation begun to be viewed as a significant health problem with negative consequences including obesity, diabetes, cardiovascular disease, and hypertension. These specific pathologies are all associated with inflammation and emphasize the crucial relationship between sleep and immune function. Given the high prevalence of insufficient sleep that has been reported in both civilian and veteran populations in recent years [1], understanding this relationship has become increasingly important.

Although the research on inflammatory pathologies related to sleep has largely been conducted in the last 20 years, our understanding of this sleep–immune relationship stems from research conducted in the early twentieth century. At that time, scientists in both Japan and France discovered that injecting cerebrospinal fluid from sleep-deprived dogs into well-rested dogs resulted in deep slumber in these otherwise healthy animals [2, 3]. This seminal research was largely unrecognized until the early 1960s, when several independent research groups began to focus their attention on the humoral regulatory mechanisms for sleep, using similar methods to those used by Ishimori and Pieron [4–6]. Following that work, Pappenheimer and colleagues demonstrated a similar transfer of cerebrospinal fluid from sleep-deprived goats to well-rested rats (resulting in sleep induction) and further characterized the sleep-inducing agent as "Factor S," a muramyl peptide [7]. These breakthroughs led directly to our current body of clinical and preclinical studies of sleep and immune function.

Accumulating and novel data from the experimental literature as well as field-based research have provided us with a more comprehensive understanding of this complex relationship. Experimental studies of sleep loss have now examined the sleep–immune relationship across multiple domains, including white blood cell counts, inflammatory mediators, and transcription factors (e.g., [8–10]). This review will present an overview of the current state of the field with respect to both innate and acquired immunity. Additionally, emerging research from clinical trials or intervention studies, which have the potential to further illuminate the bidirectional nature of the relationship between sleep and immunity, will be presented when available.

In order to best understand the sleep–immune relationship, it is also necessary to consider the relationship of hormones with respect to both sleep and immunomodulation. Many hormones demonstrate a circadian pattern, and levels of these hormones can also be affected by sleep loss. Please refer to Fig. 12.1 for a schematic of the diurnal rhythms of immune and endocrine markers and Fig. 12.2 for the impact of sleep deprivation on relevant endocrine markers. While a full description of what is known about the relationship between sleep and endocrine function is beyond the scope of this chapter, we will briefly review sleep-related endocrine effects that facilitate a balanced and well-functioning host defense system, with an emphasis on cortisol and hormones associated with energy regulation and metabolism. For a more comprehensive review of sleep and endocrine relationships, please refer to [11].

Cortisol Cortisol has long been recognized as a powerful immunomodulating hormone with a known diurnal rhythm [12]. The relationships between the diurnal rhythm of cortisol and a range of white blood cells as well as cytokines and their receptors have been well documented [13–15]. The fact that it has endogenous immunomodulating potential has

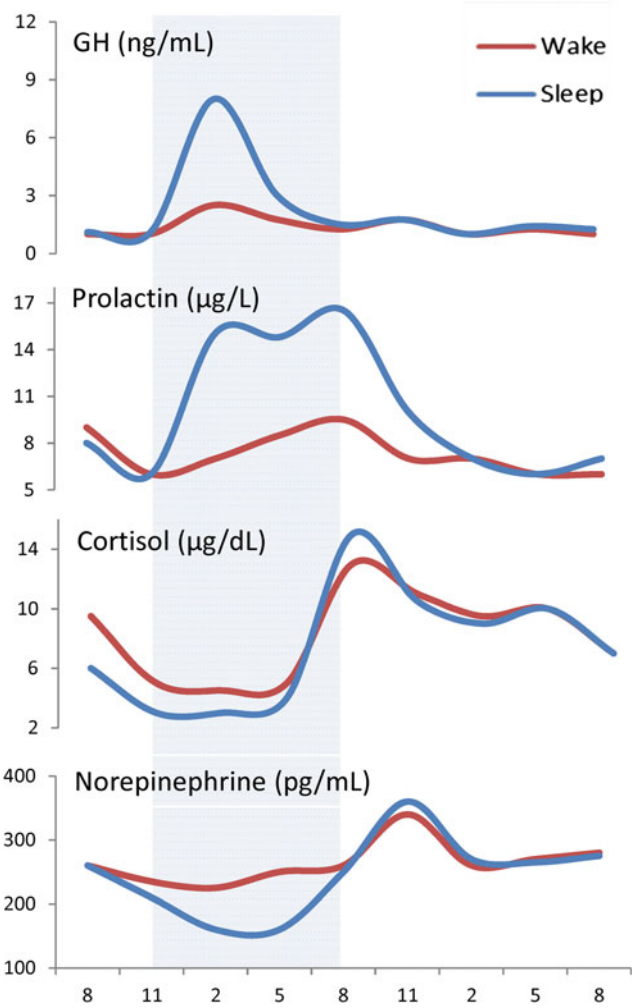

Fig. 12.2 Immunoregulatory hormones are affected by total sleep deprivation (schematic)

also been recognized at least since the 1990s when Pollmächer and colleagues showed that an injection of lipopolysaccharide LPS given in the morning when cortisol is at its peak had a greatly diminished effect on the febrile response, compared to when the challenge was administered in the evening, when cortisol was close to its nadir [16]. This effect was seen despite similar IL-6 and TNF-alpha production in response to challenge, suggesting that the endogenous corticoids have a suppressive effect on the pro-inflammatory effects of these cytokines [16]. In addition, sleep has been shown to be associated with activation of the mineralocorticoid receptor, which has been suggested as a potential mechanism through which sleep supports adaptive immunity [17].

Energy metabolism and adipose tissue hormones It is also known that sleep deprivation alters basal metabolic function, which can contribute to changes in immunological homeostasis [18]. Both total and partial sleep loss have been shown to slow glucose metabolism [19, 20]. Thus, insufficient sleep may be an important contributing mechanism in the clinical development of insulin resistance. Additionally, acute total and sustained partial sleep deprivation have been shown to reduce the diurnal rhythm amplitude [21] and levels [22] of peripheral circulation levels of leptin, an adipocyte hormone that signals satiety to the brain. Levels of ghrelin, a hormone that signals hunger to the brain, and subjective appetite are also increased during partial sleep deprivation [23]. Both changes in insulin resistance and glucose metabolism, and in appetitive hormones may lead to weight gain and changes in adiposity. As adiposity, particularly visceral adiposity, contributes to the production of interleukin 6 (IL-6) and C-reactive protein (CRP) [24, 25], these changes in endocrine system function have a direct impact on the sleep–immune relationship. These hormone changes are particularly relevant when considering the increasing prevalence of obesity [26]

and the development of the metabolic syndrome [27] along with the frequency of chronic insufficient sleep [1], in modern society.

Experimental

Largely conducted in laboratory settings, experimental sleep deprivation (or sleep restriction) studies provide a highly controlled environment in which the effects of sleep loss on immune parameters can be assessed. To date, the vast majority of these studies have been conducted in healthy young adults that have undergone thorough medical screenings in order to provide the clearest understanding of the mechanisms underlying the relationship between sleep and immunity. The field is currently lacking controlled studies that examine how sleep loss affects immune function in potentially more vulnerable populations (e.g., older adults, chronic illness).

Historically, the majority of experimental studies of sleep loss involved acute (total) sleep deprivation—the length of which ranged from 24 to 126 h. Experimental studies of sleep loss have examined the sleep–immune relationship primarily in whole cell counts and in inflammatory mediators of the immune system. There are multiple studies examining how white blood cell counts and differential cells respond under conditions of total sleep deprivation. One of the earliest studies, which was conducted in the 1960s, healthy volunteers were sleep-deprived for up to five nights and days, after which increases in white blood cells, particularly neutrophils, were observed [28]. Subsequent studies of total sleep deprivation report consistent increases in leukocyte number and function [8, 15, 29–31], as well as in some white blood cell count (WBC) subsets (neutrophils [8, 28, 30, 31] and monocytes [8, 15, 30]). Together, these findings collectively suggest that sleep loss activates the innate immune system, as well as the adaptive immune system (discussed below). This conclusion is supported by more recent studies demonstrating that total sleep loss is also associated with upregulation of a range of inflammatory markers, including IL-1 beta, IL-6, CRP TNF-alpha, and prostaglandin E2 in some studies, although results are not as uniformly consistent across studies [32–37].

More recent studies have utilized shortened sleep protocols, ranging from a single night to more chronic sleep restriction paradigms, in which participants' sleep is restricted to a particular shortened length of time each night. It is thought that this model of sleep restriction, rather than the model of total sleep loss, may more closely model the real-world phenomena of chronic insufficient sleep. Similar to participants enrolled in studies of total sleep deprivation, sleep restriction studies typically examine the effects of sleep restriction on healthy adults who typically sleep about 8 h a night. This allows for a controlled dose of sleep loss of similar relative magnitude (compared to habitual duration) across participants. In one of the earliest partial sleep loss studies, participants were restricted to four total hours of sleep per 24 h day over four nights, with sleep opportunities divided into two 2-h naps—one of which occurred in the afternoon and one at night [35]. In this study, no increases in IL-6, TNF-alpha, or TNF-alpha receptors were observed; however, in a parallel total sleep loss condition (see above), increases in TNF-alpha receptors and IL-6 were found [35]. Indeed, effects of partial sleep loss on TNF-alpha and its receptor have been mixed, with some studies finding significant increases (men only [37]) while others do not [35, 38]. IL-6 findings have been more consistent, with deprivation paradigms of sleep restricted to 6 h for 7 nights [37], 4 h/night for 10 nights [33], and 4 nights of sleep restricted to 4 h of split sleep [35] reporting increases in IL-6. Increases in other inflammatory markers have also been observed, including CRP [33, 36, 38] and IL-1 beta [36], although, again, not all studies show this consistent increase [9].

While collectively these experimental, laboratory-based studies of sleep loss demonstrate a significant upregulation of the acute host defense and inflammatory response, there are several additional factors that should be taken into consideration when interpreting these results. Many of these studies are small and thus have the potential to be underpowered, particularly when multiple immune markers are measured. Additionally, basal levels of these immune markers demonstrate considerable variability resulting from a range of factors, including individual factors (stress, temporal proximity to physical activity or meal intake, body mass index, and other metabolic factors), circadian factors (IL-6 in particular has been shown to have circadian variation [13, 39]), and measurement effects (e.g., effects of catheterization [40] and potential sample contamination [41]). All of these factors can increase the variability of the data and have the capability to mask potentially small, yet important changes in immune markers following sleep loss. Collectively, these findings reinforce the need for careful methodological consideration when comparing outcomes across studies.

More recent work has begun to explore the physiological mechanisms underlying the relationships between insufficient sleep, circadian rhythm disruption and negative health outcomes, focusing on the level of gene expression. Moller-Levet and colleagues compared transcriptome analyses after either one week of sufficient sleep (8.5 h/night) or one week of insufficient sleep (5.7 h/night) and found that expression of genes affected by insufficient sleep was associated with not only circadian rhythms and sleep homeostasis (including IL-6), but also oxidative stress and metabolism [10]. A follow-up study by the same research

team found that mis-timed sleep alone also leads to a reduction in rhythmic transcripts [42]. Together, these findings suggest that the immune system is affected by sleep alterations even at the molecular level. We expect that the study of gene expression in relation to sleep loss and immune parameters will be an increasing area of research focus in the future.

In addition to these direct relationships between sleep loss and increases in immune and inflammatory markers, there is a wealth of evidence that sleep supports components of the adaptive immune response. The effects of insufficient sleep on adaptive immune system components have been mostly tested using vaccination models, and exploring the magnitude and time line of the primary antibody response. In one of the first laboratory studies in this area, two groups of adults received a hepatitis A vaccination; one group was deprived of sleep for one night prior to the vaccination, and the other was allowed a full night of sleep. The well-rested group was observed to have an immune response of nearly twice the magnitude of their sleep-deprived comparison subjects [43]. In a follow-up study, vaccination-induced T helper (Th) cell and antibody (AB) responses were monitored over a one-year period following a series of three hepatitis A vaccines, with participants randomized to either sleep or wake the night *following* each vaccine administration. Again, the individuals in the sleep condition had twice the frequency of antigen-specific Th cells and an increased fraction of Th1 cytokine-producing cells; these differences remained significant over the one-year follow-up period [44]. There is also direct evidence that sleep duration can impact the immune systems response to an actual viral challenge, as demonstrated by Cohen and colleagues [45]. In this study that used both field and experimental techniques, habitual sleep duration was assessed via self-report prior to entering the laboratory, where they were then inoculated with a dose of the common cold virus. Participants who slept seven or fewer hours/night were at three times greater risk of developing a cold [45].

Two more recent studies provide additional support for this relationship between sleep and the adaptive immune response. Benedict and colleagues investigated the effects of acute sleep deprivation on the antibody titer response to a novel influenza A H1N1 virus (swine flu) [46]. Twenty-four healthy students received the vaccine after a single night of sleep deprivation or regular sleep. Of note, the antibody response in the sleep-deprived group was 60% lower in the early observation phase of the immune response (day five following the vaccine) although this difference was observed only in males [46]. The authors suggest that acute sleep deprivation may delay the induction of adaptive immune responses in males, but that it does not have lasting effects on the antibody titer response to influenza vaccination, with equivalent responses in both sexes on follow-up days 10, 17, and 52. These results were consistent with those of an earlier pilot study that reported lower antibody titer against a seasonal influenza virus only in the early period (10 days) but not later periods (after 28 days) following a brief exposure to acute sleep deprivation [47]. These studies suggest that insufficient sleep may delay, or at least reduce, the adaptive immune response.

Collectively, these experimental sleep loss studies demonstrate that sleep loss can affect a range of established markers of the inflammatory system, including IL-6, CRP, IL-1 beta, TNF-alpha, and prostaglandin E2. Many of these inflammatory markers are considered to be pro-inflammatory in nature; however, it is important to be mindful that the regulation of inflammatory parameters is complex and is often bidirectional, such that increases in one inflammatory parameter may eventually function to down-regulate another aspect of the system. Additionally, as described above, there is significant variation in the experimental parameters (e.g., the duration and timing of sleep loss, diet, body positional, and activity control of study participant); this, in combination with the study population itself, may help explain patterns of immune responses in a given study compared to another. Replication of specific protocols and expansion of study participants to include more vulnerable populations will provide valuable information to help us better understand the differential pattern of results.

Field and Population Studies

Field studies, which include both epidemiological studies and large-scale non-laboratory-based research, complement experimental or laboratory-based protocols. This area of research helps provide a better understanding of the relationship between sleep and immune function in a real-world setting, allowing for better estimations of the effects of, for example, the chronicity of sleep loss. This real-world validity, however, is countered to some extent by the loss of experimental control when research moves beyond the laboratory. While well-conducted studies are able to control or covary for an appropriate range of factors, they cannot execute the degree of control seen in laboratory studies given their much larger scale. Considered together, experimental and field-based studies provide a more comprehensive picture of the sleep–immune interaction.

There are numerous of epidemiological studies linking short sleep duration with negative health outcomes (e.g., body mass index, risk of hypertension [48, 49]), as well as risk of all-cause mortality. Several meta-analyses have found increased risk of all-cause mortality in both habitual short and long sleep durations, with elevated risks with short sleep of 10–12 and 23–30% with long sleep [50, 51]. While not directly linked with immune function, the overall

relationship between sleep duration and *all*-cause mortality suggests that there may be an underlying shared mechanistic link, and immune function and inflammation is one viable candidate. This hypothesis is supported by other population-based studies that have examined the relationship between sleep duration and inflammatory mediators associated with body mass index (BMI) or adiposity, which we discuss further below.

There is a large base of research demonstrating that insufficient sleep is associated with obesity, both cross-sectionally and prospectively, even when sleep duration is measured objectively [52, 53]. Given that adiposity, particularly visceral adiposity, is associated with higher circulating levels of inflammation [24, 25], the association between sleep and adiposity can also be considered from a perspective of an independent relationship between inflammatory mediators and sleep duration. To date, there are a limited number of studies that can allow for such comparisons. The available data suggest that there is weak evidence for an independent relationship between short sleep and inflammation. In one study of 907 adults (Wisconsin Sleep Cohort study), no relationship between levels of CRP and sleep duration was reported [54], while in another study of over 4600 individuals, sleep disturbances were associated with higher CRP levels in women, but not men [55]. Notably, increases in inflammatory markers associated with long sleep durations have also been reported [56, 57]. While these studies control for a range of potential covariates and comorbid factors, it is still an open question as to whether there is an independent relationship between long sleep durations and inflammation, or rather there is a yet-unidentified/unaddressed factor that is driving this relationship.

These differential results emphasize that very large study samples are required for this area of research, in order to both insure adequate representation across a range of sleep duration and also to allow for statistical control of the contributions of a range of potentially confounding factors. As described in the experimental studies section, methodological variation such as time of day of sample collection and the collection procedures themselves may have an impact on the results, independent from the actual population studied. Interpretation of these findings is also complicated given that epidemiological studies have largely relied on self-reports of habitual sleep duration. Research suggests that healthy population may overestimate by self-report their actigraphically measured sleep duration, while populations with sleep disorders (e.g., insomnia) may over-report time awake/under-report sleep duration [58–60].

Self-assessment of sleep duration via a sleep diary and objective sleep duration, as measured by a night of polysomnography, may lead to differing outcomes, however. Objectively measured shorter sleep duration has been found to be correlated with fasting levels of TNF-alpha, after controlling for covariates; however, in the same study, self-reported longer sleep durations were significantly associated with increased high-sensitivity (hs) CRP and IL-6 [61]. The authors suggest that self-reported sleep duration and single-night polysomnography may be measuring different constructs of sleep [61], which appears supported by the literature on differential findings between objectively and subjectively measured sleep durations described above. Nonetheless, these studies provide more evidence that the inflammatory system is sensitive to actual sleep duration and potentially also by longer-term subjective estimates of sleep patterns. These methodological challenges add an extra layer of complexity in our understanding of study findings, particularly relative to the experimental sleep loss literature. In addition to the investigation of basal changes in inflammatory markers in relationship to sleep duration, a few studies have looked at the inflammatory response or reactivity to challenge, such as to stress. For example, Heffner and colleagues conducted a study in which IL-6 levels were assessed at baseline and 60 min after a stressful testing period in a sample of older adults (greater than 50 years old). Individuals categorized as poor sleepers had a significantly larger inflammatory response to this acute stressor, which was not mediated by negative affect or perceived stress [44].

Field studies have also provided important insights into the relationship between sleep and adaptive immune function. Using the vaccine challenge model, Prather and colleagues investigated whether naturally occurring sleep influenced the specific immune response to a hepatitis B vaccination [62]. This larger study examined relationship between self-reported sleep duration and the primary and secondary antibody response, as well as clinical protection status after the 3rd vaccination in this series. The authors found that shorter sleep duration was associated with lower secondary antibody levels, translating into a 56% increase in secondary antibody levels with each additional hour of sleep [62]. Additionally, shorter sleep durations in this study were associated with a decreased likelihood of being clinically protected after the third vaccine in the series. Specifically, sleeping fewer than 6 h a night was associated with a significant risk of remaining unprotected against hepatitis B infection compared to those sleeping more than seven hours [62]. This relationship between sleep duration and immune response to system challenge is further supported by findings from a large (N = 56,953) study of women, which found that sleeping less than 5 h a night increased the risk of pneumonia by 70% over the four-year observation period, compared to women sleeping 8 h per night [63].

Qualitative aspects of sleep, rather than duration per se, have also been shown to modulate immune function. In one early study, 11 young adults with insomnia, who were otherwise healthy, were compared to 11 age- and sex-matched healthy control subjects. These subjects were studied in the laboratory for four nights; while there were no

differences in mean 24-h levels of IL-6 or tumor necrosis factor, a shift in the secretion timing (from nighttime to daytime) of these cytokines was observed [64]. In a similar study comparing individuals with chronic insomnia to healthy controls, increases in nocturnal IL-6 were observed in the insomnia sample [65]. Total IL-6 levels were inversely correlated with subjective sleep quality and the amount of slow wave sleep and were positively correlated with the amount of wake time at night [65], suggesting that there may be specific relationships between sleep symptoms and immune markers. However, not all studies have reported a relationship between insomnia symptoms and increased markers of inflammation. One large study of 8547 Norwegians with insomnia found no consistent associations with specific symptoms of insomnia and hsCRP levels [66]. Inconsistencies between studies may have largely to do with the wide range of insomnia phenotypes and definitions. For example, more recent findings suggest that inflammatory and other systems abnormalities are present particularly in insomniacs with objectively verified sleep abnormalities (such as short sleep duration, low sleep efficiency) [67].

A growing number of studies have also examined relationships between sleep quality and inflammation, with mixed results. While one large study found that inflammation was not related to an overall index of sleep quality [56], another smaller study found a significant relationship between sleep quality and production of IL-1 beta [68]. Two additional studies report relationships between sleep quality and inflammation in women: one in a female-only study sample (CRP, [69]) and the other in a prospectively assessed, mixed gender sample (multiple inflammatory markers, [70]). Together, this body suggests that there may be some relationship between impaired sleep quality, particularly at the disorder level (e.g., insomnia disorder), and inflammation; however, there are likely multiple factors contributing to these relationships (e.g., sex, medication use, chronicity of sleep disturbance, body mass index) that are yet to be fully understood.

Clinical Trials/Intervention Studies

The studies presented thus far in this chapter have demonstrated the relationship between acute and chronic sleep durations and immune function. There is far more that can still be learned from both experimental and field studies in this area; an exciting new area of research lies in clinical trials and intervention research. Although it is well documented that sleep can successfully be improved (e.g., through treatment of insomnia) [71, 72], few studies to date have incorporated a physiological measurement arm. In the most recent and largest of these studies, 123 older adults were randomized to either cognitive behavioral therapy for insomnia (CBT), Tai Chi Chi (TCC), or a sleep seminar education control (SS) [73]. Treatment was conducted in weekly 2-h group sessions over four months. In addition to CBT outperforming the other two conditions with respect to insomnia remission rates and improvements in sleep parameters, CBT was also associated with a reduced risk of CRP levels at the 16-month follow-up point compared to the SS control condition. Further, remission of insomnia was also associated with lower levels of CRP [73]. The authors suggest that observed inflammatory effects have implications for the cardiovascular morbidity observed with sleep disturbances in epidemiological studies [73].

Two additional studies in medical populations (breast cancer and peritoneal dialysis patients) with insomnia have also demonstrated significant changes in immune markers. In one pilot study, dialysis patients completed either individual CBT-I or a sleep education control condition, and effects on five inflammatory markers were assessed. While sleep quality improved in the intervention group, the authors observed decreases in only one inflammatory marker, IL-1 beta [74]. In another small study, 57 women with insomnia secondary to breast cancer were assigned to CBT or a control condition. The authors report that patients treated with CBT had higher levels of IFN-gamma and a smaller increase in lymphocytes at post-treatment compared to control patients. Additional changes in multiple markers were observed from pre- to post-treatment, including WBCs, lymphocytes, IFN-gamma, and IL-1 beta [75]. Interpretation of specific immune changes following sleep improvement is complex, particularly in these samples of medical populations; however, it does appear that modifying sleep has the potential to effect direct changes in immune function. While more research is needed in this area, these important findings suggest an avenue by which improving sleep can affect underlying medical conditions and also help shed light on our understanding of the mechanisms underlying the sleep duration and health risk epidemiological literature.

Another new area examining the reversibility of inflammatory and autonomic changes related to insufficient sleep is sleep extension. One pilot study in this area assessed 22 adults with hypertension or pre-hypertension and a habitual sleep duration of less than 7 h a night; participants were then randomized to a control condition or an intervention designed to facilitate extension of bedtimes by 60 min/night over a six-week period [76]. Beat-to-beat blood pressure, and stress and inflammatory markers were both assessed pre- and post-treatment in a controlled laboratory setting. Sleep duration increased significantly in the extension group by an average of 35 min/night, and this was accompanied by a significant decrease in systolic blood pressure and

nonsignificant decreases in WBC, IL-6, CRP, and norepinephrine [76]. While small in scale, this study suggests that reversing chronic insufficient sleep even for a period of six weeks can result in significant improvement in autonomic markers related to inflammation.

There is also a small amount of intriguing research that has assessed the relationship between sleep and inflammatory activity in an intervention model by testing the effects of an anti-inflammatory medication (tocilizumab, an antibody against the IL-6 receptor) for six months on sleep disturbances in a small sample of women with rheumatoid arthritis [77]. Researchers found that this IL-6 receptor antibody treatment led to a slight, but significant improvement in sleep quality that was independent of decreased disease activity [77]. This study will require replication but provides more evidence to support the responsivity aspect of the relationship between sleep and immune function, where poor sleep can result in a stronger inflammatory response to stress (see [78]) and reducing the inflammatory response (with use of medication) can improve sleep quality [77].

Conclusion

Accumulating experimental data from laboratory-based studies of sleep loss suggest that insufficient sleep affects basal levels of immune and inflammatory mediators, as well as the inflammatory reactivity to stressors. In field settings, short sleep duration has been associated with increased inflammatory markers, reduced antibody responses, and lower clinical protection induced by vaccinations. Epidemiological and intervention data also suggest that infection rates are higher when sleep durations are lower. This raises the possibility that interventions designed to improve sleep may reduce disease risk to infections through either direct protection by the early and adaptive immune systems or indirect antibody support mechanisms.

While the mechanisms underlying the sleep–immune relationship are yet to be fully understood, preliminary evidence suggests that inflammatory mediators may not only be affected by changes in basal levels of various immune regulatory hormones, but also by changes in receptor density or sensitivity of immune cells to hormonal signals. Future research in this area will benefit from greater understanding of individual differences, and genetic and epigenetic factors so that interventions can be optimized to better address biological system-specific risk.

Sleep and Memory Consolidation

13

Rebecca M.C. Spencer, Matthew P. Walker, and Robert Stickgold

Introduction

The functions of sleep are not fully understood, a surprising fact given the vast amount of time that this state takes from our lives. One of the most exciting and contentious hypotheses is that sleep makes an important contribution to learning and memory processing. Over the last decade, a large number of studies, from a range of disciplines, have begun to provide a substantive body of evidence supporting this role of sleep in what is becoming known as sleep-dependent memory processing. While this renaissance is relatively recent in the annals of sleep research, the topic itself has a surprisingly long history. The earliest reference to a relationship between sleep and memory is from the Roman rhetorician Quintillian, stating "*It is a curious fact, of which the reason is not obvious, that the interval of a single night will greatly increase the strength of the memory*" and suggesting that "*the power of recollection…undergoes a process of ripening and maturing*" (Quintillian; first century AD). This is striking not only for the level of insight at a time when knowledge of brain function was so anemic, but also considering that it represented the first suggestion of memory requiring a time-dependent process of development, resulting in improved memory recall. Perhaps what is most surprising, however, is that these two fields of research (sleep and memory) then remained separate for almost two millennia.

In the mid-eighteenth century, the British psychologist David Hartley proposed that the processes of dreaming might alter the strength of associative memory links within the brain [1]. Yet the fields of sleep and memory research remained independent until 1924 when Jenkins and Dallenbach [2] performed the first systematic studies of sleep and memory to test Ebbinghaus' theory of memory decay [3]. Jenkins and Dallenbach [2] showed that memory retention was better following a night of sleep than after an equivalent amount of time awake. However, they concluded that the memory benefit following sleep was simply a passive one, due to a lack of sensory interference in contrast to wake. They did not consider that the physiologic state of sleep itself could actively orchestrate these memory modifications. It is only in the last half-century, following the discovery of rapid eye movement (REM) and non-REM (NREM) sleep, that researchers began testing the hypothesis that specific aspects of sleep physiology may actively participate in memory processing.

This chapter explores what has become known as sleep-dependent memory processing, and its associated brain basis, sleep-dependent plasticity. It is divided into three primary sections: (1) an overview of memory categories and the unique stages of memory development; (2) a review of the specific relationships between sleep and memory, both in humans and in animals; and (3) a brief survey of the wide range of evidence describing sleep-dependent brain plasticity, including human brain imaging studies as well as animal studies of cellular neurophysiology and molecular biology. We close with a consideration of unanswered questions that are the focus of ongoing research.

Delineations and Definitions

Before discussing interactions between sleep and memory, we must first understand what these terms represent and encompass. The process of sleep, with its varied stages and equally diverse physiology and biology, has already been

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_13

described in earlier chapters in this section, clearly demonstrating that sleep itself cannot be treated as a homogeneous state that either does or does not affect memory. Instead, sleep possesses a range of physiologic and neurochemical mechanisms that can contribute to memory consolidation. Moreover, just as sleep cannot be considered homogeneous, the spectrum of memory processes believed to exist in the human brain, and the unique stages that create and sustain memory, are likewise diverse.

Memory Categories

Although often used as a unitary term, "memory" is not a single entity. Human memory has been subjected to several different classification schemes, the most popular being based on the distinction between declarative versus nondeclarative memory [4, 5] (Fig. 13.1a).

Declarative memory is the consciously accessible memories of fact-based information (i.e., knowing "what"). Several subcategories of the declarative system exist, including episodic memory (memory for events of one's past) and semantic memory (memory for general knowledge, not tied to a specific event) [5]. Current neural models of declarative memory formation emphasize the critical importance of structures in the medial temporal lobe, predominantly the hippocampus [6, 7], a structure that is thought to form a contextual retrieval code for neocortically stored information.

In contrast, nondeclarative memory can be regarded as unconsciously acquired learning. The nondeclarative category includes procedural memory (i.e., knowing "how"), such as the learning of habits and motor skills (e.g., playing a piano, athletic sports, surgical skills, etc.), as well as classical conditioning and non-associative learning. The neural basis for nondeclarative learning appears to be more diverse, varying with task characteristics (e.g., motor versus non-motor) [7].

While these categories offer convenient and distinct separations, they rarely operate in isolation in real life. For example, language learning requires a combination of memory sources, ranging from nondeclarative memory for procedural motor programs to articulate speech, to memory of grammatical rules and structure, to aspects of declarative memory for the source of word selection. Such interactions must be kept in mind as we consider the role of sleep in learning and memory.

Memory Stages

Just as memory cannot be considered monolithic, similarly, there does not appear to be one sole event that creates or

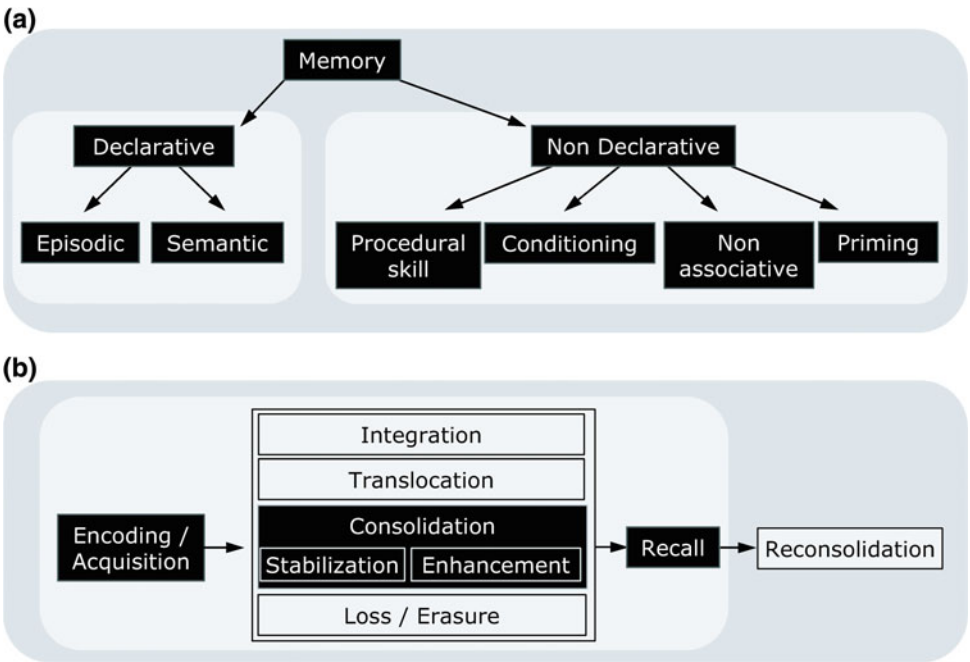

Fig. 13.1 Memory systems and memory stages. **a** Memory systems. Human memory is most commonly divided into declarative forms, with further subdivisions into episodic and semantic, and nondeclarative forms, subdivided into an array of different types including procedural skill memory. **b** Developing stages of memory. Following initial encoding of a memory, several ensuing stages are proposed, beginning with consolidation, as well as integration of the memory representation, and translocation of the representation or erasure of the memory. Also, following later recall, the memory representation is believed to become unstable once again, requiring periods of reconsolidation

sustains it. Instead, memory appears to develop in several unique stages over time (Fig. 13.1b). For example, memories can be initially *encoded* by engaging with an object or performing an action, leading to the formation of a representation of the object or action within the brain. In a subsequent *recall* stage, memories can be actively recalled or recognized by comparison with the representation. However, the memory continues to evolve between encoding and recall through the process of consolidation. Classically, the term *memory consolidation* refers to a process whereby a memory becomes increasingly resistant to interference from competing or disrupting factors in the absence of further practice, through the simple passage of time [8]. That is to say, the memory becomes more stable even with time away from the task.

Important memory stabilization can occur over periods of both wake [9, 10] and sleep [11, 12]. Sleep-dependent consolidation refers to the fact that consolidation is greatest over sleep, compared to wake, for most tasks [13–15]. From this perspective, the enhancement phase of consolidation causes either the active retention of a memory instead of its decay, or the enhancement of a memory over and above its simple maintenance. There is also accumulating evidence that memory consolidation is accompanied by a process of memory integration and generalization [e.g., 16, 17]. Thus, consolidation can be expanded to include more than one phase of post-acquisition memory processing, with each phase occurring in specific brain states such as wake or sleep, or even specific stages of sleep [18].

Although this chapter focuses primarily on the effects of sleep on post-acquisition memory stabilization and generalization, it is important to note that there are additional post-acquisition stages of memory processing that perhaps should also fall under the rubric of consolidation. These include the anatomic reorganization of memory representations (memory translocation), reconsolidation of memory representations following conscious recall (memory reconsolidation), and even the active erasure of memory representations, all of which appear to occur outside of awareness and without additional training or exposure to the original stimuli. It is interesting to note that, while not reviewed here, sleep has been implicated in all of these steps [19–22].

Summary

There are a number of stages of memory processing, which use distinct brain mechanisms to perform separate functions. When multiple classes of memories and the several stages of sleep are combined, one is faced with a truly staggering number of possible ways that sleep might affect memory consolidation.

Behavioral Studies of Sleep and Memory

Evidence of sleep-dependent memory processing has been found in numerous species using a variety of behavioral paradigms. Here, we provide an overview of these studies. The reader is referred to recent reviews for more detail than is provided here [23–25].

Human Studies of Declarative Memory

Much of the early work investigating sleep and memory in humans focused on declarative learning tasks. These studies offered mixed conclusions, some arguing for sleep-dependent memory processing and others against it. For example, De Koninck et al. [26] demonstrated significant increases in post-training REM sleep after intensive foreign language learning, with the degree of successful learning correlating with the percentage increase of REM sleep. Such findings suggest that REM sleep plays an active role in memory consolidation, and that post-training increases reflect a homeostatic response to the increased demands for REM-dependent consolidation.

To the contrary, most recent studies suggest a critical function of slow wave sleep (SWS) in declarative memory consolidation. Perhaps most convincing are studies demonstrating the reactivation of declarative memories during SWS. Rasch et al. [27] taught participants a visuospatial task requiring learning the spatial location of a matrix of images. Learning occurred in the presence of an odor (scent of roses). The experimental odor was re-presented during subsequent SWS for a subset of the participants (Fig. 13.2a). Recall was superior following sleep when the odor present during learning was re-presented during sleep. In a similar study, Rudoy et al. [28] had participants learn a similar visuospatial task, but in this case, each image was paired with a specific sound. Half of these sounds were re-presented during subsequent SWS. Delayed recall was greater for those items for which the associated sound was re-presented during sleep relative to those items for which the associated sound was not re-presented. It is thought that cues presented during sleep, selectively trigger associated memories to be reactivated. Notably, when Rasch et al. [27] presented odors during wake and REM sleep, there was no benefit for subsequent recall beyond that seen in a no-odor (vehicle) control condition (Fig. 13.2b), supporting the specific role of SWS in declarative memory consolidation.

Marshall et al. [29] showed that experimentally boosting human *slow oscillations*, widespread oscillations between "up" and "down" states that are characteristic of SWS, results in improved memory performance the following day. Following learning of a word-pair list, a technique called

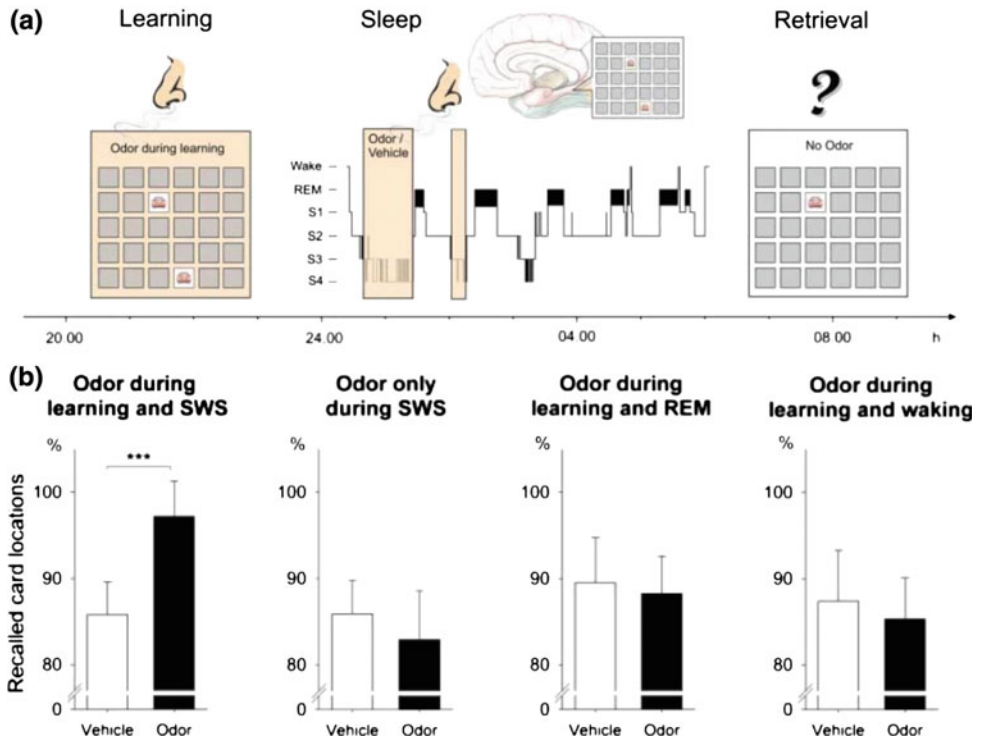

Fig. 13.2 Declarative memory reactivation during slow wave sleep. **a** Subjects performed a visuospatial learning task in the presence of an experimental odor (scent of roses). During subsequent slow wave sleep, this odor or a non-odor vehicle control was presented. Memory for the visuospatial task was tested following sleep. **b** Participants recalled more locations following sleep when the experimental odor was re-presented during slow wave sleep compared to vehicle (*first panel*). Such an effect was not observed if the odor present during slow wave sleep was not also present during learning (*second panel*), if the odor cue was re-presented during REM (*third panel*), or if the odor was re-presented during waking (Permissions needed from Rasch et al. [27])

transcranial direct current stimulation (tDCS) was used to induce these slow oscillation-like (in this case, 0.75 Hz) field potentials during early delta-rich sleep. The tDCS not only increased the amount of delta sleep during the stimulation period (and for some time after), but also enhanced the retention of these hippocampal-dependent factual memories, suggesting a causal benefit of delta sleep neurophysiology.

Memory enhancement reported in this study is striking in the face of earlier studies that showed memory protection but not enhancement. Notably, this study used a classic paired associates task (semantically related word-pair learning). This task tends to show sleep-dependent memory enhancements [30, 31], while those using semantically unrelated word pairs report sleep-dependent memory protection [32, 33]. The nature of the learning task thus shifts from forming and retaining completely novel associations (dog-leaf) to the strengthening or tagging of well-formed associations (dog-bone) for recall at testing [34].

Sleep's role in declarative memory consolidation, rather than being absolute, depends on several aspects of the task including task difficulty, future relevance, and emotional salience. More difficult tasks are thought to benefit most from sleep [12, 35]. This may reflect enhanced consolidation for weak compared to strong memories. For instance, learning a second list of word pairs weakens the memory for the first list. Yet, recall of the first list following sleep is greater than when recalled following an equivalent interval of wake while recall of list two differed little following sleep and wake [36].

The benefit of sleep on declarative memories may also be greatest for memories with clear future relevance. Wilhelm et al. [37] demonstrated this preferential effect of sleep by comparing recall after sleep and wake for two groups of participants: one group was informed that they would be asked to recall the learned word pairs in a subsequent session and a second group was not informed of the later recall. Sleep-dependent enhancement in performance was evident for those who expected to recall the words following the delay interval, whereas there was no difference for sleep and wake groups who performed the surprise delayed recall test. Future relevance implied by associating items with a reward (monetary or points) also yields greater performance benefits following sleep compared to unrewarded items [38, 39].

Emotional salience may cue future relevance as well, as memory for items with negative valence is important for self-preservation. A number of studies have illustrated the

preferential consolidation of negative emotional memories over neutral memories. Hu et al. [40] found greater recognition of emotionally arousing images after sleep compared to wake while no condition differences were found for neutral images. Moreover, when negative items are embedded in neutral scenes, sleep preferentially enhanced recognition of the negative items relative to the neutral items while the scenes themselves, which were neutral in valence, were uninfluenced by the type of interval (sleep vs. wake) [41]. These behavioral effects have been associated with REM sleep [42]. Likewise, oversleep protection of emotional reactivity to negative images is predicted by the time spent in REM sleep [43].

While these examples highlight when sleep functions to stabilize and enhance veridical memories, as discussed earlier, sleep also functions to generalize declarative memories and integrate them into existing representations [44]. Indeed, the end goal of sleep-dependent memory processing may not be simply the enhancement of individual memories in isolation, but instead, the integration of these memories into a common schema and, by doing so, facilitation of the extraction of universal rules, which may be the basis of generalized knowledge. The most basic demonstration of this comes from studies using the Deese–Roediger–McDermott paradigm in which participants are presented with lists of semantically related words (e.g., BOWL, SPOON, MILK) that lack a critical word representing the gist of the list (e.g., CEREAL). When these lists are learned prior to sleep, recall of the list words is greater than following wake. Notably, sleep also yields greater recall of those critical, "gist" words that were never presented. This suggests that declarative memories are generalized and integrated into the existing lexicon over sleep, thereby allowing the extraction of the more general form of the memory after sleep [17, 45, 46].

Sleep-dependent generalization of declarative memories may provide other cognitive benefits of sleep such as enhancing rule learning, decision-making, and creativity. For instance, it has also been demonstrated that, following initial practice on a numeric-sequence problem-solving task, a night of sleep can trigger insight into a hidden rule and thus improve performance strategy the following morning [47]. Likewise, performance on the Iowa gambling task, a measure of affectively guided decision-making, becomes more optimal after sleep as subjects gain more insight into the statistical probabilities of the four decks of cards from which they must choose [48]. Integrating new memories with prior representations may also yield novel, creative solutions [49, 50].

Taken as a whole, these studies suggest a rich and multifaceted role for sleep in the processing of human declarative memories. While SWS is associated with learning of nonemotional veridical memory processing, REM sleep appears to contribute to changes in the emotional memory representation. How sleep facilitates memory generalization and the function of sleep in translocation and reconsolidation of declarative memories are a matter of ongoing research.

Human Studies of Procedural Memory

The benefit of sleep has been demonstrated across a wide variety of procedural tasks spanning the visual, auditory, and motor systems. In this section, we review evidence of procedural memory improvements following sleep as well as possible limitations.

Motor Skill Learning

Motor skill learning is defined as the process by which movements are more quickly and accurately executed after practice [51, 52]. Motor skills are often broadly classified into two forms: motor sequence learning (e.g., learning a piano scale) and motor adaptation (e.g., learning to use a computer mouse) [53].

The movement sequencing task, a common task for measuring sequence learning, requires that subjects repeatedly tap a sequence of response keys as quickly and accurately as possible. With training, movement time decreases, indicating that learning has occurred. A night of sleep can trigger significant performance improvements in speed and accuracy on a sequential finger-tapping task, while equivalent periods of time awake provide little to no benefit [15, 33]. These sleep-dependent benefits appear to be specific to both the motor sequence learned [54, 55] and the hand used to perform the task [56]. Furthermore, the amount of overnight learning expressed the following morning correlated positively with the amount of stage 2 NREM sleep, particularly late in the night (Fig. 13.3) [15]. This late-night stage 2 NREM window corresponds to a time when sleep spindles, a defining electrophysiologic characteristic of stage 2 sleep, reach peak density [57]. Interestingly, spindles have been shown to increase following training on a motor task [58, 59] and are associated with cellular plasticity as discussed later in this chapter.

A more detailed analysis of the performance improvements on the motor sequencing task after sleep provides insight into how improvements come about [60]. Prior to sleep, individual key-press transitions within the sequence are uneven (Fig. 13.4a, light circles), with some transitions seemingly easy (fast) and others problematic (slow), as if the entire sequence was being parsed into smaller subsequences during initial learning (a phenomenon termed *chunking* [61]). Surprisingly, after a night of sleep, the problematic slow transitions are preferentially improved, while transitions that were already mastered prior to sleep did not change (Fig. 13.4a, dark circles). In contrast, if subjects were

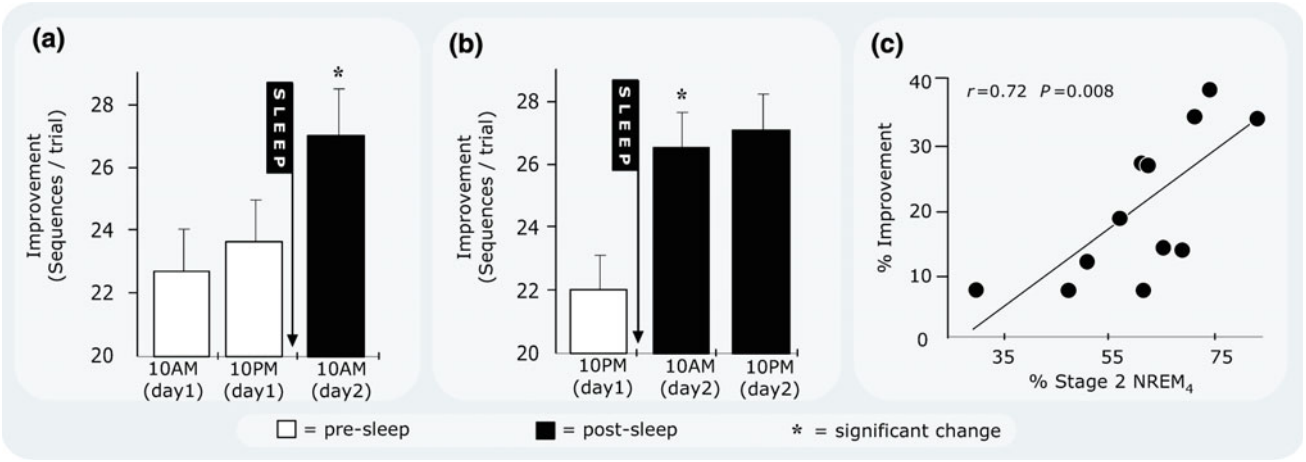

Fig. 13.3 Sleep-dependent motor skill learning in the human brain. **a** Wake 1st: After morning training (10 am, *light blue bar*), subjects showed no significant change in performance when tested after 12 h of wake time (10 pm, *light blue bar*). However, when tested again following a night of sleep (10 am, *dark blue bar*), performance had improved significantly. **b** Sleep 1st: After evening training (10 pm, *light blue bar*), subjects displayed significant performance improvements just 12 h after training following a night of sleep (10 am, *dark blue bar*), yet expressed no further significant change in performance following an additional 12 h of wake time (10 pm, *dark blue bar*). **c** Sleep stage correlation: The amount of overnight improvement on the motor skill task correlated with the percentage of stage 2 NREM sleep in the last (fourth) quarter of the night (stage 2 $NREM_4$). *Asterisk,* significant improvement relative to training; error bars, standard error of the mean (*SEM*)

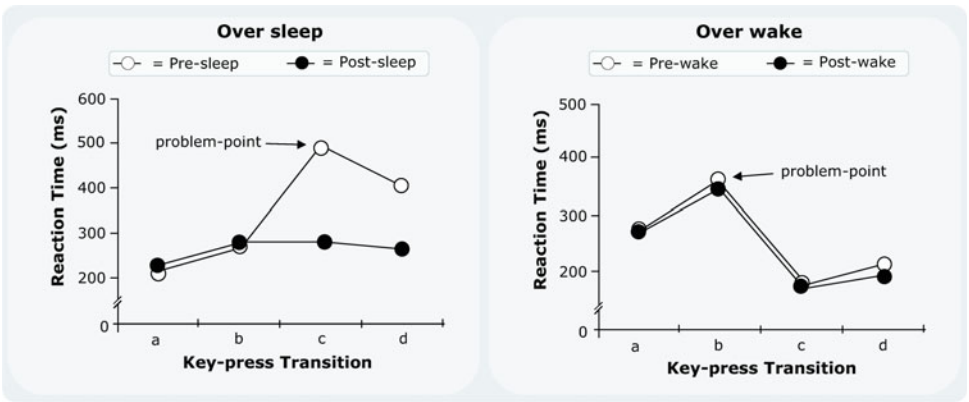

Fig. 13.4 Single-subject examples of changes in transition speeds. Within a five-element motor sequence (e.g., "4-1-3-2-4"), there are four unique key press transitions: (1) from 4 to 1, (2) from 1 to 3, (3) from 3 to 2, and (4) from 2 to 4. **a** The transition profile at the end of training before sleep (*light circles*) demonstrated considerable variability, with certain transitions being particularly slow (most difficult; "problem points"), whereas other transitions appear to be relatively rapid (easy). Following a night of sleep (*dark circles*), there was a specific reduction (improvement) in the time required for the slowest problem point transition. **b** Similarly, at the end of training before a waking interval, transition profiles were uneven (*light circles*), with some particularly slow transitions ("problem points") and other relatively fast transitions (easy). However, in contrast to post-sleep changes, no change in transition profile was observed following 8 h of wakefulness (*dark circles*)

retested after an 8-h waking interval across the day, no such improvement in the profile of key-press transitions, at any location within the sequence, was observed (Fig. 13.4b). These changes suggest that the sleep-dependent consolidation process may involve the unification of smaller motor memory units into one single memory element by selectively improving problem regions of the sequence. This overnight process would therefore offer a greater degree of performance automation and effectively optimize skill speed throughout the entire motor program.

The role of sleep in motor adaptation is less clear. Doyon and colleagues [62, 63] compared off-line changes in motor sequence learning to off-line changes in visuomotor adaptation. To measure adaptation, subjects used a joystick to move a cursor on the screen to a target. After practice, mapping between the joystick space and the cursor on screen

was inverted. Movements that were initially slow and inaccurate under inverted mapping conditions became faster and more accurate over time as participants adapted to the visuospatial shift. While replicating sleep-dependent performance changes on the motor sequence learning task, Doyon and colleagues failed to find preferential changes in performance over sleep on the motor adaptation task. Rather, motor adaptation improved equally over intervals with wake and sleep. These results are in contrast to an earlier study by Huber et al. [64]. Moreover, a rather consistent benefit of sleep has been observed for learning on a mirror tracing task which, like the visuomotor adaptation task of Doyon, requires learning of novel mapping between motor output and visual input. For example, Plihal and Born [65] found improvements in mirror tracing performance following late-night sleep, where REM and stage 2 non-REM dominate, even when early-night sleep was deprived. No such improvements were observed when participants had SWS-rich early-night sleep and late-night sleep was deprived. Moreover, Tamaki [66] found increased sleep spindle amplitude and duration after learning a mirror-tracing task, and this increase was associated with over-sleep improvements in performance.

Conflicting results across studies of motor skill consolidation may reflect limitations on sleep-dependent consolidation of motor skills. For instance, motor skill consolidation over sleep is biased by task difficulty. Kuriyama investigated the effects of increasing task complexity on sleep-dependent motor learning [60]. Subjects trained on a variety of task configurations involving either a short or long motor sequence performed either with one hand (unimanual) or coordinated between two hands (bimanual). Interestingly, the more complex the task became (long sequence, bimanual), the greater the overnight, sleep-dependent memory enhancement. This would indicate that, as task difficulty increases, the overnight sleep-dependent process responds with even greater performance improvements. Consistent with this, sleep was reported to benefit motor sequence learning for adults who were trained to an intermediate level of performance prior to sleep, whereas there was no benefit of sleep for experts [67].

Additionally, performance benefits from sleep are greater when participants are aware of the information to be learned [68]. This was demonstrated in a study comparing implicit motor sequence learning (subjects were not aware that finger responses to visual cues were in a sequence) under conditions which were either contextual—the sequence was embedded in a unique repeating context—or non-contextual. Sleep-dependent consolidation was present for the implicit contextual learning condition but not the non-contextual condition. Given that contextual learning is known to engage the hippocampus [69], we interpret these results as demonstrating the role of the hippocampus in consolidation of motor skills.

Taken together, overnight sleep has been shown to benefit motor skill performance, a benefit primarily associated with stage 2 NREM sleep and associated sleep spindles. Discrepancies across studies may be explained by limitations on this process with preferential consolidation for difficult tasks and those that engage the hippocampus [reviewed in 24].

Perceptual Learning

Karni et al. [70] have demonstrated that learning on a visual texture discrimination task improves significantly following a night of sleep. Furthermore, they established that selective REM, but not NREM sleep appears essential for these performance gains. Using the same task, Stickgold et al. [71] have shown that these enhancements are specifically sleep- and not time-dependent. Specifically, performance gains were correlated positively with the amount of both early-night SWS and late-night REM sleep, and the product of these two sleep parameters explained over 80 % of intersubject variance, an incredibly strong correlation.

Performance on a repeated visual search task also improves with sleep. In this task, participants are presented with arrays of L's in various orientations and must find a hidden T. When displays are repeated, although unbeknownst to the observer, reaction time decreases. In spite of the implicit nature of learning, individuals with medial-temporal lobe lesions (including the hippocampus) fail to learn this task [72]. Geyer et al. [73] demonstrated sleep-dependent improvements on this task, as measured by reduced reaction times to repeated displays further supporting a role of the hippocampus in sleep-dependent consolidation even in the procedural domain.

The Weather Prediction Task is a probabilistic category-learning task in which participants learn to predict the "weather" from a set of cards, each of which has a learned probability of "sun" or "clouds" [74]. Djonlagic et al. [75] found that a group of subjects who slept after observing responses on the task made significantly more accurate weather predictions than a group who stayed awake. Here too, the performance benefits for the sleep group varied by the level of encoding: Those participants for whom the task was less difficult (high accuracy) before sleep showed less improvement than those for whom the task was more difficult (intermediate accuracy). Moreover, when the study was repeated and subjects were required to learn the probabilities through feedback, now sleep had no effect on performance. Given that observational learning is hippocampus-dependent while feedback-based learning of this task is associated with the striatum [e.g., 76], the authors interpreted these results to suggest that sleep may consolidate hippocampal-based learning but not memories encoded in the striatum.

Summary

In summary, delayed off-line learning of many perceptual and motor skills appears to develop during overnight sleep and not across equivalent time periods awake. Such changes have been associated with stage 2 NREM and sleep spindles that are predominantly found in this sleep stage. However, the function of hippocampal-dependent reactivation in SWS is suggested to play a parallel role. How these functions interact across sleep is a matter of ongoing research [e.g., 24, 77]

Animal Studies

Studies using animal models have provided evidence for the role of sleep in primarily hippocampus-dependent tasks. Training on both spatial and shock avoidance tasks triggers alterations in sleep-stage characteristics [78–82], suggesting, as in humans, a homeostatic response to increased demands on sleep-dependent consolidation mechanisms. In one such study, the magnitude of change in sleep architecture following learning demonstrated a strong relationship to initial performance during acquisition, with animals that learned quickly showing the largest change in sleep structure, while those that learned poorly showed relatively little [83].

The benefit of sleep after learning on subsequent performance has been demonstrated in a range of species including non-human primates [84], cats [85], rats [86, 87], starlings [13, 88], honeybees [89], and fruit flies [90]. In one such study, Inostroza et al. [87] examined memory for object-place pairs in rats following an 80-min interval that either contained sleep or was spent fully awake. Memory for the location of objects was greater following sleep, whereas animals performed at chance if kept awake after encoding the object location (Fig. 13.5a). Moreover, sleep did not benefit the memory for a novel object recognition task, which is thought to be encoded independent of the hippocampus (Fig. 13.5b).

Memories are not only protected over sleep but enhanced as demonstrated in starlings, a songbird known for its ability to imitate the sounds of other birds. If two songs are learned in parallel, the memories interfere with one another as seen by impaired performance following an interval spent awake. However, when birds slept following the exposure to the interfering songs, performance improvements were observed, even when sleep followed a significant waking delay. These results suggest that sleep actively restored and enhanced the song memories. Additionally, when interference was presented following sleep, it did not impair performance for the song learned prior to sleep. Collectively, this work in song birds, similar to observations in humans [91], suggests that learning is actively consolidated and

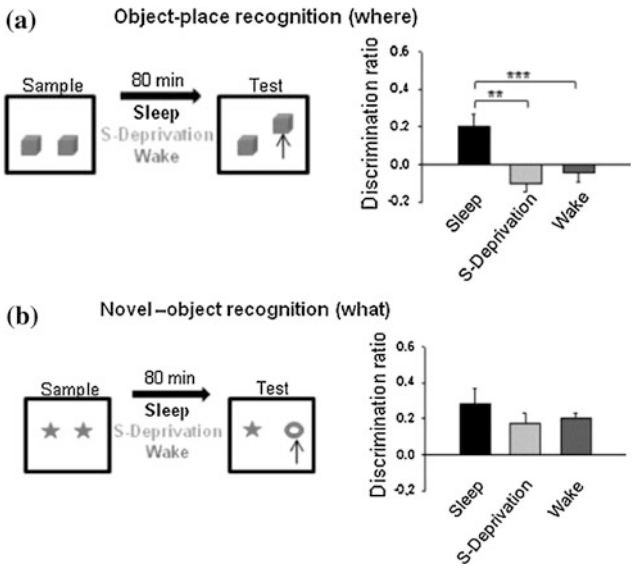

Fig. 13.5 Sleep-dependent learning in rats. **a** Animals learned an object-location task in the morning followed by normal sleep (*Sleep*) or sleep deprivation (*S-Deprivation*). The *Wake* condition took place in the evening when wakefulness is typical (i.e., not sleep deprived). Animals were significantly more likely to identify the misplaced object following sleep compared to both the sleep-deprivation and wake conditions as measured by the discrimination ratio (time spent at novel minus time spent at familiar divided by total exploration time). **b** In the novel-object recognition task, thought to be encoded independent of the hippocampus, animals were probed for their memory of a new object in the arena following sleep. There was no difference in discriminability for the novel object following sleep compared to the sleep-deprivation and wake conditions (Permissions needed from Inostroza et al. [87])

enhanced over sleep, leaving it more resistant to interference after sleep.

Summary

Taken as a whole, behavioral studies in humans and animal models leave little doubt that sleep plays a critical role in post-training memory consolidation. While both declarative and procedural memories have been shown to improve following sleep compared to wake, these memory systems appear to require subtly different sleep stages or even sleep-stage time windows, for consolidation and overnight improvement. With such evidence, it is important to consider the impact of little to no sleep as measured by studies of napping and sleep deprivation.

Sleep Deprivation

Reinforcing the role of sleep in memory consolidation is a wealth of literature illustrating the converse that sleep deprivation results in impaired declarative and procedural learning [80, 89, 92–100]. For example, total sleep deprivation (38 h awake) [101] and sleep restriction (overnight

sleep reduced to 4 h) [102], both yield performance impairments on a number of cognitive tasks including declarative learning.

However, many of these studies have been legitimately criticized for a failure to control for general effects of sleep deprivation on performance [103, 104]. Retesting in a sleep-deprived state may mask evidence of successful consolidation due to lowered alertness and attention. Alternatively, the increased stress of prolonged wakefulness, rather than the lack of sleep itself, may be the cause of unsuccessful consolidation.

More recent studies in both humans and animals have, however, demonstrated that impaired performance can still be seen several days after the end of sleep deprivation, when alertness and attention have returned to normal [105]. In addition, selective deprivation of specific sleep stages inhibits memory consolidation [98, 106], making arguments of sleep deprivation-induced stress relatively untenable, since the stress effects would have to be uniquely produced by deprivation of specific sleep stages during specific time windows following training.

Napping

Given this clear evidence that sleep is advantageous and sleep deprivation is disadvantageous for learning, several studies have asked the question "how much sleep is enough?" These studies have consistently revealed that a nap is sufficient for sleep-dependent changes in declarative [31, 107] and procedural memories [108–112]. Even a very brief nap of 6 min has been reported to increase recall of a declarative, word-list learning task [113]. Nonetheless, more sleep is better. Mednick and colleagues have shown that a 30- to 60-min daytime nap between repeated administrations of a texture discrimination task protects learning from the performance deterioration that is seen when subjects stay awake. If a longer nap period is introduced, ranging from 60 to 90 min and containing both REM sleep and NREM SWS, performance not only returns back to baseline but may be enhanced.

Sleep-Dependent Brain Plasticity

Memory formation depends on brain "plasticity"—lasting structural and functional changes in a neuron's response to a stimulus. The behavioral studies described above indirectly suggest a role of hippocampal plasticity in sleep-dependent memory consolidation, but recent direct evidence of sleep-dependent plasticity greatly strengthens this claim. In this section, we consider a wealth of data describing sleep-dependent brain plasticity at a variety of different levels in both animals and humans, complementing evidence of sleep-dependent changes in behavior.

Neuroimaging Studies

Modification of Post-training Sleep and Brain Activation

Several studies have investigated whether initial daytime training is capable of modifying functional brain activation during later sleep episodes. Based on earlier animal findings (described below), neuroimaging experiments have focused on whether the signature pattern of brain activity elicited while practicing a memory task actually re-emerges, or is "replayed" during sleep.

Maquet and colleagues have shown that patterns of brain activity expressed during motor skill training reappear during subsequent REM sleep, while no such change in REM sleep brain activity occurs in subjects who received no daytime training [114] (Fig. 13.6). Furthermore, these researchers have gone on to show that the extent of learning during daytime practice exhibits a positive relationship to the amount of reactivation during REM sleep [115]. Training on a hippocampus-dependent virtual maze task during the day has similarly been associated with a subsequent increase in hippocampal reactivation in NREM SWS [116], with the magnitude of reactivation correlating with performance on the task the following day, suggesting a function for neuronal replay. Such findings suggest that it is not simply experiencing the task that modifies subsequent sleep physiology, but the process of learning itself, and that this reactivation can lead to next-day behavioral improvements.

Overnight Reorganization of Memory Representations

An alternative approach to investigate sleep-dependent plasticity is to compare patterns of brain activation after a night of sleep. In contrast to measuring changes in functional activity *during* sleep, this approach aims to determine whether there is evidence that the neural representation of a memory has been reorganized following a night of sleep and whether this reorganization differs from that which may occur over wake.

With the behavioral characteristics of sleep-dependent motor sequence learning well established, Walker et al. were the first to examine the neural basis of sleep-dependent changes in learning by investigating differences in brain activation before and after sleep using functional magnetic resonance imaging (fMRI) [117]. Following a night of sleep, relative to an equivalent intervening time period awake, increased activation was identified in motor control structures of the right primary motor cortex (Fig. 13.7a) and left cerebellum (Fig. 13.7b)—changes that likely allow faster motor output to the trained, left hand, and more precise mapping of key-press movements post-sleep. There were

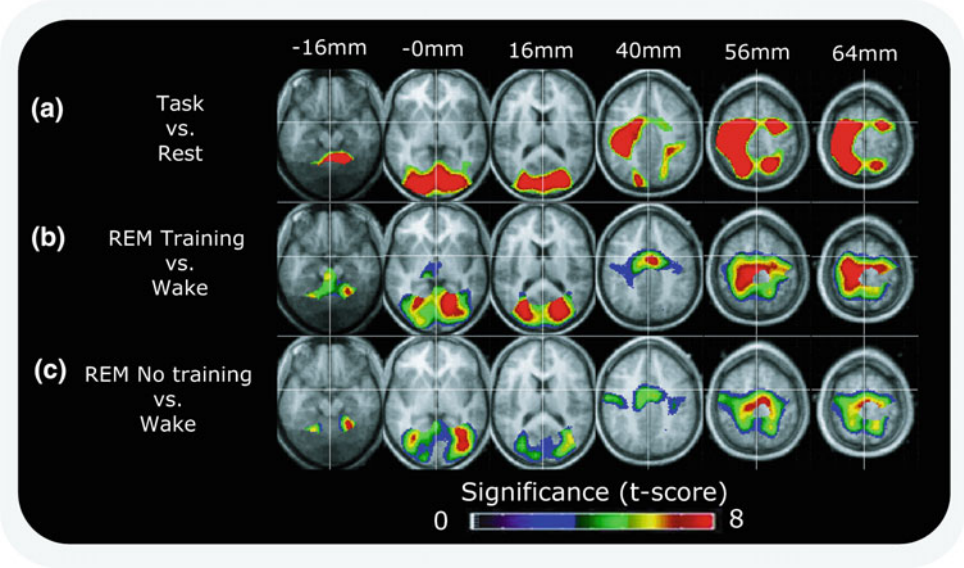

Fig. 13.6 Task-dependent reactivation of human brain activity during REM sleep. Statistical activation maps of different experimental contrasts. Maps are displayed at six different brain levels (from 16 mm below to 64 mm above the bicommissural plane), superimposed on the average magnetic resonance imaging (*MRI*) scan of subjects. All maps are thresholded at $p < 0.001$ (uncorrected), except for A, which is thresholded at voxel-level-corrected $p < 0.05$. **a** Brain regions activated during daytime performance of the motor skill task (Task–Rest). **b** Brain regions activated during subsequent REM sleep in subjects who received daytime training (REM Sleep Training–Rest); note considerable overlap with daytime task-dependent activity patterns. **c** Brain regions activated during REM sleep in subjects who did not receive any daytime training (REM Sleep No Training–Rest) (Reproduced with permission from Maquet et al. [114])

also regions of increased activation in the right medial prefrontal lobe and hippocampus (Fig. 13.7c, d), structures that support improved sequencing of motor movements in the correct order. In contrast, decreased activity post-sleep was identified bilaterally in the parietal cortices (Fig. 13.7e), possibly reflecting a reduced need for conscious spatial monitoring, and throughout the limbic system (Fig. 13.7f–h), indicating a decreased emotional task burden. In total, these results suggest that sleep-dependent motor learning is associated with a large-scale plastic reorganization of memory throughout several brain regions, allowing skilled motor movements to be executed more quickly, more accurately, and more automatically following sleep.

Debas et al. [62] contrasted changes in neural activation following sleep and wake for a motor skill learning task and a motor adaptation task. Consistent with their behavioral observations described above, there was an increase in activation in the primary motor cortex, the cerebellum, and the striatum for the motor sequence learning task following the off-line interval, with the activation of the striatum specifically modulated by sleep. However, there were no sleep-specific changes in neural activation patterns in conjunction with the motor adaptation task, consistent with the observation of limited over-sleep change in performance for this task.

Visual skill learning is also associated with underlying cortical plasticity. Post-sleep performance was associated with significantly increased activity not only in the primary visual cortex, but also in several downstream visual processing regions following sleep, at the occipital–temporal junction and in the medial temporal and inferior parietal lobes (regions involved in object detection and identification) [118]. These findings strengthen the claim that a night of sleep reorganizes the representation of a visual skill memory, with greater activation throughout the visual system following sleep likely offering improved identification of both the visual stimulus form and its location in space.

While most studies of over-sleep neural reorganization have focused on procedural learning, the neural basis of declarative memory consolidation has more recently been investigated. Takashima et al. [119] examined the long-term effects of a nap following the encoding phase of a picture recognition task. Picture recognition and the associated neural correlates were measured following a delay of 1, 2, 30, and 90 days. Following a delay of 1 day, the amount of time spent in SWS correlated positively with recognition performance and negatively with hippocampal activity during correct recognition. With time, recognition was associated with a decrease in the hippocampus activation coupled with a corresponding increase in ventromedial prefrontal cortex activation. This result is interpreted to suggest that SWS is associated with transfer of memories from the labile storage in the hippocampus to a more permanent representation in the cortex.

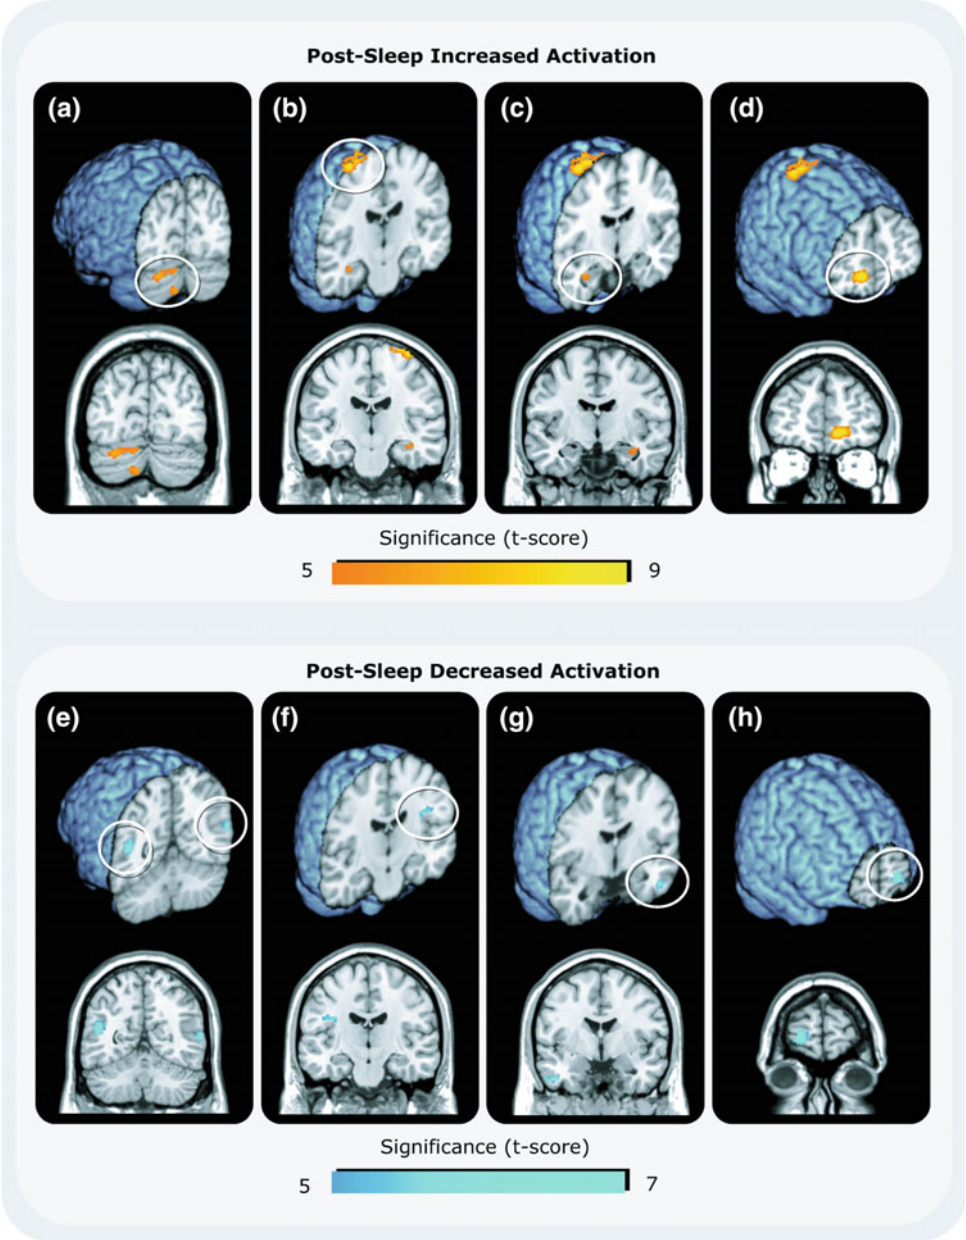

Fig. 13.7 Sleep-dependent motor memory reorganization. Subjects were trained on a sleep-dependent motor skill task and retested 12 h later, either following a night of sleep or following intervening wakefulness, during a functional MRI (*fMRI*) brain scanning session. Scans after sleep and wakefulness were compared (subtracted), resulting in regions showing increased fMRI activity post-sleep (in *red/yellow*; **a**–**d**) or decreased signal activity (in *blue*; **e**–**h**) post-sleep, relative to post-wakefulness. Activation patterns are displayed on three-dimensional rendered brains (*top panel* of each graphic), together with corresponding coronal sections (*bottom panel* of each graphic). Following sleep, regions of increased activation were identified in the right primary motor cortex (**b**), the left cerebellum (**a**), the right hippocampus (**c**), and the right medial prefrontal cortex (**d**). Regions of decreased activity post-sleep were expressed bilaterally in the parietal lobes (**e**), together with the left insula cortex (**f**), left temporal pole (**g**), and left frontopolar area (**h**), all regions of the extended limbic system. All data are displayed at a corrected threshold of $p < 0.05$

Overnight reorganization of emotional declarative memories has been the focus of many recent studies [120–122]. Similar to non-emotional declarative memories, memory for negative images following sleep is associated with less diffuse hippocampal activation. Specifically, Payne and Kensinger [120] examined changes in neural activity associated with an emotional picture recognition task following retention intervals with sleep or wake. Patterns of neural activation associated with successful recognition were distinct following sleep versus wake. After an interval of daytime wake, successful recognition of the negative images was associated with activation in a broad network including the lateral prefrontal,

parietal, and medial temporal lobes (including the hippocampus). In contrast, recognition performance following sleep was concentrated to a smaller network including the ventromedial prefrontal cortex, left amygdala, and cingulate gyrus.

Summary

Learning and memory are dependent on processes of brain plasticity, and sleep-dependent learning and memory consolidation must be mediated by such processes. Using brain imaging techniques, several studies have now identified changes in (1) the patterns of functional brain activity during post-training sleep periods (both REM and NREM) and (2) the reorganization of newly formed memories following a night of sleep. These plastic brain changes likely contribute to the refinement of the memory representations, resulting in improved next-day behavioral performance.

Electrophysiologic Studies

Evidence of sleep-dependent neuronal replay of waking experiences has accumulated from studies using multi-electrode recordings in the hippocampus of rodents. During waking exploration, the pattern of neural firing in hippocampal CA1 and CA3 cells, known as "place cells," is predictable as these cells exhibit an increased firing rate when the animal is in a particular location in space [123]. Initially, Wilson and McNaughton [124] observed that place cells that fired together during waking exploration tended to also fire together during subsequent sleep. Notably, in a subsequent study, Skaggs and McNaughton [125] found that not only was the same neural ensemble active, but cells were reactivated in the same order during sleep as they were during waking behavior. Dave and Margoliash [126, 127] have also shown that waking patterns of premotor activity observed during song learning in the zebra finch are also replayed during sleep, with a temporal structural similar to that seen in wakefulness.

Similar to studies in humans using contextual cues (odors, sounds) associated with learning to reactivate memories during sleep, Bendor and Wilson [128] selectively reactivated memories in rats during sleep and measured associated hippocampal replay. Prior to sleep, rats learned to move either left or right depending on a sound cue. During subsequent non-REM sleep, neurons associated with learning of this task were reactivated in the absence of any sound cue. However, when a task-related sound cue was presented, neurons associated with movements in the direction corresponding to that sound cue were preferentially fired. These results demonstrate a direct association between recent learning and the content of hippocampal replay.

Replay occurs in conjunction with sharp wave/ripple complexes in the hippocampus. Sharp waves are fast depolarizing events that overlap with high-frequency local field potential oscillations (ripples) and originate from pyramidal neurons in the CA1 region of the hippocampus [129–132]. Ripples have been associated with long-term potentiation (LTP), believed to be a physiologic mediator of memory formation [133, 134]; the frequency of ripples is conducive for LTP [135] and experimental suppression of hippocampal ripples has been shown to impair memory [136, 137].

Sleep spindles, generated by the thalamus and spread throughout the neocortex, co-occur with sharp wave/ripple complexes [138]. Rosanova and Ulrich [139] have shown that spike trains designed to mimic sleep spindles, delivered in vivo, produce both short-term and LTP. Moreover, functional connectivity between the hippocampus and the neocortex is increased in conjunction with spindles [140]. Thus, while behavioral evidence suggests that sleep spindles are associated with sleep-dependent performance changes, physiologically, spindles have been shown to support plasticity. Consistent with this, pharmacological manipulations which enhance spindle density in humans increase memory performance [141].

Together these data indicate that sleep-dependent reactivation of temporal patterns of network activity consistently occurs following learning experiences during wakefulness, across a broad spectrum of species. Neuronal replay of recent memories in the hippocampus via ripple events co-occurs with widespread neocortical activity driven by spindles. Such a mechanism is consistent with the proposal of hippocampal–neocortical transfer of memories over sleep, making memories less resistant to interference as new memories are encoded in the hippocampus [131, 142].

Cellular Studies

Sleep-dependent plasticity at the cellular level has been elegantly demonstrated during early post-natal development of the cat visual system [143, 144]. Under normal circumstances, brief periods of monocular visual deprivation during critical periods of development lead to the remodeling of synaptic connectivity, with the deprived eye's inputs to cortical neurons being first functionally weakened and then anatomically diminished [145]. Frank et al. [146] demonstrated that when 6 h of monocular deprivation are followed by 6 h of sleep, the size of the shift in cortical representation doubles. In contrast, if the cats are kept awake for these same 6 h (in the dark, without input to either eye), a nonsignificant *reduction* in the size of the shift occurs. Thus, sleep can contribute as much to developmental changes in synaptic connectivity as does visual experience, presumably by enhancing the initial changes occurring during a prior period of monocular deprivation. In contrast, sleep deprivation

results in a loss of previously formed, experience-dependent synaptic change, consistent with behavioral studies in humans [71].

Shaffery et al. [147] have reported complimentary findings of sleep-dependent plasticity in the rat visual cortex, suggesting that REM sleep, in conjunction with visual experience, modulates the initial time course of visual cortex maturation. In rats under 30 days of age, electrical stimulation produces increased excitability (potentiation) in specific layers of the visual cortex, while stimulation after this early developmental stage is unable to produce such potentiation. Depriving rats of REM sleep during this period can extend the window of plasticity by as much as 7 additional days, suggesting events occurring during REM sleep normally control the duration of this period of experience-dependent plasticity.

Molecular Studies

At the molecular level, Smith et al. [148] have shown that administration of protein synthesis inhibitors to rats during REM sleep windows thought to be critical for consolidation prevents behavioral improvement following the sleep period, while rats receiving saline injections show normal sleep-dependent learning. Such protein synthesis could reflect a fundamental mechanism regulating plasticity, namely the activation of genetic cascades that produce key molecules for synaptic remodeling. Such gene inductions during sleep have been the focus of more recent investigations. In their initial studies, Cirelli and Tononi reported that several of the known "immediate early genes" (IEGs) are specifically downregulated during sleep [149–151]. These findings have been used to argue that sleep is incapable of supporting plasticity and hence memory consolidation [103]. However, ample, more recent research by Cirelli et al. [152] has described approximately 100 genes that are specifically upregulated during sleep—almost the same number that are upregulated during wakefulness.

This extensive upregulation of genes was seen in the absence of any specific learning tasks being performed prior to sleep. Insofar as this upregulation is related to learning and memory consolidation, one might expect that such gene induction would only be seen after training on tasks that undergo sleep-dependent consolidation. Indeed, Ribeiro et al. [153, 154] have found upregulation of *zif*-268 and other plasticity-associated IEGs [155] in rats during REM sleep following exposure to a rich sensorimotor environment or induced hippocampal LTP, but found *zif*-268 downregulation during both SWS and REM sleep in the absence of such exposure. Thus, there appears to be a window for increased neuronal plasticity during REM sleep periods following enriched waking experience (Fig. 13.8).

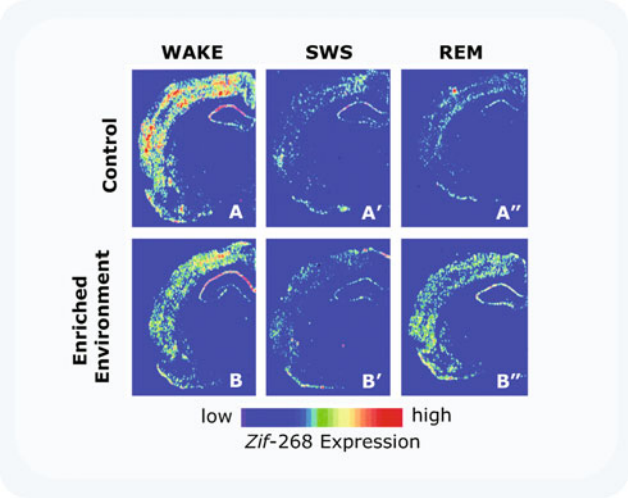

Fig. 13.8 Experience-dependent upregulation of *zif*-268 gene expression during wakefulness (WAKE) and slow-wave sleep (*SWS*) and REM sleep (REM) states in the rat. Autoradiograms of frontal coronal brain sections whose gene expression levels best represent the means for each group studied. In controls, *zif*-268 expression decreased from WAKE (A) to SWS (A′) and REM (A″). In enriched-environment animals, *zif*-268 levels decreased from WAKE (B) to SWS (B′), but increased from the latter to REM (B″). This effect was particularly noticeable in the cerebral cortex and the hippocampus (Reproduced with permission from Ribeiro et al. [153])

Summary

These studies at the cellular and molecular level illustrate the physiological basis of the changes in memory over sleep observed in behavioral studies. Although initial work failed to integrate behavioral changes with physiological findings, recent studies have successfully demonstrated sleep-dependent plasticity directly associated with waking behavior. While further work is needed to continue to integrate measures of plasticity and behavioral changes over sleep, evidence is accumulating in support for this relationship.

Unresolved Questions

Over the last several years, as evidence of sleep's role in learning and memory consolidation has grown, some researchers have raised questions concerning the nature of this relationship and specific mechanisms that are necessary to support it. Having focused our attention so far on the evidence in support of sleep's role, we turn now to concerns

and objections to this research, many of which hold clinical relevance.

Antidepressants, Sleep, and Memory

A recurring issue in the sleep and memory debate has been the REM sleep suppressant effects of monoamine oxidase inhibitors (MAOIs) and other antidepressants and the impact, or lack thereof, on memory functioning. These findings appear to suggest REM suppressants can be taken for years with no deleterious effects on learning [103, 104, 156]. First, although MAOIs appear to reduce REM sleep to a greater or lesser extent early in medication [157, 158], REM sleep re-emerges later in the course of medication [159–161], suggesting a strong REM compensatory mechanism. Furthermore, there is a potent REM rebound during periods when medication is paused—the so-called drug holidays [160, 162, 163]. As such, the claim that patients live for years without REM sleep is unfounded.

It is also important to keep in mind that most of these studies use a single test of memory which does not address the question of intact or impaired sleep-dependent learning, which requires a retest following sleep. No studies, to date, have retested performance following sleep, or recorded subjects' sleep to determine the extent of REM suppression. As a result, current studies are not conclusive regarding the role of post-training REM sleep in memory consolidation. A systematic study focusing on the effects of antidepressant medication on memory consolidation represents an important future goal, particularly considering the implications of such sleep-dependent memory impairment as a consequence of these drugs.

State Versus Trait

Some physiological measures of sleep that have been associated with memory have high within-subject correlations overtime, suggesting that they are a stable trait or phenotype. For instance, twin studies indicate that a significant proportion of the variability in stage 2 NREM and SWS is genetically determined [164]. Likewise, Geiger et al. [165] found low intra-individual (night-to-night) variability and high inter-individual variability in sleep-stage distributions and spectral power including the spindle range (sigma power). Of note, sigma power correlated with IQ. Thus, it is possible that associations between over-sleep changes in performance with sleep physiology, particularly sleep spindles, reflects these known associations between phenotypes. While research disentangling the state and trait relationships is ongoing, Schabus et al. [166] found state-specific spindle increases following learning in addition to the baseline association between spindles and cognitive abilities. This suggests that spindles, and perhaps other sleep features, may play both a state and trait role in learning.

Contributions of Sleep Micro- and macrostructure

As reviewed here, it is apparent that sleep spindles, occurring predominately in NREM, contribute to sleep-dependent hippocampal plasticity. However, it is clear that other aspects of sleep microstructure and macrostructure contribute to memory consolidation and how these factors work independent of or in conjunction with NREM sleep spindles has yet to be elucidated. For instance, Datta has suggested that ponto-geniculo-occipital (PGO) waves present in REM sleep underlie consolidation. PGO waves increase following training on an avoidance task and the increase is proportional to the degree of retention of performance over sleep [167]. These results imply that more time in REM sleep should be associated with greater memory consolidation. Given that Datta's observations were based on an avoidance task in which a foot shock is delivered, one possibility is that the role of PGO waves and, more generally, REM sleep may be restricted to aversive memory processing as suggested in human studies cited above. Likewise, it has been suggested that the macrostructure of sleep is important. Ficca and colleagues have reported that pre-sleep learning can result in an increase in the number of sleep cycles across the night and an increase in cycle time, and this increase is proportional to post-sleep performance [168]. Disturbing sleep cycle organization also resulted in impaired verbal recall following sleep [169]. More than likely memories evolve throughout sleep and reported associations with sleep micro and macrostructure may reflect the predominant contributing process. How the form of memory processing changes across a bout of sleep continues to provide fuel for theoretical debate [24] and future research.

Summary

Over the last 25 years, the field of sleep and memory research has grown exponentially. These reports, ranging from studies of cellular and molecular processes in animals to behavioral studies in humans, have provided a wealth of converging evidence that sleep-dependent mechanisms of neural plasticity lead to the consolidation of learning and memory across a range of animal species.

At the molecular level, a significant number of genes appear to be upregulated specifically in brain tissue during sleep. IEGs related to synaptic plasticity, including *zif*-286, are upregulated during REM sleep expressly in response to environmental or direct electrical stimulation of the

hippocampus. In rats, patterns of neuronal activation expressed during waking exploration reappear during subsequent sleep, and, in humans, patterns of regional brain activation seen during daytime task training are repeated during subsequent REM sleep.

At the electrophysiologic level, studies have shown enhanced hippocampal plasticity in conjunction with sleep spindles. In humans, spindle density increases following training on a declarative memory task, and, again, this increase correlates with subsequent improvement on the task.

At the behavioral level, animal studies have found robust increases in REM sleep following task training and decrements in performance after REM deprivation, even when retesting is delayed up to a week after the end of deprivation. In contrast, several animal studies have failed to find evidence of either increased REM sleep or deterioration following deprivation. Most likely, this reflects a combination of methodologic problems and conditions under which consolidation is, in fact, not sleep-dependent. Similarly, human studies have provided examples in which increases in REM sleep are seen following training; REM, SWS, or stage 2 NREM deprivation diminishes subsequent performance; and overnight improvement correlates with REM, SWS, or stage 2 NREM sleep.

In the end, the question appears not to be whether sleep mediates learning and memory consolidation, but instead, how and when it does so. The future of the field is truly exciting, and the challenge to neuroscience will be to both uncover the mechanisms of brain plasticity that underlie sleep-dependent memory consolidation, and to expand our understanding of sleep's role in memory processes beyond simple consolidation, into the constellation of additional processes that are critical for efficient memory development. Work across the neurosciences will be necessary to answer these questions, but with the current rate of growth of research in the field, the next decade should provide important advances in our understanding of this critical function of sleep. By way of this multidisciplinary approach, and with a measured appreciation that sleep plays a fundamental role in consolidating and reforming memories, we can look forward to new advances in treating disorders of memory, and perhaps even improving the capacity of our own.

Dreaming and Sleep Disorder

14

James F. Pagel and Seithikurippu R. Pandi-Perumal

A Short History of Dream Study

Dreams are ubiquitous yet poorly defined cognitive experiences that have been the focus of human interest and study since the dawn of recorded history. In the ancient Sumerian city of Ladak, about 6000 years ago, King Gudea inscribed multiple copies of a dream instructing him to orient his temple to the cardinal points. The dreams experienced by rulers, priests, and prophets were thought to be messages from gods, resulting in the incorporation of dreams and nightmares onto the walls of Egyptian Tombs, as well as into the texts of the Torah, the Bhagavad Gita, the Bible, and the Koran [1]. The ancient Greeks incorporated dreams as reflections of physical and psychological health into the Asclepius (the god of medicine) temple cults where patients slept at the foot of the god and reported their dreams in the morning to the priests. This ritual and the results of each prescribed treatment were recorded, laying an epistemological groundwork for the field of medicine. Dreams were an early focus of philosophy as reflected in Plato's records, in which Socrates was asking, "What proof could you give if anyone should ask us now, at the present moment, whether we are asleep and our thoughts are a dream, or whether we are awake and talking to each other in the waking condition?" [2]. In the seventeenth century, René Descartes developed the process of logic that we now call the scientific method based on a series of dreams. He first used that method in an attempt to differentiate his waking consciousness from that of his dreams, and like modern theorists found evidence through addressing the processes of memory. "I should no longer fear lest those things that are daily shown me by my senses are false; rather the hyperbolic doubts of the last few days ought to be rejected as worthy of derision—especially the principal doubt regarding sleep, which I did not distinguish from being awake. For I now notice that a very great difference exists between these two; dreams are never joined with all the other actions of life by the memory, as is the case with those actions that occur when one is awake" [3]. The philosophers, artists, and writers of the nineteenth century found much of the creative inspiration for modernism in the extreme experiences of nightmares and dreams [4]. Freud [5] at the turn of the twentieth century incorporated this perspective into the diagnostic and therapeutic process of psychoanalysis, in which dreams supplied insight into the psychodynamics of psychiatric illness. For much of that century, dreams were used and viewed as markers for the role of the unconscious. When in the 1950s sleep researchers at the University Chicago noted the strange phenomena of repetitious conjugate eye movements occurring periodically during the night, the immediate question was as to whether this physiological state (i.e., rapid eye movement or REM sleep) might be related to dreaming. When Dement awakened test subjects during this REM sleep state, most reported dreaming [6]. For many, this finding was the psychoanalytic "smoking gun" demonstrating a biological basis for postulated psychoanalytical constructs of brain function.

REM Sleep and Neuroconsciousness Theories

In the last 50 years, the scientific focus on dreaming has been on REM sleep as a scientifically measurable correlate of dreaming. Hobson and McCarley incorporated this perspective in their theory of activation-synthesis, proposing that all cognitive behaviors, both conscious and non-conscious, reflect physiological activity occurring in the central nervous system (CNS) [7]. Dreaming was viewed as a higher cerebral cognitive process utilizing the CNS activation associated with the primitive electrophysiologic-activated state of REM

sleep. A derivative of activation-synthesis, Activation, Integration, Modulation (AIM) theory, is currently the most fully developed and widely accepted theory of CNS functioning [8]. It is a primary postulate of AIM that the neurons and neurochemicals that modulate REM sleep also alter dreaming. Modern measures of the "dream" (e.g., REM sleep and associated position emission tomography [PET] and functional magnetic resonance imaging [fMRI] activity) are often confounded with the cognitive experience of dreaming. Research into the neuroanatomy, neurochemistry, and electrophysiology of REM sleep is often presented as dream research [9].

Defining Dreaming

The lack of an accepted definition for dream has created considerable confusion in the literature [10, 11]. In this chapter, a psychologically based definition will be used: dream is defined phenomenologically as cognition characterized by the presence of images, emotions, memories, as well as CNS activity that typifies dreaming.

The Neurochemistry of REM Sleep and Dreaming

The neurotransmitter acetylcholine was the first neurochemical discovered thought to trigger REM sleep. This effect is modulated by a wide spectrum of neuromodulators including serotonin, norepinephrine, and dopamine. It has been presumed that any neurochemical which alters REM sleep should alter dreaming [12]. Anti-cholinesterase inhibitors are agents known to produce an increase in acetylcholine levels and are reported in some studies to induce increased REM sleep percentages on polysomnography [13]. These agents are used as nerve gas agents and pesticides, and at low doses, donepezil, rivastigmine, and similar nutritional supplements are used to treat Alzheimer's disease. Case reports and small uncontrolled studies have been used to support utilization of these agents in attempting to increase dream intensity and lucidity [14, 15]. Data derived from clinical trials indicate a very different neurochemical association between medications and dreaming. A wide spectrum of agents including REM sleep suppressants, anesthetics, and anti-infectives induces nightmares and abnormal/disturbed dreaming in greater than 1 % of subjects enrolled in clinical trials [16] (Table 14.1). Donepezil is not included in this list, since during clinical trials, only 3 of 747 subjects reported changes in dreaming. Rivastigmine induced no reports of changes in dreaming in 1634 subjects [17]. Clinical trials include a large number of subjects, a control group, and methodology that avoid the plethora of competing variables and biases that characterize much dream research. Clinical trial data indicate that the medications utilized to suppress nightmares, alpha-adrenergic and beta-blocking anti-hypertensive medications, exert primary effects on norepinephrine, while suppressing or having minimal effect on REM sleep [18]. Medications that increase or suppress REM sleep have minimal effects on dreaming. Medications that alter dreaming often have no effect on REM sleep.

REM Sleep and Dreaming

After 50 years of research, we now understand far more about the electrophysiology, neuroanatomy, and neurochemistry of REM sleep than we understand about the cognitive state of dreaming. Multiple studies have demonstrated a bidirectional dissociation between REM sleep and dreaming. Dreaming can occur without REM sleep, and REM sleep can occur without dreaming [19–21]. Those researchers who are reluctant to separate REM sleep from dreaming have suggested a theory of covert REM sleep: when dreaming (defined as bizarre or hallucinatory mentation) is reported, REM sleep must have occurred whether or not it is evident on polysomnography [22]. Many neuroscientists have asserted that dreaming occurs during other stages of sleep but has a special relationship with REM sleep. According to these researchers, REM sleep dreams are the most emotional, vivid, bizarre, have the highest recall of any sleep state, are the only dream state with lucidity, and the only sleep mentation with "dream-like" content [23, 24].

Dream Bizarreness. In the 1950s, Hall and Van der Castle designed an analytic scale used for recording and statistically comparing dream content [25]. This classic and well-validated scale did not address bizarreness, a characteristic that has become important to dream scientists attempting to support a special relationship between REM sleep and dreaming. The Hobson bizarreness scale was developed that rates bizarreness based on the storyline content of the dream. Dreams that include incongruous, uncertain, and discontinuous wording and story are rated as the most bizarre [26]. Since REM sleep dreams tend to be longer and include more words and a more developed storyline, studies using this bizarreness scale consistently demonstrate that REM sleep dreams are the most bizarre. Bizarreness ratings for dreaming based on sleep state of origin vary markedly based on the scale utilized [27]. When factors such as hallucination, confusion, and atypical behavior are included in the assessment, the non-REM (NREM) sleep dream experiences of sleep onset and arousal

Table 14.1 Medications reported to induce nightmares and disturbed/abnormal dreaming in >1 % of clinical trial (ct) subjects

Affected neuroreceptor—drug class	Patient reports of nightmares and/or disturbed/abnormal dreaming
Norepinephrine—beta blockers	
Atenolol	CT [nightmares 3/20 patients]
Bisoprolol	CT [nightmares 3/68 patients]
Labetalol	CT [nightmares 5/175 patients]
Oxprenolol	CT [nightmares 11/130 patients]
Propranolol	CT [nightmares 8/107 patients]
Norepinephrine affecting agents	
Guanethidine	CT [nightmares 4/48 patients]
Serotonin—SSRI—antidepressants	
Fluoxetine	CT [nightmares 1–5 %—greater frequency in OCD and bulemia trials
Escitalopram oxalate	CT [Abnormal dreaming—1 % of 999 patients]
Nefazodone	CT [nightmares 3 % (372) vs. 2 % control]
Paroxetine	CT [nightmares 4 % (392) vs. 1 % control]
Agents affecting serotonin and norepinephrine—antidepressants	
Desvenlafaxine	CT [Abnormal dreams 4 % [400 mg] 2–3 % at lower doses vs. 1 % placebo]
Duloxetine	CT [2 % abnormal dreams (N = 3917) vs. <1 % placebo (N = 2548)]
Mirtazapine	CT [4 % abnormal dreams (N = 453) vs. 1 % placebo (N = 361)]
Risperidone	CT [1 % increased dream activity—2607 patients]
Venlafaxine	CT [nightmares 4 % (N = 1033) vs. 3 % control]
Dopamine agonists	
Amantadine	CT [5 % report abnormal dreams]: CR [1]
Levodopa	CT [nightmares 2/9 patients]
Ropinirole	CT [3 % (208) report abnormal dreaming vs. 2 % placebo]
Selegiline	CT [2/49 reporting vivid dreams]
Dopamine—amphetamine like agents	
Bethanidine	CT [nightmares 2/44 patients]
Fenfluramine	CT [nightmares 7/28 patients]: CR [1] de and re-challenge
Phenmetrazine	CT [nightmares 3/81 patients]
GABA	
Gaba hydroxy butyrate	CT [nightmares >1 % 473 patients]
Triazolam	CT [nightmares—7/21 patients]
Zopiclone	CT [nightmares in 3–5/83 patients]
Anti-infectives and immunosuppressants	
Amantadine	CT [5 % reporting abnormal dreams]: CR [1]
Fleroxacin	CT [nightmares in 7/84 patients]
Gusperimus	CT [nightmares in 13/36 patient]
Antipsychotics	
Clozapine	CT [4 % nightmares]
Antihistamine	
Chlorpheniramine	CT [nightmares in 4/80 patients]
ACE inhibitors	
Enalapril	CT [0.5–1 % abnormal dreaming—2987 patients]
Losartan potassium	CT [>1 % dream abnormality—858 patients]
Quinapril	CT [>3 % nightmares]
Other agents	
Sodium oxybate	CT—Nightmares in 3/102 subjects vs. 0/34 in control group

disorders of deep sleep are far more bizarre than those associated with REM sleep [9].

Vivid Dreams. If vivid is defined as an intense visual experience, the hypnagogic phenomena of sleep onset are clearly more vivid and more hallucinatory than REM sleep dreams. Methodologically controlled dream content analysis reveals that the primary correlate for dream content is waking experience (continuity) [21]. Such studies have not revealed a sleep stage correlate for content; however, if vivid is defined as content that is most like wake, the anxiety dreams of light sleep (Stage-2) have more continuity with the waking experience as do the dreams of REM sleep [9].

Lucid Dreaming. Lucid dreaming is often characterized as occurring only during REM sleep; however, this postulate was developed during the period, in which all dreaming was presumed to be related to REM sleep. Even those who initially described the state noted that up to 18 % of lucid dreams were reported from sleep onset, a period during which REM sleep rarely occurs [28]. During lucid dreaming, rather than the brain stem activation classically associated with REM sleep, multiple CNS sites are activated that are normally de-activated during REM sleep including the bilateral precuneus, cuneus, parietal lobules, prefrontal, and occipito-temporal cortices—sites associated with waking visual perceptual control and not usually associated with dreaming [29]. From an electrophysiological standpoint, the signaling criteria used in establishing the state of lucidity occur during episodes of arousal. The high level of alpha frequency associated with lucid dreaming has also led to suggestions that lucid dreaming may be a state of consciously controlled sleep offset between sleep and waking [30].

Empirical Evidence. Good empirical evidence refutes many of the postulates that have been used to support the perspective that a special relationship exists between REM sleep and dreaming. Sleep onset and REM sleep, both states that are close to waking, have similar recall frequency and content when length of the report is taken into account [19]. Dream content studies designed to eliminate transfer effects and researcher bias have indicated that the content of REM sleep dreaming may not be significantly different from the content of NREM sleep dreams [31]. Today, it remains problematic as to how our understandings of REM sleep electrophysiology, neuroanatomy, and neurochemistry can be applied to the cognitive state of dreaming.

The Sleep/Dream States—REM Sleep Dreaming

All mammals, almost all monotremes, and many birds demonstrate the electrophysiological state of REM sleep. Most humans, even those with extensive neurological damage, have episodes of REM sleep which persist even in very old age.

The dreams of all electrophysiologically described sleep states differ phenomenologically from each other. REM sleep dreams differ from other dreams. The best evidence for this difference is in the number of words and length of report—REM sleep dreams are longer than other dreams [32]. In part, at least, due to their length, REM sleep dreams are more likely to be organized into full narrative structures than are other dreams [4, 9]. Because of their length and narrative structure, REM sleep dreams are often the classic big dreams of psychoanalysis, creative discovery, religious, and ecstatic insight. The narrative structure associated with REM sleep dreams most resemble the narrative genre of personal experiences that we call "soap operas" [33].

Nightmares. Nightmares are the most common of all the parasomnias. They are more closely tied to REM sleep than are other dreams. Except in individuals with Post-traumatic stress disorder (PTSD), nightmares occur almost exclusively during REM sleep. Five percent of the general population report nightmares to be a problem, and among insomniacs, nightmares are reported at even higher frequencies [34]. For those who suffer from nightmares, it is the associated distress, rather than the frequency of occurrence that is most closely tied to waking dysfunction. When an individual experiences significant psychological or physical trauma, recurrent nightmares can mark the failure of CNS systems involved in emotional processing [35]. Nightmares are the most commonly reported symptom of PTSD. Recurrent nightmares that disturb sleep in individuals without a history of trauma denote the presence of nightmare disorder [36].

REM Sleep Parasomnias. The other REM sleep parasomnias that frequently include dream content include sleep paralysis; that often includes dreams with negative and frightening content, developed in great detail, and associated with distress that extends into awakening. The dreams of REM sleep behavior disorder (RBD) can be physically aggressive interactions in which the dreamer is attacked by unfamiliar people or animals. Individuals with RBD sometimes exhibit complex and violent behaviors associated with their dream mentation. Injuries to the sleeper or bed-partner are the most common symptom that leads them to seek medical attention. On video-polysomnographic monitoring, most of these individuals demonstrate increased muscle activity during REM sleep, a state that is normally characterized by motor atonia. This motor block that keeps us from moving during dreaming—fails, and individuals with RBD apparently act out their dreams. The parasomnias of RBD sometimes occur outside of REM sleep [37]. Dreaming bizarreness (both scales) and thought processing characteristics as based on work by Wolman and Kozmova for REM sleep dreams are summarized in Box 14.1 [38].

Box 14.1—REM Sleep Dreams: Formal Characteristics, Bizarreness, and Thought Processing

Formal Characteristics

- Coherent dream sequences
  - Detailed plot, character, or actions
- High recall
- Increased length of report
- Disturbing, intense emotions (nightmares and sleep paralysis)
- Potential lucidity
- Recurrent (reality based) PTSD
  - Comparative reality-based memory

Bizarreness

[Hobson Scale]
Discontinuities—high, Incongruities—high, and Uncertainties—high
[Hunt Scale]
Hallucinations—low, Clouding/confusion—low, and General—high—(uncanny emotion)

Rational Thought Processing

- Analytical—high
- Perceptual—high
- Memory and time awareness—high
- Affective—high
- Executive—high
- Subjective—high
- Intuitive/projective—high
- Operational—mod

Adapted and updated from Pagel and Helfter [16].

Some clinical trials did not query as to dream-associated drug side effects. This is particularly true for older medications >20 years.

The Sleep/Dream States—Sleep Onset

Despite high dream recall frequency (>80 %), the cognitive associations of sleep onset (Stage 1) have received only limited study. Most of what we know of sleep-onset dreaming comes from the study of hypnagogic parasomnias. Hypnagogic hallucinations commonly occur in otherwise normal people at the onset of sleep. These are true hallucinations, most often auditory but frequently visual, and seemingly real to the dreamer. These experiences can be quite bizarre and frightening, ranging from the sounds of a dog barking, a baby crying, or an alarm ringing that wakes the dreamer, to the extreme experience of suffocation at the hands of a succubus. Artists and writers have sometimes induced hypnagogic dreaming and used the resultant dream experiences in their work. Both Salvador Dali and John Keats, known to have used this technique, would attempt to fall asleep while sitting in a chair and holding a coin between thumb and index finger. When they fell asleep, their hands would relax, and the coin would fall into a dish set beside the chair and startling them to awake. There are those who insist that sleep-onset dreams are less bizarre than REM sleep dreams [23]. The surrealistic images that Salvador Dali derived using this technique argue otherwise. Sleep paralysis, most often associated with REM sleep and commonly present in patients with narcolepsy, can also occur at sleep onset. More than half the Americans queried report having experienced either sleep paralysis or hypnagogic hallucinations [39].

Sleep-onset dreams differ from the dreams of other stages of sleep. They are short in duration. They include intense visual imagery and only limited content or story. They can be reality based (particularly in individuals with PTSD) and are sometimes associated with intense distress and anxiety. Each occurs at the initiation of perceptual dissociation that marks the onset of sleep, forming a snapshot of non-perceptual visual consciousness present at sleep onset. These sleep-onset dreams convey an apparent perceptual consciousness but without perception and with limited associated content and memories, without control, yet with intense emotion, visual intensity, and detailed recall. Recent brain scanning studies indicate that compared to other sleep/dream states, large areas of the visual cortex continue to maintain activity despite the eyes-closed perceptual isolation of the state [40]. Sleep-onset dreams include apparently "bizarre" hallucinations, extreme emotional distress, and intense disassociation from reality, yet based on the Hobson scale, sleep-onset dreams due to their short and limited storyline scale are consistently rated as less bizarre than REM sleep dreams. Sleep-onset dream scores are completely different when based on alternative bizarreness scale scores developed by Hunt [27]. Formal characteristics, comparative bizarreness per scale, and characteristic dream state associated thought processes are included in Box 14.2.

Box 14.2—Sleep-Onset Dreaming [Formal Characteristics, Assessment of Bizarreness, and Thought Process]

Formal Characteristics

- Primarily visual hallucinations perceived as potentially real
- Coherent dream stories
- High recall
- Potential lucidity

- Impression of falling (Sleep Starts)
- Intense anxiety (PTSD, Sleep Paralysis)
- Recurrent (reality based) PTSD

Bizarreness

[Hobson Scale]
Discontinuities—high, Incongruities—low, and Uncertainties—low
[Hunt Scale]
Hallucinations—high, Clouding/confusion—high, and General—high (emotion, bizarre personification)

Rational Thought Processing

- Analytical—low
- Perceptual—high
- Memory and time awareness—high
- Affective—high
- Executive—low
- Subjective—high
- Intuitive/projective—low
- Operational—low

The Sleep/Dream States—Stage 2 Dreaming

Most of sleep is Stage 2, a stage that can be viewed as the junkyard of sleep, including all of sleep that is not sleep-onset, REM sleep, or deep sleep. Dream recall frequency is generally low, in the range of 40 %, and varies across the night. Since Stage 2 includes a majority of sleep, dream researchers in attempting to emphasize the association between REM sleep and dreaming have often extended this low recall percentage to NREM sleep [41]. Stage 2 dreams are often fragmentary containing thought-like content and disconnected visual imagery in which the dreamer is emotionally uninvolved. It has been suggested that this "degraded" mentation might be memory remnants from preceding REM sleep state or thoughts that developed after awakening [22]. Stage 2 dreams include fewer elements, a rather fragmented narrative structure, predominantly static impressions, and less emotional self-participatory involvement. The dream-like parasomnias associated with Stage 2 include sleep talking, anxiety dreams, and the brief moments of terror we call sleep panic attacks. These parasomnias share the characteristics of anxiousness and day reflective content. Panic attacks can include extreme emotion. Stage 2 dreams may extend throughout the night. They are rarely profound or particularly interesting. The formal characteristics, bizarreness, and thought processing of Stage 2 dreams and parasomnias are summarized in Box 14.3.

Box 14.3—Stage 2 Dreams: Formal Characteristics, Bizarreness, and Thought Process
Formal Characteristics

- Day reflective content
- Associated anxiety and panic
- Variable recall across night

Bizarreness

[Hobson Scale]
Discontinuities—low, Incongruities—low, and Uncertainties—low
[Hunt Scale]
Hallucinations—low, Clouding/confusion—low, and General—low

Rational Thought Processing

- Analytical—low
- Perceptual—mod (perceptual integration associated with K-complexes)
- Memory and time awareness—low
- Affective—low
- Executive—low
- Subjective—low
- Intuitive/projective—low
- Operational—mod (potential for arousal)

The Sleep/Dream States—Deep Sleep

Deep sleep (Stage 3) differs markedly from other stages of sleep. During deep sleep, perceptions are fully blocked, and we may not respond to pain. Tertiary aspects of consciousness are absent, and there is no volitional or executive control. During deep sleep, frontal cortex activity drops to a very low level. This is the one conscious state, during which the default network is minimally active and apparently decoupled, potentially contributing to an alteration or suspension of consciousness during deep sleep [42]. The reduced recall from this stage may be due in part to its cognitive distance from waking [43]. The dreams of deep sleep that we do remember differ markedly from waking consciousness. The dream content of deep sleep is most often reported as an emotion, a visual color, or perhaps an awareness that dreaming has occurred. Behaviorally, we would understand very little about the mental activity of deep sleep if it were not for the remarkable parasomnias (e.g., sleep terrors, somnambulism, and confusional arousals) occurring in this stage. These parasomnias (particularly somnambulism) are associated with autonomic

"zombie-like" motor activity during which complicated but common waking tasks can be clumsily accomplished (e.g., opening a door or window, preparing food, walking down stairs, picking up and loading a weapon, and running down the street). Computation is only minimally possible, and combination locks can be useful for patients wanting to protect themselves from the more dangerous nocturnal behaviors outside their room. Deep sleep parasomnias often include intense fear and extreme emotions, usually negative, frequently occurring in association with autonomic discharge (sweating, shaking, flushing, and nausea). The dreamer can become extremely angry, hitting out when awake occurring without the subject's conscious waking knowledge. The emotional outbursts of night terrors include a fright-ridden cry, sweating, flushing, and apparent abject terror. Confusional arousals typically include disorientation, slow speech, diminished mentation, and inappropriate behaviors that can be vigorous, highly resistive, and violent [44]. The arousal disorders are the most bizarre and emotional of the dream-associated parasomnias. They are frightening and disturbing to the observer. The formal characteristics of deep sleep dreaming as well as characteristic thought and bizarreness are specified in Box 14.4.

Box 14.4—Deep Sleep Dreaming: Formal Characteristics, Bizarreness, and Thought Process

- Somnambulism (sleepwalking)—Autonomic and inappropriate behaviors, frantic attempts to escape a perceived threat, fragmentary recall
- Confusional Arousals—Mental confusion and disorientation on arousal from sleep, inappropriate and violent behaviors
- Night Terrors—Incoherent vocalizations, extreme fear, intense autonomic discharge, confusion and disorientation, and fragmentary recall

Formal Characteristics

- Mental confusion and disorientation on arousal
- Fragmentary recall
- Autonomic and inappropriate behaviors
- Frantic attempts to escape a perceived threat

Bizarreness

[Hobson scale]
Discontinuities—low, Incongruities—low, and Uncertainties—high (explicit vagueness)
[Hunt Scale]
Hallucinations—low, Clouding/confusion—high (low recall), and General—high (emotion, bizarre personification)

Thought Process

- Analytical—low
- Perceptual—low
- Memory and time awareness—low
- Affective—high
- Executive—low
- Subjective—low
- Intuitive/projective—low
- Operational—low

Dreamless Sleep?

Since dreams are reported from all stages of sleep and since CNS activity in various forms is maintained throughout sleep, the question can be raised as to whether, like thought in waking, cognitive mentation (dreaming) may persist throughout sleep. Many years ago, Descartes suggested that dreamless sleep was a state of non-consciousness. He suggested that sleep without dreaming could not exist. Since "thinking" defined consciousness, a non-thinking, non-dreaming state could be neither conscious nor alive [3].

Variables Affecting Dream Recall. Individuals will sometimes report an absence of dreaming even when awakened during states characterized by high dream recall such as REM sleep and sleep onset. A reported lack of dream recall occurs even more often during episodes of Stage-2 and Stage-3 when reported dream recall declines to approximately 40 % of awakenings [19]. In other words, up to 1/3 of sleep in otherwise normal individuals can be considered to be "dreamless." Memory instability during the state transition from sleep to waking likely accounts for an overall 20 % of reported loss of dream recall, since that is the portion of dream recall typically lost even in the high recall states of sleep onset and REM sleep. The further diminution of recall from Stage 2 may be due to low dream probability secondary to low emotionality, uninteresting content, and anxiety-based characteristics of dreaming in that state. The lower levels of dream recall from Stage 3 (deep sleep) are most likely based on the stage's difference from waking [45].

There are a variety of reasons that individuals do not recall dreams. Variables known to affect the process of recall include time since dreaming and distraction after waking [46]. Dream content characteristics including salience and emotion can increase our tendency to recall a particular dream [47]. A lack of interest in dreaming, particularly in individuals without creative outlets, is also associated with diminished recall [48]. Some personality types (thick boundaries) have diminished dream recall [49]. Other

variables known to alter recall include gender, age, type of report collection (diary, awakening, and interview), and perceived definition of dream by both subject and researcher [50]. Dream studies are also extremely susceptible to collection, transference factors, methodology, and researcher bias [21, 51].

Non-dreamers. A loss of dreaming has been reported after extensive damage to the basilar bi-frontal cortex damage [52]. While rare, 1/262 (0.38 %) of sleep clinic patients will report after questionnaires and interview that they have never experienced a dream. These individuals report a lack of dream recall even when awakened multiple times during REM sleep and NREM sleep [53]. It has been suggested that these individuals are dreaming, but they just do not remember their dreams on waking. Current dream research, however, suggests that dreaming requires and uses many of the same memory systems that are required for waking functioning [54]. If the lack of dream recall indicates that memory systems are somehow compromised, waking memory impairment should be apparent (it was not for these individuals). The question remains as to whether these individuals, those who have experienced major brain trauma, or other individuals who occasionally report a lack of dream recall on awakening are truly experiencing dreamless sleep.

Dreaming in Other Sleep and Psychiatric Disorders

Obstructive Sleep Apnea (OSA) and Insomnia. Individuals with the complaint of insomnia report a higher frequency of both dream and nightmare recall [55]. However, when sleep is objectively measured in these patients, recall is significantly lower for those with lower sleep quality (prolonged latency, decreased time and efficiency, and increased wake after sleep onset [WASO]) [56]. Individuals who have recently developed PTSD and associated nightmares are likely to have at least mild sleep apnea [57]. In individuals with more severe sleep apnea, however, while dream recall is maintained, nightmares occur at a significantly lower frequency [58]. These studies suggest the possibility that for milder levels of both OSA and insomnia, increased arousals may contribute to increased dream and nightmare recall. However, as sleep becomes increasingly disturbed as the disorders worsen, dream recall declines. The initial approach to the diagnosis and treatment of most parasomnias requires polysomnographic study, in part to diagnose and treat OSA and periodic limb movement disorder (PLMD), and associated arousals that can contribute to increased expression of parasomnias.

Psychiatric Disorders. An extensive psychoanalytic-based literature has addressed the role of dreaming in the diagnosis and treatment of psychiatric disorders. A majority of these studies are clinical case reports. There are very few psychoanalytic dream content studies that use scientific methodology such as control groups and statistical analysis to control for conflicting variables. Recent studies that have controlled for the wide spectrum of variables known to affect dream content have been unable to demonstrate clear psychiatric diagnostic correlates for dream content: the two primary and persistent correlates for dream content and recall are clearly gender and waking experience (continuity) [21]. Recently, large diagnostic databases have become available, some including psychological questionnaires and questions regarding dreaming and nightmares. Some of these studies reopen the psychoanalytic question for the role of dreaming and nightmares in psychiatry, suggesting correlates for dream content for a wide spectrum of psychiatric diagnoses [59]. None of these studies, to this point, have used validated dream content questionnaires (e.g., Hall and Vander Castle), and addressed known conflicting variables including continuity, definition, transference, and researcher bias (particularly a problem when new questionnaires are utilized—note the discussion of dream bizarreness scales in this text). Continuity is a particularly difficult variable to control for such studies. It is not surprising that depressed patients might have more negative dreams, and violent patients have more dreams of aggression—such dreams reflect continuity with their waking experience.

Post-traumatic Stress Disorder

Post-traumatic stress disorder (PTSD) is the only psychiatric disorder clearly secondary to the environmental factors (major psychological or physical trauma). It is also the only psychiatric disorder in which the most common symptom is dream based, with recurrent distressing nightmares the most common symptom [60]. PTSD is a diagnosis for which psychoanalytic theory and practice have been utilized with particular intensity, and after all, it was Freud's perspective that all psychiatric disorders had a "traumatic trigger" [61]. Nightmares are more closely tied to REM sleep than other dreams. While in patients with PTSD these nightmares can occur at sleep onset and outside REM sleep, sleep-onset REM sleep periods and increased REM sleep pressure (short REM sleep latencies) are often present [62]. Due to these characteristics, activation-synthesis and the other neuroconsciousness theories have proven to be more coherent when used to address nightmares than when forcefully applied to all forms of dreaming [63]. Brain scanning studies have lent support to various theories that propose a function for REM sleep in emotional regulation by demonstrating that many of the neuroanatomic areas involved in the processing of fear and negative emotions have increased activity during REM sleep [64]. It has been proposed that PTSD nightmares occur secondary to the failure of a system of fear-memory

extinction that functions during REM sleep dreaming. The trauma-related nightmares of PTSD could mark the failure of this system [34, 35]. Central to this theory is the suggestion that nightmares reflect psychopathology, and that changes in nightmare prevalence, frequency, and severity, reflect a patient's emotional pressure and distress. [60]. Behavioral approaches to nightmare therapy (exposure/extinction and imagery) as well as the use of alpha-agonist medications (primarily prazosin) can lead to a marked reduction in nightmare frequency. Treatment can lead to decreased nightmare distress and improved sleep [18]. PTSD is a common and physiologically dangerous diagnosis that often has a chronic and persistent course. Currently available therapeutic approaches have limited efficacy [65]. However, the long-term benefits for nightmare suppression therapies have yet to be shown [66].

The Future of Dream Science

In the years since the initial excitement surrounding the discovery of REM sleep, the percentage of scientific papers addressing dreaming has declined [67]. Fifty years ago, the field of sleep medicine was dominated by dream-based psychodynamic perspectives. The associated focus on REM sleep as dreaming led to great leaps in our understanding of the neurophysiology of REM sleep, yet contributed little to our understanding of dreaming. In the mainstream of allopathic sleep medicine, the cognitive state of dreaming is considered primarily in association with disruptive behaviors, parasomnias, affecting sleep. Today, empiric dream science rests on smaller studies addressing competing variables, methodology, validity, and definition that have quietly persisted in a field dominated by grand yet experimentally unsubstantiated theories. The cognitive states of dreaming have been the focus of only minimal study. The future of dream science is wide open.

Study Design and Analysis in Sleep Medicine

15

Vincent A. DeBari

Introduction

The proper design and analysis of studies in sleep medicine is a critical aspect of research in this field. Likewise, the practice of evidence-based medicine demands that the clinician apply principles of epidemiology and biostatistics to his or her analysis of the literature. In this chapter, the fundamental principles of epidemiology and biostatistics will be presented by focusing on specific examples from the field of sleep disorders.

Clearly, this chapter cannot be an exhaustive tome on research methodology. The aim is to provide a vehicle in which basic principles of epidemiology and biostatistics can be presented in a manner which allows a better understanding of the strength of evidence provided by studies in sleep medicine.

An in-depth presentation of both of these areas of research methodology can be found in numerous books dedicated to them. It is hoped that this chapter will acquaint the reader with basic constructs in the design and analysis of sleep medicine studies in a decidedly non-mathematical manner. For the practicing sleep medicine physician for whom this chapter is intended, the widely available statistical software packages limit the need for detailed mathematical derivations. Practical concepts serve well in this regard.

Classification of Research Designs

Figure 15.1 presents a schematic representation of the hierarchy of research designs. Fundamentally, all modalities of clinical research can be classified as either *observational* or *interventional*. The simplest description of the difference between these methods is that in an observational study, the outcomes and exposures are preexisting, whereas in the interventional study, the researcher provides some (usually) therapeutic measure in an attempt to influence the outcome. In other words, in the former, the investigator is simply an observer (hence the term, *observational* study). These models range from the most basic observational activity, the *case report,* to the, generally, most definitive model, the *cohort study*.

Observational Studies

The value of case reports has been the subject of considerable debate among clinical researchers. Primarily, this negative attitude comes from a preponderance of cases that provide limited insight into the nature of the disease entity under investigation; these vignettes are simply "me too" reports of well-studied clinical conditions for which a minor variation in presentation or outcome is of some educational interest. On the other hand, documentation of a single case of an entirely novel clinical condition ultimately may lead to studies yielding potentially valuable insights into epidemiologic issues related to this condition. These could include both numerical estimates of the prevalence or incidence of the condition and its association with exposures from the environment, pathophysiological or pharmacologic risks, and infectious agents.

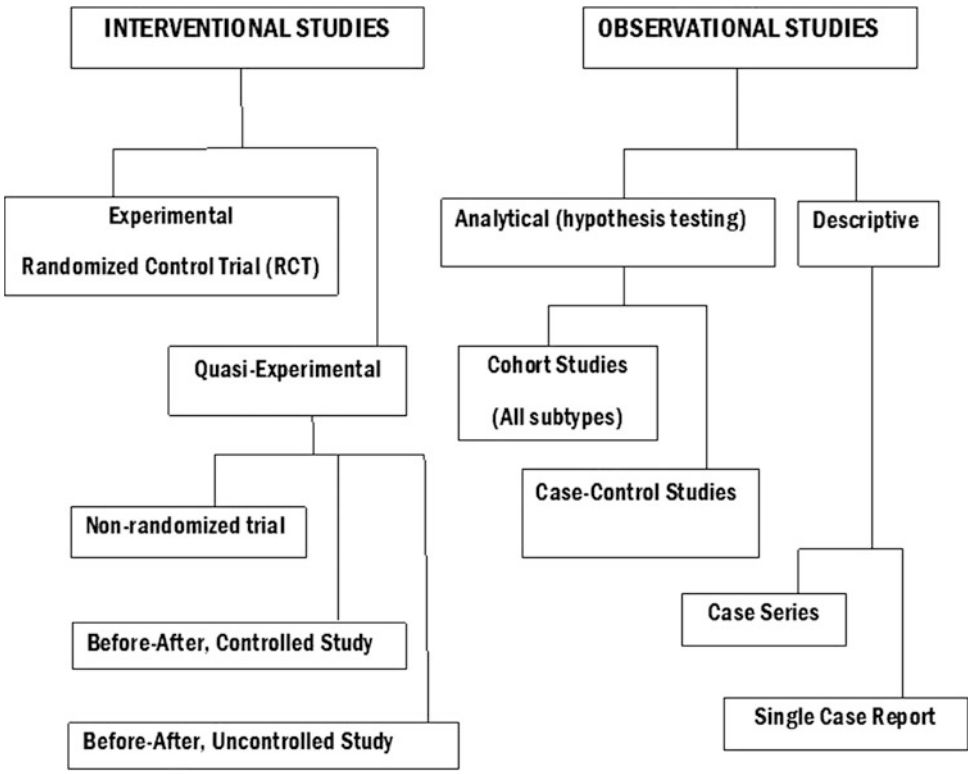

Fig. 15.1 Overview of analytical approaches in clinical research

Hierarchically, the next category of observational studies is the *case series*. As the name implies, this group of studies presents detailed accounts of multiple cases (typically three or more) of a given condition. For epidemiological utility, the cases within the series usually have some degree of commonality beyond the clinical outcome. Thus, in their entirety, they present a cohesive group of entities which are, not only, related to outcome but by the presence of one or more potentially common exposures. Of course, the great danger in attempting to relate these exposures to the outcomes presented by these cases is the temptation to attribute the status of association or, worse yet, of causality to these observations. However, careful documentation of a series of related cases can be valuable in identifying epidemiological factors related to the disease under investigation. Thus, a carefully presented case series is an important first step in the analytical study of diseases because of its ability to generate one or more hypotheses, which can be tested in a formal, analytical manner. This leads to the next group of observational designs, the *hypothesis testing* or *analytical* studies. In this group of observational studies, formal statistical approaches are used to glean information on the occurrence and on the associations of the outcomes with exposures that might ultimately be found to be risk factors for a given outcome.

The most basic of the analytical designs is the *case–control study* (Fig. 15.2). In this model, the individuals with a given clinical outcome (symptom, disease, or syndrome), i.e., *cases,* are compared in some manner with a *control* group of usually healthy individuals or individuals not exhibiting any symptomatology similar to the *case* group. Thus, the comparison is made between the two groups and subject inclusion in either group is based simply on which group the individual belongs. Once the groups have been delineated, the investigator examines such issue differences in numerical occurrence between the groups (incidence or prevalence), quantitative differences between observed exposures or putative risk factors, and associations between these exposures and the occurrence of disease. Lam et al. [1] effectively used this design to examine association of daytime sleepiness and restless legs syndrome with type 2 myotonic dystrophy (DM2).

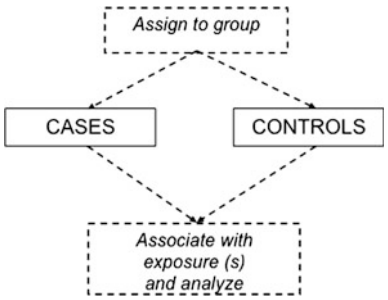

Fig. 15.2 Basic flow chart for the case–control study. Assignment to group is based on the presence (*cases*) or absence (*controls*) of the clinical entity of interest

Most case–control studies are retrospective, but this is not an absolute: Subjects can be recruited into the assigned groups in a prospective fashion. Case–control studies have the advantage of being able to study relatively rare conditions in which the numbers of cases are small. To increase the statistical power of the study (more on this, later), the number of controls is often increased from two to ten times the number of cases. For example, in the previously cited paper [1], there were 54 DM2 subjects enrolled in the study, but these patients were compared with a control group of 104 individuals drawn from the general clinic population of the authors' institution.

Case–control studies, especially retrospective ones, however, have several drawbacks. The degree of risk imposed by a given exposure is difficult to ascertain. In fact, there is no way of determining whether a control will eventually exhibit symptoms suggesting of the disease state present in the cases. Moreover, the primary patient record, which is surveyed for the pertinent data, may not have included relevant information—or may have large amounts of data excluded. Therefore, in case–control studies, the *odds ratio* (OR) rather than *relative risk* (or *risk ratio*, RR) is used to provide an estimate of the magnitude of effect. Another drawback of case–control studies is the difficulty in obtaining *longitudinal* data; the data obtained from most case–control studies is *cross-sectional*, based on observations of simultaneously occurring events such as outcomes and exposures. All these factors lead to the consideration of the case–control study as a relatively weak design from the point of view of strength of medical evidence. The aforementioned technique of increasing the size of the control group (or having a large number of cases) and the use of matching for age, gender, or other potential confounders can increase the evidentiary value of the study.

A far stronger and more versatile group of studies are the *cohort* studies (Fig. 15.3). These start with a group of individuals with a common attribute or clinical finding. For example, the cohort might be drawn from the general public or some subset of the general public. This would be considered to be a *population-based* cohort study such as that conducted by Lai et al. [2] on the risk of type 2 diabetes mellitus (DM type 2) in subjects with non-apnea sleep disorders. In this study, the cohort was drawn from a large health insurance database of Taiwanese subjects. Another possibility would be to select an at-risk cohort sharing some common clinical entity, e.g., congestive heart failure, DM type 2, or obstructive sleep apnea. Cleator et al. [3] developed a cohort based on severe obesity (BMI > 40 kg/m^2) in a group of British subjects. They examined point prevalence and differences in characteristics such as age, gender and data from several questionnaire-based instruments (e.g., the Pittsburgh Sleep Quality Index, the Epworth Sleepiness Score, and the night eating questionnaire). In either type of

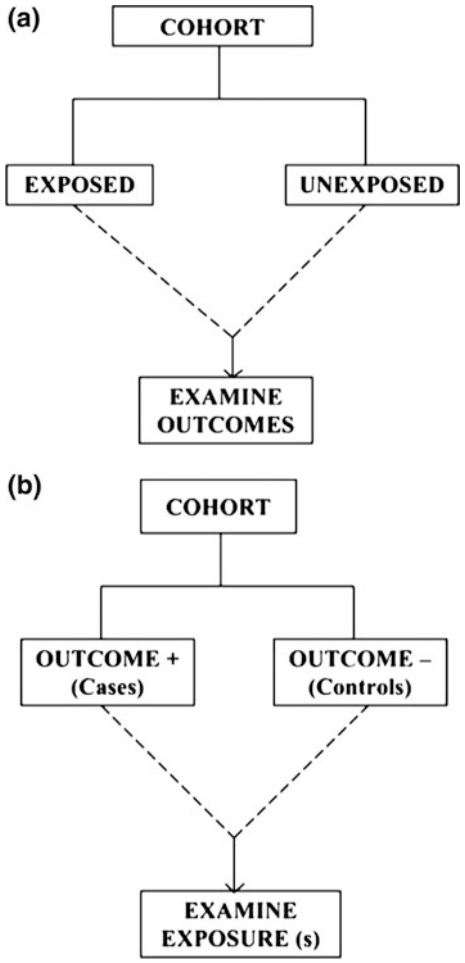

Fig. 15.3 Flow charts for cohort studies. **a** The cohort is bifurcated into subjects with and subjects without a putative risk factor (exposure). **b** The cohort is divided based on the presence or absence of a given outcome or symptomatology. This is referred to as cohort-nested case–control study

cohort study, the cohort can be divided into two or more comparative groups based on some exposure including genotypic or phenotypic *biomarkers*, (Fig. 15.3a) or by the presence or absence of some additional symptomatology or comorbidity (Fig. 15.3b). The latter study is referred to as a *cohort-nested* (or just, "*nested*") case–control study.

Cohort studies may be either retrospective or prospective and have several advantages over case–control studies. Cohort studies, as noted above, offer a degree of versatility difficult to obtain in case–control studies. They may, for example, contain several arms, i.e., essentially substudies examining more than one facet of the cohort. They also provide longitudinal data in a far more facile manner than case–control studies. Also, in the case of prospective cohort studies, potential biases can be negated by careful planning and early consideration of confounding factors. An important thing to remember in the case of all observational studies is that association, except in several very rare cases,

never implies causality. Cause-and-effect is virtually always the domain of the interventional study. This leads to an examination of that group of studies.

Interventional Studies

Among interventional studies, as noted in Fig. 15.1, we consider several designs, *experimental* and *quasi-experimental*. In both types, the investigator provides one or more *independent variables*, almost always related to treatment (the intervention or interventions) and examines one or more *dependent variables*, related to outcomes.

In medical disciplines, the experimental design is typified by the *randomized controlled trial* (RCT). As the name implies, the subjects are randomly assigned to groups. The manner in which they are randomized may vary from simple randomization methods, requiring nothing more than a coin toss (although assignment in modern studies is based not on the heads or tails result of a flipped coin but rather on the use of a computer-generated random number) to more complex randomization schemes. These include several variations of randomization in *block*s of various sizes used to avoid unequal distributions of one or more potential *confounders*, variables which might introduce a bias into the study.

Another issue in the RCT is the comparison group. As noted above, by virtual definition, the group receiving the active intervention will be compared with the control group. In the past, the expectation in examining most RCTs was that the control group would be given a *placebo*, essentially a mimic of the active treatment that is expected to lack any activity, in and of itself. However, with the plethora of treatment options available today, the use of a placebo renders the ethical use of an expectedly ineffective placebo ethically dubious, particularly when effective therapy is available to clinicians. Thus, a technique that is used in many modern studies is to compare the experimental intervention with a therapy of established efficacy. Chihara et al. [4] randomized ninety-three subjects to three groups: Auto-adjusting positive airway pressure (APAP) was applied to one group, and APAP with pressure flexing devices (A-Flex and C-Flex) were provided to the other two groups.

Occasionally, evaluations are often performed initially with a *non-inferiority* study such as the study by White and Shafazand [5] which examined the hypothesis that treatment with a mandibular advancement device is just as effective as continuous positive airway pressure). As the name implies, the object of this type of study is to establish that the experimental treatment performs no poorer than the treatment with established efficacy by a level known as the *non-inferiority margin* [6]. As will be discussed further in this chapter, the statistical approach used in the analysis of non-inferiority trials is somewhat different than a "head-to-head" trial in that the investigators, *a priori*, account only for the possibility that the experimental maneuver will be no worse than the comparator or control modality.

At this point, several additional aspects of the RCT should be mentioned. Investigators are often faced with the need to control for differences in dosing schedule or route of administration between the experimental intervention and the comparator. In this case, the need to include placebos for both differences becomes apparent. This maneuver, called a *double-dummy*, is frequently employed in the RCT and is exemplified by the study by Valente et al. [7] comparing sublingual and oral Zolpidem to initiate sleep onset in healthy subjects.

In addition to the RCT, other interventional models are occasionally used in interventional studies. Foremost among these are *quasi-experimental* studies, in which the subjects are not randomized [8]. One of the most commonly used quasi-experimental approaches is the *pre-* and *post*-model, in which the individual essentially acts as his or her own control. Such a study was conducted by Wei et al. [9] to determine the value of implanting blue-light blocking intraocular lenses in improvement of the quality of sleep in cataract patients. It should be recognized that in the absence of an external control, differences in the dependent variable before treatment and after treatment may be solely a function of some unknown confounder, e.g., time. Thus, a study such as this can be strengthened by the addition of a control group in which the difference in the dependent variable is also measured.

In terms of analyzing the result of an interventional study, the research team needs to determine whether only subjects who completed the study, as designed, should be included in the data analysis—or whether all subjects initially enrolled should be included. The former analytical approach is called *per protocol* analysis, and the latter, *intention-to-treat* (ITT) analysis. In that, it gives a better gauge of the overall utility of a given treatment, and most studies, today, use ITT as the primary approach to analysis.

Factors Involved in Determining Validity

Validity, in essence, deals with the correctness of conclusions drawn from an experiment. Various facets (construct validity, content validity, face validity, and predictive validity) can be examined separately; however, in most sleep studies (as is the case with most examples of clinical research), two main components of validity are examined: *internal validity* and *external validity*.

When designing a study, invariably a group or groups of subjects are examined in terms of their response (a dependent variable) to an intervention (an independent variable) or the association or differences of some outcome variable with respect to some exposure or predictor variable (more on this further in this chapter). The first issue relating to the process of relating dependent variables or outcomes to independent variables or exposures is the correctness of the process, i.e., getting the right answer about the individuals that the researchers, i.e., studied. This is internal validity. However, the ultimate goal is to determine whether that answer is applicable to the population which is represented by the sample used in the research. The ability to generalize from the sample to the population is external validity. In order to achieve external validity, the investigators must, first and foremost, apply appropriate inclusion and exclusion criteria to the process of subject recruitment. Simply put, the sample must be representative of the population with which the study deals. Clearly, then, the sample should have the demographic and clinical characteristics of the population of interest (inclusion criteria) and avoid subjects with demographic or clinical characteristics that render them different (exclusion criteria) from the population of interest.

Basics of Statistical Analysis in Clinical Research

Fundamentally, the application of statistical methods in clinical research serves two purposes: first, to compare the result of an observation or experiment with that result which would occur purely by chance, and second, to determine the magnitude of the observed effect so that the clinician can interpret just how useful the information garnered from a study might be to the provider as well as the patient. This section will review the basic steps that are taken in the analysis of different types of data emanating from research studies.

Variables in Clinical Studies

The data from clinical studies can be categorized as variables in terms of both how the investigator obtained it (a relational description) and the kind of information it provides (a functional description). In the first case, the question asked is "did the observer provide, as part of the protocol, the variable in question or was that variable the expected result of the experiment?" If the former, the variable is an *independent variable*; if the latter, it is a *dependent variable*. It is easy to see how this applies in an interventional study: The intervention is the independent variable and the result, as measured, is the dependent variable, but what of observational studies, in which the investigator does not apply the intervention? In this case, one may reasonably consider the construct in which the study exists as an experiment of nature. In other words, the experiment has already occurred through genetic, pathophysiologic, nutritional, or other epidemiological forces. Thus, the role of the researcher is to simply analyze the result, in terms of some independent variable (as noted above, the *exposure*), and a dependent variable, the *outcome*.

Variables are also described in terms of their functionality as measurements. This is often called the *levels of measurement*. A convenient approach is to consider three broad categories of data: *quantitative*, *qualitative,* and *ordinal*. In the former, two subtypes are included: *interval* and *ratio* data. Interval data are those which provide numerical values with a continuum that lacks a set zero value or for which a zero value is arbitrary. Temperature scales other than absolute are examples of this type of data. Ratio data have a true zero value and numbers in a ratio data set are referenced directly to that zero value. So, temperatures from the Celsius or Fahrenheit scale being interval in nature and not referenced to a non-arbitrary zero point are interval in nature: 40 °C is not half as warm as 80 °C. On the other hand, a serum analyte, e.g., glucose of 200 mg/dl is, indeed, twice the actual concentration of a serum glucose level of 100 mg/dl. These are ratio data because they can be referenced to a theoretical level of 0 mg/dl. Another set of descriptors used for quantitative data (not included in Fig. 15.3) is *continuous* and *discreet*. Continuous data are those which are infinitely divisible, limited only by our instruments of measurement. Discreet data are indivisible: They are either naturally discreet (number of siblings or copies of an amplified gene) or conveniently discreet such as age, most often recorded to the completed year of life. For all of the aforementioned quantitative data, descriptive statistics reasonably include properties of their distribution including measures of the central tendency (*mean*, *median,* and *mode*) and measures of *dispersion* ("variability," to be discussed later in this chapter).

Quantitative data are easily recognized in that rather than having numerical values, they have names, i.e., are *nominal* or *categorical.* They can range from *dichotomous* (dead, alive, or exposure present/absent) to categories with multiple descriptive choices such as race and ethnicity. In describing these data, only a number of subjects with the quality apply.

Ordinal data represent a sort of hybrid: They are described with numbers but the numerical values are purely representative of degree rather than any true mathematical relationship. Several types of ordinal data are encountered in clinical studies. Most commonly used are the *visual analog scale* (VAS) and the *Likert* scale. In a VAS, the numerical values represent the intensity of a measurement on a mathematical continuum and, as conceptually analog, can be

subdivided to some degree. An example of a VAS is the commonly used clinical pain scale which ranges from 0 (no pain) to 10 (worst pain imaginable). In this scale, being conceptually analog, a patient's response such as "5.5" would be acceptable (however, would ordinarily be given a value of 5 or 6). In a Likert scale, commonly used in survey instruments such as questionnaires, an item is generally given a numerical value indicating a property such as frequency, with "never" being assigned a value of 0 and "always" having a value of 5. Likert items are virtually always treated as discreet values. It is easy to recognize that ordinal numbers are purely representative and arbitrary. An individual who describes his or her pain as an "8" does not necessarily have twice as much pain as an individual whose pain is described as "4." This being the case, we treat the numerical values emanating from an ordinal scale differently than we do true quantitative data. In terms of descriptive statistics, the central tendency of an ordinal data set is best described by the median and the dispersion by some measure of range, such as minimum–maximum or *interquartile range* (IQR), the 25th to 75th percentile of values.

There are also clinical scales, such as the Acute Physiology and Chronic Health Evaluation (APACHE II) and the Pneumonia Severity Index (PSI) which are based on the totality of a group of clinical signs and symptoms. There is no consensus as to whether these should be treated as discreet interval data or ordinal data; however, the wide range of values attributable to these scales suggests that there is an inherent mathematical relationship among scores from these clinical scales. Moreover, global scores from questionnaires utilizing Likert items are frequently treated as interval data.

Descriptive Statistics

That branch of biostatistics that examines how values of a variable are distributed is called *descriptive statistics*. In the case of qualitative data, descriptive statistics, as previously noted, is limited simply to counts, i.e., number of subjects exhibiting a particular quality. Of course, a necessary outcome of that description, albeit secondary, is the proportion (percentage or percent) of subjects with that quality.

Quantitative data, however, are examined in terms of how they are distributed. They are described in terms of their central tendencies and dispersion. Precisely, *how* they are distributed generally determines the choice of central tendency and unit(s) of dispersion.

It is extremely important to recognize whether a set of quantitative data is distributed *normally* (described by a *Gaussian* distribution). The reason for this is because when inferential statistical methods (collectively, those statistical tests which provide information about how likely or unlikely what we have observed has occurred purely by chance) are applied, the nature of the distribution will bear on this choice in nearly all cases.

The normal distribution is easily recognized as the classic "bell curve," i.e., it has two "tails" set about a central tendency. Examples of this distribution abound in the literature and can easily be located in elementary statistics texts and on the Internet. The tails are symmetrical, that is they lack *skewness* and are neither too peaked nor too flat (the degree of "peakedness" or flatness is called *kurtosis*). The range of values between the points of inflection on both the rising and falling sides of the distribution curve is equivalent to roughly 67 % of all the values in the data set. This is ± 1 *standard deviation* (SD). Taking twice this value, 2 SD, yields approximately 95 % of the values and, at 3 SD, over 99 % of the values are accounted for. For data which are normally distributed, the branch of inferential statistical tests known as *parametric* (because they are based on the actual value of the parameter or variable) methods can be applied. With the exception of extremely large data sets for which the choice is unnecessary, those data sets that are not normally distributed should be subjected to *nonparametric* tests, which are generally based on rank order of the parameter rather than the parameter itself. Ordinal data are always treated with nonparametric methods, as the parameter is essentially meaningless from a mathematical standpoint.

The question then arises, how is one to determine whether a data set is normally distributed or at least approximates a normal distribution well enough to warrant the application of parametric tests? Simply graphing the values as a differential distribution plot (number or percentage of subjects vs. the incremental value of the variable), in most cases, requires a very large sample to visually observe a normal distribution. This conundrum has been addressed many times in the statistics literature, and the approach most often taken is to apply one of the more commonly used "normality tests," collectively, a group of statistical maneuvers designed to determine how much the distribution of a variable differs from a normal distribution. Some of the most common tests are based on the comparison of a simulated distribution best fit to a normal distribution with the actual distribution of the data. A good example of this is the Lilliefors (Kolmogorov–Smirnov) test, which dates back to 1967 [10]. The normality tests developed by D'Agostino and Pearson [11] take a different approach, in which a parameter, K^2, summarizes the skewness and kurtosis of the distribution. Thus, the fit to normality is based on the actual shape of the distribution.

At this point, it might be wise to recognize that remarkably few physiologic parameters distribute normally. In many cases, a *log-normal* distribution is observed, in which case the distribution exhibits considerable skew to the right, i.e., toward increasing values of the variable. In this case, simply transforming the data by taking the log of the

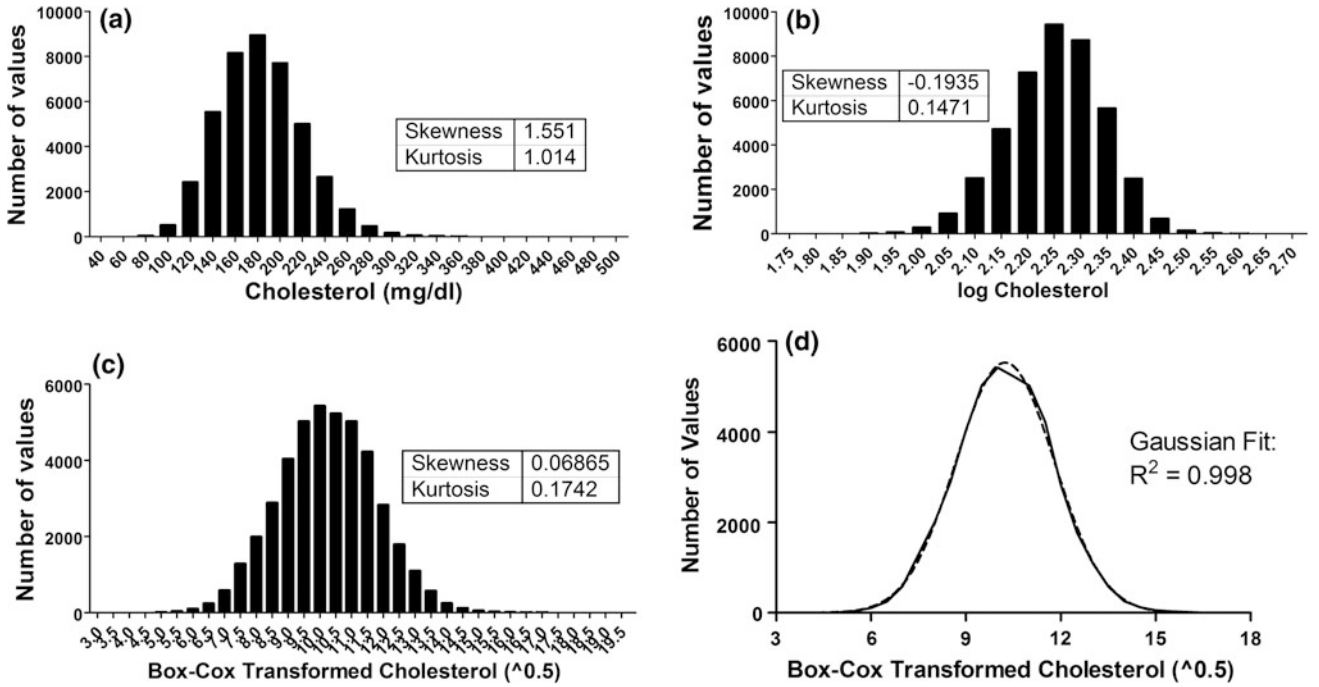

Fig. 15.4 Transformations of a large database of cholesterol measurements in the general population. The untransformed (raw) data are shown in (**a**). **b** and **c** are, respectively, a log transform and a power (Box-Cox) transform of these data. **d** The distribution in (**c**) (*solid line*) is fitted to a Gaussian (normal) distribution (*dashed line*) and shown to exhibit a very strong fit, as described by the value of R^2

variable will provide a reasonable fit to normality. Another approach is the *power-normal* or *Box-Cox* transformation [12] that will occasionally provide a better fit than a simple log transformation. In Fig. 15.4, a large database of over 44,000 serum total cholesterol samples is depicted prior to transformation (Fig. 15.4a) and after log (Fig. 15.4b) and Box-Cox (Fig. 15.4c) transformations. In Fig. 15.4d, the Box-Cox transformed data distribution is compared with the best-fitted Gaussian distribution. The fit to normality is extremely strong, as demonstrated by the R^2 value of 0.998 (more on the "R^2" later in this chapter).

Caution in interpreting normality tests is always warranted. There are numerous assumptions in the development of these tests that lead to potential errors in their misapplication. Realistically, very small samples cannot be expected to provide a reasonable interpretation of fit to normality for a given variable. Similarly, testing very large samples will often result in a test result suggesting a deviation from normality when, in fact, the fit to normality is excellent.

Real or Chance: Hypothesis Testing

Earlier, the differentiation of chance occurrence from something likely to be a real phenomenon was noted to be the primary purpose of biostatistical analysis. The conceptual approach that is taken in this regard is to provide evidence about the unlikelihood of a chance occurrence. This is done with a theoretical device called the *null hypothesis*, symbolized as H_0. One can liken this approach to playing "devil's advocate" in that what an investigator does with this device is to, *a priori*, assume that the hypothesis of true interest, called the *alternate hypothesis* (H_A), is likely to be real only if H_0 can be rejected with some satisfactory assurance of certainty. It is important at this point to keep in mind the fact that sleep medicine researchers, as is the case with scientists in any field, cannot "prove" anything; they simply attempt to demonstrate that a given phenomenon is quite unlikely to have occurred purely by chance. How sure does one need to be? This level of assuredness is given the designation, alpha (α). By tradition, the value of α is almost invariably set at 0.05, the equivalent of 95 % certainty about the decision to reject H_0. The error in deciding to reject H_0 when, in fact, it is operant, is called a *type I or alpha error*.

The converse can also be in effect: One can accept H_0 when, in fact, it should be rejected. This is called a *type II* or *beta* (β) error. Beta is a measure of how well the construct in H_A holds in terms of the percent of times the experiment can be repeated and the authentically valid conclusion reached. The level of β usually accepted in clinical studies is minimally 0.20 (20 %). This relates to the *power* of an experiment or observation, where power is defined as β.

Thus, a clinical study usually is set to provide a power of ≥ 0.8 (80 %). Power depends on several factors: The value

of α, i.e., 0.05, is invariably preset. The other factors are the difference between the groups being compared (for group-wise comparisons, obviously) in terms of the difference in the means and the size of the SD for each group. Finally, and generally the parameter of interest in power analysis is the sample size! A study with too few subjects to reasonably assert acceptance of H_0 is, thus, said to be "underpowered." In any event, acceptance of H_0 in any clinical study should be met with considerable caution. Even if the study has "adequate" power, most investigators would eschew the verbiage, "there was no difference" or "there was no association" and instead choose to say, "no difference (or no association) could be detected".

The precise nature of the H_A will determine how H_0 is phrased. For example, if an investigator is attempting to demonstrate a difference between two groups of subjects, the H_0 will be stated as "there is no difference between group A and group B." Similarly, if there are more than two groups being compared in terms of a difference in the level of some quantitative variable, H_0 would be stated as, "there is no difference *among* the groups being compared." In the case of examining the association of two quantitative or ordinal variables, H_0 would be, "there is no correlation between variable *A* and variable *B*" and, in associating two nominal variables, "there is no association between exposure *A* and outcome *B*".

P-values, Confidence Intervals, and Measures of Effect Size

Having established a "comfort level" about assuredness for rejecting H_0, i.e., $\alpha = 0.05$ or 95 %, it is obviously necessary to have a value with which to compare α. This value is the *p-value,* and for any given test statistic, this is based on the sample size, the magnitude of the difference between the groups for whatever parameter has been evaluated, and the degree of dispersion in each group for the parameter. For the $p < \alpha$, H_0 is rejected and the difference is said to be *statistically significant*. Of course, at a level where p is barely less than α, the certainty is only approximately better than 95 %. However, at very small values of p, the certainty with which H_0 can be rejected is substantially greater; a *p*-value 0.0001 represents a level of assuredness of 99.99 %. Although some software routines can detect *p*-values <0.0001, most often, this is the smallest value usually reported.

An alternative to rejecting H_0 based on *p*-values is the examination of *confidence intervals*. Confidence intervals can be calculated at any desired level but are most often calculated at the 95 % level. They result from the central limit theorem which allows us to determine numerical properties of a population based on the *standard error of the mean* (SEM) for the sample. Thus, confidence intervals (abbreviated *CI*) represent the upper and lower limits of values that can be expected to be observed in a population based on the sample. So, a 95 % CI of 2 units to 4 units means that one could be 95 % sure that any value between 2 units and 4 units would belong to the population being studied.

Confidence intervals are particularly useful when evaluating *magnitudes of effect*. These include ratios of effect in the treatment group compared to placebo, or cases versus controls, or similarly, the association of any given exposure with disease group compared to the effect of that exposure on a group without disease. They include *relative risk* (also called *risk ratio*, *RR*), the risk of morbidity or mortality in the presence of a given exposure, *odds ratio* (*OR*), the odds that given exposure is associated with a given disease or with death, compared with the odds that it is not. The OR is appropriately used for retrospective studies whereas the RR is used for prospective observational studies or for interventional studies. Other magnitude-of-effect measures include the *hazard ratio* (*HR*), which is the difference between the risks in two groups and is analogous to RR except that it is derived from longitudinal studies of *time to event*, such as *survival analysis* and *absolute risk reduction* (*ARR*). Although ARR, as such, is not often used, its reciprocal (1/ARR) yields the *number needed to treat* (*NNT*) which, in an interventional study, allows the investigator to estimate the number of subjects that need to be treated to affect one "success" compared to the number with placebo or comparator control. In a study examining the association of a treatment or exposure that may be harmful, the corresponding effect measure is the *number needed to harm* or *NNH*. These effect measures are summarized in Table 15.1.

In the case of ratio measures such as OR, RR, or HR, whenever the confidence intervals do not include the value 1, the *p*-value will almost always be <0.05. In fact, it is only the vagaries of software programming that occasionally will provide a *p*-value of, perhaps, 0.045 when the 95 % CI interval is, say, 0.98 to 3.52, i.e., the lower or upper confidence limit is very close to unity. In such a case, perhaps it is wisest to suggest that a trend toward statistical significance

Table 15.1 Commonly used magnitude-of-event measures for categorical variables

Odds ratio (OR): $A \times D/B \times C$
Relative risk (RR): $A/(A + B)/C/(C + D)$ [this is the exposed or experimental event rate (EER), given by $A/(A + B)$ divided by the control event rate, $C/(C + D)$]
Absolute risk reduction (ARR): EER—CER
Number needed to treat: 1/ARR

Letters *A*, *B*, *C,* and *D* refer to the cells as shown in the contingency table in Fig. 15.5

exists. For absolute magnitude-of-effect measures such as ARR or *difference in proportions*, the value that must be excluded from the CI is zero.

Examining Groupwise Differences in Quantitative Parameters

One of the most basic needs in clinical science is to determine whether two groups, e.g., a case group and a control group, differ in the presentation of some variable. In other words, is the level of some parameter different in the two samples?

First, consider the case of two groups. Here, the distinction between parametric and nonparametric methods must be made. When data are demonstrably not normally distributed, a nonparametric test should be used, as these rank-based (rather than parameter-based) tests do not require the condition of normality to be extant. Wei et al. [9] used the *Wilcoxon signed rank test* to examine differences in a pretest versus posttest scores in a quasi-experimental study noted earlier in this chapter. This test is a *paired test*, i.e., it requires that the groups being compared are identical (or almost so, in that matched controls are frequently treated as subjects paired with case or treatment groups) and, in this respect, differ from independently assorted or unpaired groups. In the latter case, the use of the *Wilcoxon rank sum test* (or the similarly designed *Mann–Whitney test*) would be the appropriate analytical approach. These nonparametric tests should always be used when comparing ordinal data. The ranked nature of the design of these tests actually matches the ranking inherent in ordinal scales.

When two groupwise quantitative differences are normally distributed (or can safely be assumed to be normally distributed), *t-tests* are invariably used. It should also be recognized that when very large samples are being compared such as the case in population-based cohort studies [2], *t*-tests may be safely used even if normality cannot be demonstrated as, with large samples, parametric methods are suitably robust. These very well-known tests are based on an extension of the *standard difference test* (the *Z-test*) which relies on the normal distribution to evaluate *p*-values. This extension dates back to the early twentieth century when W. S. Gosset, a quality control chemist for the Guinness brewery in Dublin, developed the *t*-distribution. To keep his employer's competitors unaware of this development, he published this under the self-deprecating pseudonym, "Student"; thus, the *t-test* is sometimes referred to as "*Student's t-test.*" The *t*-test for two groupwise comparisons is also modified to account for independently assorted groups (the *unpaired t-test*) and for paired groups (the *paired t-test*). It should also be noted that both *Z*-tests and *t*-tests can be used to evaluate the null hypothesis that a sample does not differ from a known population. This is the so-called one-sample *Z*-test or *t*-test.

Analysis of Variance (ANOVA)

Having considered, above, cases in which two groups were compared, consider the case of more than two groups. Chihara et al. [4] evaluated the results of three treatment groups: APAP, APAP with A-Flex, and APAP with C-Flex. Differences among the three groups were evaluated by ANOVA, in this case a *one-way ANOVA for independently assorted samples* (remember that these groups were randomized and, thus, completely different subjects). If a study were to compare the same subjects with measurements at different time periods, e.g., cortisol levels at different times of the day, a *repeated-measures* ANOVA would be the appropriate analytical approach.

The relevant test statistic for ANOVA is the *F-ratio*, the ratio of the within-sample and between-sample variances. These are calculated at different degrees of freedom and, as expected, depend on the number of groups and sample sizes.

As ANOVA tests the null hypothesis that there is no difference *among* the groups, when a *p*-value less than α is obtained, the null hypothesis is rejected: There is a statistically significant difference among the groups. However, that still leaves the investigator to determine which groups are different than which other groups. There are several approaches to this. The simplest (and, unfortunately, least reliable) is the application of the *Bonferroni* correction to *t*-tests of the various pairs. This correction, in its simplest form, is simply α divided by the number of groups to account for multiple comparisons. Better approaches are available, including *Tukey's*, the *Studentized Newman–Keuls*, *Dunnett's*, *Scheffe's,* and *Holm's* tests.

One-way ANOVA, as described above, is a parametric test and, as was the case with two groupwise comparisons, require the assumption that our groups be normally distributed. When this assumption cannot be met, there are nonparametric options available based, as was the case with the Wilcoxon and Mann–Whitney tests, on ranks rather than the actual value of the variable. In the case of independently assorted groups, the *Kruskal–Wallis test* is the nonparametric analog; the *Friedman test* is the nonparametric analog of the one-way ANOVA for repeated measures.

Several variations in ANOVA exist. The case of two independent variables provides a need to apply *two-way ANOVA*. For example, subjects are randomized to three groups, a control group, a group given a putative therapeutic agent at dose A, and the third group given the agent at dose B. Clearly, the groups (representing one independent variable) are randomly assorted. Now another independent variable is introduced: time, i.e., the investigator wants to

examine an outcome (the dependent variable) at 1, 6, and 24 h. In this case, the outcome can be assessed at different times for the different groups based on the interaction between the two independent variables. The specific example used here is called a mixed-model 2-way ANOVA because it incorporates both a repeated-measures variable (time) and an independently assorted variable (group) into the analysis.

Another useful derivative of ANOVA is called analysis of covariance (ANCOVA). This can best be conceptualized as a combination of ANOVA and regression analysis.

For the effect size of the differences between (or among) continuous variables, several measures have been developed. Perhaps best known are those developed by Cohen [13], the parameter d for two groupwise comparisons [14] and f^2 for comparisons of >2 groups, as in ANOVA.

Measures of Association with Quantitative Variables: Correlation and Regression

The previous section described the measures used to compare quantitative data when the need was to examine a single variable in two or more groups. There is often the need to see whether two different continuous variables are associated or vary with one another. This issue is addressed using two interrelated but, nevertheless distinct approaches, *correlation* and *regression*.

Correlation is assessed by either of two methods depending, once again, on whether or not we can assume that the data at hand are normally distributed or not. For correlation, the null hypothesis is "there is no association between the variables" (usually a dependent variable and an independent variable), i.e., any presumed relationship between the two variables has occurred purely by chance.

If the data are (or can reasonably assumed to be) normally distributed, the method of choice would be Pearson's product–moment method. This generates a test statistic, R (or r) called the Pearson *correlation coefficient*. This coefficient has values ranging from −1 (a perfect negative correlation) through 0 (no correlation at all) to +1 (a perfect positive correlation). One can derive a p-value from R, depending on the number of degrees of freedom. This can create some degree of misunderstanding about the strength of the association: A value of R that is quite weak can yield a p-value that suggests very strong statistical significance. In that case, it should be recognized that the correlation may not have occurred purely by chance; however, the association lacks the strength necessary for it to be of any use. Thus, R is, as noted above, an appropriate measure of effect size. Jiang et al. [15] used Pearson's correlation analysis to assess the strength of the relationship between Montreal Cognitive Assessment (MoCA) scores and sleep efficiency; they also determined negative associations between MoCA scores and the Pittsburgh Sleep Quality index, the arousal index, and sleep latency.

In the event that we are dealing with data that are not normally distributed, most often Spearman's correlation analysis will be applied. This is related to Pearson's method, but rather than use the actual value of the variable, the two variables are ranked separately, and these ranks are then mathematically processed in a manner somewhat similar to its parametric counterpart (Pearson's). The relevant correlation coefficient is, in recent years, indicated by a subscript s, i.e., R_s or r_s. In older work, one may see the Greek letter rho (ρ) used for Spearman's correlation coefficient. In a study of endothelial dysfunction and OSA, Jafari and Mohsenin [16] used Spearman's correlation to examine the relationship between flow mediated vasodilation (FMD) and endoglin and between FMD and fms-like tyrosine kinase. Under certain circumstances usually involving ordinal data, one of several variations in Kendall's tau (τ) may be more appropriate as a measure of nonparametric correlation.

A related process is the development of a mathematical model that describes the relationship between two variables. Intuitively, one recognizes that for the case of linear relationships, the mathematical model that would describe the dependence of a variable on another variable would suggest the correlation of the two variables. In fact, this is nearly always the case with linear regression, as computed by ordinary least-squares (OLS) analysis, in which the mathematical approach is to minimize the distance in both the x and y directions between the coordinates of the x, y pairs and the line describing the relationship between the dependent (always on the y-axis) and the independent variable (on the x-axis). This analysis yields not only a mathematical description of the line (slope and y-intercept) but also the *coefficient of determination*, R^2 (or r^2). The formerly only "intuitive" relationship now is established formally in that $R = (R^2)^{1/2}$, i.e., the Pearson correlation coefficient (but not Spearman's correlation coefficient) is the square root of the coefficient of determination. The null hypothesis for linear regression can be stated as follows: The slope of the line describing the linear relationship between the dependent and independent variables is zero, i.e., parallel to the x-axis. It should also be noted that the coefficient of determination provides an estimate of the strength of the relationship in that if converted to a percent value, it gives an estimate of how well the data are represented by the linear model. A confidence band at the 95 % inclusion level can also be developed.

Not unexpectedly, the mathematical model describing the relationship between two variables need not be a straight line; in fact, there are numerous models that describe nonlinear relationships between two variables. Modern computer software can easily perform curve-fitting routines that,

again, not only provide the mathematical model of the relationship but also provide a coefficient of determination. This may be especially useful for circumstances in which it is necessary to predict the value of a dependent variable from an independent variable when the best-fit model is not a straight line. Nonlinear regression is a complex issue and should be approached with considerable caution, notwithstanding the ease of performance with modern software routines.

Another area related to regression analysis is based on models where time is the independent variable. These models are frequently seen in time-to-event analytics, usually termed *survival analysis.* This will be discussed further on.

Measures of Association with Categorical Variables

Just as was done with quantitative variables, the relationship between categorical variables can be ascertained. In this case, the dependent variable is usually described as an outcome while the dependent variable is called the exposure (in the case of an observational study) or the treatment/intervention in the case of experimental or quasi-experimental investigation. The process of relating these variables is, strictly speaking, not called correlation, a term that in statistical terminology is limited to quantitative association. It should be described, simply, as association.

The construct for the association of a categorical exposure with a categorical outcome is nearly invariably set up as a *cross-tabulation* or *contingency table*. In this tabulation, the absolute counts are input into columns (representing outcomes) and rows (representing exposures or treatments). In Fig. 15.5, just such tabulation is represented. Using either of several analytical approaches, one can derive the level of statistical significance. For simple 2 × 2 tabulations, the best approach is the use of *Fisher's exact test*, because it provides a computed exact *p*-value, obviating the need for an intermediate test statistic. However, because of the arithmetically cumbersome nature of the calculation, some software routines limit the total number of observations (the total count for all four cells) to not much more than one thousand. For larger samples and for contingency tables, more expansive than 2 × 2, the *chi-square test* is invariably used, as was the case in the study by Lai et al. [2] in which the very large sample size (>45,000) precluded the use of Fisher's exact test. Computationally, chi-square is not difficult to perform, but performs poorly when any of the cells have fewer than ten counts. In this case, the deficit may be partially overcome with the use of a correction factor (the *Yates correction*). In the case of analysis where one or more cells has fewer than ten counts, Fisher's exact test should be used. In addition to ascertaining the level of statistical significance, magnitude-of-effect measures can also be calculated from contingency tables (Table 15.1).

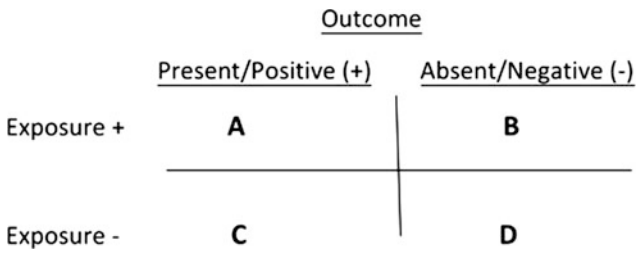

Fig. 15.5 Cross-tabulation of exposures and outcomes for categorical variables. This is commonly referred to as a contingency table

Logistic Regression

In the two previous sections, measures were described that evaluated the association between continuous or ordinal variables (correlation) and the association between categorical variables (contingency table analysis). There exists an extremely useful analytic approach that can be used to associate a (usually binary) categorical outcome, e.g., the presence or absence of disease, with a continuous exposure variable. This analysis yields a curve of probability of the outcome versus the value of the predictor variable (Fig. 15.6).

Logistic regression is also extremely useful in that it allows one to consider potential confounders as covariates in a *multivariable* analysis, i.e., a model in which a given outcome can be evaluated as being associated with more than one predictor variable. Thus, in the event that a significant difference in one or more potential confounders exists between subjects with two different outcomes, those potential confounders can be used to adjust the OR for the primary exposure. Precisely how different the characteristic

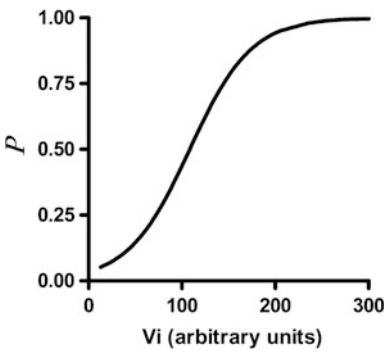

Fig. 15.6 Logit curve resulting from logistic regression analysis. The probability (*P*) is given as a function of some independent variable (Vi). Note that this *P* is an estimate of the true probability of an outcome as a function of the value of the continuous independent variable and is distinct from the *p*-value

should be in order to consider it as a covariate is a subject of some debate but, generally, *p*-values in excess of $\alpha = 0.05$ are considered; minimally 0.1 but often ≥ 0.25 [17].

Time-to-event Analysis

An important aspect of clinical research is the determination of how long it takes for a given exposure or treatment to cause a clinically relevant event to occur. Because this technique, time-to-event analysis, is so often applied to time to death, it is frequently called *survival analysis*. Usually, the technique that is used to perform this analysis is the *Kaplan–Meier* (*K–M*) *method*. In K–M analysis, the percent of individuals not exhibiting an event is plotted, invariably in a stepwise fashion, versus time. Thus, simple inspection of this specialized regression analysis gives the probability of an event occurring over a specified period of time. Figure 15.7 shows data from the Lai et al.'s study [2] in which K–M analysis is used to examine the probability, over a 14-year period, of development of DM type 2 between non-apnea sleep disorders and the cohort to which they were compared. As noted, the *log-rank test* was used to compare the two curves. The log-rank test is a nonparametric method that can be used whenever the hazard ratio is relatively constant over time; a condition described as *proportional hazards*, as described by Cox [18].

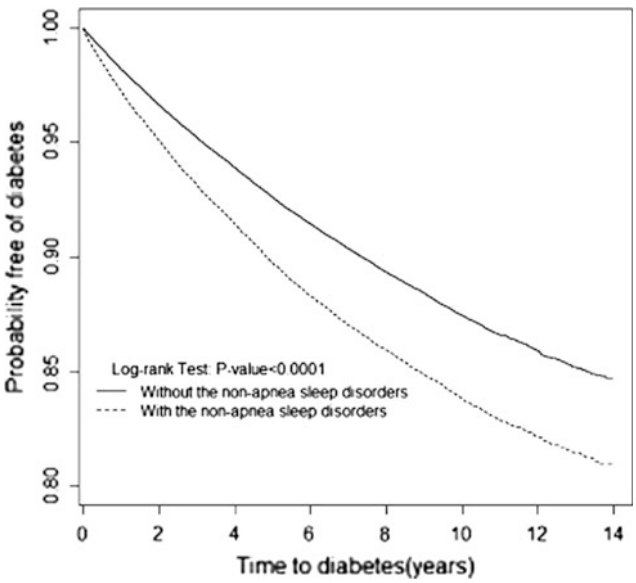

Fig. 15.7 Kaplan–Meier plot of the probability of not having type 2 diabetes (DM2) in patients with and without non-apnea sleep disorders. The log-rank test yielded a highly significant *p*-value (<0.0001), suggesting that patients with non-apnea sleep disorders are more likely to develop DM2 over the time period covered by the study. Note that the probability (*Y*) axis ranges only from 0.80 to 1.00, giving a visually exaggerated suggestion of the actual difference which, at 12 years, is only ~5 %. From Lai et al. [2]

The Cox regression model, as is the case with logistic regression, is adaptable to multivariable models, and is often used to adjust hazard ratios based on the presence of covariates which might be expected to alter the HR resulting from the primary exposure.

Using Questionnaire-type Instruments

Sleep medicine specialists make frequent use of questionnaires. Earlier in this chapter, the ESS and PSQI, both of which see frequent application, were mentioned. These and other questionnaire tools are useful in that they simplify the gathering of relevant survey data but are fraught with potential information biases that should be recognized. First and foremost, they depend upon self-reporting; thus, both are dependent on the recall and forthrightness of the study subjects. Another difficulty is the requirement that cultural and linguistic subtleties are taken into consideration, i.e., that the instrument, as originally developed, is extensible to other cultures and languages.

The most common and, perhaps best, validation parameter for questionnaires is *Cronbach's alpha* [19]. Alpha is a measure of the reliability of the survey instrument and has values ranging between 0 and 1. Generally values ≥ 0.7 are considered good but Tavakol and Dennick [20] caution against high values of alpha (≥ 0.9), which may suggest redundancy of test items.

Investigators attempting to use survey instruments of the questionnaire type should assure themselves that the instrument is valid for the particular population to which the study is intended to be generalizable. For example, Baumgartel et al. [21] studied the reliability of the ESS in pregnant women. Similarly, in evaluating the published results of a survey, the reader is cautioned to examine the available literature to be assured that the authors have validated these tools for their population.

Evaluating Agreement Between or Among Observers

In clinical research, the need frequently arises to assess agreement between two or more, usually expert, observers with regard to the subjective evaluation of some test. This can be done by the use of the *intraclass correlation coefficient* (*ICC*), using widely available statistical software packages [22]. The ICC is, fundamentally, an extension of correlation of individual values, as described earlier in this chapter, to values from groups of data. In a manner analogous to ANOVA, the ICC is a function of both within-observer agreement and between/among-observer agreement.

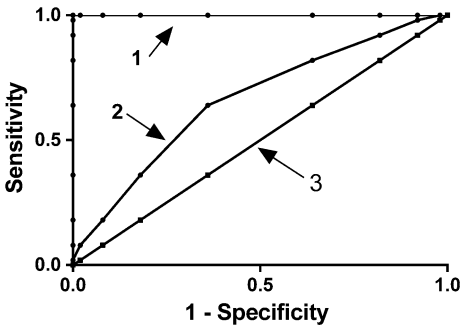

Fig. 15.8 ROC curves of 3 data sets. The area under curve (AUC) *1* is 1.00 that is it represents a test which completely discriminates between two conditions. In curve *2*, the AUC is 0.66, which represents poor discriminatory ability. The line in number *3* is from a test with no discriminatory ability at all; it has an AUC of 0.50 and represents a condition described as "identity"

The kappa statistic (κ) is an alternative to the ICC that has seen wide use in clinical practice, including studies relating to sleep medicine. One such example is a recent study of inter-rater reliability of sleep videofluoroscopy to assess airway obstruction in subjects with OSA by three independent observers [23]. These authors found that depending on the anatomical level studied, values of κ range from 0.635 to 0.938. Values of $\kappa > 0.6$ suggest acceptable agreement.

Specialized Diagnostic Biostatistical Procedures

Basic diagnostic parameters such as *sensitivity*, *specificity*, *positive predictive value* (*PPV*), *negative predictive value* (*NPV*), and *overall test efficiency* (sometimes called *clinical accuracy*) should be familiar to readers of this book. One commonly used (actually required by some standardized publication protocols for diagnostic tests) device to evaluate the utility of diagnostic tests is the *receiver operating characteristic* (*ROC*) *curve*. The ROC curve is a plot of sensitivity (*y*-axis) as a function of 1-specificity (*x*-axis) as demonstrated in Fig. 15.8. The "perfect" test would exhibit a value of 1.0 (100 %) for sensitivity and 0 for 1-specificity (100 % specificity); this point is at the upper left-hand corner of the ROC curve and would result in an *area under the curve* (*AUC,* sometimes called the *c-statistic*) of 1.0. A test with no discriminatory ability (no diagnostic value) would be represented by the *line of identity*, a straight line with a slope = 1.0 (45° angle from the *x*-axis). For this line, the AUC would ½ or 0.5. The point that yields the optimum value of sensitivity and specificity (the *Youden point*) is the point which is tangent to a line parallel to the line of identity at the upper left-hand point of the curve.

ROC curves are frequently used to evaluate diagnostic procedures in sleep medicine, as exemplified by the recent work of Sangal [24] who evaluated the diagnostic efficacy of a group of sleep scales in two groups of subjects with OSA: a group between the ages of 18 and 45 years and a group of subjects with an age >45 years.

Concluding Remarks

This chapter can only serve to introduce fundamental aspects of study design and statistical analysis to those who may require a bit of help in understanding and evaluating the literature in sleep medicine. It was never intended to provide a guide to "do-it-yourself" statistical analysis using one or more of the many commercial statistical software packages or the ever-increasing online, free, statistical computation routines (although some of these are, indeed, quite good). Hopefully, this chapter may have whetted the reader's appetite for more information on the fundamentals of study design and biostatistics. Books by Hulley et al. [25] and Motulsky [26] are highly recommended to the sleep medicine specialist wishing to expand his or her horizons in clinical epidemiology and statistics.

Introduction

In order to understand the significance of polysomnographic (PSG) and other clinical neurophysiologic tests to practice first-rate sleep medicine, it is important to have a basic knowledge about the principles of physics and electronics underlying the techniques for recording multiple physiological characteristics. Biological, physical, and chemical environment of the body tissues (e.g., brain, heart, lungs, and others) continually generates electromagnetic signals movements of which tell us about internal physiological changes in the body from which we can differentiate normal from abnormal phenomena. The physiological signals are minute in magnitude and hence must be amplified to recognize them visually. Amplification of essential signals and filtering of unwanted signals are the two most fundamental processes in understanding PSG and other neurophysiologic recording techniques. It should be noted that electrical signals in human body manifested as waveforms are generated by flow of charged ions (e.g., Na, K, Cl) opposed by the resistance and capacitance of the tissues. Using analog and now digital electronic devices, we can measure and analyze current flow and potential differences between different areas of the body and scalp to assess normal functions and alterations by disease. This chapter briefly outlines the basic electronics for sleep specialists and clinical neurophysiologists.

Definitions and Circuit Analysis

Charge

In a copper wire at room temperature with no externally applied force, the outermost shell of a copper atom loses an electron as a result of surrounding thermal energy. When a copper atom loses a free electron, it becomes a positive ion because electrons carry a negative charge. With no applied force on the wire, electrons continue to move about in a random manner without a net flow. As the electron moves about randomly the positive ion it leaves behind does little more than oscillate in place; the electron thus acts as a charge carrier. Coulombs law states that like charges repel and opposite charges attract and is the reason why free negatively charged electrons are attracted to positive ions. The symbol for charge is "Q." One coulomb of electrons is equal to 6.242×10^{18}. If one coulomb of electrons flows at uniform velocity through a circular cross-sectional area of conductor in one second, the flow of charge is said to be one ampere. Charge or Q may also be expressed as shown in Eq. 16.1 where I equals current and t is time in seconds [1–3]. For current to flow and perform work in a circuit, such as to light an incandescent bulb, electrons must move in the same direction through the load. Recording an electrographic event requires the movement of ions in large populations of neurons. An applied force causes the electrons or ions to move directionally, and in a basic electric circuit, this applied force is the source voltage also referred to as an electromotive force. In the case of a neuron, the applied force is the stimulus (spontaneous or applied) with the electrons replaced by ions. The flow of charge regardless of form is accomplished through the application of an applied force.

$$Q = I * t \tag{16.1}$$

Power Sources

The two types of power sources are alternating current or AC and direct current or DC. The most commonly encountered DC source is the battery. A battery is the conversion of chemical or solar energy using positive and negative electrodes and electrolytes to provide direct current. Direct current moves in one direction and remains constant for the life of the source. Generators on the other hand produce AC power through the use of any number of energy sources to turn a rotor housed in a set of windings called a stator, inducing a voltage in the wires of the stator. One end product is the common 120-V household outlet. In North America, AC power is delivered at 60 Hz, whereas in Europe 50 Hz is the predominant frequency. Both AC and DC provide the electromotive force to move electrons directionally supplying current to power the recording equipment.

Fig. 16.1 Schematic symbol of a resistor

Resistors and Resistance

Resistance is the ability to inhibit the flow of current or charge. Resistance is one of the things that slows down electron movement described earlier. While copper wire has resistive properties, it has better conductive properties which make it ideal for movement of charge. Resistance occurs naturally, and resistors are specifically manufactured for use in circuit design. Resistors behave the same regardless of the type of power applied. The current through a resistor is in phase with the applied voltage. This means both current and voltage follow the same path at the same time. Resistors do not store energy, and they dissipate energy through heat. Figure 16.1 illustrates the schematic symbol of the resistor. The unit of resistance for a resistor is ohms and is indicated by the capital Greek symbol omega "Ω." Resistors can be connected in parallel or series.

The manner in which resistors are connected determines the total resistance of the circuit. Figure 16.2a, b illustrates simple series and parallel resistive circuits, respectively, arrows indicating direction of voltage and current. Notice that in the series circuit, the voltage has only one path to travel; it must pass through each resistor in an orderly manner. In the parallel circuit, the full voltage is applied to each resistor at the same time. When voltage is applied, it pushes the electrons in a uniform direction; in Fig. 16.2a, b, it is through the resistors of the circuit. When electrons are pushed, they develop a charge or Q which is current over time as shown in Eq. 16.1.

As voltage passes through each resistor in the series circuit, some of the supply voltage is lost because the resistor dissipates the supplied energy in the form of heat and this is called voltage drop. The amount of voltage dropped or consumed by each resistor is determined by the size of the resistor and the charge or current through it. In Fig. 16.2a, resistor R_1 receives the full voltage and is the first to consume some of voltage dissipating the energy as heat. Resistor R_2 receives the voltage left over following the voltage drop from R_1, and it too consumes voltage passing on to R_3 the remaining voltage leftover from the source.

In the parallel circuit, the full voltage is impressed upon each resistor immediately. Each resistor drops voltage, and how much voltage is consumed by each resistor is dependent

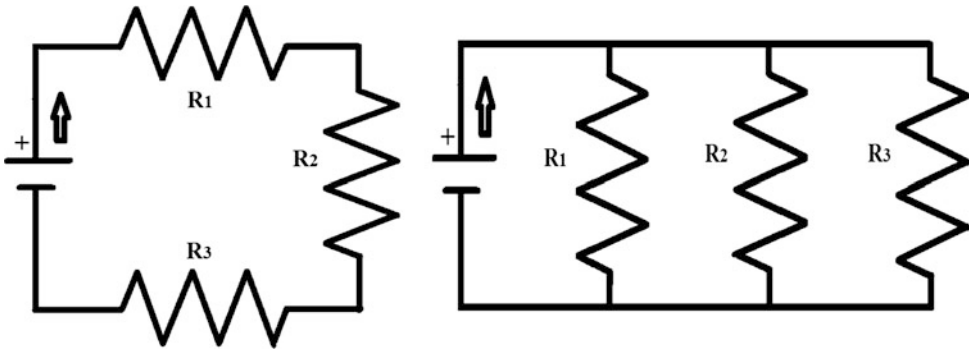

Fig. 16.2 Resistors in series in (**a**) and in parallel in (**b**); *arrow* indicates direction of voltage and current flow

Fig. 16.3 Schematic symbol of a capacitor

upon the resistive value and current through each branch. The relationship between current, voltage, and resistance is explained and easily calculated by Ohm's law discussed further on.

Calculation of the total amount of resistance in a given circuit is different for series or parallel configurations. In a series circuit, the resistance value of each resistor is added to obtain the total resistance of the circuit. The total resistance in a series circuit is higher than the highest value of any single circuit resistor. In a parallel circuit, total resistance is calculated by adding the reciprocal of each individual resistor and then taking the reciprocal of that sum. The total resistance in a parallel circuit is lower than the lowest single resistive value in the circuit. Equations 16.2 and 16.3 illustrate the formulas used to calculate the total resistance in series and parallel resistive circuits, respectively [1–4]. Whether in parallel or series circuit, the current and voltage in a purely resistive circuit are in phase with one another. This means they both follow the same path at the same time.

$$R_T = R_1 + R_2 + R_3 + \cdots + R_n \qquad (16.2)$$

Series Circuit

$$R_T = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots + \frac{1}{R_n}} \qquad (16.3)$$

Parallel Circuit

Capacitors and Capacitance

Capacitors are formed by two metal plates or any two conducting surfaces that are separated by a dielectric. A dielectric is an electrical insulator, e.g., air is a dielectric. Two parallel ribbons of wire on a printed circuit board create a capacitor. Power lines running parallel between poles create capacitors by virtue of the definition of a capacitor. An electrode on the surface of the body creates a capacitor. Capacitors are no more than two conductive surfaces separated by a dielectric. There are additional criteria to further define the properties of capacitance; however, this discussion is limited to series and parallel configurations of capacitors and the resistive value they pose in a circuit based on applied frequency. Figure 16.3 shows the schematic symbol of a capacitor.

A capacitor is rated in farads, "*F*" described below, its symbol is "*C*," and the resistance it poses to a circuit is called capacitive reactance symbolized by X_C (X of $_C$) and is calculated as shown in Eq. 16.4 [1, 4].

$$X_C = \frac{1}{2\pi f C} \qquad (16.4)$$

Similar to a resistor, the capacitive reactance or X_C is indicated in ohms "Ω," and unlike a resistor, the capacitive reactance of a capacitor changes with the applied frequency. In Eq. 16.4, the only variable that is not a constant is the frequency or "*f*," the remaining terms are fixed with 2π equivalent to 6.28, and C is the value of the capacitor in farads. In the case of a DC source, "*f*" is equal to zero. If the denominator becomes zero, the resistance is infinite. If that is true what happens when a capacitor is connected across a DC source such as a battery? Electrons move between the battery terminals and the metal surfaces of the capacitor until the capacitor is fully charged with one of the metal conductive plates (positive or negative). You now have an additional power source. How long does this take? The answer depends on time constants. It is important that you understand the behavior of capacitors. Capacitors are effectively an open circuit with a DC source after charging up to their final capacitive value [1, 4].

We still have to account for the energy applied to a capacitor because the law of conservation of energy dictates that energy cannot be lost. Unlike resistors which dissipate energy in heat and drop voltage, capacitors store charge. The ability of a capacitor to store charge is termed capacitance, and its units are farads (*F*), the higher the rating (*F*), the more charge it can store. The symbol of the charge stored on

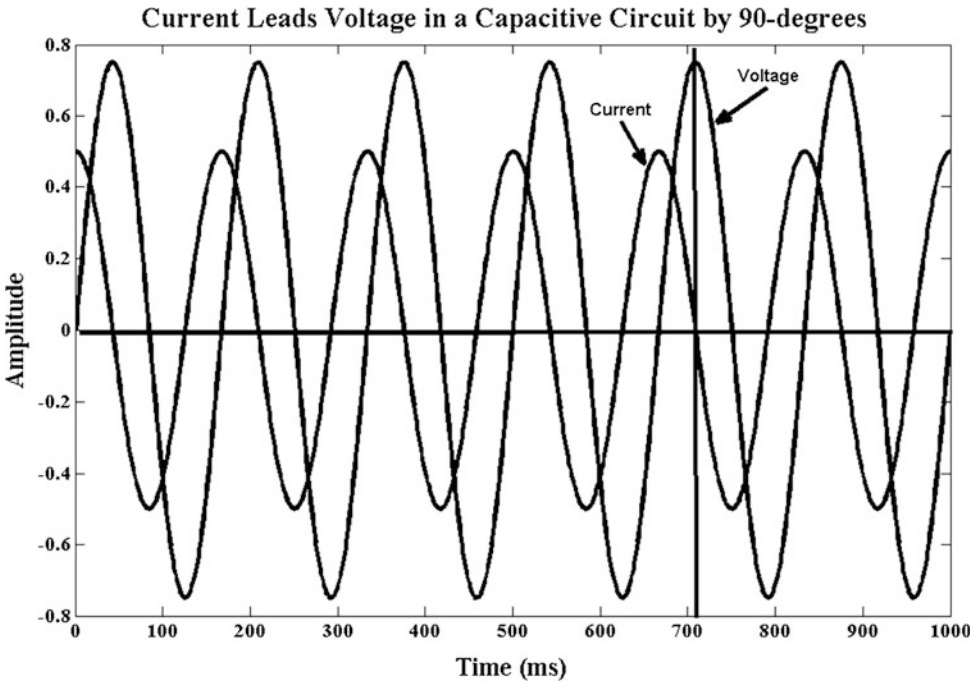

Fig. 16.4 The relationship between current and voltage in a purely capacitive circuit. Voltage lags current by 90°. When the voltage waveform (higher amplitude) is at its peak, the current waveform (lower amplitude) is crossing zero, and this equates to 90°. This is illustrated by the *vertical line* just beyond the 700 ms point. Current flow began 90° prior to any voltage change on the capacitor. Code and output created using MatLab R2012a

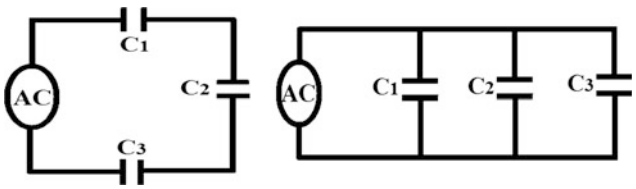

Fig. 16.5 Circuit configurations of capacitors in series (**a**) and in parallel (**b**)

a capacitor is termed "*Q*," because it is electrons that move charging the capacitor. It is the nature of capacitors to resist a change in voltage across them; therefore, the applied voltage lags the current in a purely capacitive circuit by 90°. Figure 16.4 illustrates the phase difference between voltage and current in a purely capacitive circuit. Equation 16.5 states the law of capacitors, where *C* is the capacitor in farads, *Q* is the charge, and *V* is the applied voltage [1, 4].

$$C = \frac{Q}{V} \tag{16.5}$$

Figure 16.5 illustrates capacitors in series (a) and parallel (b) left to right, respectively. In a series, circuit capacitors add like resistors in parallel that is the total capacitance in the circuit is lower than the lowest capacitive value in the entire series circuit. Capacitors in parallel, as you may have guessed, add like resistors in series that is the total capacitance in the circuit is higher than the highest capacitive value in the entire parallel circuit. Formulas for total capacitance in parallel and series circuits are shown in Eqs. 16.6 and 16.7, respectively [1, 3, 4].

$$C_T = C_1 + C_2 + C_3 + \cdots + C_n \tag{16.6}$$
Parallel Circuit

$$C_T = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \cdots + \frac{1}{C_n}} \tag{16.7}$$
Series Circuit

Table 16.1 illustrates the changes in resistance of a 1 μF (10^{-6}) capacitor as the applied frequency increases. Equation 16.4 was used to calculate the change in resistance. It is easily seen that there is a dramatic change in the resistance offered to the circuit by the capacitor as the frequency increases even slightly. This is due to the alternating positive and negative phases of an AC power source. As the alternating phases of the input signal change, more and more rapidly the capacitor ceases to become a resistive factor in the circuit.

Inductors and Inductance

Inductors are coils of wire. The coils of wire can be hollow or the coil can be wrapped around a magnetic or non-magnetic core. Inductors are rated in henries and are indicated by a capital *H* and are identified in a circuit by capital *L*. Figure 16.6 illustrates the circuit schematic symbol for an inductor.

Inductors also store energy, but in a magnetic field, they cannot, however, store energy in the absence of a power source. Once the power source is removed from an inductor, it releases its stored energy. Unlike a capacitor, the resistance of an inductor is directly proportional to the applied

Table 16.1 Capacitive reactance as a result of applied frequency

Capacitor in farads (μF)	Applied frequency	Capacitive reactance (X_C)
1	0.5 Hz	318.3 kΩ
1	1 Hz	159.2 kΩ
1	5 Hz	31.8 kΩ
1	15 Hz	10.6 kΩ
1	20 Hz	8 kΩ
1	25 Hz	6.4 kΩ
1	50 Hz	3.2 kΩ
1	100 Hz	1.59 kΩ
1	1 kHz	159 Ω
1	10 kHz	15.9 Ω
1	100 kHz	1.59 Ω

Fig. 16.6 Schematic symbol of an inductor

frequency of the source. The nature of an inductor is to resist a change in current through it; thus, current lags voltage in a purely inductive circuit by 90°. Like a capacitor, the resistance of an inductor, called inductive reactance which is rated in ohms, is termed X_L (X of $_L$) with symbol Ω and is calculated as indicated in Eq. 16.8 [1].

$$X_L = 2\pi fL \tag{16.8}$$

There is only one variable in Eq. 16.8 that is not a constant, and this is "f" or the applied frequency, 2π is equivalent to 6.28, and L is the measure of the inductor in henries. The phase relationship between an inductor and capacitor is 180°.

Representative circuits for inductors are not shown. The circuit configuration for inductors in series and parallel is identical to the circuit configurations previously shown for resistors and capacitors with the simple change of circuit components to inductors. Figure 16.7 illustrates the output of an inductive circuit with voltage leading current by 90°; this is identical to Fig. 16.4, but voltage and current have changed places. This phase relationship exists because inductors resist a change in current through them so current lags voltage.

It should be remembered that the physical properties of a capacitor cause it to resist an instantaneous change in voltage across it and that an inductor resists an instantaneous change in current through it. This is why each of these properties lags in their respective circuit as illustrated in Fig. 16.7 for inductors and Fig. 16.4 for capacitors.

Circuit calculations for the total inductance of inductors in series or parallel configurations are identical to those of resistors in the same configuration and are shown in Eqs. 16.9 and 16.10, respectively [1].

$$L_T = L_1 + L_2 + L_3 + \cdots + L_n \tag{16.9}$$
Series Circuit

$$L_T = \frac{1}{\frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3} + \cdots + \frac{1}{L_n}} \tag{16.10}$$
Parallel Circuit

Cartesian Plane

A Cartesian plane is a coordinate system with four quadrants that are labeled with Roman numerals I–IV counterclockwise beginning in the upper right quadrant. The "X" or real axis is the horizontal plane, and the "Y" or imaginary axis is the vertical plane. The zero point in the Cartesian coordinate system is where the X and Y axes cross. All X-coordinate points to the left of zero are negative; all X-coordinate points to the right of zero are positive. All Y-coordinate points below zero are negative; all Y-coordinate points above zero are positive. This coordinate system allows for the unique identification of points in space with two specific coordinates, an X value and a Y value. These points are always shown in that order and usually in parentheses as (X, Y). For instance, a point on the Cartesian coordinate system of (3, −3) indicates that it is located three positive units along the X axis horizontally and three negative units along the Y axis vertically, so the point is located in the lower right quadrant or quadrant IV. Figure 16.8 shows an illustration of a Cartesian coordinate system or Cartesian plane.

Here, the Cartesian system is used to create an impedance diagram by plotting resistance, capacitive reactance, and inductive reactance using vectors. Vectors are lines with arrowheads that indicate direction and magnitude. The longer the vector the greater the magnitude of the representative quantity; the arrowhead is an indication of direction. Discussion of phase is not addressed other than what

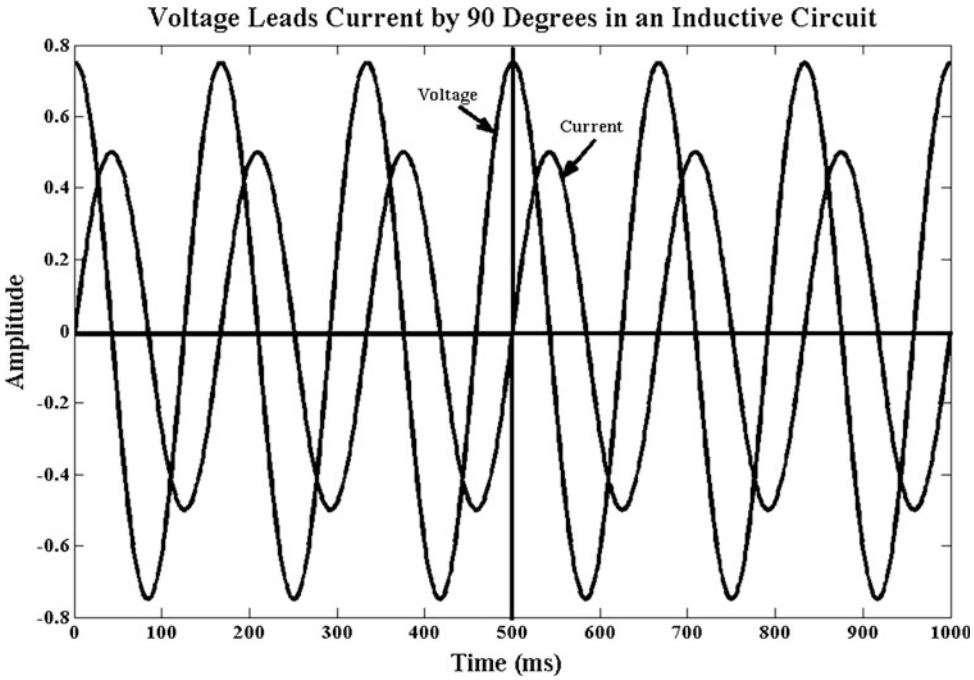

Fig. 16.7 The relationship between current and voltage in a purely inductive circuit. Voltage leads current by 90°. When the voltage waveform (higher amplitude) is at its peak, the current waveform (lower amplitude) is crossing zero, and this equates to 90°. The *vertical line* through the 500 ms point illustrates this point. The voltage through the inductor began 90° prior to current flow. Code and output created using MatLab R2012a

has previously been described in resistive and purely capacitive or inductive circuits. Resistance R is always plotted on the positive X axis, capacitive reactance X_C on the negative Y axis, and inductive reactance X_L on the positive Y axis all by vectors. The phase relationship between inductive and capacitive reactance is 180° which is why X_L points up and X_C points down. The length of the vector indicates the magnitude of the resistance in each case. Because X_C and X_L are 180° out of phase, the smaller value is subtracted from the larger value to determine their combined reactance. The direction, pointing up or down in the impedance diagram, is dependent upon the larger value. The resultant vector will point up if X_L is larger than X_C or will point down if X_C is larger than X_L and should be scaled to indicate the relative reactance value. In Fig. 16.8, X_C is a longer vector than X_L, so capacitive reactance has a higher value than inductive reactance leaving a resultant X_C vector on the Y axis pointing downward. Drawing a straight line from the arrowhead of the resultant vector, here it would be X_C to the vector representing R forms a right triangle. This new line is the hypotenuse of a right triangle, and Pythagoreans theorem shown in Eq. 16.11 is used to calculate this value which is the total impedance of the circuit indicated by the capital letter "Z" [1, 4, 5].

In a circuit containing R, X_L, and X_C, the phase angle between voltage and current is less than 90° and depends on the relative size of the resistor compared to the resultant reactance.

$$Z = \sqrt{(R^2 + (X_{\text{Larger}} - X_{\text{Smaller}})^2)} \tag{16.11}$$

Impedance Z is a complex value; in simple AC circuits such as those with a single voltage or current source, Eq. 16.11 will suffice, but for complex circuitry, more sophisticated circuit analysis is required.

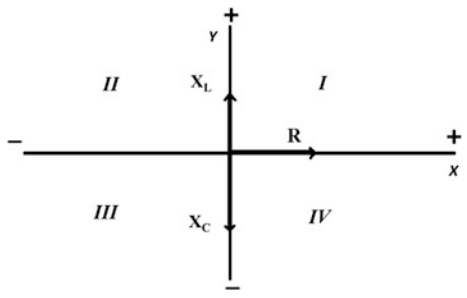

Fig. 16.8 Cartesian coordinate system with labeled quadrants and vectors indicating resistance "R," inductive reactance "X_L," and capacitive reactance "X_C"

Ohm's Law

Ohm's law is the equation that defines the relationship between resistance, voltage, and current. Equation 16.12 illustrates the Ohm's law voltage equation where "R" is resistance, "E" is voltage, and "I" is current, voltage may be shown as "V," and this does not change the formula [1–4].

$$E = I * R \tag{16.12}$$

From Eq. 16.12, it is clear that voltage (E) is directly proportional to resistance and current. Manipulation of this

basic formula reveals that both current (I) and resistance (R) are proportional to the applied voltage and inversely proportional to one another. These relationships are illustrated in Eqs. 16.13 (a) and (b) for current and resistance, respectively [1, 3, 4].

$$\underset{(\mathbf{a})}{I = \frac{E}{R}} \quad \underset{(\mathbf{b})}{R = \frac{E}{I}} \tag{16.13}$$

In Eq. 16.13 (a), for a fixed resistance as the applied voltage increases so does the current. Conversely, if the applied voltage remains the same and the resistance is increased, the current decreases. Using Eq. 16.13 (b), the applied voltage and current resistance are easily calculated.

Power

Power in an electrical circuit is a measure of the rate of performing work and is measured in watts, indicated by a capital "W," and is calculated by the formula in Eq. 16.14 [1]. A light bulb rated 60 W utilizes 60 W of energy, and a 120-W bulb provides more light and consumes more energy.

$$P = E * I \tag{16.14}$$

Through direct substitution of Ohm's law, Eq. 16.13 (a) for current, and Eq. 16.12 for voltage, power can be expressed as indicated in Eqs. 16.15 (a) and (b), respectively.

$$\underset{(\mathbf{a})}{P = \frac{E^2}{R}} \quad \underset{(\mathbf{b})}{P = I^2 * R} \tag{16.15}$$

Kirchhoff's Voltage and Current Laws

Kirchhoff's laws will be defined simply without consideration or explanation of power supply orientation or polarity of any circuit devices. Kirchhoff's voltage law states that the sum of the voltage drops in a closed loop must equal the applied source. Kirchhoff's current law states that the current into a junction, node, or system must equal the current exiting that same junction, node, or system [1–6]. Energy must always be accounted because it cannot be lost. Kirchhoff's voltage and current laws are mathematically stated in Eqs. 16.16 (a) and (b), respectively, and illustrated graphically in Fig. 16.9.

$$\begin{aligned} \Sigma_{\text{Current In}} &= \Sigma_{\text{Current Out}} \quad (\mathbf{a}) \\ \Sigma_{\text{Source}} &= \Sigma_{\text{Voltage Drops}} \quad (\mathbf{b}) \end{aligned} \tag{16.16}$$

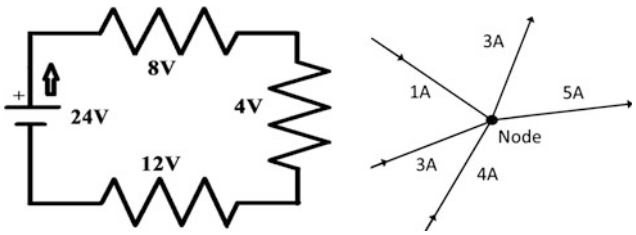

Fig. 16.9 Kirchhoff's voltage law in **a** the sum of the voltage drops 8 V + 12 V + 4 V = 24 V, which equals the source voltage. In **b**, three current values are entering one central node (*arrows* pointing into the node) and two exiting (*arrows* pointing away from the node) current pathways. The sum of the input current is 8 A which equals the sum of the output current meeting the requirements of Kirchhoff's current law

Frequency and Period

Frequency is a rate quantity measured in cycles per second. Frequency is an indication of how often something happens in one second time. The symbol for frequency is lower case "f," and its units are Hertz, abbreviated Hz. Period is a time quantity and is a measure of the time it takes for one cycle of a periodic waveform to occur. The symbol for period is capital "T" and is expressed as a unit of time. Frequency and period are inversely related, as one increases the other decreases. The period of a signal with a frequency of 60 Hz is 1/60th of a second. This means there are 60 cycles per second in a 60 Hz periodic signal, and it takes 1/60th of a second for one of those cycles to occur [1]. If you know one quantity you know the other. Equation 16.17 indicates the inverse relationship between period and frequency.

$$f = \frac{1}{T} \quad T = \frac{1}{f} \tag{16.17}$$

When identifying frequency of any waveform, verify the time line and determine the frequency in one second. Figure 16.10 shows a 3 Hz signal with one period indicated.

Decibels, Logarithms, Gain, and Bode Plots

These topics are discussed briefly because filter frequency response curves are shown in logarithmic scale in "Bode" plots, filters are designed with a cutoff stated in decibels, and gain is usually indicated in decibels. Gain is the output of an amplifier; in neurodiagnostic technology, this is termed a differential amplifier which is a sophisticated device made up of resistors, capacitors, and transistors. When transistors are used in filter design, they are called active filters, whereas passive filters only use resistors and capacitors in their design.

The voltage gain of a circuit denoted "A_V" is a ratio of the output voltage to the input voltage as shown in Eq. 16.18 (a). Gain is a measure of how much larger the output is

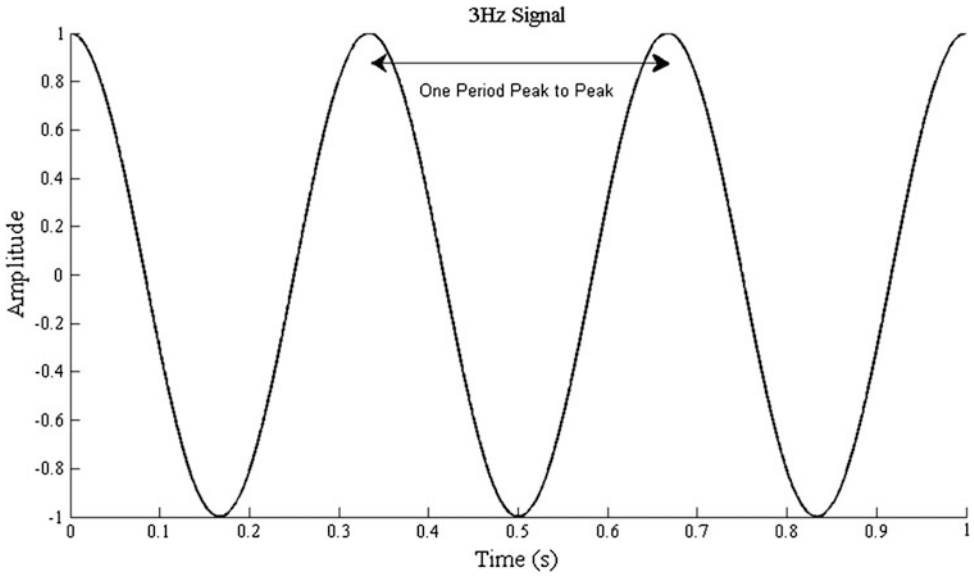

Fig. 16.10 3 Hz signal, its period from one peak to the next, is indicated by the *double arrow*, and this equals one cycle whose period is 1/3 s the inverse of the signal frequency. Code and output created using MatLab R2012a

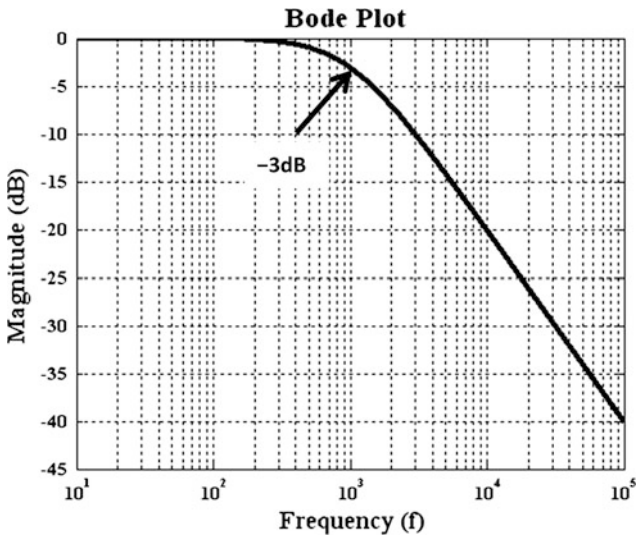

Fig. 16.11 The "y" axis in the Bode plot indicates magnitude in dB, and a logarithmic "x" axis indicates frequency. Maximum signal magnitude begins at "0" and slopes negative as the frequency increases. The −3 dB point or filter cutoff is indicated by the *arrow*, and this is a high-frequency filter (HFF) with cutoff of 1 kHz. Code and output created using MatLab R2012a

compared to the input and is a term used in reference to amplifiers. The voltage gain of an amplifier expressed in decibels (dB) is found by using logarithms as illustrated in Eq. 16.18 (b) [1, 7].

$$\underset{(\mathbf{a})}{A_V = \frac{V_{\text{Out}}}{V_{\text{In}}}} \quad \underset{(\mathbf{b})}{A_{V\text{dB}} = 20\log\frac{V_{\text{Out}}}{V_{\text{In}}}} \tag{16.18}$$

The technical specifications of a machine can indicate the gain in decibels (dB) or as a whole number, i.e., 100,000 that can be obtained by using Eqs. 16.18 (a) and (b). For example, given 1 μV input and an output of 0.1 V, the gain would be 100,000 or 100 dB.

Bode plots represent the frequency response of a filter and are plotted on a log frequency axis. An example of a Bode plot is shown in Fig. 16.11; in this example, the cutoff frequency of the filter is 1 kHz and is indicated on the plot as the −3 dB point.

There are several names for the cutoff of a filter. We already are familiar with −3 dB; there is also f_C for frequency cutoff, and half power point, and there are others. The term half power point means that the effective value of the voltage is 0.707 V, and the signal is now equivalent to half its original power. Rather than introducing additional equations, I will illustrate this property using the power formula of Eq. 16.15(a). In reiteration, I have just stated that −3 dB is equal to the half power point of the signal, and the output effective value has dropped to 0.707 V of its full value [1, 6, 7]. By inserting 0.707 into Eq. 16.15(a) as shown in Eq. 16.19, the output at −3 dB is half the power of the input.

$$P = \frac{E_{\text{Max}}^2}{R} = \frac{(0.707 * E_{\text{Max}})^2}{R} = \frac{0.707^2 * E_{\text{Max}}^2}{R}$$

$$= 0.5 * \frac{E_{\text{Max}}^2}{R} = 0.5 * P \tag{16.19}$$

The Bode plot of Fig. 16.11 is initially flat at zero and does not begin to drop off until the frequency of the signal approaches the filter cutoff. This flat part of the Bode plot is maximum power passing through the filter; any signal in this frequency range is passing through the filter at full amplitude or full power. As frequency increases and nears the −3 dB

point, or the filter cutoff, the amplitude of the input voltage drops to 70.7 % of its maximum value. For the Bode plot of Fig. 16.11, the filter cutoff is 1 kHz; if a 2 V 1 kHz signal was passed through the filter, the output would be 1.414 V or 70.7 % of the input amplitude [1]. This is illustrated in Eq. 16.20 and is called **attenuation**. This is how filters work; they are not perfect, and they incrementally remove the power from the signal as the frequency increases by dropping the signal amplitude.

$$2V * 0.707 = 1.414V \tag{16.20}$$

Filters vary in design and can be cascaded to improve attenuation at the filters cutoff point. In this chapter, we discuss simple single-stage filter circuits with a −3 dB cutoff.

Filters

The three types of filters used in neurodiagnostic equipment are high pass, low pass, and notch [2–6]. The low-pass filter (LPF), in clinical neurophysiology, is commonly referred to as a high-frequency filter (HFF) because it eliminates high frequencies allowing low frequencies to pass up to the design cutoff of the filter. The high-pass filter (HPF) is commonly called a low-frequency filter (LFF) because it excludes low frequencies and passes high frequencies. The notch filter is designed to eliminate a specific frequency band. In North America, power is generated at a frequency of 60 Hz, whereas in Europe it is generated at 50 Hz. In equipment design, the notch filter would be set to match the generated frequency, and thus, in North America, the notch would eliminate 60 Hz, and in Europe, it would eliminate 50 Hz.

What separates a LFF from a HFF is the location of the capacitor in the circuit which dictates filter behavior. If a capacitor is the first component the signal encounters, the capacitor will resist a change in voltage across it and have a very high resistance at low frequencies, and so this must be a low-frequency filter. The high resistance at low frequencies causes these signals to be severely attenuated. As the capacitive reactance of the capacitor decreases with increasing frequency, the filter will incrementally pass the higher-frequency components. When the incoming signal frequency reaches the filter cutoff, 70.7 % of the signal amplitude passes (this assumes a—3 dB design). As frequency increases beyond the −3 dB point, increasing amounts of the signals are passed until the full signal strength is passed through the filter.

If a capacitor is second in line in a filter circuit, the design is that of a high-frequency filter. A high-frequency filter will allow low frequencies to pass until the frequency of the incoming signal approaches the design cutoff of the filter. At the filter cutoff, the signal is attenuated to 70.7 % of its amplitude. Amplitude continues to decrease and is attenuated as frequency increases. The frequencies that filters pass are called the pass band of the filter, and those that are attenuated are considered in the stop band of the filter. In any filter, attenuation is indicated in a Bode plot by the slope of the line, the steeper the slope, the higher the percentage of attenuation with increasing frequency. Figure 16.12a, b illustrates the circuit design, frequency behavior, and the stop and pass bands of high- and low-frequency filters, respectively.

The output of a HFF as illustrated in Fig. 16.12a is taken across the capacitor; for an LFF, the output is taken across the resistor as in Fig. 16.12b. The filter behavior at the respective output can be demonstrated through the use of Eqs. 16.21 (a) and (b) as shown in Table 16.2.

$$\begin{gathered} V_{\text{Out}} = V_{\text{In}} * \frac{X_C}{\sqrt{R^2 + X_C^2}} \\ (\mathbf{a})\ \mathbf{HFF} \\ V_{\text{Out}} = V_{\text{In}} * \frac{R}{\sqrt{R^2 + X_C^2}} \\ (\mathbf{b})\ \mathbf{LFF} \end{gathered} \tag{16.21}$$

The cutoff frequency of a filter is determined by the combination of the resistive and capacitive values of the

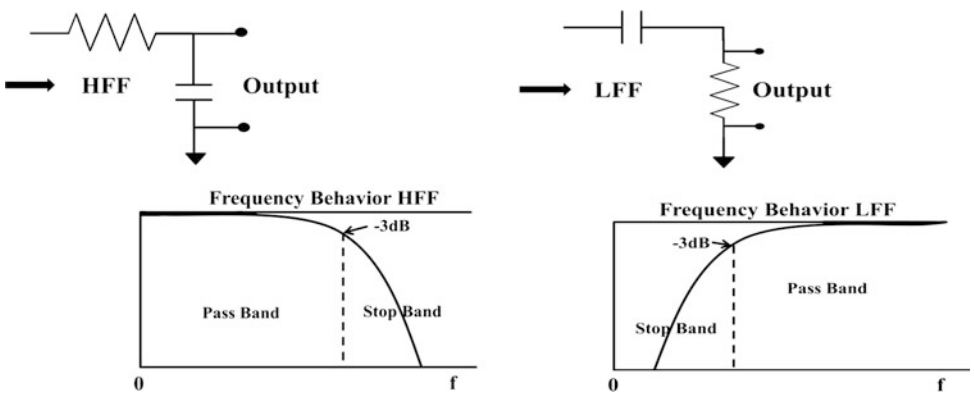

Fig. 16.12 High-frequency filter circuit (**a**), low-frequency filter circuit (**b**). Frequency behavior, −3 dB and the stop and pass bands are identified for each circuit

Table 16.2 Filter output at varying input frequencies with V_{In} 1 V, resistance 5 kΩ, and capacitance 50 nF. Equation 16.4 was used to calculate X_C. Equations 16.21 (a) and (b) were used to calculate V_{Out} for the respective filter

Frequency (f)	Capacitive reactance X_C	V_{Out} HFF	V_{Out} LFF
2 Hz	1.59 MΩ	1 V	0 V
200 Hz	15.9 kΩ	0.95 V	0.30 V
2 kHz	1.59 kΩ	0.30 V	0.95 V
20 kHz	159 Ω	0.03 V	1 V
200 kHz	15.9 Ω	0 V	1 V

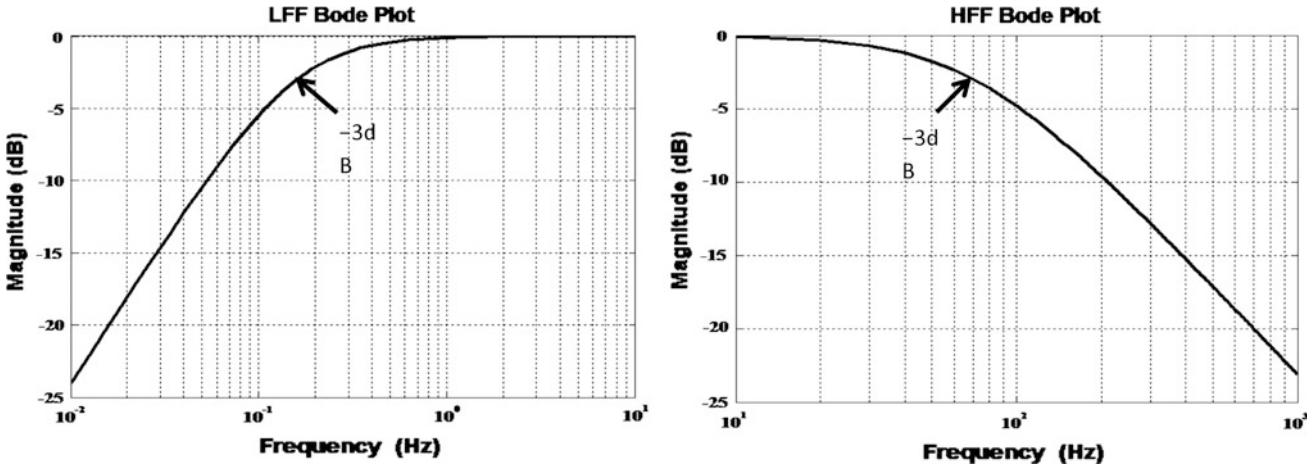

Fig. 16.13 Frequency response plots of the filters in Fig. 16.12a, b, respectively. In **a**, the filter attenuates high frequencies, and in **b**, the filter attenuates low frequencies. An *arrow* indicates the −3 dB point; in (**a**), f_C is 70 Hz, and in (**b**), f_C is 0.16 Hz. Code and output created using MatLab R2012a

filter circuit. This is shown in Eq. 16.22 where 2π is equivalent to 6.28, R is the resistor value in ohms, and C is the capacitor value in farads. The product $R * C$ is called tau, is indicated by the lower case Greek letter τ, represents a time constant, and can be substituted for RC as shown in Eq. 16.22 [1–5]. Time constants are discussed in the next section; however, it is important to understand that filters may be discussed in their cutoff point in Hz or by their time constant tau.

$$f_C = \frac{1}{2\pi RC} = f_C = \frac{1}{2\pi\tau} \tag{16.22}$$

Bode plots of HFF and LFF are shown in Fig. 16.13a, b, respectively. In the Bode plot of Fig. 16.13a, the HFF pass band extends from the vertical axis to the −3 dB point, and beyond the filter cutoff is the filter stop band. This is also true for the LFF Bode plot in Fig. 16.13b; however, the stop band and pass bands are reversed relative to the vertical axis.

Time Constants

A time constant is the product of the resistor and capacitor values in a filter circuit (RC) and is measured in seconds [1–5]. How does the product of a resistor in ohms and a capacitor in farads result in a time quantity? Using formulas already discussed for resistance (R), capacitance (C), and current (I), this can be answered and is shown in Eq. 16.23.

$$RC = \frac{E}{I} * \frac{Q}{E} = \frac{E}{\frac{Q}{t}} * \frac{Q}{E} = t \tag{16.23}$$

Filters may be described in terms of their time constant or frequency cutoff. It is important to be conversant between the two and to understand the behavior of the charge and discharge cycles for each filter. The voltage charge and discharge cycles of a capacitive transient are illustrated in Fig. 16.14a, b, respectively. A typical HFF setting in clinical neurophysiology is 70 Hz, with tau of 2.2 ms, and a 1-Hz LFF is synonymous with tau of 0.159 s. The term tau was introduced in the section on Filters and illustrated in Eq. 16.22, the formula for frequency cutoff of a filter. Equation 16.22 solved for tau is shown in Eq. 16.24.

$$\tau = \frac{1}{2\pi f_C} \tag{16.24}$$

Time constants can quite effectively be explained through the use of calculus; however, I will eliminate derivations and illustrate the equations along with a table. Equation 16.25

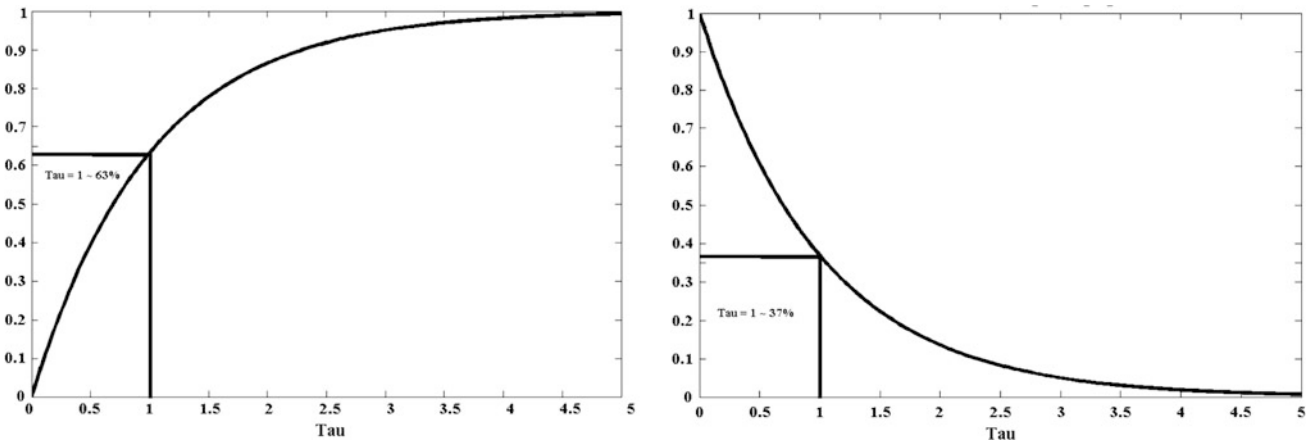

Fig. 16.14 The capacitive transient characteristics of Eqs. 16.25 (a) and (b) are shown in (**a**) and (**b**), respectively. In 1τ, the output has risen to 63 % in (**a**) and declined to 37 % in (**b**). In 5τ, in a DC circuit the components are either fully charged or discharged. Code and output created using MatLab R2012a

Table 16.3 Behavior of rising and decaying exponential time constants 0τ is initial conditions

Tau (τ)	Rise $V(t) = 1 * (1 - e^{\frac{-t}{\tau}})$		Decay $V(t) = 1 * e^{\frac{-t}{\tau}}$	
τ = tau	V	% of rise	V	% of decay
0	0	0	1	0
1	0.63	63	0.37	63
2	0.86	86	0.14	86
3	0.95	95	0.05	95
4	0.98	98	0.02	98
5	0.99	99	0.01	99

(a) and (b) are the rise and decay of voltage in a capacitor, respectively.

$$\underset{(\mathbf{a})}{V(t) = V(1 - e^{\frac{-t}{\tau}})} \quad \underset{(\mathbf{b})}{V(t) = Ve^{\frac{-t}{\tau}}} \tag{16.25}$$

The results of Eqs. 16.25 (a) and (b) are shown graphically in Fig. 16.14a, b respectively and numerically in Table 16.3.

It is clear from Fig. 16.14a, b and the values in Table 16.3 that in five time constants (5τ), the capacitor resistor combination has either completely charged or discharged. Another useful observation is this: Following one time constant, the circuit has completed 63 % of its course regardless of direction, charging, or discharging. With a DC source after 5τ, the capacitor has fully charged, and current has stopped flowing. With a DC source applied after 5tau, the capacitor has fully charged and current has stopped flowing. With an AC source applied charging and discharging of the capacitor alternate with the alternating AC source. The higher the applied frequency of the AC source the faster the alternating state of the capacitor. The higher the frequency the lower the capacitive reactance as illustrated in Eq. 16.4. The higher the frequency, the faster the alternating states. The time constant remains the product of the resistance and capacitance (RC), and this is the design of the circuit.

In terms of Bode plots if the time constant is a small value, the −3 dB point would be further from zero on the frequency scale, and the filter cutoff would be a larger value. If the time constant is a relatively large value, the −3 dB point would be closer to zero on the frequency scale, and the frequency cutoff would be a smaller value. This can be illustrated in several ways: One is using Eqs. 16.25 (a) and (b) to form Table 16.3. Another method is to use Eq. 16.24 to derive tau with various values of f_C as illustrated in Table 16.4. A third way is to view the concept graphically as in Fig. 16.15.

Differential Amplifiers and Polarity Convention

This is a general discussion of the operation of differential amplifiers in clinical neurophysiology. There is no in-depth electrical or electronic explanation, and the internal operation and electrical requirements of the operational amplifier are assumed satisfied.

Differential amplifiers do exactly what their name implies, and they take the difference of two inputs, amplify, and output the result. The schematic diagram of a differential amplifier is indicated in Fig. 16.16.

Table 16.4 The inverse relationship between tau and f_C. Values are rounded up to the highest integer. Note the change in units from seconds (s) to milliseconds (ms) at 3 Hz

Cutoff −3 dB f_C (Hz)	$\tau = \frac{1}{2\pi f_C}$
0.25	0.64 s
0.5	0.32 s
1	0.16 s
1.5	0.11 s
3	53 ms
5	32 ms
10	16 ms
15	10.6 ms
35	4.5 ms
70	2.3 ms
100	1.6 ms

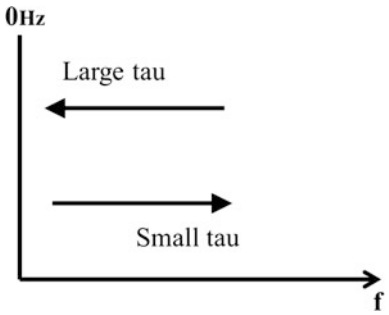

Fig. 16.15 Graphic illustration of the inverse relationship between the filter frequency cutoff and the value of its time constant. Horizontal axis begins at 0 Hz with increasing frequency moving to the right. With larger values of tau, the frequency cutoff moves toward 0 Hz indicated by a lower-frequency value cutoff. With smaller values of tau, the frequency cutoff moves away from 0 Hz taking on a larger-frequency cutoff value

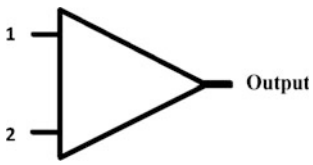
Fig. 16.16 Schematic symbol of a differential amplifier



As can be seen in Fig. 16.16, the amplifier has two inputs, input 1 and input 2, and a single output representing the amplified difference of the two inputs. Input 1 is referred to as the active input and input 2 the reference input [2–6]. Each amplifier represents one channel of digital recording. In clinical neurophysiology, electrodes are connected to the differential amplifier with one on each input. The differential amplifier then subtracts input 2 from input 1, amplifies, and outputs the difference as one channel of recording.

The deflection of the channel output up or down is a result of the polarity convention [4, 5]. All electroencephalography (EEG) machines are designed the same way allowing for a standard definition of polarity. If input 1 is relatively more negative than input 2, the deflection of the output is upward, and if input 2 is more negative than input 1, the deflection of the output is downward. In short, the deflection of the output follows the negativity [4].

Common mode rejection ratio (CMRR) is a design parameter of a differential amplifier. It is a measure of the amplifiers ability to reject common signals [2–7]. Common mode rejection is a ratio of two measured outputs of the amplifier. One output, called A_{Diff}, is measured with a different and controlled voltage level applied to each amplifier input. This may also be accomplished by applying a voltage to one input and grounding the other. The other output termed A_{Com} is measured with an identical, i.e., common and controlled voltage level applied to both amplifier inputs [1, 7]. In this way, it is possible to determine the integrity of the amplifier. Does the amplifier properly take the difference of the inputs, amplify, and output the result and is the output zero when identical voltage levels are applied to both inputs? There are inherent imperfections in electronic design, so the output is rarely if ever zero when identical and controlled voltages are applied to the inputs; however, the output is extremely low. CMRR is indicated in decibels (dB) although it may be shown as a whole number. The equation for CMRR and its conversion to decibels are shown in Eqs. 16.26 (a) and (b) [2, 3, 7].

$$\underset{(\mathbf{a})}{A_{\text{CMRR}} = \frac{A_{\text{Diff}}}{A_{\text{Com}}}} \quad \underset{(\mathbf{b})}{\text{dB}_{\text{CMRR}} = 20\log(A_{\text{CMRR}})} \tag{16.26}$$

This is an important design criterion of the amplifier, the higher the CMRR, the better the component design. Common mode voltage would be noise, such as 60 Hz induced on the electrode wires from a variety of sources. If it is common to both inputs, it should be rejected, and so it is not amplified as part of the signal of interest which could potentially lead to misinterpretation. One way to assist an amplifier to perform up to its design potential is to bundle all

connected electrode wires together. Bundling the wires causes induced noise to be common to all the wires allowing the differential amplifier to remove common mode noise.

Analog-to-Digital Conversion

Neurodiagnostic recording captures analog signals through the application of externally applied electrodes. Analog signals are continuous in time versus a digital signal which is composed of discrete points in time. In older pen and paper machines, it was the analog signal that was captured and faithfully recorded in full. Digital equipment has many advantages over older pen-driven machines; however, computers cannot capture and store signals that are continuous in time; they must be converted to digital form for storage and display. All neurodiagnostic equipments begin with an analog signal, and all convert it to a digital signal through a circuit called an analog-to-digital converter or ADC. Digital signals are discrete points in time represented by 1's and 0's and stored in memory on a computer.

All biological signals are analog, but all stored signals are digitally obtained by sampling and analog-to-digital conversion. The signal being recorded is filtered, sampled at equidistant points in time, and stored transforming it into a digital signal. An ADC has several design parameters, which come in various speeds and have differing degrees of accuracy and resolution, and an input voltage range, but all are rated in the number of bits of information they can store [4, 6, 7]. A bit is a single unit of information represented by a 1 or a 0 in binary notation; calculation of bits is shown in Eq. 16.27.

$$2^n = \#\text{ of bits} \quad 2^4 = 16\text{ bits} \tag{16.27}$$

The design criterion of the ADC dictates the price, and hence the more bits, the higher is the cost. A typical ADC size of 2^{16} is 65,536 bits, and if the ADC had a resolution of 0.06 μV, its dynamic range would be ±1.97 mV. Calculation of dynamic range requires knowledge about the size of the ADC and its resolution. Calculation of dynamic range (DR) indicated in our example is shown in Eq. 16.28.

$$\begin{aligned} \text{DR} &= 2^n * \frac{\text{resolution}}{\text{per bit}} = 65536\text{ bits} * \frac{0.06\ \mu\text{V}}{\text{bit}} \\ &= \pm 0.001966\text{ V} \end{aligned} \tag{16.28}$$

This means that the ADC can assign values to the samples with a minimum or maximum value of 1.97 mV. Without consideration for sign bits, the number of bins available to assign values to these samples is 65,536, with half (32,768) dedicated to the positive values and the other 32,768 is dedicated to the negative values. Each bin in this ADC represents a 60 nV increment, that is 10^{-9}, lending to very accurate placement of the digital samples to match their true analog values. The current American Clinical Neurophysiology Society (ACNS) guideline #8 calls for a minimum of an 11 bit ADC with 12 or higher preferred, to resolve the EEG to 0.5 μV or better and record up to plus or minus several millivolts without clipping [8]. Clipping may occur when the sample falls out of the range of the ADC as it has nowhere left to place a value larger than its dynamic range (positive or negative). Anything beyond these values is assigned to the maximum available value and appears clipped off in the positive or negative range.

Quantization (or signal processing is the process of mapping a large set of input values to a smaller set) is an indication of how much rounding, up or down, the ADC will have to do with the samples taken to make the value "fit" into its available steps [6, 7]. The higher the number of bits, the less rounding the ADC has to do, and thus, the sample will be assigned a value closer to its actual value. Our example of ±32,768 available steps at a resolution of 0.06 μV decreases the quantization error, which is defined as the round-off error introduced by quantization, for example, a decimal number of 12.65 representing as 13 in which there is an inherent error. This is what a larger number of bits does; it provides more alternatives for the ADC to more accurately represent the value of the samples taken as they are converted to digital form.

Nyquist Theorem

We need to sample and convert analog to digital signal, but we do not know yet how often to sample. This is where the Nyquist sampling theorem will help. Nyquist theorem states that a band-limited signal can be faithfully reproduced, providing the sampling rate is twice the maximum frequency of the signal being sampled [4–6]. For example, if the highest frequency content of a signal of interest is 70 Hz, then per Nyquist theorem it must be sampled at a **minimum** of 140 samples per second or 140 Hz for perfect reconstruction. What happens to the information between each sample? It is discarded, and the computer does not store any information other than the value of the analog signal at the time a sample is taken. One must understand the frequency content of a signal and ensure Nyquist criterion is met to obtain perfect reconstruction of an analog signal in digital form. If Nyquist theorem is not followed, "**aliasing**" of the signal occurs. Aliasing describes a situation that generates false (i.e., alias) frequency signals with jagged distortions making it difficult to recognize the original signal. Aliasing results in misinterpretation of the recorded signal because the original signal can no longer be perfectly reconstructed from its digital samples as there is not enough information from which to properly reconstruct the signal [4–6].

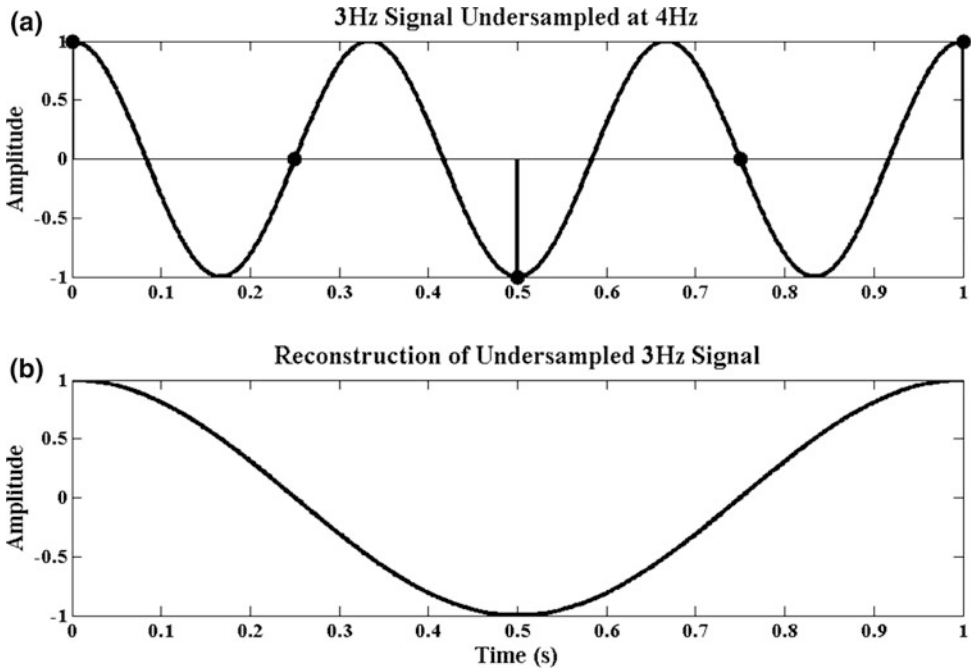


Fig. 16.17 The consequences of violating Nyquist sampling criteria. In **a**, 3 Hz signal is sampled at 4 Hz. In **b**, it has been reconstructed from its samples and appears to have been a 0.5-Hz signal, and this is aliasing, improper reconstruction due to insufficient sampling. Code and output created using MatLab R2012a

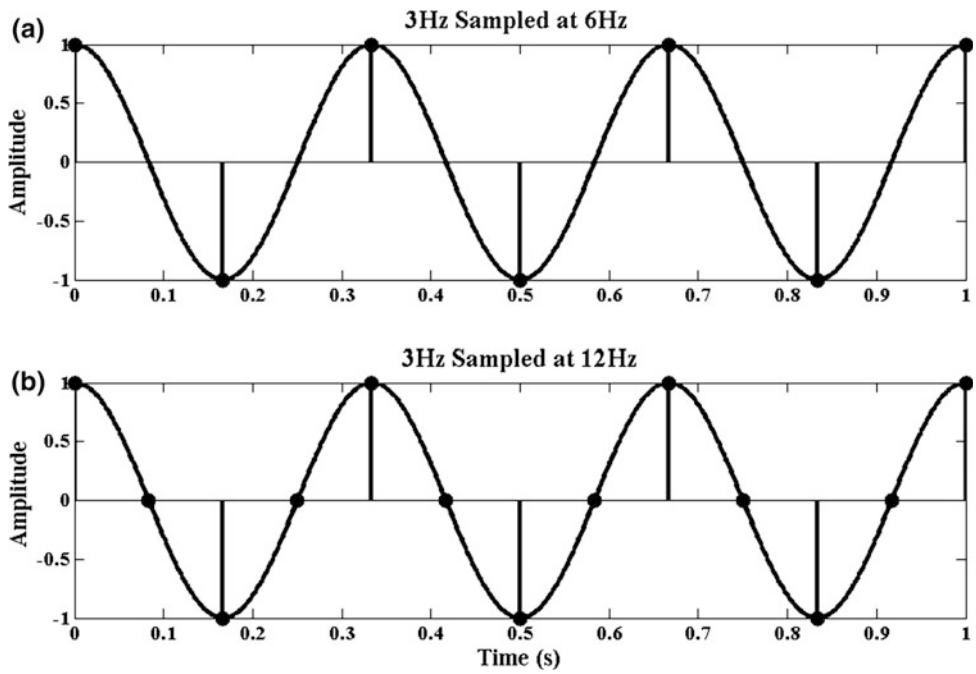

Fig. 16.18 In **a**, 3-Hz signal is sampled at 6 Hz meeting Nyquist criteria, and in **b**, the signal is over sampled at four times the signal frequency or 12 Hz. Perfect reconstruction is virtually ensured in both (**a**) and (**b**); however, (**b**) provides additional information for reconstruction with preserved morphology. Code and output created using MatLab R2012a

To faithfully follow the Nyquist theorem, the signal is filtered before sampling so the maximum frequency is known and Nyquist sampling theorem can be applied. In practice, sampling is performed at a higher rate than Nyquist theorem. The current American Clinical Neurophysiology Society (ACNS) guideline #8 requires a minimum sampling rate of three times the highest frequency content of the signal [8]. Higher sampling rate or over sampling is preferable and not generally an issue as the cost of storage is fairly inexpensive. More storage capacity is needed with a higher sampling rate because the faster a signal is sampled the more discrete points in time are taken that must be stored by the analog-to-digital converter. Taking constant snapshots of an event at evenly spaced intervals, stacking up all the snapshots sequentially, and flipping through them will give a fairly accurate and animated picture of the event. If sufficient snapshots are not available, there would be missing information and voids without properly depicting the event as it

occurred. During sampling, the values are briefly held up in a sample, and the circuit reassembled time locked and then displayed as "*X*" number of channels.

Figure 16.17a illustrates a 3 Hz signal that has been under sampled at 4 Hz violating Nyquist criteria. Note that the samples would never faithfully reproduce a 3 Hz signal, and on reconstruction, it would appear to have been a 0.5 Hz signal as shown in Fig. 16.17b; this is **aliasing**. Remember information between samples is lost, and the only values available to reconstruct the signal are the stored sampled values.

In Fig. 16.18a, the 3 Hz signal has been sampled at 6 Hz, meeting Nyquist criteria; notice, however, that only the peaks have been captured during sampling. While this would be sufficient to reconstruct the original signal, its morphology could be compromised upon reconstruction. It may appear to have had sharper peaks than the original signal. It is best to oversample as in Fig. 16.18b to capture additional information and ensure reconstruction.

Conclusion

The recording of a biological signal requires the application of electrodes that interface with sophisticated electronic equipment in order to capture and record minute electrical activity generated by the movement of ions in biological tissue. Neurodiagnostic machines have a variety of settings that must be adjusted during the course of the recording to enhance data acquisition providing meticulous recording.

In order to appropriately adjust variables, it is vital to possess an understanding of the controls available, the appropriateness of making variable adjustments, and a complete understanding of the effect on the integrity of the recording.

An Overview of Polysomnographic Technique

17

Nic Butkov and Sharon A. Keenan

Introduction

The term *polysomnography* (PSG) was proposed by Holland et al. [1] in 1974 to describe the recording, analysis, and interpretation of multiple, simultaneous physiologic characteristics during sleep. PSG is an essential tool in the formulation of diagnoses for sleep disorder patients and in the enhancement of our understanding of normal sleep [2–14]. It is a complex procedure that should be performed by trained technologists. Innovations for monitoring changes in physiology during sleep continue to hold great promise in the quest to understand healthy sleep and to diagnose sleep disorders.

Over the past decade, PSG has been increasingly employed in the diagnosis and treatment of complicated sleep-related breathing disorders (SRBDs), as seen in patients with chronic obstructive pulmonary disease (COPD), neuromuscular disease, congestive heart failure (CHF), obesity hypoventilation syndrome (OHS), and patients using opioid medications, whereas limited-channel home sleep apnea testing (HSAT) is increasingly used for diagnosing uncomplicated obstructive sleep apnea (OSA) [15–17]. Overnight in-laboratory PSG remains the gold standard when comprehensive physiologic sleep measures are required. These measures are particularly relevant as newer methods of nocturnal noninvasive ventilation (NIV) treatments are being developed. The importance of properly diagnosing patients with complicated SRBD and evaluating treatment response to NIV within the context of multiple physiologic parameters cannot be understated.

This chapter is a review of the technical aspects of PSG, describing traditional, classic in-laboratory PSG recording techniques. Problems likely to be encountered during a recording are examined, as are ways to alleviate them. Figures and tracing samples augment the text and help identify artifacts. Elsewhere in this volume, specified protocols are discussed and physiologic recording techniques are reviewed in detail.

Clinical Indications for PSG

According to the 2005 American Academy of Sleep Medicine (AASM) guidelines [18], attended PSG is considered the standard of practice for: (see also Chap. 26)

- Diagnosis of SRBD
- Positive airway pressure titration
- Preoperative assessment for snoring or OSA
- Evaluating results of the following treatments:
  - Oral appliances for moderate to severe OSA
  - Surgical procedures for moderate to severe OSA
  - Surgical or dental procedures in SRBD for return of symptoms.
- Treatment results requiring follow-up PSG:
  - Substantial weight loss or gain (10 % of body weight)
  - When clinical response is insufficient or when symptoms return.
- Patients with systolic or diastolic heart failure and nocturnal symptoms of SRBD
- Patients whose symptoms continue despite optimal management of CHF
- Neuromuscular disorders with sleep-related symptoms
- Narcolepsy (Multiple Sleep Latency Test [MSLT] after PSG)
- Periodic limb movement disorder in cases secondary to complaints by patient or observer (movements during sleep, frequent awakenings, excessive daytime sleepiness).

According to the AASM guidelines, PSG is not required to diagnose:

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_17

- Uncomplicated Parasomnias
- Seizure disorders, unless suspected nocturnal seizures
- Restless legs syndrome
- Common, uncomplicated, non-injurious events (arousals, nightmares, enuresis, sleep-talking, bruxism)
- Circadian rhythm disorders.

Diagnosis with clinical evaluation alone is the standard in these cases. Standard evaluation includes history, details of behavior, age of onset, time, frequency, regularity, and duration.

Patient Contact

A number of factors need to be kept in mind when a PSG is scheduled. Issues such as shift work, time zone change, or suspected advanced or delayed sleep phase syndrome should be taken into consideration. The study should be conducted during the patient's usual major sleep period, to avoid confounding circadian rhythm factors.

When the PSG is scheduled, the patient is sent a questionnaire about his or her sleep–wake history and a sleep diary that solicits information about major sleep periods and naps for 2 weeks prior to the study (Appendix 17.1). Information is provided to the patient about the purpose and procedures of the sleep study. The goal is to make the patient's experience of the sleep study as uncomplicated and comfortable as possible.

In the sleep laboratory setting, the technologist should ensure that patients are familiar with the surroundings and that they receive explicit information about the process. Patients should be made aware that someone will be monitoring their sleep throughout the entire study and told how to contact the technologist if necessary.

Before the study is undertaken, a full medical, psychiatric, and drug history should be completed and made available to the technologist performing the study. This information is necessary for correct interpretation of the data, and it allows the technologist to anticipate difficulties that may arise during the study. Technologists must also understand what questions the study seeks to answer. This enhances their ability to make protocol adjustments when necessary and ensures that the most pertinent information is recorded.

Prestudy Questionnaire

It is not uncommon for patients, particularly those with excessive sleepiness, to have a diminished capacity to evaluate their level of alertness [19]. In addition, patients with difficulty initiating and maintaining sleep often report a subjective evaluation of their total sleep time and quality that is at odds with the objective data collected in the laboratory. For these reasons, it is recommended that subjective data be collected systematically as part of the sleep laboratory evaluation.

The Stanford Sleepiness Scale (SSS) [20, 21] (Appendix 17.2) is an instrument used to assess a patient's subjective evaluation of sleepiness prior to the PSG. The SSS is presented to the patient immediately before the beginning of the study. Patients respond to a series of phrases by selecting the set of adjectives most closely corresponding to their current state of sleepiness or alertness. The scale is used extensively in both clinical and research environments. However, it has two noteworthy limitations: It is not suitable for children who have a limited vocabulary or for adults whose primary language is not English. In these situations, a linear analog scale is recommended to provide an introspective measure of sleepiness (see Appendix 17.2). One end of the scale represents extreme sleepiness and the other end alertness. Patients mark the scale to describe their state just prior to testing.

Another instrument, the Epworth Sleepiness Scale [22], lends information about chronic sleepiness. Patients are asked to report the likelihood of dozing in situations such as riding as a passenger in a car, watching television, and the like.

Patients are also asked about their medication history, smoking history, any unusual events during the course of the day, their last meal prior to the study, alcohol intake, and a sleep history for the last 24 h, including naps. Involvement of the patient in providing this information usually translates into increased cooperation for the study. A technologist's complete awareness of specific patient idiosyncrasies, in the context of the questions to be addressed by the study, ensures a good foundation for the collection of high-quality data.

Recording Parameters

A conventional PSG recording montage used in clinical sleep studies typically includes the following parameters:

- Central, frontal, and occipital electroencephalogram (EEG)
- The recording of eye movements (electrooculogram or EOG)
- The recording of chin muscle activity (chin electromyogram or EMG)
- The recording of leg muscle activity (right and left anterior tibialis EMG)
- The electrocardiogram (ECG)
- Nasal and oral airflow

- Respiratory effort (based on chest and abdomen excursion)
- Pulse oximetry.

Additional parameters can be added depending on the intent of the study. For example, when PSG is used in conjunction with noninvasive ventilation, additional parameters would typically include delivered positive airway pressures, estimated tidal volumes, inspiratory to expiratory ratios, leak values, and other essential data relevant for comprehensive treatment evaluation. On the other hand, if PSG is used with the intent of evaluating nocturnal seizures or parasomnias, additional recording parameters might include an expanded number of EEG channels and possibly additional limb EMG channels.

Understanding the Equipment

PSG Amplifiers

Although PSG equipment has undergone many changes since the early days of analog paper-based recordings, the basic concepts of bio-physiologic data collection remain the same. Bioelectrical signals, such as the EEG, EOG, EMG, and ECG, are derived from surface electrodes attached directly to the patient's skin. Other signals, such as those representing respiratory airflow and effort, are derived from transducers that respond to certain physiologic markers, such as changes in temperature or pressure, or body motion.

The signals received by the PSG equipment are extremely low in voltage (generally measured in microvolts) and must be greatly amplified to be converted into visible tracings. The key component of every PSG recording system is the bank of amplifiers used for processing the derived signals. In the past, these amplifiers were large in size and constituted a major part of the polysomnograph. In the present day, the amplifiers have been miniaturized and are typically integrated with the electrode jack box in the patient's room. The amplified signals are converted into digital form and transmitted by cable to the computer in the control room.

The amplifiers used in PSG recordings are described as differential amplifiers, specially designed to preserve essential physiologic data while rejecting undesirable signal interference. The process by which differential amplifiers accomplish this is called common mode rejection. For each physiologic derivation, two signals are compared to each other and only those signals that are dissimilar in voltage or polarity are amplified, while any identical in-phase signals are rejected. For example, when recording EEG activity, signals derived from the C4 electrode are referenced to signals derived from the M1 electrode (see Electrode and Sensor Application Process). The output from this derivation represents only those signals, which are dissimilar in voltage or polarity between the two inputs, while any identical, in-phase signals are rejected (these would include 50 or 60 Hz power line interference, or any other extraneous signals that are identical in both inputs).

It is important to understand that common mode rejection is only effective when the input signals are of equal quality, i.e., the signals are not degraded by high electrode impedances or poor electrical connections. If the signal quality varies significantly between the two inputs to the amplifier, the effect of common mode rejection is diminished and unwanted interfering signals (such as 50 or 60 Hz) will be amplified along with the signals of interest [23].

Gain and Sensitivity

The amount of signal amplification produced by PSG equipment is determined by the amplifier gain, defined as the number of times the raw signal is amplified. On most contemporary equipment, the gain is a fixed value. However, the actual size of the signal on a computer screen can be adjusted by the user. In doing so, the user can choose a specific ratio of input voltage to the vertical height of the signal. This is defined as signal sensitivity, which allows for precise signal measurements. Historically, sensitivity settings for the EEG, EOG, and EMG have been either 50 or 70 μV/cm for adult subjects (higher voltage-per-centimeter values equate to lower displayed amplitudes). For pediatric studies, the EEG channels are typically set to 100 μV/cm because of the higher EEG amplitudes seen in children, which might cause excessive signal blocking if displayed at high sensitivities. It is important to note that unlike sensitivity settings used in paper-based recordings, which were uniformly adjusted to grid marks on paper, sensitivity settings on contemporary digital equipment must be adjusted specifically for the type of display used. The size of the monitor, the available workspace on the monitor screen, and the total number of channels on the screen are all factors that can affect the actual size and aspect ratio of the displayed signals. To ensure consistency in recording and interpreting the polysomnogram, it is recommended that the sensitivity settings (and all other controls) at each workstation within the sleep laboratory are set identically, so that everyone involved in the process views the data in the same way.

Filters

Whereas common mode rejection is intended to eliminate major sources of external signal interference such as 50 or 60 Hz, additional signal conditioning is necessary to minimize localized signal interference within each recorded

Table 17.1 Examples of filter and sampling rate settings for various PSG parameters based on recommendations by the AASM

Recommendations for filter settings and sensitivity for various physiologic parameters				
Channel[a]	Low-frequency filter (Hz)	Time constant (s)	High-frequency filter (Hz)	Sensitivity
EEG	0.3	0.4	35	50 (μV/cm)
EOG	0.3	0.4	35	50 (μV/cm)
EMG	5[b]	0.03	90–120	20–50 (μV/cm)
ECG	1	0.12	15	1 MV/cm
Index of airflow	0.15	5[b]	15	[c]
Index of effort	0.15	5[b]	15	[c]

Some modifications to these settings may be appropriate, based on the types of signals recorded, or the types of transducers used in the study. For example, a lower LFF setting in the respiratory channels may be advantageous, to better resolve the "flattening" effect seen with flow limitation
[a]EEG includes C3/A2, C4/A1, O1/A2, and O2/A1 (or any other EEG derivation). EOG includes right outer canthus and left outer canthus referred to opposite reference (or any other EOG derivation)
[b]If shorter time constant or higher low-frequency filter is available, it should be used. This includes settings for all EMG channels, including mentalis, submental masseter, anterior tibialis, intercostal, and extensor digitorum muscles. Because breathing has such a slow frequency (as compared to the other physiologic parameters), the longest time constant available, or the lowest setting on the low-frequency filter options, would provide the best signal. It is also possible to use a DC amplifier (with no low-frequency filter, time constant = infinity) to record these signals
[c]It is common in clinical practice to index changes in airflow and effort to breathe by displaying qualitative changes in oral/nasal pressure, temperature, and chest and abdominal movement. It is well recognized that quantitative methods (such as endoesophageal pressure changes) provide a more sensitive and accurate measure of work of breathing. Ideally, a multi-method approach is used to increase confidence in detecting events of sleep-related breathing anomalies ECG, electrocardiography; EEG, electroencephalography; EMG, electromyography; EOG, electrooculography

parameter. This is accomplished by the use of low- and high-frequency filters (LFF and HFF). Historically, filters used in EEG and PSG recording equipment were built with resistors and capacitors that limited the range of frequencies allowed to pass through the amplifiers during data collection [24]. These filters were designed to attenuate undesirable signal frequencies relative to a gradually descending curve at each end of the selected frequency bandwidth. Contemporary digital filters are software-based and can be applied or changed either during the recording or during playback. This offers a significant advantage over traditional filtering, because changes can be made at any time without affecting the raw data. However, as with analog filters, caution should be exercised not to overuse digital filtering to the extent that faulty signals are made to appear "clean." When analyzing PSG data, it is essential to understand the effects of filtering on the raw data, making certain that unwanted interference is minimized, yet not completely eliminated, in order to alert the reader if a faulty signal occurs [23].

The selection of filter settings is made on the basis of the desired frequency range to be displayed within each channel. For example, in PSG recordings, EEG data are generally read within a bandwidth of 0.5 and 25 Hz. To preserve each end of the frequency spectrum, the low- and high-frequency filters are set slightly beyond this range; the LFF is generally set to 0.3 Hz and the HFF is set to 30 or 35 Hz. This creates a frequency window of 0.5–25 Hz, with some extra margin at each end to ensure full resolution of EEG waveforms relevant to sleep stage and arousal scoring. Likewise, the LFF and HFF settings for other PSG parameters, such as the EMG and ECG, are set according to the frequency ranges expected to be read within those channels. Table 17.1 presents recommended filter settings for the various PSG parameters.

Bit Resolution and Sampling Rates

Unlike paper-based recording systems of the past that transformed the continuous analog signals into mechanical pen movements, contemporary PSG systems require analog-to-digital converters (ADCs) to convert the analog signals into digital form. The ADC converts the signals by assigning a numeric value to the amplitude of the analog waveforms at predetermined intervals. The number of binary units (bits) used to represent the numeric value of each sampled interval determines the amplitude resolution of the digital recording. For adequate amplitude resolution, a 12-bit or higher system is recommended.

The number of sampled intervals collected within the span of one second is defined as the sampling rate, which

determines the frequency resolution of the recorded waveforms. The reconstruction of a digitized waveform follows the Nyquist theorem, which states that for basic frequency resolution the minimum sampling rate must be twice the rate of the highest frequency sampled (Nyquist rate). While the Nyquist rate is acceptable for processing signals that do not require detailed waveform reconstruction (such as the EMG), sampling rates that are significantly higher than the Nyquist rate are necessary for adequate graphic resolution of waveforms that require close scrutiny (such as EEG, EOG, and ECG waveforms) [25]. In these instances, the sampling rates should be at least 5–10 times higher than the highest frequency expected within the channel.

Unlike digital filtering, bit resolution and sampling rates must be applied during the recording process and cannot be changed afterward. To reduce overall file sizes and processing times, sampling rates can be selected channel by channel, depending on the type of signal recorded. Recommended sampling rates for various PSG parameters are included in Table 17.1.

Also to be considered is the display resolution, which is determined by the resolution of the monitor. The computer screen for review of the recording should have a sufficiently high resolution. Ideally, the screen should be at least 20 in. with a resolution of at least 1600 × 1200 pixels.

Time Scale

Historically, the speed of the chart drive for the recording instrument established the time scale and the epoch length (amount of time per page) of the recording. A common paper speed for traditional PSG was 10 mm/s, providing a 30-s epoch. Another widely accepted paper speed was 15 mm/s, a 20-s epoch length. For patients with suspected sleep-related seizure activity, a paper speed of 30 mm/s enhanced the ability to visualize EEG data. Data such as oxygen saturation and respiratory signals, however, were more easily visualized with slower paper speeds.

The issue of selecting the appropriate paper speed became moot when digital systems became the norm. In the present day, digital technology allows for multiple time-scale settings, which can be applied either during the recording or during playback (Figs. 17.1 and 17.2). For sleep stage and arousal scoring, the 30-s epoch continues to be the established standard [26]; however, alternative time scales can be used for evaluating sleep-related events. For example, an epoch length of 10–15 s can be useful for closely examining EEG or ECG abnormalities, whereas epoch lengths of 2–5 min are useful for evaluating respiratory patterns, periodic limb movements, and oximetry trends.

The Study

Electrode and Sensor Application Process

The quality of the tracing generated in the sleep laboratory depends on the quality of the electrode application [27]. Before any electrode or sensor is applied, the patient should be instructed about the procedure and given an opportunity to ask questions. The first step in the electrode application process involves measurement of the patient's head. The International 10–20 system [28] of electrode placement is used to localize specific electrode sites (Figs. 17.3 and 17.4) (see also Chap. 24). The following sections address the application process for EEG, EOG, EMG, and ECG electrodes.

Electroencephalography

As originally described in the Rechtschaffen and Kales manual [29], standard electrode derivations for monitoring EEG activity during sleep are C3/A2 or C4/A1 for central EEG activity, and O1/A2 or O2/A1 for occipital EEG activity (see also Chap. 18). The AASM Scoring Manual terminology uses the terms "M1" and "M2" instead of "A1" and "A2" for the reference electrodes placed on the mastoid process. In this case, the derivations are C3/M2 or C4/M1, and O1/M2 or O2/M1 (the AASM recommends using C4/M1 and O2/M1 as the default derivations, with C3/M2 and O1/M2 as alternative back-up derivations). The AASM also recommends the use of frontal EEG recordings (F4/M1 and F3/M2) when considering decisions regarding K complexes or slow-wave activity [26].

In some situations, there may be a need for additional electrodes. For example, to rule out the possibility of epileptic seizures during sleep or to detect the presence of other sleep-related EEG abnormalities, it may be necessary to apply the full complement of EEG electrodes according to the International 10–20 system. An abbreviated montage to screen for EEG abnormalities during PSG is discussed in Appendix 17.3. For recording EEG, gold cup electrodes are commonly used. The electrode cups are filled with conductive cream or electrode paste and adhered to the scalp with collodion or with additional electrode paste. The collodion technique [27] has long been an accepted and preferred method of application for EEG scalp and reference electrodes. Other methods using electrode paste and a conductive medium are acceptable and may be preferred in certain conditions.

The International 10–20 system of electrode placement determines the placement of EEG electrodes. Reference electrodes are placed on the bony surface of the mastoid process. A description of the measurement procedure appears in Appendix 17.4.

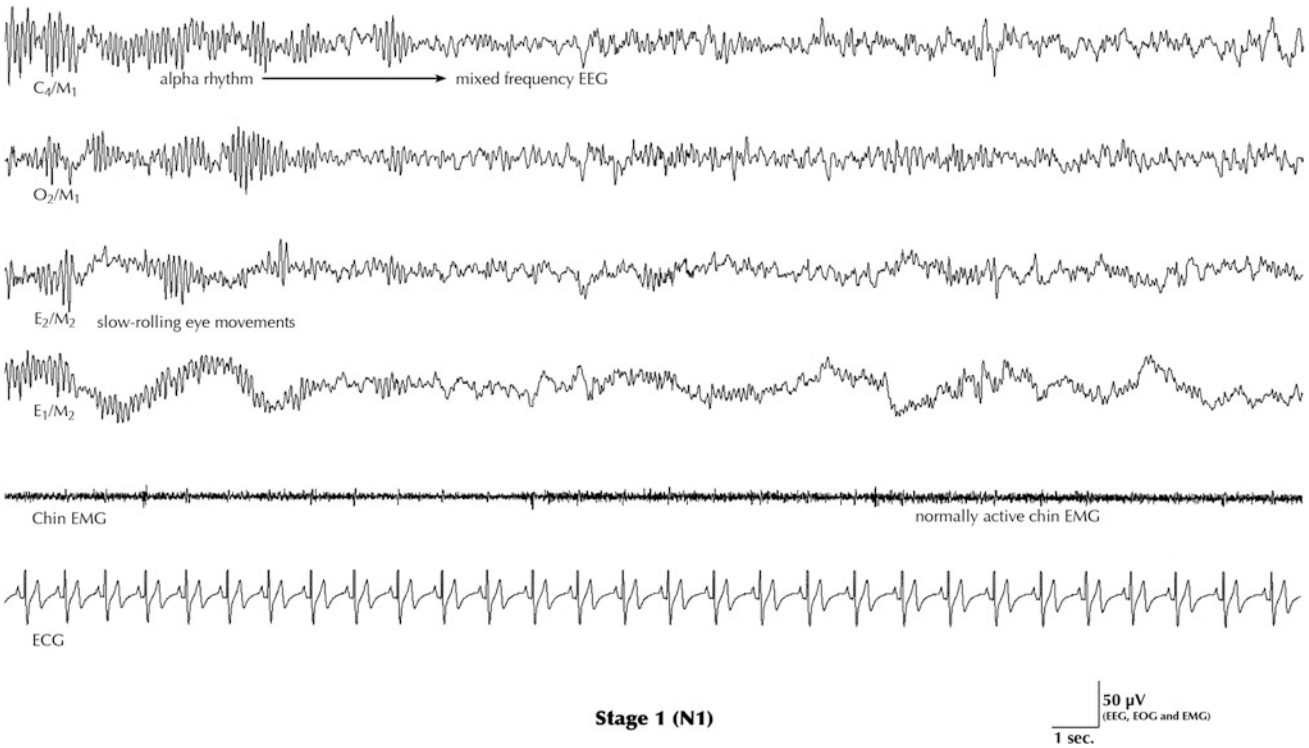

Fig. 17.1 PSG recording viewed in a 30-s epoch window. A time scale of 30 s per epoch provides a high level of detail in the EEG and EOG channels and is the standard scale for scoring sleep stages and arousals. This sample demonstrates the onset of stage 1 sleep. Reprinted with permission from Butkov [23]

Electrooculography

The EOG is a recording of the movement of the corneo-retinal potential difference that exists in the eye. It is the movement of this dipole with respect to the placement of the EOG electrodes that is recorded (Fig. 17.5) (see also Chap. 18). Gold cup electrodes or silver–silver chloride electrodes can be used to record the EOG. EOG electrodes are typically applied to the surface of the skin with an adhesive collar; this method avoids the risk of collodion contacting the patient's eyes.

The AASM Scoring Manual recommends placing the right EOG electrode (E2) one centimeter directly above the right outer canthus (ROC) and the left EOG electrode (E1) one centimeter directly below the left outer canthus (LOC) [26]. Some adjustments might be necessary to these placements, to avoid placing the E2 electrode directly over the right eyebrow or to avoid placing either of the electrodes too close to the sensitive tissue of the eyelid. The AASM also recommends referencing both EOG electrodes to the right mastoid (M2); however, a contralateral reference (E2/M1 and E1/M2) may be preferable for maximizing signal amplitudes in both EOG channels and equalizing the out-of-phase signals deflections seen with conjugate eye movements [30].

It should be noted that many variations of electrode placement and recording derivations have been used in a variety of clinical and research settings. Additional infraorbital and supraorbital electrodes enhance the ability to detect eye movements that occur in the vertical plane and can be particularly useful in the MSLT [31, 32]. Given the existing variations in methodology within the clinical and research environments, it is important to know the exact electrode placements and inputs to the EOG channels when interpretation of EOG activity has significant impact on diagnosis or treatment outcome (Fig. 17.6).

Electromyography

To record chin EMG activity, gold cup or silver–silver chloride electrodes are placed over the mentalis and submentalis muscles. The electrodes can be attached with double-sided electrode collars and paper tape, or they can be adhered with collodion or paste if the patient has a beard. The AASM Scoring Manual recommends placing one electrode on the midline, 1 cm above the inferior edge of the mandible, and two electrodes 2 cm below the inferior edge of the mandible, offset 2 cm to the right and left of midline, respectively [26]. Two of the electrodes are used to create a bipolar EMG recording, while the third electrode serves as a backup. Some practitioners place an electrode over a masseter muscle to better detect bursts of EMG activity associated with bruxism (see Fig. 17.6).

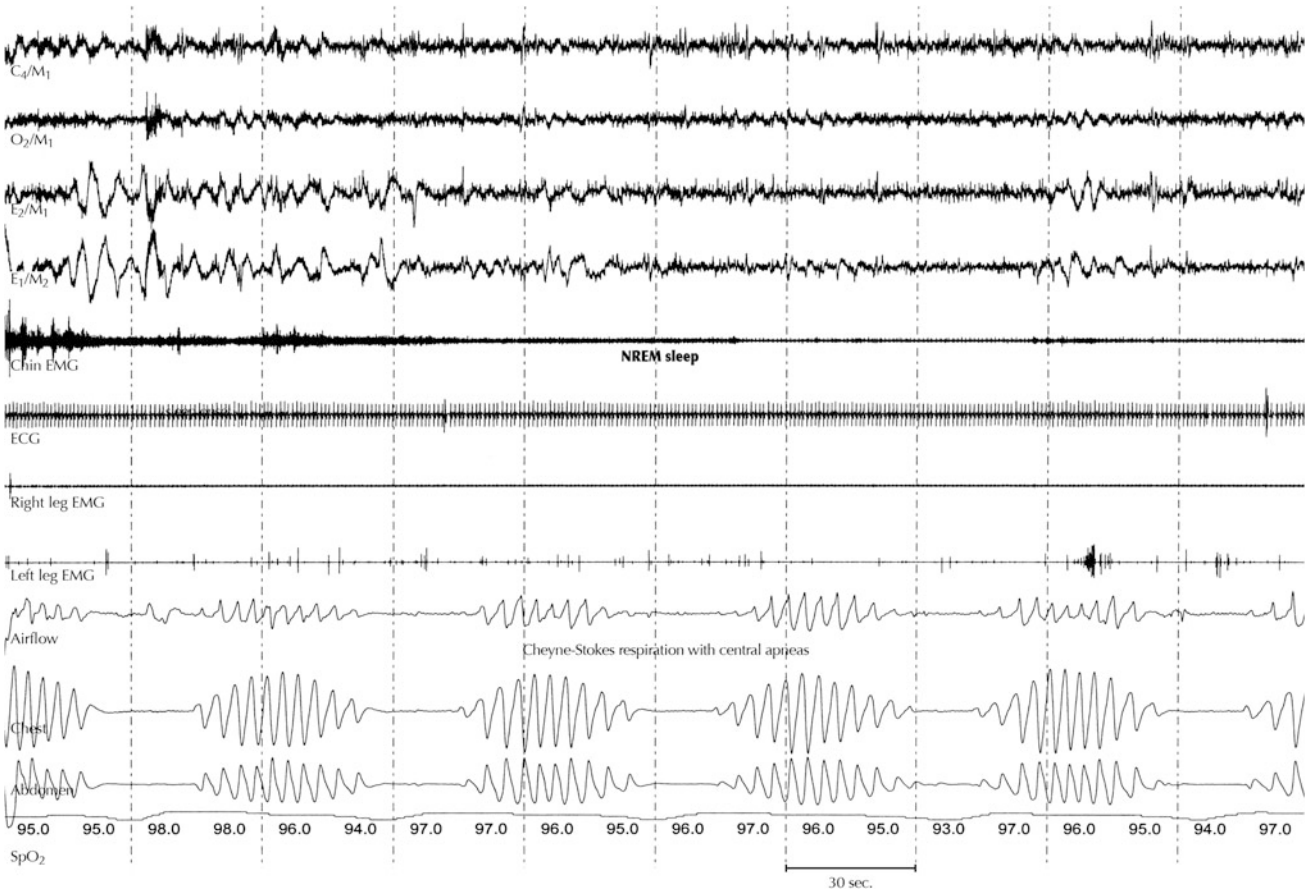

Fig. 17.2 PSG recording viewed in a 5-min epoch window. After scoring sleep stages and arousals in 30-s epochs, the time scale can be compressed into 2- to 5-min epochs, to better discern respiratory patterns while correlating them to the patient's sleep and wake physiology. This example shows a pattern of Cheyne–Stokes respiration emerging with the onset of NREM sleep. Reprinted with permission from Butkov [23]

To record leg EMG, a pair of electrodes is placed over the anterior tibialis muscle of each leg. The electrodes are spaced approximately 2–3 cm apart and referenced to each other in a bipolar derivation.

Electrocardiography

There are a variety of approaches for recording the ECG during PSG. The simplest approach is to use disposable ECG patches with a stress loop incorporated into the lead wire to ensure long-term placement. A modified lead II is obtained by placing an electrode slightly below the right clavicle and referencing it to an electrode placed over the left lower thorax. A third electrode placed slightly below the left clavicle allows for recording a modified lead I (left subclavicular to right subclavicular) and lead III (left subclavicular to left lower thorax) ECG.

Patient Ground and System Reference Electrodes

A single patient ground electrode is applied typically to the patient's forehead, slightly below the hair line. The purpose of a patient ground is to divert excessive 50 or 60 Hz line frequency interference from the patient's body. The input for the ground electrode must be isolated to prevent the possibility of stray current passing through the patient, and only a single ground electrode should be used on the patient to avoid the possibility of creating a ground loop.

If system referencing capabilities are provided by the PSG equipment, then an additional system reference electrode is attached to the patient, typically placed on the midline of the scalp (Cz). System referencing offers a way to select or to change input signal derivations either during data collection or during playback. During data collection, the signals from all of the applied electrodes are initially referenced to the Cz electrode. This configuration is not seen by the operator, but is used as a framework for selecting the desired derivations. For each selected derivation, the computer subtracts the common reference (Cz) from the chosen pair of input signals and displays the resulting derivation on the computer monitor [23].

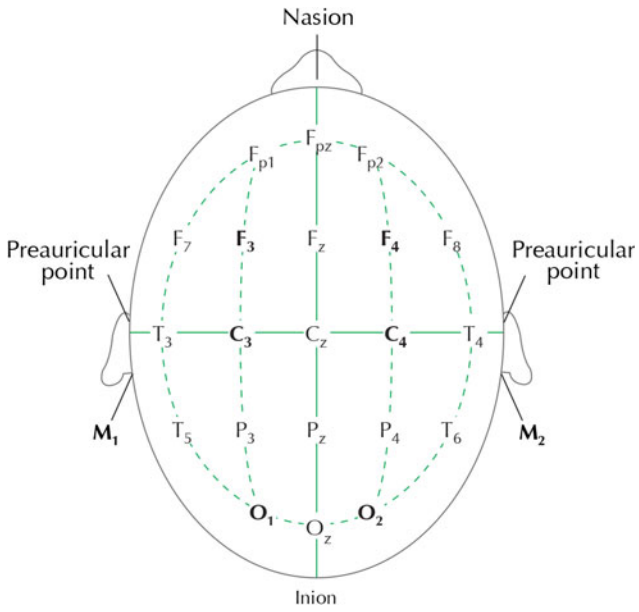

Fig. 17.3 International 10/20 system of electrode placement (*top view*). Reprinted with permission from Butkov [23]

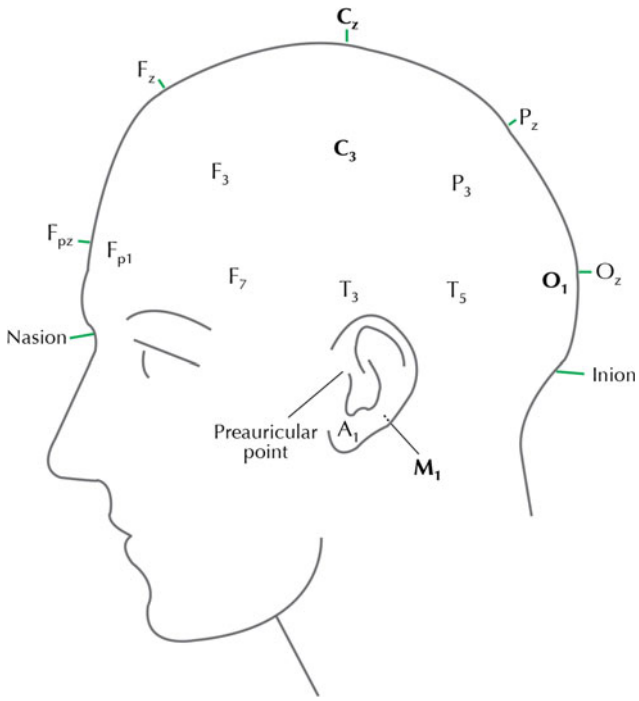

Fig. 17.4 International 10/20 system of electrode placement (*side view*). Reprinted with permission from Butkov [23]

It is important to note that a faulty connection to either the patient ground or the system reference electrode will result in signal degradation that can affect all of the PSG channels. A faulty patient ground connection can cause excessive 50 or 60 Hz interference in the recording, while a faulty system reference connection can cause complete signal loss in all channels (with the exception of any dedicated bipolar or transduced signals that bypass the common reference). Consequently, extra care should be taken to ensure that these two electrodes are properly applied and well maintained throughout the duration of the recording.

Electrode Impedances

Before recording, all electrodes should be visually inspected to check the security of their placement and an impedance check should be performed and documented. An impedance meter is ideally part of the recording system. Alternatively, a separate device can be used. Adjustments should be made to any electrode with impedance readings of greater than 5000 Ω (5 kΩ). Impedance levels are reduced by carefully cleansing and scrubbing each electrode site with a gel-based skin prepping solution before applying the electrode. Only a small area of skin should be scrubbed, no larger than the size of the electrode cup, to prevent electrical bridging and to minimize the occurrence of artifacts in the recording [23].

Physiologic Calibrations

Physiologic calibrations are performed after the electrode and sensor application is complete. This calibration documents proper functioning of the electrodes and other recording devices and provides baseline data for review and comparison when scoring the PSG. The specific instructions given to the patient for this calibration include

- Eyes open, look straight ahead for 30 s.
- Eyes closed, look straight ahead for 30 s.
- Hold head still, look to left and right, up and down. Repeat.
- Hold head still, blink eyes slowly, five times.
- Clench the jaw and grit the teeth.
- Inhale and exhale slowly, three times.
- Hold breath for 10 s.
- Dorsiflex right foot (i.e., bend the foot upward), dorsiflex left foot (this ensures contraction of the tibialis anterior muscle).

As these instructions are given to the patient, the technologist examines the tracings and documents the patient's responses. When the patient stares straight ahead for 30 s with eyes open, the background EEG activity is examined. As the patient looks right and left, the tracing is examined for out-of-phase deflections of the signals associated with recording the EOG. Out-of-phase deflection occurs if the inputs to consecutive channels of the polygraph are E2/M1

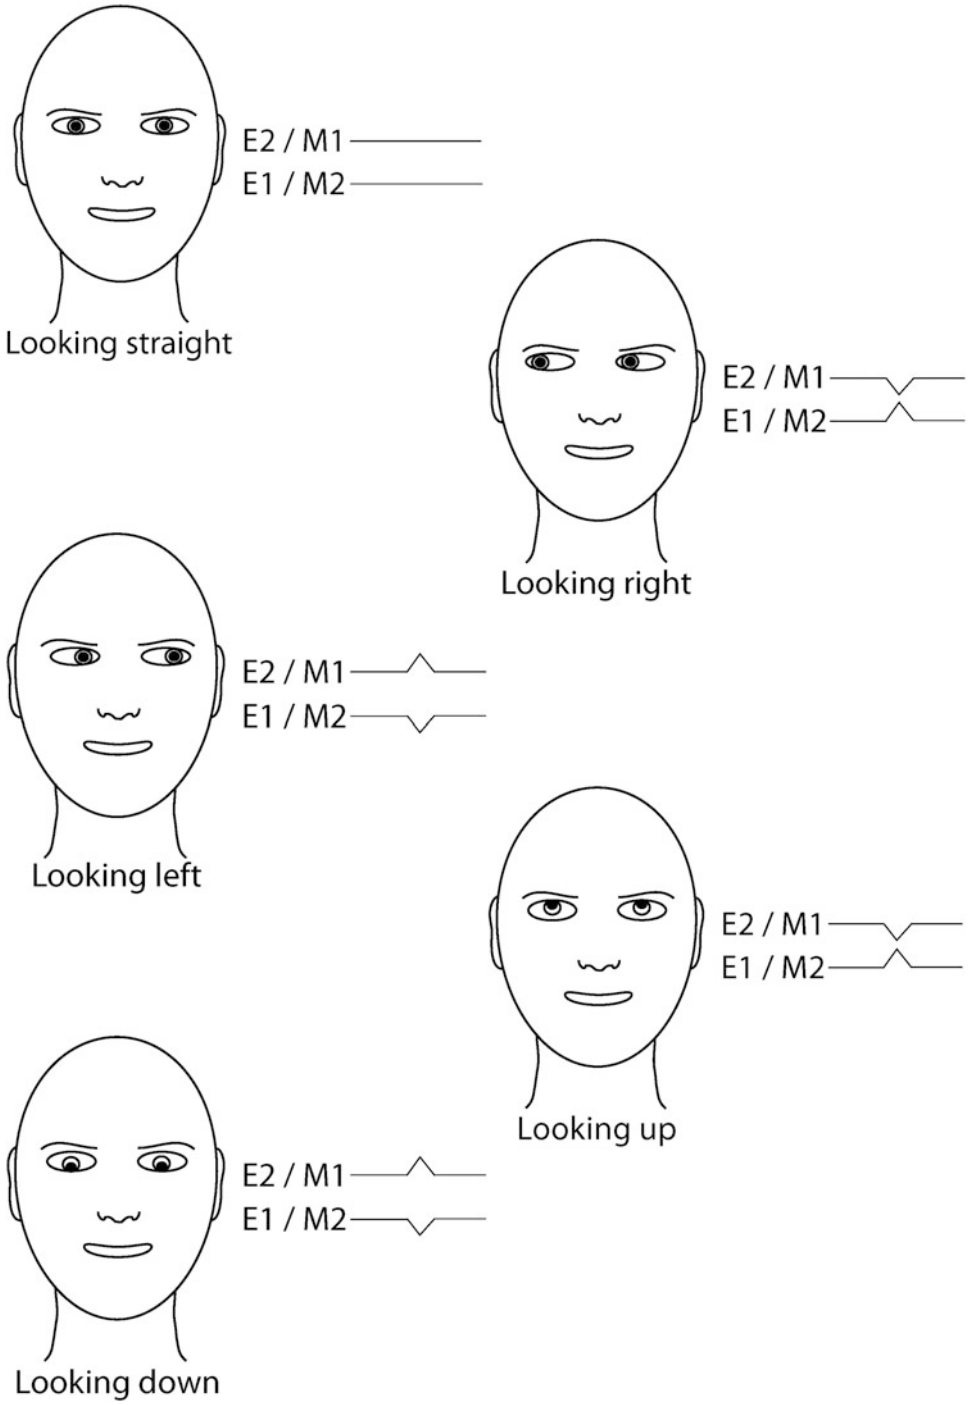

Fig. 17.5 Recording montage for a 2-channel EOG demonstrates out-of-phase deflections in the EOG tracings associated with conjugate eye movements. The deflections in the EOG tracings follow the standard EEG and PSG polarity convention (negative voltage = upward deflection; positive voltage = downward deflection)

for the first EOG channel and E1/M2 for the second. It is also important, when the patient closes his or her eyes, to observe the reactivity of the alpha rhythm seen most prominently in the occipital EEG; alpha rhythm is usually best visualized when the patient's eyes are closed.

The mentalis/submental EMG signal is checked by asking the patient to clench the jaws, grit the teeth, or yawn. The technologist documents proper functioning of the electrodes and amplifiers used to monitor anterior tibialis EMG activity by asking the patient to dorsiflex the right foot and the left foot in turn. If rapid eye movement (REM) sleep behavior disorder is suspected, additional electrodes should be applied to the surface of the skin above the extensor digitorum communis muscles of each arm. Patients are asked to extend their wrists while the technologist examines the recording for the associated increase in amplitude in the corresponding EMG channel.

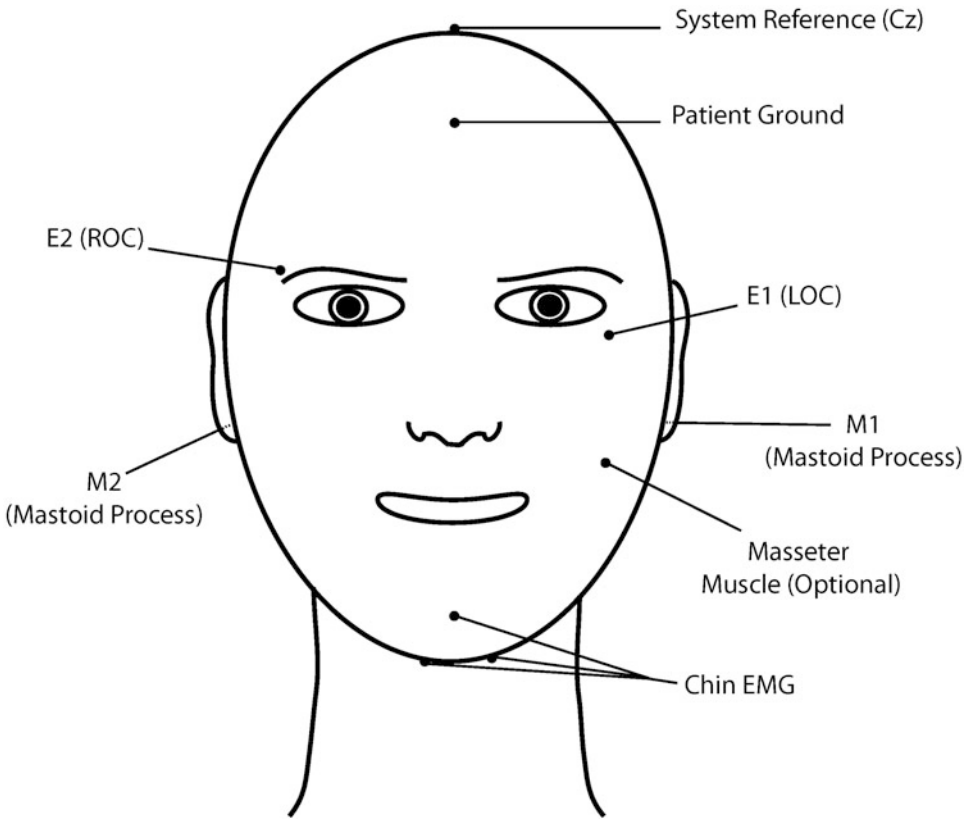

Fig. 17.6 Schematic diagram showing the placement of the EOG, chin EMG, patient ground and system reference electrodes

Inspiration and expiration allow for examination of the channels monitoring airflow and respiratory effort [33, 34]. A suggested convention is that inspiration causes an upward deflection of the signal and expiration a downward deflection. It is important that the signals in all the channels recording respiration are in phase with each other to avoid confusion with paradoxical breathing. The technologist should observe a flattening of the trace for the duration of a voluntary apnea. [Note: It is recommended to include end-tidal or transcutaneous CO_2 monitoring when studying children [35], or adult patients with underlying lung or neuromuscular diseases. The addition of CO_2 monitoring increases the sensitivity of the study of hypoventilation.

If the 50 or 60 Hz notch filter (also called "line filter" or "AC filter") is in use, a brief examination (2–4 s) of portions of the tracing with the filter in the "out" position is essential. This allows for identification of any 50 or 60 Hz interference that may be masked by the filter. Care should be taken to eliminate any source of interference and to ensure that the 50 or 60 Hz notch filter is used only as a last resort. This is most important when recording patients suspected of having seizure activity, because the notch filter attenuates the amplitude of the cortical spike activity seen in association with epileptogenic activity.

The physiologic calibrations enable the technologist to determine the quality of data before the PSG begins. If artifacts are noted during the physiologic calibrations, it is imperative that every effort be made to correct the problem, as the condition is likely to get worse through the remaining portions of the recording. The functioning of alternative backup electrodes should also be examined during this calibration. If any additional monitoring devices are used for the study, the technologist should incorporate the necessary calibrations.

When a satisfactory calibration procedure and all other aspects of patient and equipment preparation are completed, the patient is told to assume a comfortable sleeping position and to try to fall asleep. Then, the lights are turned out in the patient's room and the "lights-out" time is noted on the tracing and in the recording log.

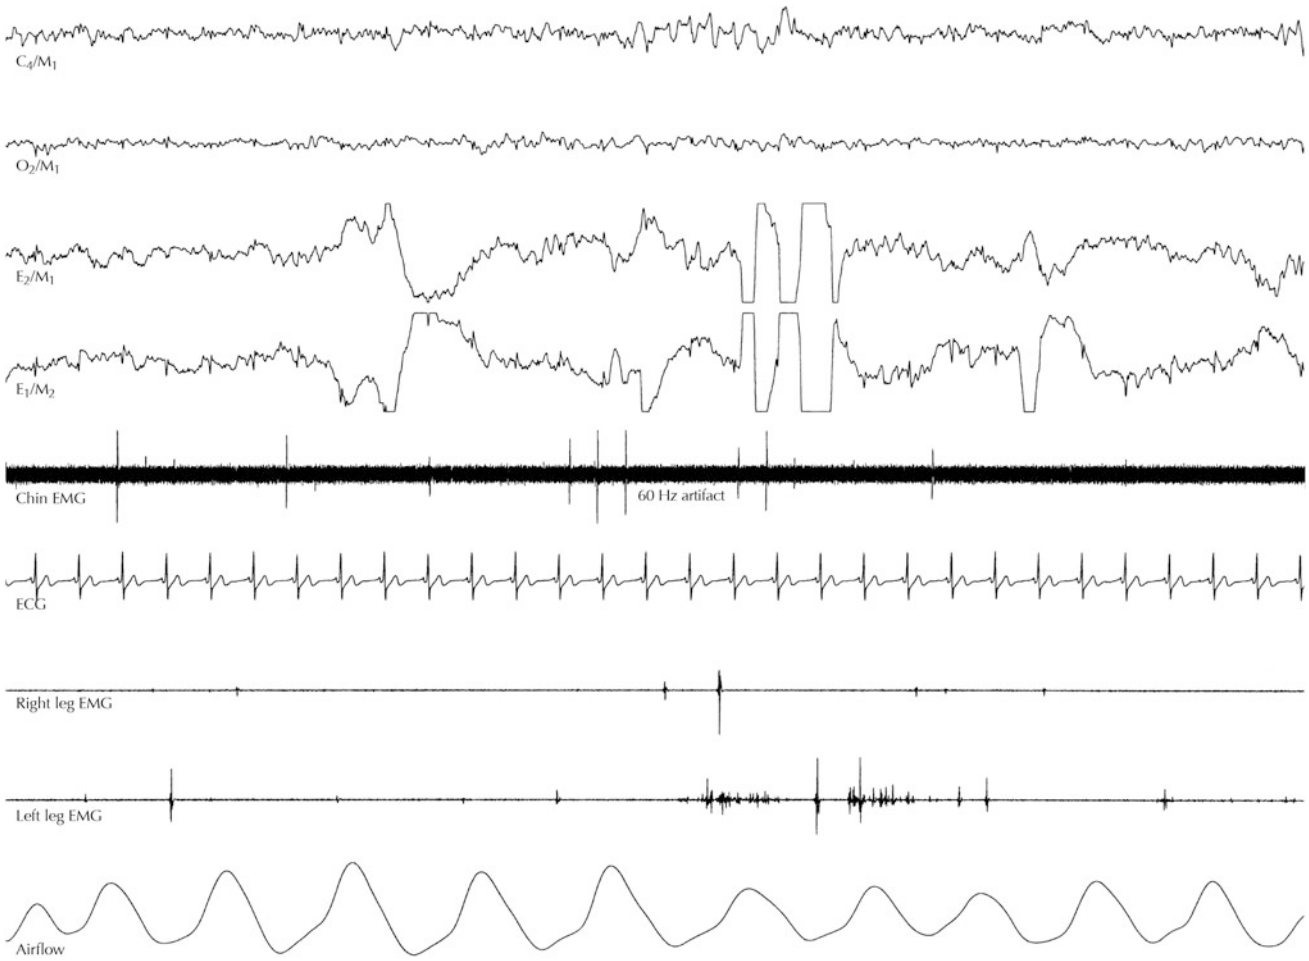

Fig. 17.7 60 Hz artifact. This is an example of 60 Hz artifact in the chin EMG channel caused by faulty electrode connection. Reprinted with permission from Butkov [23]

Monitoring and Recording

Complete documentation for the PSG is essential. This includes patient identification (patient's full name and medical record number), date of recording, and a full description of the study. The name of the technologist performing the recording, as well as those of any technologists who prepared the patient or the equipment, should be noted. In laboratories that use multiple pieces of equipment, the specific instrument used to generate the recording should be identified. This is particularly useful in the event that artifacts are noted during the analysis portion (scoring) of the sleep study.

Specific parameters recorded on each channel should be clearly identified, as should a full description of sensitivity, filter, and calibration settings for each channel. The time of the beginning and end of the recording must be recorded, as well as specific events that occurred during the night. Any changes made to filter, sensitivity, or derivation settings during the recording should be clearly noted in the study.

The technologist is also responsible for providing a clinical description of unusual events. For example, if a patient experiences an epileptic seizure during the study, the clinical manifestations of the seizure must be detailed: deviation of eyes or head to one side or the other, movement of extremities, presence of vomiting or incontinence, duration of the seizure, and postictal status. Similar information should be reported on any clinical event observed in the laboratory, such as somnambulism or clinical features of REM sleep behavior disorder. Physical complaints reported by the patient are also noteworthy. When studying patients with SRBD, documentation of snoring, wheezing, labored breathing, or other descriptive observations of the patient's breathing patterns provide essential information that can assist the reading physician in interpreting the PSG recording.

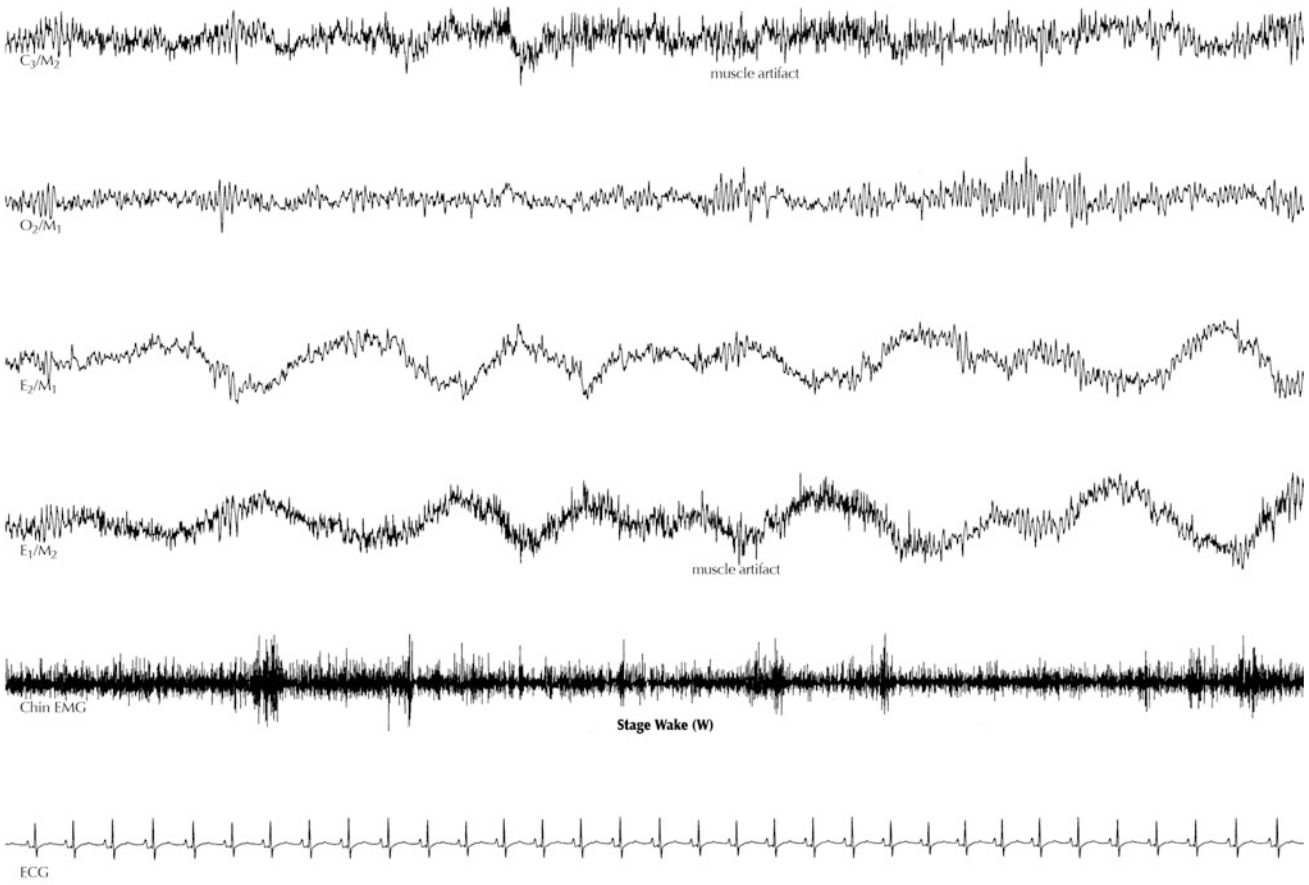

Fig. 17.8 60 Hz Artifact. This is an example of 60 Hz artifact in the chin EMG channel caused by faulty electrode connection. Reprinted with permission from Butkov [23]

Troubleshooting and Artifact Recognition

In general, when difficulties arise during recording, the troubleshooting inquiry begins with the patient and follows the path of the signal to the recording device. More often than not, the problem can be identified as a displaced or faulty electrode or sensor. It is less likely that artifact is the result of a problem with an amplifier. If the artifact is generalized (i.e., in most channels), then the integrity of the ground electrode, system reference electrode, or the cable from the electrode jack box should be checked. If the artifact is localized (i.e., in a limited number of channels), then the question should be: which channels have this artifact in common and what is common to the channels involved? The artifact is probably the result of a problem with an electrode or sensor that is common to both channels. If the artifact is isolated to a single channel, then the problem most likely stems from the specific electrode or sensor used only for that channel. In many instances, localized artifacts can be corrected by changing the derivation(s) to an alternative reference electrode, or by using alternative backup derivations.

50 or 60 Hz Artifact

50 or 60 Hz interference (Figs. 17.7 and 17.8) stems from power line frequency in the vicinity of the study.[1] As described earlier in this chapter, common mode rejection (a function of the PSG differential amplifiers) serves to eliminate 50/60 Hz artifact from the PSG recording. In addition, the patient ground electrode is used to divert stray electrical interference from the patient. The effectiveness of common mode rejection and the function of the patient ground are both dependent on the integrity of the electrode connections to the patient. Consequently, the presence of 50 or 60 Hz artifact is most often caused either by high electrode impedances (which defeat the function of common mode rejection), or by a faulty ground connection (which prevents effective diversion of electrical interference from the patient), or a combination of both. Such 50 or 60 Hz interference can also be aggravated by excessive leakage current, which can stem from any electrical equipment in the vicinity of the study.

[1] 50 Hz is used in most European and Australasian countries; 60 Hz is used in the USA, Canada, and many South American countries.

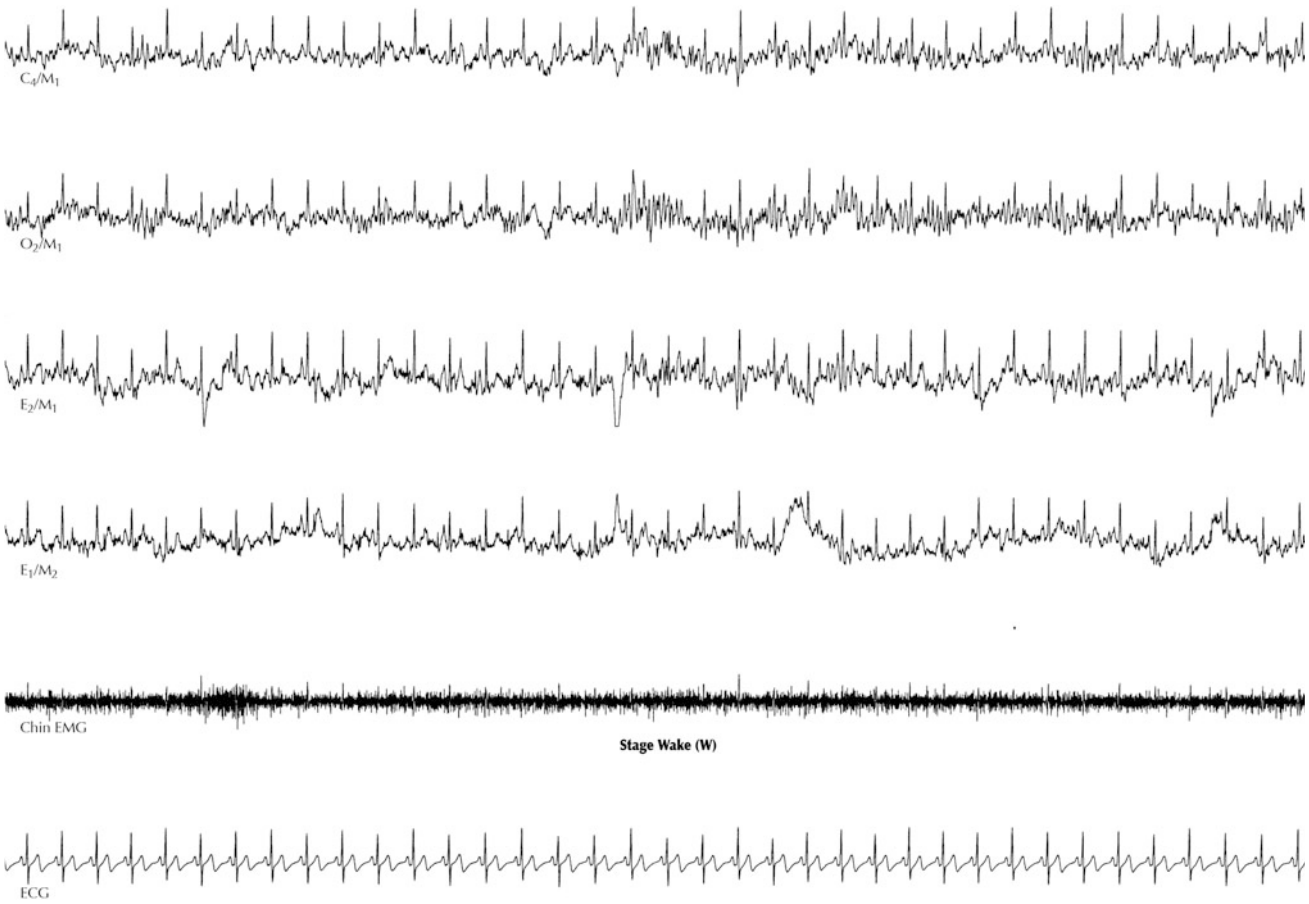

Fig. 17.9 Muscle artifact in the EEG and EOG. This is an example of muscle artifact appearing in the C3/M2 and E1/M2 channels. Because the artifact is identical in both channels sharing the same reference, it is evident that the artifact originates form the M2 electrode. Reprinted with permission from Butkov [23]

It is not recommended to routinely use 50/60 Hz filters to eliminate power line frequency interference, because this only serves to cover up potential problems with the recording and in some instances may attenuate important physiologic data, such as seizure spikes in the EEG. An exception to this is leg EMG recordings, which may require the use of 50/60 Hz filters due to the extended length of the electrode leads, and because in some instances it may be difficult to obtain optimal impedance levels in the leg EMG due to skin conditions or concerns over excessive skin scrubbing. It is recommended that PSG recording systems provide individual channel-by-channel 50/60 Hz filters, so they can be applied only to those channels where needed.

The best insurance against 50 or 60 Hz artifact is to pay close attention to the integrity of the electrode connections to the patient. If problems with 50 or 60 Hz artifacts persist, the laboratory environment should be checked for sources of excessive electrical interference. A common source of interference can be an electric bed, which may need to be unplugged during the study to prevent problems with the recording.

Muscle Artifact

Muscle artifact appearing in the EEG and EOG (Fig. 17.9) can be expected whenever the patient moves or tenses the scalp or facial muscles. Muscle artifact is sometimes confused with 50 or 60 Hz, because both are high-frequency artifacts. Unlike 50/60 Hz, which is uniform in appearance, muscle artifact is irregular and tends to wax and wane with increased or decreased muscle tension. Excessive muscle artifact can be caused by placing the mastoid reference electrodes (M1 and M2) too low or too far from the ear flap (pinna), in close proximity to the muscles of the neck. Repositioning the mastoid electrode to a firm bony area close to the pinna can often help minimize the problem.

ECG Artifact

The presence of ECG artifacts in the EEG and/or EOG channels is common, due to the relatively long inter-electrode distances used in PSG recordings. However, excessive ECG artifacts (Fig. 17.10) can be caused by high electrode impedances in the EEG and EOG channels, or by placing the mastoid reference electrodes (M1 and M2) too low or too far

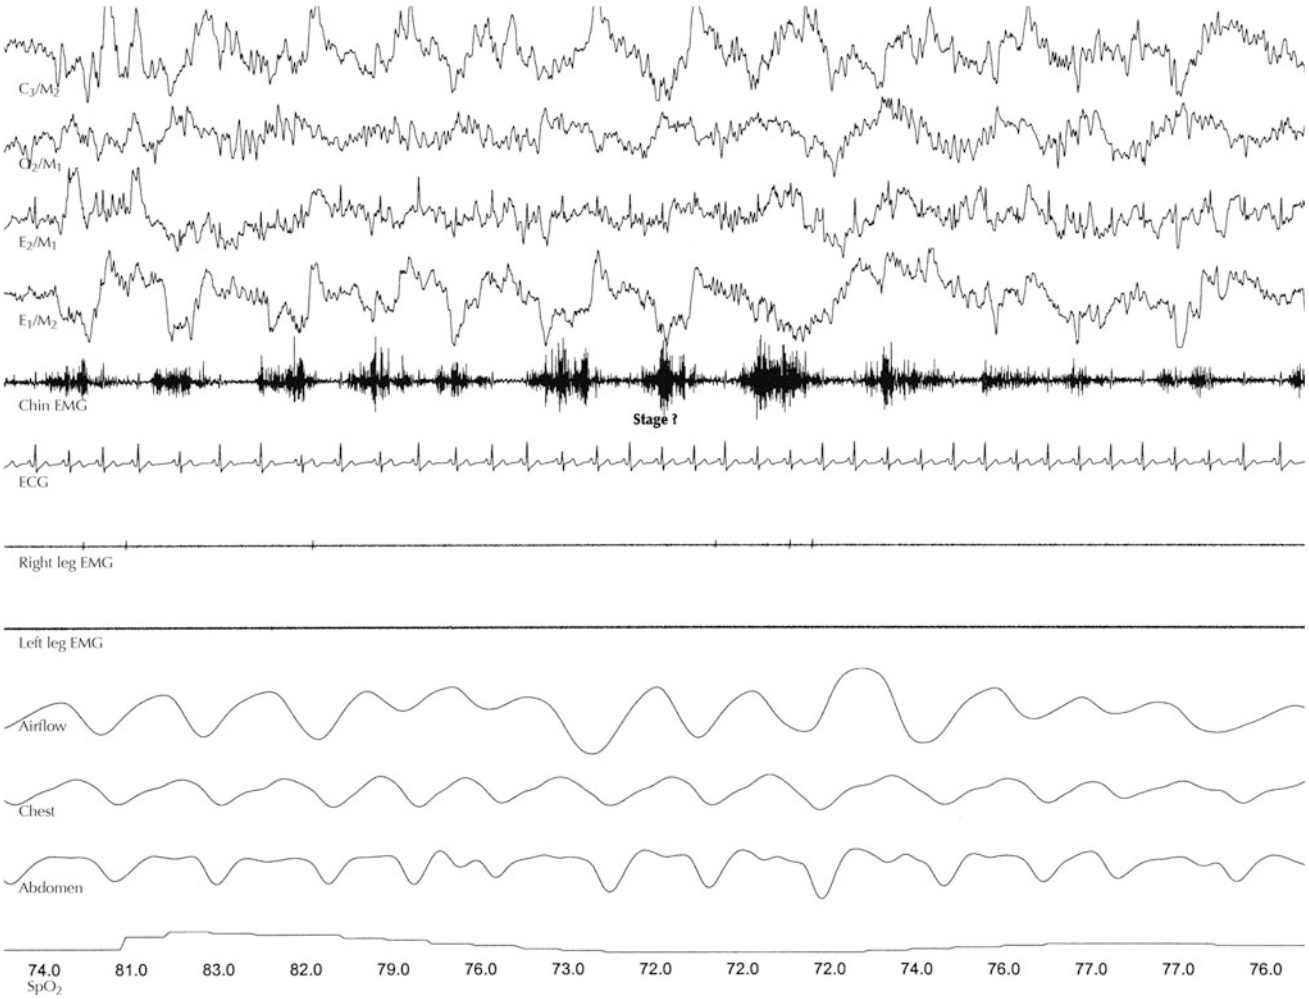

Fig. 17.10 ECG artifact in the EEG and EOG. This is an example of excessive ECG artifact in the EEG and EOG channels. Although small amounts of ECG artifact are sometimes unavoidable, ECG artifacts can be exacerbated by impedance imbalances between the EEG and EOG electrode connections, or by poor placement of the mastoid reference electrode. Reprinted with permission from Butkov [23]

from the pinna. As mentioned above, the reference electrodes are best positioned over a firm bony area close to the pinna, away from muscle or fatty tissue of the neck.

ECG artifact can also be minimized or corrected by combining M1 and M2 as a dual reference. However, this should not be used as routine practice, because it can attenuate the EEG, and because any other form of interference stemming from either of the mastoid reference electrodes can subsequently affect all of the multi-referenced channels.

Slow Frequency Artifacts

Slow frequency artifacts in the EEG or EOG (Fig. 17.11) are most often caused by perspiration or by direct pressure against an electrode. Perspiration induces chemical changes in the electrolyte interface between the electrode and the patient's skin, causing the appearance of slow-oscillating waves in the EEG or EOG, commonly described as "sweat artifact." A similar pattern, although more pronounced and abrupt, can be caused by intermittent pressure against an electrode or by tugging an electrode lead. This is commonly described as "popping artifact." Popping artifact can also be caused by dirty or faulty electrodes, or by electrodes that are loosely attached to the skin.

Both sweat and popping artifacts can be exacerbated by patient movement. Often, these slow frequency artifacts coincide with the patient's respiratory patterns, most likely caused by the slight head movements associated with breathing. Slow frequency artifacts that appear synchronous with breathing are often labeled as "respiration artifacts"; however, this term may be misleading, because the source of the artifact is not respiration, but rather a combination of chemical and mechanical instability of the EEG and EOG electrode–patient interface.

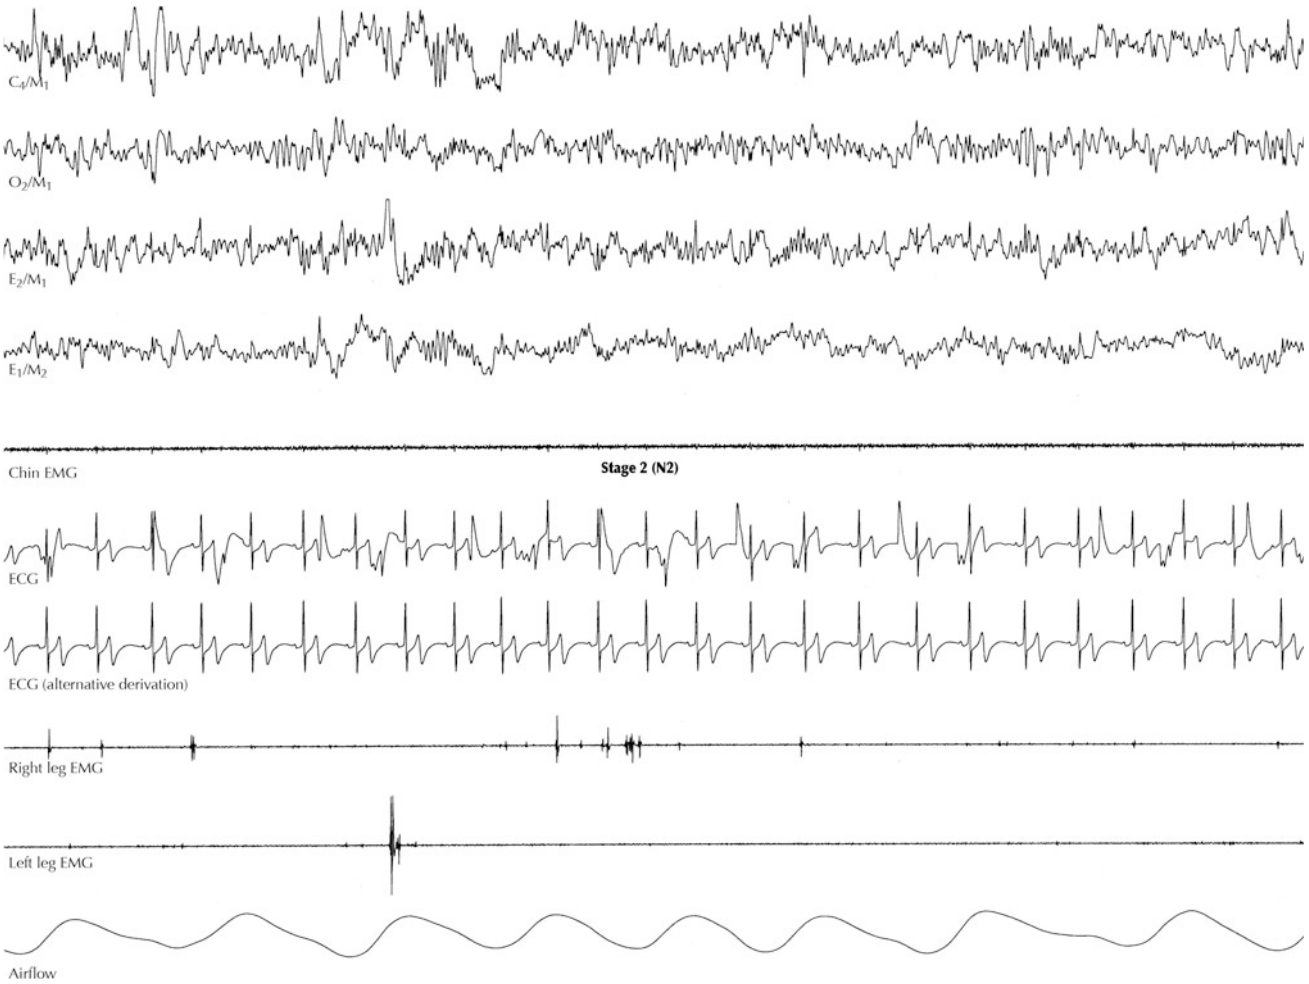

Fig. 17.11 Slow frequency artifacts in the EEG and EOG. The slow frequency artifacts in this example are most likely caused by a combination of sweat and slight rhythmic head motion associated with breathing. The artifacts are limited to the C3/M2 and E1/M2 channels. They are identified by their exaggerated appearance and by lack of correlation with the O2/M1 and E2/M1 derivations. These artifacts can be corrected by changing the affected derivations to C4/M1 and E1/M1. Note also the pattern of "snoring artifact" in the chin EMG channel, which is actually useful for confirming that the patient snores. Reprinted with permission from Butkov [23]

Slow frequency artifacts can be minimized by practicing proper electrode application technique. It is important to make sure that all electrodes are well adhered, with a tight seal between the electrode and the patient's skin. This prevents the electrodes from "floating" over the electrode sites, which can cause signal disruption from even the slightest movement. It is equally important not to spread conductive substances (including skin prepping materials) beyond the boundary of the electrode cup when preparing the electrode site and when applying the electrodes. Additionally, slow frequency artifacts that are caused by perspiration can be reduced by cooling the patient with a fan or air-conditioning.

Artifacts in the ECG Channel

Although ECG voltages are considerably higher than EEG, EOG, or EMG voltages, tracings derived from ECG electrodes can be equally susceptible to artifacts caused by high electrode impedances, faulty connections, pressure against an electrode, sweat, or patient movement. In some instances, artifacts in the ECG can resemble ectopic beats or missed beats. To avoid misinterpreting the ECG, it is useful to compare any questionable tracings to alternative ECG derivations. If the recording equipment provides system referencing, an alternative ECG signal can be obtained from any two electrodes that are sufficiently distant from each other, such as the C4 electrode referenced to one of the left leg electrodes (Fig. 17.12).

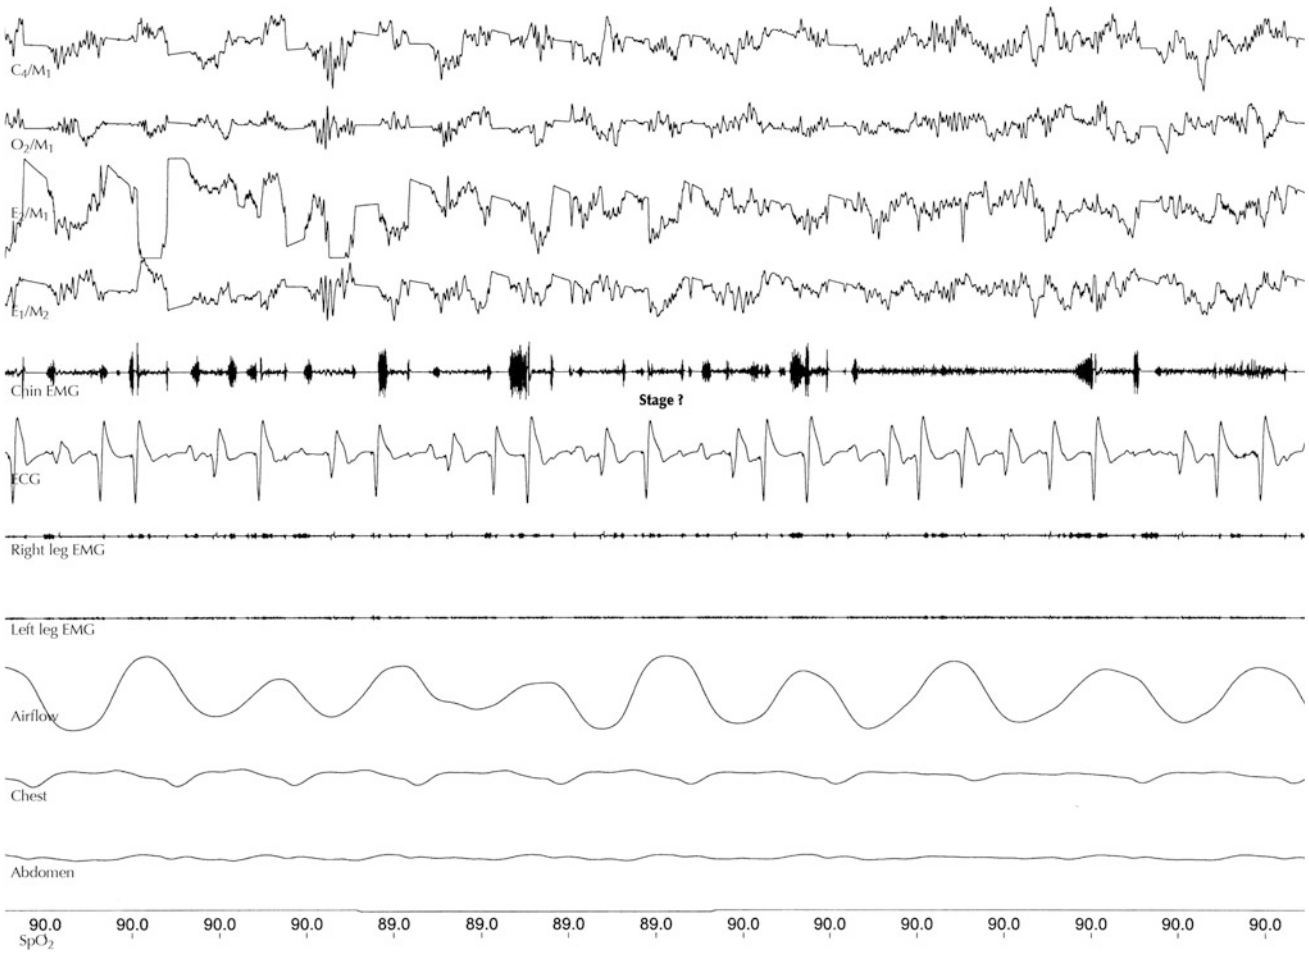

Fig. 17.12 Artifacts in an ECG channel. In this example, the primary ECG channel is distorted with artifact. An alternative ECG derivation has been added to the recording and demonstrates a normal sinus rhythm. The alternative derivation was obtained by referencing an ECG electrode to one of the left leg electrodes. Reprinted with permission from Butkov [23]

Artifacts Caused by a Faulty System Reference

If the PSG recording provides system referencing, it is essential to make certain that the integrity of the system reference electrode is maintained throughout the duration of the study. If the system reference electrode becomes detached, or the signal is degraded, all of the channels relying on the system reference will become affected (Fig. 17.13). Operators of equipment that relies on system referencing must pay close attention to the recording and be able to identify and correct problems with the system reference electrode if they occur.

Artifacts in the Respiratory and Oximetry Channels

For practical reasons, most forms of respiratory monitoring during sleep rely on sensors that provide non-quantitative, indirect representations of respiratory airflow and effort. As such, these representations are often imprecise and subject to many forms of signal distortion. In some instances, artifacts in the respiratory channels can resemble physiologic respiratory events. It is important for those who read the PSG data to be aware of the characteristics and limitations of respiratory sensors and interpret the study accordingly. An advantage of multi-channel PSG recordings is that all

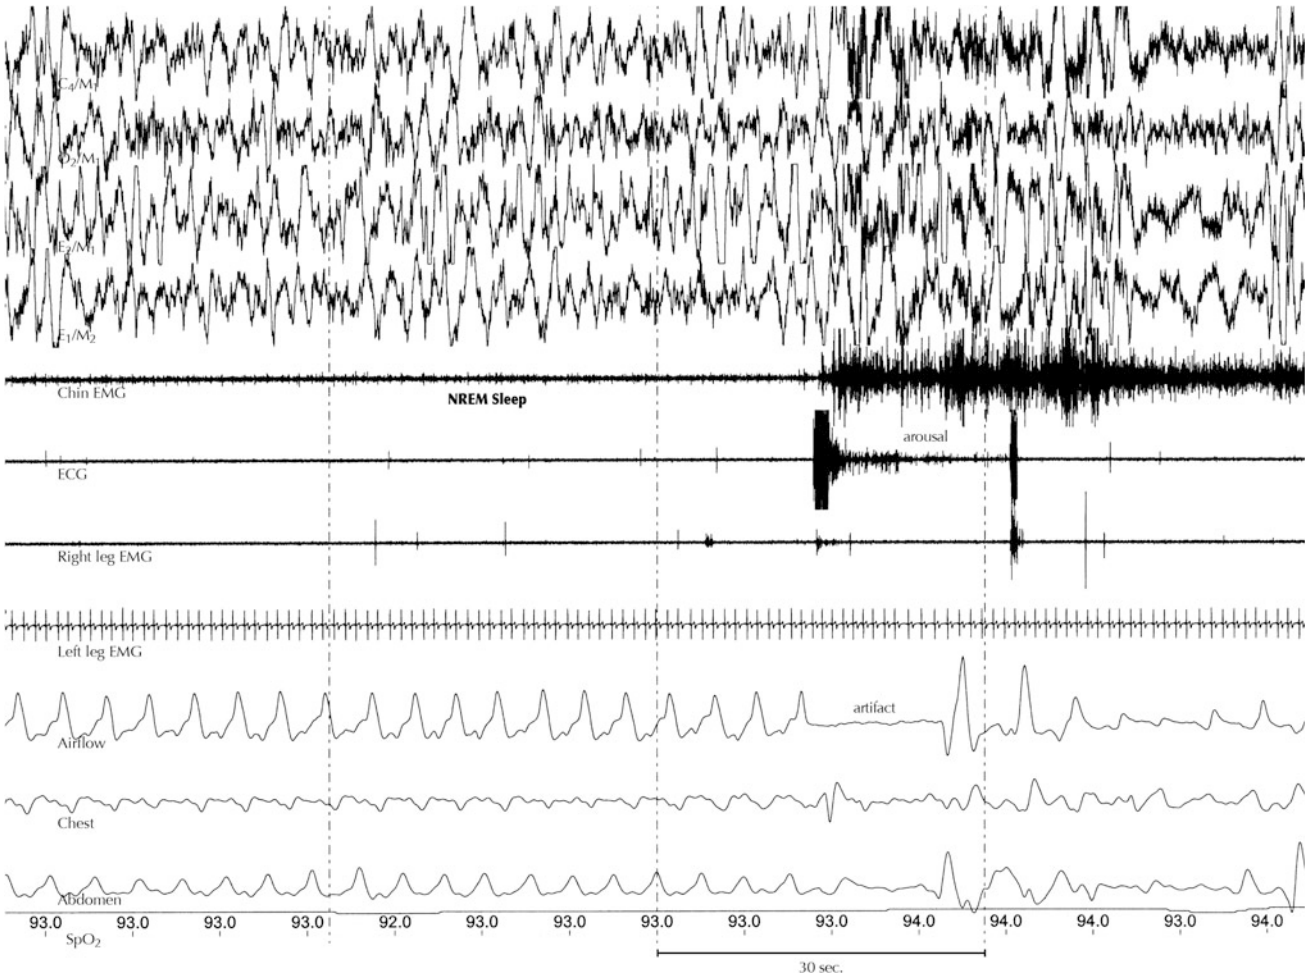

Fig. 17.13 Artifacts originating from the system reference electrode. In this example, a faulty system electrode connection is causing artifacts to appear in all of the channels that are linked to the system reference. Reprinted with permission from Butkov [23]

respiratory data can be evaluated within the context of sleep and wake physiology, thereby helping the reader confirm or refute the validity or etiology of any suspected event (Fig. 17.14).

It is equally important to carefully examine the oximetry tracing and identify any potentially erroneous data. Faulty oximetry tracings can be caused by probe displacement, by over-tightening the probe on a patient's finger, by poor perfusion, by motion artifact, or by placing a probe over painted or artificial nails. Any questionable oximetry data should be flagged, to prevent erroneous interpretation. This especially applies to unattended oximetry recordings, as used with HSAT or overnight oximetry screening (Fig. 17.15).

Using Filters to Correct Artifacts

Changing a filter setting to correct an artifact should always be a last resort. Filters should not be relied upon to "clean up" a poor quality study. However, there are some instances when changing a filter setting can be useful; for example, when attempting to score or read a PSG study with excessive slow-wave artifacts in the EEG or EOG. Unlike analog filters of the past that were limited to only a few specific settings, contemporary digital filters available on some of the more advanced equipment can be configured to virtually any setting. Thus, the reader of the study can choose to make minor filter adjustments, enough to minimize the artifact, yet preserve most of the physiologic data. For example, if slow

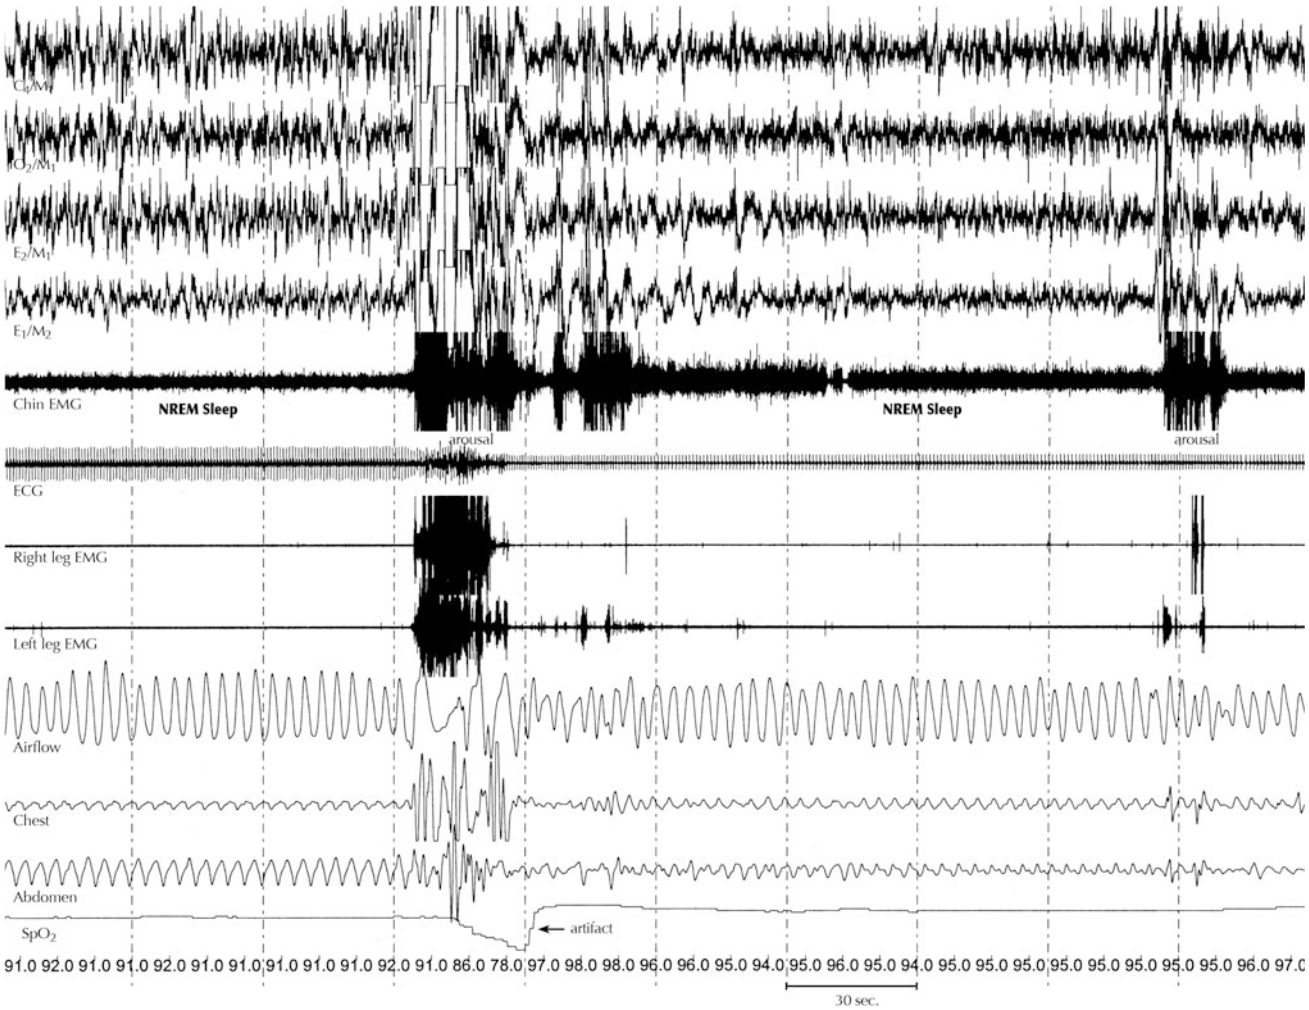

Fig. 17.14 Artifact in the airflow channel resembling an apnea. By examining the respiratory channels within the context of the patient's sleep and wake physiology (as documented by the top channels), it is evident that the apparent "absence of airflow" is actually an artifact caused by patient movement during an arousal. The flattening of the airflow signal may have been caused by the patient's mouth dropping open, or by a dislodged airflow sensor. Note the continued attenuation of the airflow signal following the arousal. This is an example of an artifact that could be erroneously scored as an apneic event. Reprinted with permission from Butkov [23]

artifacts in the EEG are a problem, the low-frequency filter can be adjusted from 0.3 to 0.5 or 0.6 Hz (instead of changing the filter to 1 Hz, which was common practice in the past). This reduces the slow-wave artifacts to a more manageable level, without overly attenuating slow-wave EEG activity (although some attenuation of the EEG can still be expected with *any* increase in the low-frequency filter setting).

As noted before, the best way to minimize recording artifacts and reduce the need for excessive post-collection data manipulation (which can significantly alter the data) is

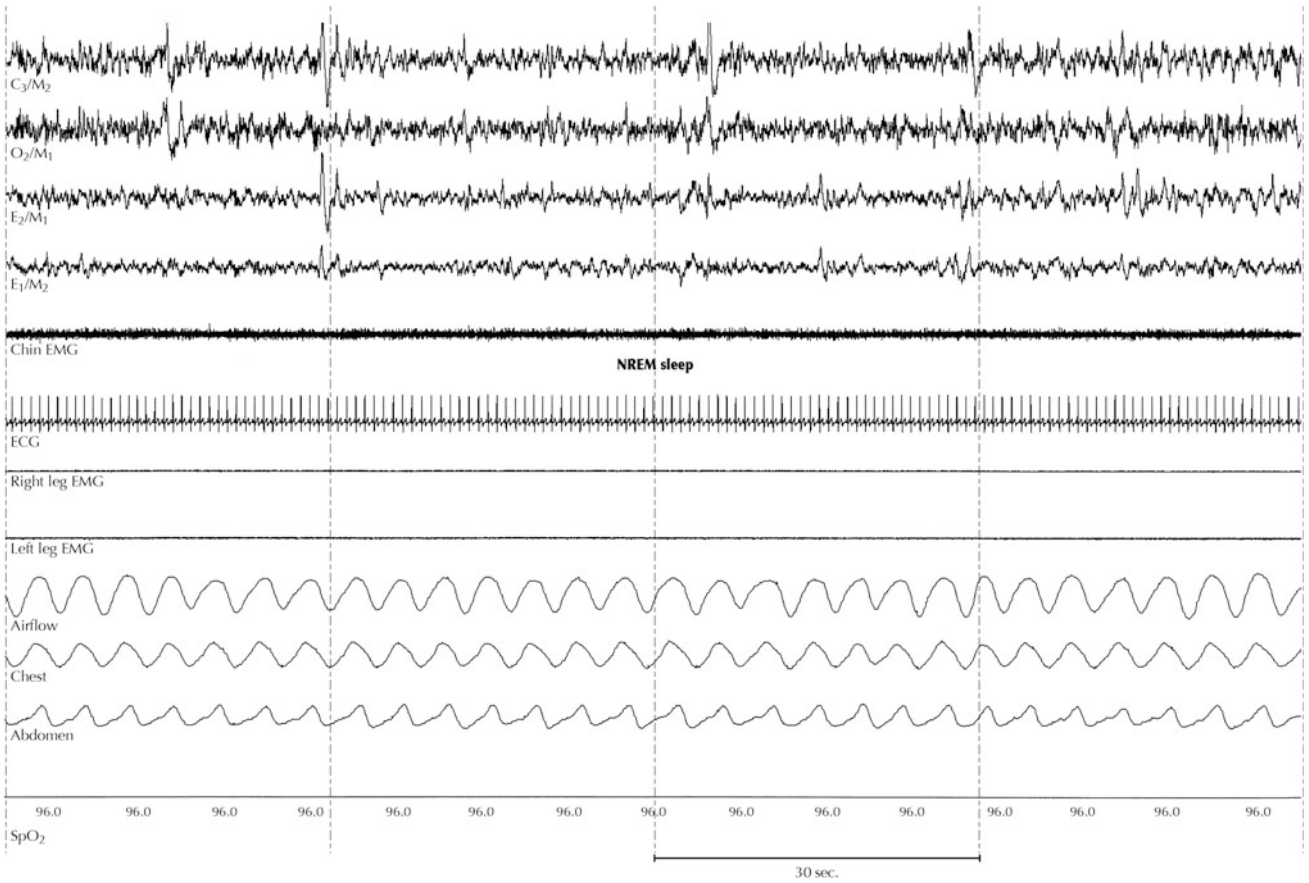

Fig. 17.15 Artifact in the oximetry channel. Artifacts in the oximetry channel are common and may be caused by a number of factors including patient movement or sensor displacement. It is important to identify and delete these artifacts during the scoring and interpretation process, to prevent false oximetry data from appearing on the final report. Reprinted with permission from Butkov [23]

to pay close attention to the quality of the electrode and sensor application.

Ending the Study

Often, clinical circumstances and laboratory protocols dictate whether the patient is awakened at a specific time or allowed to awaken spontaneously. Ideally patients should be allowed to sleep for the duration of their normal sleep period, and any deviation from their normal sleep patterns should be clearly noted. After awakening at the end of the study, the patient should be asked to perform the physiologic calibrations to ensure that the electrodes and other monitoring devices are still functioning properly.

A subjective evaluation is made by the patient. The patient is asked to estimate how long it took to fall asleep, the amount of time spent asleep, and whether there were any

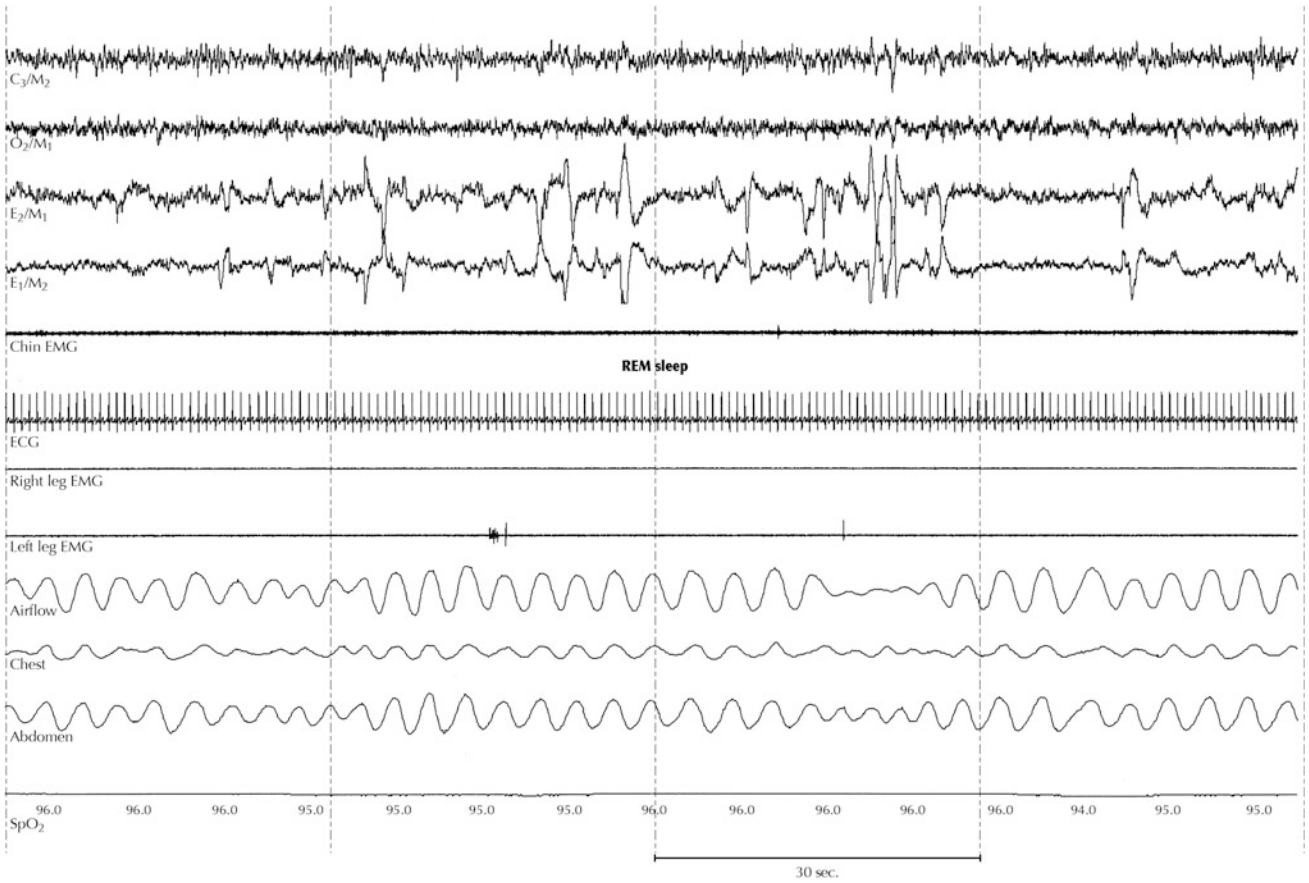

Fig. 17.16 PSG recording sample of non-rapid eye movement (NREM) sleep using time-scale compression. This sample and the samples shown in Figs. 17.17, 17.8, and 17.19 have been compressed to accommodate 4 epochs of data (2 min) to a page. This type of display offers the scorer or interpreter a general overview of the sleep recording, as well as a practical method of counting any prominent sleep-related events such as obstructive apneas, hypopneas, or body movements. The resolution of the EEG data is inadequate, however, for precise EEG evaluation or sleep-stage scoring. This sample shows a normal respiratory pattern during NREM sleep, without any apparent evidence of arousal, movement, or other form of sleep disturbance. Reprinted with permission from Butkov [23]

disruptions during the sleep period. Patients should also report on quality of their sleep and level of alertness upon arousal.

For patient safety, a plan needs to be made for patients leaving the laboratory after a study. A patient who has a severe sleep disorder should avoid driving. An arranged ride or public transportation should be used, particularly if the patient has withdrawn from stimulant medications for the purpose of the study, or was using a pharmaceutical sleeping aid during the study.

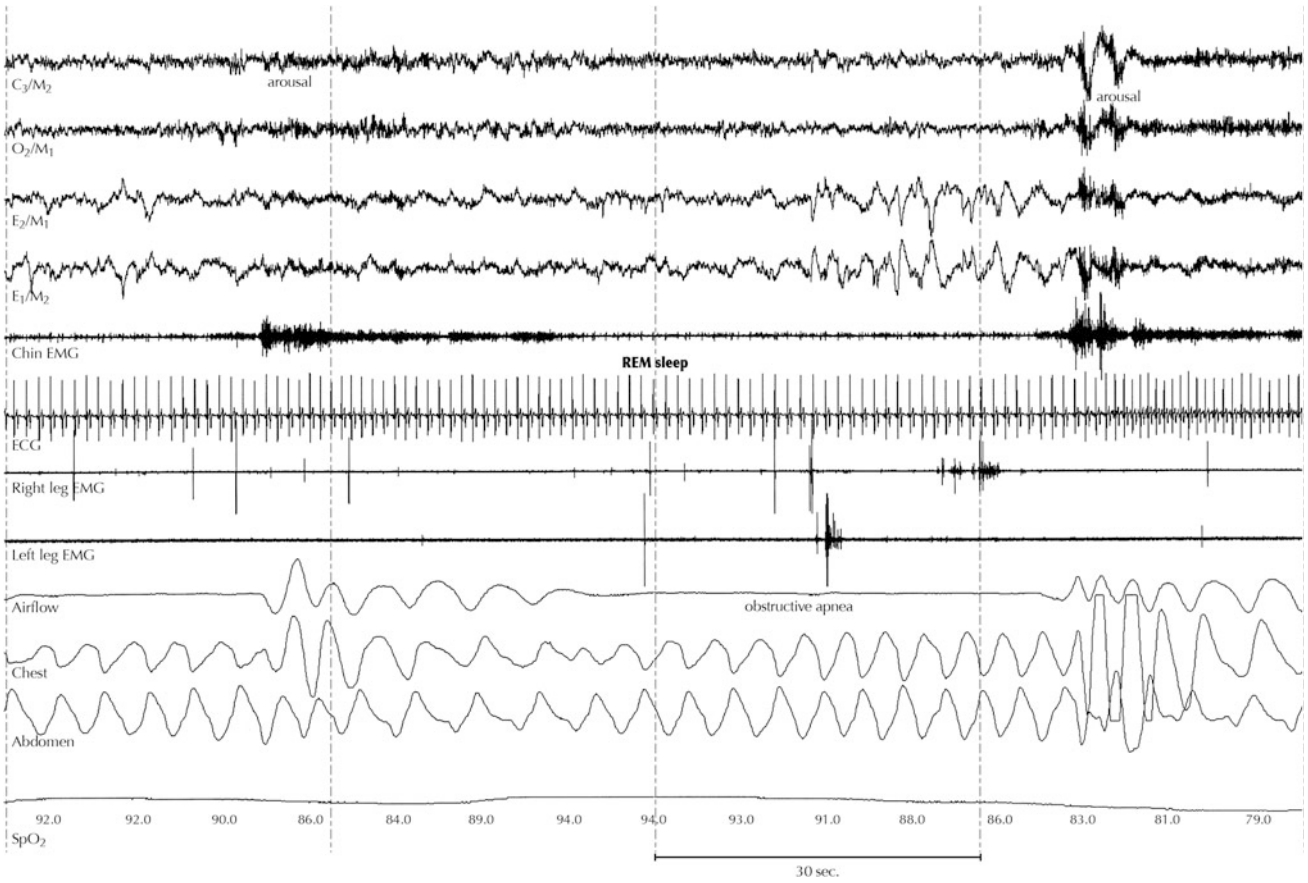

Fig. 17.17 PSG recording sample of REM sleep. Although altered by time-scale compression, the sleep-stage pattern can readily be identified as REM. Note the mild respiratory irregularity, which is a normal variant of REM sleep physiology. Reprinted with permission from Butkov [23]

Perspective on Polysomnography

Technical advances and increases in clinical knowledge provide great potential for our ability to monitor physiologic changes in our quest to understand sleep and its disorders. The *Atlas of Sleep Medicine* [36] provides an excellent review of PSG and hypnogram analysis. Specialized techniques, including pulse transit time, peripheral arterial tonometry, and cyclic alternating patterns, are illustrated and discussed. Special attention is given to motor disorders, sleep and epilepsy, and a variety of other neurologic disorders. A number of other atlases of PSG data have been published [23, 37–42] expanding the knowledge of PSG, normal sleep, and sleep disorders. Access to PSG recording samples is especially helpful for those who wish to expand their scoring and reading skills. Some examples of diagnostic PSG recordings are shown in Figs. 17.16, 17.7, 17.18, 17.19 and 17.20 [23]. Figure 17.21 is an additional (see also Chap. 18) suggested montage for patients with suspected seizure disorder.

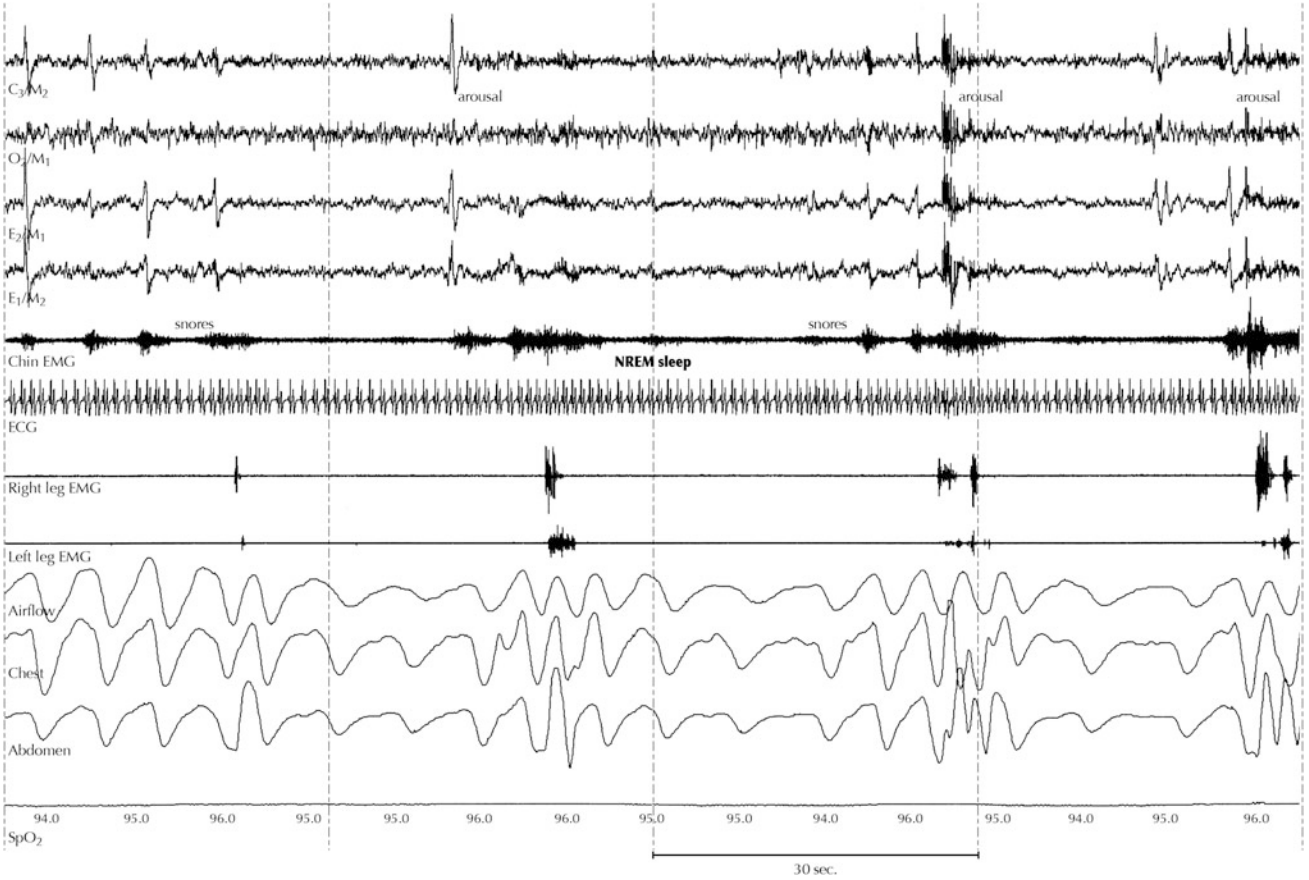

Fig. 17.18 PSG recording sample showing repetitive obstructive apneas occurring during REM sleep. In this example, all the features of classic obstructive sleep apnea are present, including distinct paradoxical (out-of-phase) respiratory effort, instances of complete cessation of airflow, subsequent EEG arousals, and cyclic oxygen desaturations. Reprinted with permission from Butkov [23]

Also recently published is an excellent review of the critical differences between children and adults [35] who have SRBD and restless legs syndrome. It is imperative that we identify sleep disorders as early as possible in order to prevent needless suffering. In order to achieve this goal, it is crucial for clinicians and technologists to understand that the clinical presentation of sleep disorders may be different in children than in adults. For example, as mentioned

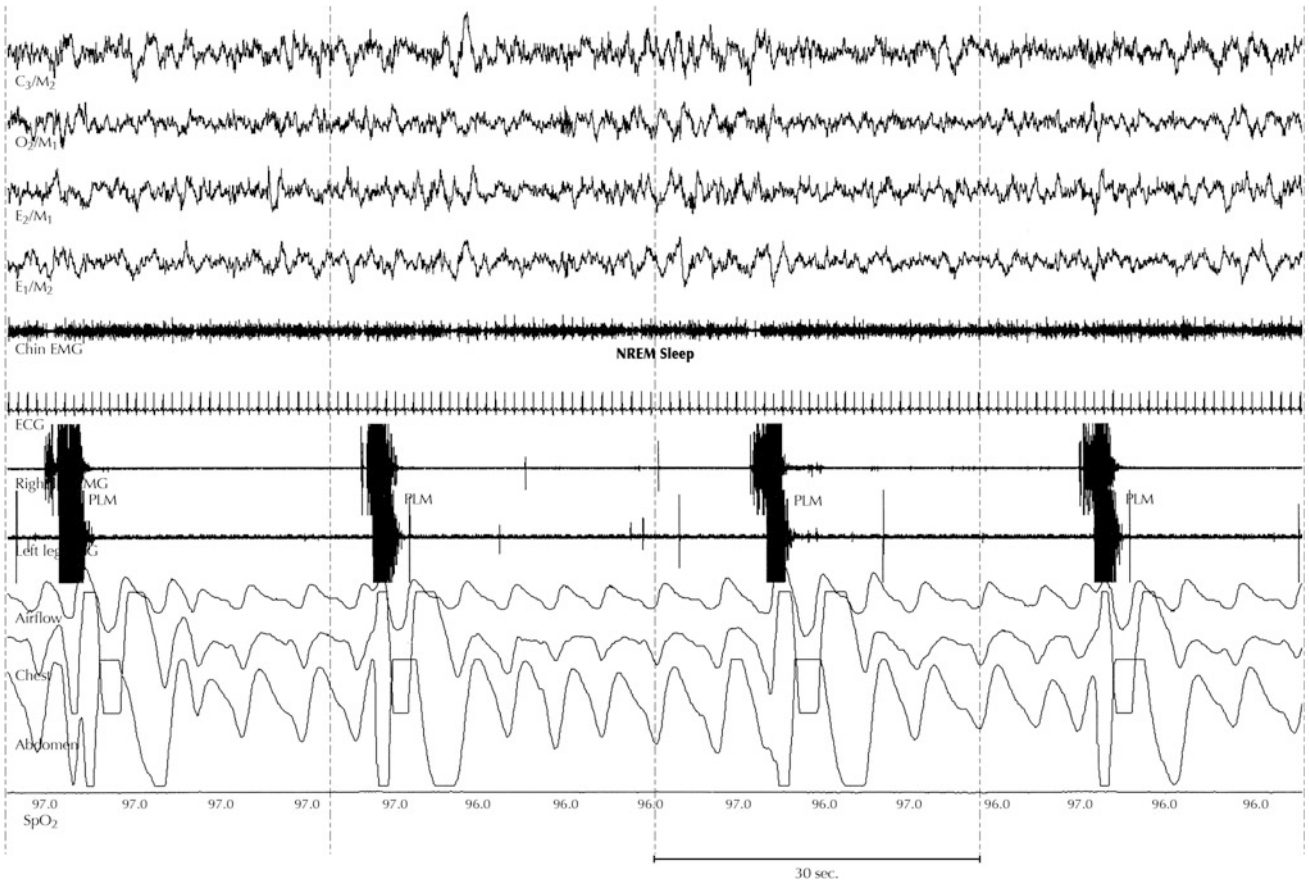

Fig. 17.19 PSG recording sample showing cyclic obstructive hypopneas with minimal O2 desaturation. This example demonstrates a pattern of cyclic obstructive hypopneas, as evidenced by the respiratory tracings in conjunction with snoring artifacts in the chin EMG and arousals occurring at the end of each event. Although these events appear quite obvious, they do not meet current reimbursement criteria for treatment due to lack of sufficient O2 desaturation. Reprinted with permission from Butkov [23]

previously, it is important to record CO_2 changes in children as they may show retention of CO_2 more commonly than dramatic changes in arterial O_2 saturation (as compared to adults with SRBD).

Throughout its evolution, PSG has proven a robust tool for enhancing our understanding of sleep and its disorders. It is an essential diagnostic procedure. Increased public awareness of sleep disorders as a major public health concern will drive the need for diagnosis and treatment. We must be effective and efficient in providing the highest quality of patient care. It is well recognized that questionnaires [43] have proven to be excellent tools in

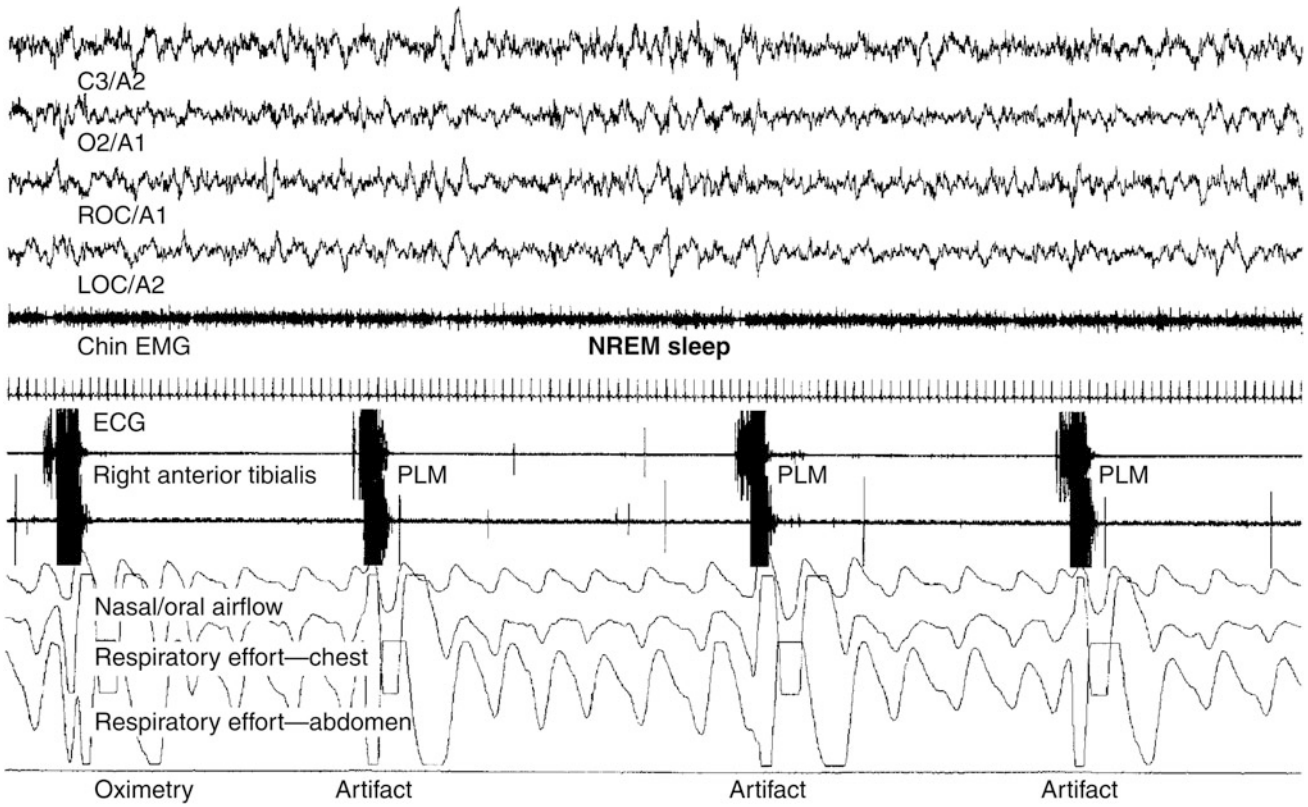

Fig. 17.20 PSG recording sample of periodic limb movements, with artifacts in the respiratory channels that appear similar to cyclic hypopneas. This sample shows a compressed version of the characteristic pattern of periodic limb movements (*PLMs*), recorded by the right and left anterior tibialis EMG. Significant leg and body movements can potentially generate artifacts in the respiratory channels that resemble respiratory events. Note that the pattern of artifact appears similar to the cyclic hypopneas seen in Fig. 17.19. Reprinted with permission from Butkov [23]

helping to triage patients in need of further evaluation. PSG remains the "gold standard" for diagnosis when indicated.

PSG is complex and labor intensive. It requires specialized technical skills and knowledge of normal sleep and sleep disorders. Technologists need to be experts with equipment, competent in dealing with medically ill patients, and capable of dealing with emergencies that may be encountered. The establishment of accredited training programs, standardized board certification requirements, and state licensure are tangible signs of the growth and development of the field of PSG technology.

It is our responsibility to millions of patients awaiting optimal sleep health care to demand that all studies performed during sleep meet the highest standards of practice. With this commitment, we maximize our ability to facilitate improved patient health outcomes for all those suffering from sleep disorders.

Appendix 17.1: Template for 24-h Sleep–Wake Log

This log should be completed by the patient for a period of 2 weeks prior to the study.

For each hour of the day:

indicate sleep or wake time with an (*X*) in the appropriate box(es)
indicate naps with an (*N*) in the appropriate box(es)
indicate periods of extreme sleepiness with an (*S*) in the appropriate box(es)

Appendix 17.2: Subjective Evaluation of Sleepiness

Stanford Sleepiness Scale

1. Feeling active and vital; alert; wide awake.
2. Functioning at a high level, but not at peak; able to concentrate.
3. Relaxed; awake; not at full alertness; responsive.
4. A little foggy; not at peak; let down.
5. Fogginess; beginning to lose interest in remaining awake; slowed down.
6. Sleepiness; prefer to be lying down; fighting sleep; woozy.
7. Almost in reverie; sleep onset soon; lost struggle to remain awake.

Linear Analog Scale/Introspective Measure of Sleepiness

Ask patient to make a mark on the scale that corresponds to state (level of alertness versus sleepiness) prior to testing.

Adapted from Hoddes E, Dement WC, Zarcone V. The development and use of the Stanford Sleepiness Scale (SSS). Psychophysiology 1972;9:150.

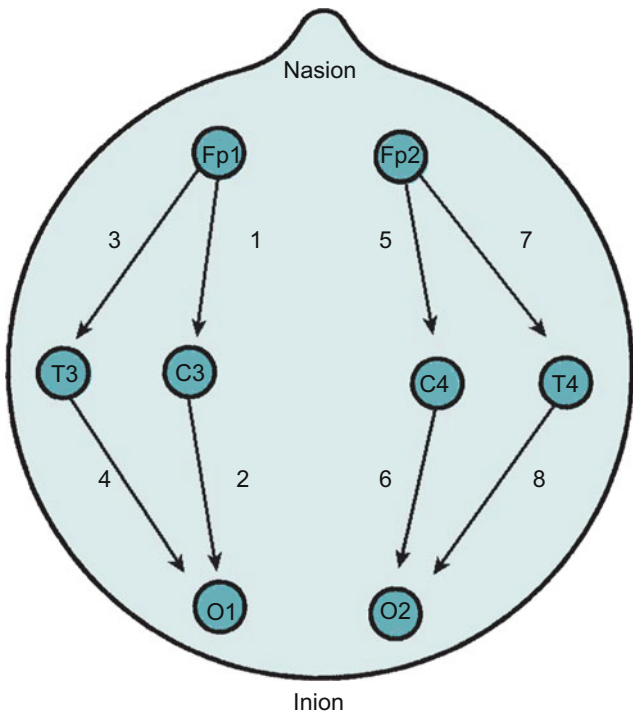

Fig. 17.21 Suggested montage to be used to screen for possible seizure activity during sleep. Use of wide inter-electrode distance affords for a global view of EEG activity and conserves the channels. To more adequately localize epileptogenic activity, a full complement of electrodes should be used. For a more comprehensive review of montages, the reader is referred to standard EEG montages as proposed by American EEG Society Guidelines No. 7, Grass Instruments (1980)

Appendix 17.4: Measuring the Head for C3, C4, O1, and O2

Before measuring the head, it is helpful to make an initial mark at the inion, the nasion, and the two preauricular points.

1. Measure the distance from the nasion to inion along the midline through the vertex. Make a preliminary mark at the midpoint (Cz). An electrode will not be placed on this spot, but it will be used as a landmark.
2. Center this point in the transverse plane by marking the halfway point between the left and right preauricular points. The intersection of marks from steps 1 and 2 gives the precise location of Cz.
3. Reposition the measuring tape at the midline through Cz and mark the points 10 % up from the inion (Oz) and nasion (Fpz).
4. Reposition the measuring tape in the transverse plane, through Cz, and mark 10 % (T3) and 30 % (C3) up from the left preauricular point and 10 % (T4) and 30 % (C4) up from the right preauricular point.
5. Position the tape around the head through Fpz, T3, Oz, and T4. Ten percent of this circumference distance is the distance between Fp1 and Fp2 and between O1 and O2. Mark these four locations on either side of the midline.
6. The second marks for O1 and O2 are made by continuing the horizontal mark for Oz. Do this by holding the tape at T3 and T4 through Oz and extend the horizontal mark to intersect the previous O1 and O2 marks.
7. To establish the final mark for C3, place the tape from O1 to Fp1, and make a mark at the midpoint of this line. When extended, this mark will intersect the previous C3 mark. Repeat on the right side for C4.

Sushanth Bhat and Sudhansu Chokroverty

Physiologic Basis of EEG

The traditional scalp EEG (as obtained during PSG) records the difference in electrical potentials between two electrodes placed over the head [2]. The recorded activity results from extracerebral current flow due to summated excitatory postsynaptic potentials (EPSP) and inhibitory postsynaptic potentials (IPSP), rather than from single neurons that have action potentials too localized and too short (generally shorter than 1 ms) to be recorded. On the other hand, EPSP and IPSP currents last for 15–200 ms or more and induce more extensive voltage changes in extracellular space, rendering them easily recordable [3]. The source of the EPSP and IPSP currents, in turn, is the rhythmic oscillations of the thalamocortical neuronal projections to areas of the cortex. This has been experimentally proven; neither lesioning the cerebral cortex nor sectioning the brainstem abolishes sleep spindles, for example, but destruction of the thalamus does [4]. Neurons in other brain structures, including the inferior olivary nucleus, hippocampus, and temporal neocortex, exhibit oscillatory behavior and may play a role in generating EEG rhythms [5]. The scalp EEG recording voltages are attenuated by the skull and intervening tissues (including the cerebrospinal fluid and dura) and reflect about one tenth of the voltage recorded over the cortical surface; they therefore need to be amplified to be interpretable.

Figure 18.1 provides a schematic representation of how synaptic potentials induce voltage changes recorded at the scalp. An excitatory input on a deep dendrite causes positive ions to flow into the pyramidal neuron, resulting in a lack of positive charges, or negativity, outside the neuron. Everywhere else, including the superficial dendrite, positive ions flow out of the cell into the extracellular space to complete the current loop. This results in a relative positivity in the superficial extracellular space. Because the superficial dendrite and surrounding extracellular space are closer to the scalp electrode, a positive deflection is recorded. The separation of superficial positive and deep negative charges allows one to view the pyramidal neuron as a dipole. This permits a more complete analysis of how synaptic potentials result in scalp EEG changes [6].

Methods of EEG Recording

Amplification of the exceedingly minute electracerebral voltage changes into interpretable waveforms is the function of the EEG equipment (Fig. 18.2). EEG voltage changes are transmitted by the electrodes and conducting gel applied to the scalp through electrode wires, which connect the electrodes to the jack box of the EEG equipment. While different types of electrodes are available, most standard laboratories employ gold cup electrodes with holes in the center and silver–silver chloride electrodes for EEG recordings. Silver–silver chloride electrodes need repeated chloriding for proper maintenance. Positive and negative charges are generated between the scalp and recording electrode as a result of ionic dissociation in the electrodes. Paste or conducting gel is used to secure the electrodes. The electrode–electrolyte interface is the most critical link in the EEG machine, as most artifacts originate at this site; careful preparation is therefore very important. The impedance in a pair of electrodes should be measured by an impedance meter and should be less than 5000 (5 K) ohms. High impedance impairs the ability of the electrical signal to reach the amplifier and interferes with the capacity of the amplifier to eliminate environmental noise, thus increasing artifacts [7]. Impedance and impedance-related artifacts are described in greater detail in Chap. 17.

Electrode Placement, Channels, and Montages

The placement of the electrodes is determined by the 10–20 electrode placement system which is recommended by the International Federation of Societies for EEG and Clinical Neurophysiology and was published by Jasper in 1958 [8]. This system is based on definable anatomical landmarks (see Fig. 24.1) and consists of letters denoting the parts of the brain underneath the area of the scalp and numbers denoting specific locations. The odd numbers refer to the left side of the head, and the even numbers refer to the right side. Important landmarks for measuring include the inion, the nasion, and the right and left preauricular points. The distance from the nasion to inion along the midline through the vertex should be measured. FPz in the midline is 10 % above the nasion of the total distance between the inion and nasion. The electrodes marked FP1 and FP2 are located laterally 10 % above the nasion of the total distance between the inion and nasion measured along the temporal regions through the preauricular points. Oz denotes an electrode placed at a distance of 10 % above the inion of the total distance between the nasion and inion. T3 and T4 electrodes are placed in a location 10 % above the preauricular points of a total distance between the two preauricular points. The rest of the electrodes are located at a distance of 20 % measured from inion to nasion anteroposteriorly or laterally through the ears as well as transversely between the ears. The nomenclature was recently changed to rename T3, T4, T5, and T6 to T7, T8, P7, and P8, respectively, in what has been designated the "Modified Combinatorial Nomenclature."

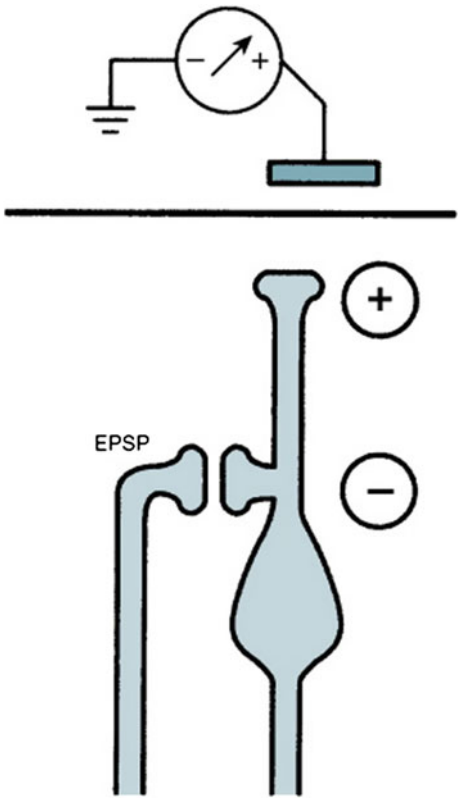

Fig. 18.1 Scalp EEG voltage recordings resulting from an excitatory input on a deep synapse. *EPSP* excitatory postsynaptic potential. Modified from Kandel and Schwartz [69]

Two electrodes connected to each other constitute a *channel* or a *derivation* (e.g., F7-T3 is a channel). A *montage* refers to the manner in which these channels are arranged. Both *bipolar* montages (connection of the electrodes between two relatively active sites over the scalp; e.g., F7-T3) and *referential* montages (connection of the electrodes between an active and relatively inactive site; e.g., F7-M1, F8-M2, and T4-Cz) are recommended. Electrode inputs for digital systems always include one or more additional inputs for reference electrodes. A location between Fpz and Fz is often chosen for the reference electrode but any location on the scalp that is relatively electrically neutral and where firm attachment to the scalp is possible can be used. Reference electrodes are necessary because digital EEG recording is always referential.

Despite the pivotal role that EEG plays in the analysis of sleep, the limited number of inputs available on most PSG equipment results in a less than desirable number of channels dedicated to EEG. In fact, the American Academy of Sleep Medicine (AASM) guidelines [9] call for a minimum of just three channels that record from a single hemisphere and

Channels 1–8 record electroencephalogram activity from bilateral cerebral hemispheres in a referential chain; electrode designation per the 10-20 International System of electrode placement. M1 and M2, left and right mastoid, respectively. Channel 19 and 20 record airflow ("flow channels"). Channels 21 and 22 record respiratory effort ("effort channels")

[a]In a CPAP titration study, flow channels are replaced by a CPAP signal (C-flow signal)

which do not record from the temporal lobes; such a limited montage would result in an inability to capture focal epileptiform activity arising from the most common location for such discharges (e.g., temporal lobes), as well as missing focal abnormalities from the hemisphere not being recorded [10]. Given the pro-epileptogenic effect of drowsiness and nonrapid eye movement (NREM) sleep, and the fact that nocturnal seizures that are often mistaken for parasomnias and are sometimes encountered during an in-laboratory PSG, it would be unfortunate if a clinically important finding were to be missed or improperly interpreted because of an inadequate number of EEG channels.

For this reason, in our own laboratory, we use between 4 and 8 EEG channels including temporal leads from both hemispheres (Table 18.1); such montages increase the yield of capturing focal or diffuse slow-waves or epileptiform activities compared to recording with 2–4 channels. When nocturnal seizures are suspected, an extended *EEG montage* (Table 18.2; Fig. 18.3), covering bilateral temporal and parasagittal regions and including both bipolar and referential channels is recommended. Full complement of electrodes and special electrode placements (e.g., Tl and T2 electrodes) should be used. Simultaneous video recording (video-PSG study) for correlation of EEG activities with the actual behavior of the patients is crucial. In computerized PSG recordings (digital PSG recordings), which are currently performed in most laboratories, it is easy to change the recording speed from the standard 10 mm per second of the usual sleep recording to 30 mm/s of the standard EEG recording for proper identification of epileptiform discharges.

Differential Amplification and Sensitivity

An understanding of the physiological basis of recorded waveforms is important. While a detailed description of the elementary concepts of electricity, resistance, and capacitance is provided in Chap. 16, and an overview of digital equipment and recording techniques with regards to PSG is provided in Chap. 17, a review of a few key concepts is

Channels 1–20 record electroencephalogram activity from bilateral cerebral hemispheres with referential and bipolar montages including both temporal and parasagittal chains; electrode designation per 10-20 International System of electrode placement. Channel 30 and 31 record airflow ("flow channels"). Channels 32 and 33 record respiratory effort ("effort channels")

[a]In a CPAP titration study, flow channels are replaced by a CPAP signal (C-flow signal)

provided here, especially with regards to EEG recording and analysis. EEG equipment measures and amplifies potential differences, which are always measured between two points; in this case, it is the potential difference between the two scalp electrodes. This is referred to as *differential amplification*. This is an extremely important concept to understand. Figure 18.4 provides an illustration. If electrode A (the "active" electrode) is connected to input 1 of an

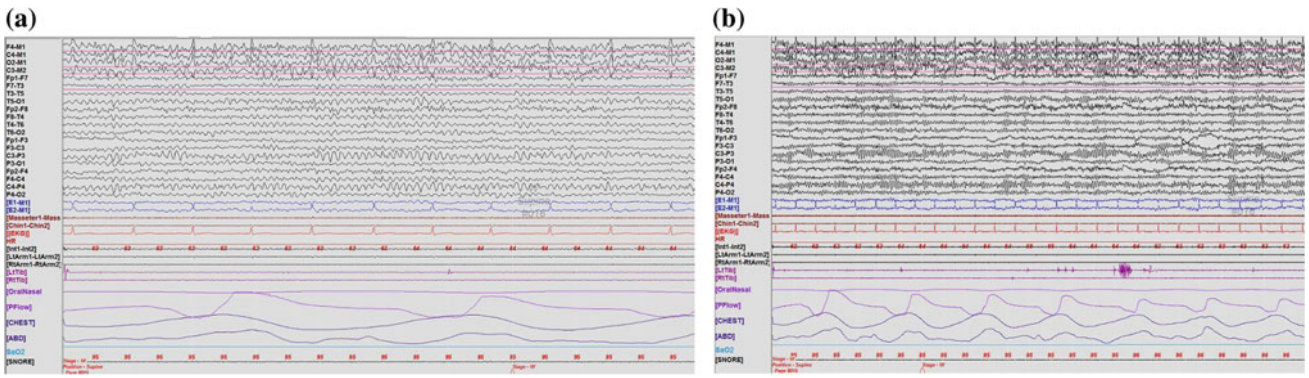

Fig. 18.3 **a** A 10-s and **b** 30-s epoch from the polysomnogram of a 32-year-old man referred to the sleep laboratory for possible OSA. He has a history of epilepsy; hence, an extended EEG ("seizure") montage was requested. Normal awake EEG pattern characterized by symmetrical, sinusoidal posterior dominant alpha rhythm at 9–10 Hz is noted. The top four channels are referential channels connected to the left mastoid. The next 16 are bipolar channels arranged in a double banana montage covering parasagittal and temporal regions as per the International 10–20 electrode placement system. E1-M1 and E2-M1, electrooculogram (EOG) channels; Masseter1-Masseter2 and Chin1-Chin2, masseter (right) and submental electromyogram (EMG); ECG, electrcardiogram; HR, heart rate; Int1-Int2, intercostal EMG; LtArm1-LtArm2; RtArm1-RtArm2, left and right biceps EMG, LTIB; RTIB, left and right tibilais anterior EMG. OroNs1-OroNS2, oronasal airflow (thermistor); PFlow, nasal pressure transducer; Chest and ABD, effort belts; SaO_2, arterial oxygen saturation by finger oximetry. Also included is a snore channel. ECG artifact is noted in the referential leads and EOG leads. Reproduced with permission from: Chokroverty and Thomas [65]

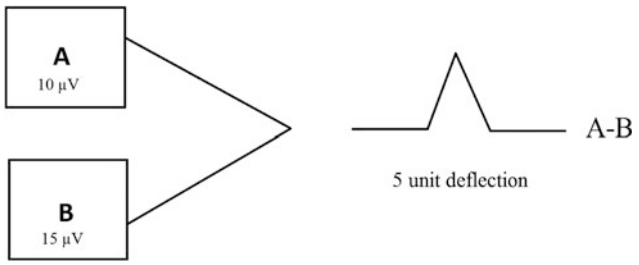

Fig. 18.4 Illustration of the concept of differential amplification. Electrode A, at 10 μV, is connected into input 1 of the differential amplifier, and Electrode B, at 15 μV, is connected into input 2, resulting in the creation of channel A-B. A potential difference of 5 μV results in a corresponding deflection of 5 units in channel A-B. In this case, the deflection is negative or upwards; the direction in any given situation would depend on the polarity convention (see Figs. 18.6 and 18.7 for details)

amplifier and electrode B (the "reference" electrode) is connected to input 2 of the same amplifier, the amplifier would determine the difference between the two inputs (in this case, 5 μV) and there would be a deflection of 5 units. The actual amount of the deflection in millimeters would depend on the sensitivity (see below). Similarly, the direction of the deflection (upwards or downwards) depends on the relative polarity of the two electrodes (as discussed below). The key concept here is that the differential amplifier is displaying the difference between the two electrode inputs rather than absolute voltages; if the two electrodes are at the same voltage, there would be no deflection at all. This does not mean that neither site is electrically active, just that there is no difference in the voltages between the two. This is a useful feature, because environmental noise, which is likely to be the same at the two electrodes, is "subtracted out" and therefore does not contaminate the recording. The *common mode rejection ratio* measures the ability of the amplifier to suppress a signal, such as noise, that is present simultaneously at both electrodes (Fig. 18.5). This ratio should exceed 1000 to 1; most amplifiers currently in service have values that exceed 10,000 to 1. On the other hand, electrodes that are too close to each other may miss significant electrocerebral activity because the area involved is large enough to involve both almost equally; thus the need to reference to a distant electrically inactive site or to use double-distance electrodes as is done, for example, in brain death studies. Analyzing the same EEG using different reformattable montages helps increase the sensitivity of the study overall.

Amplifiers can faithfully amplify input voltages only within a certain range known as the *dynamic range*. Input voltages below the lower limit of the dynamic range are lost in noise; voltages above the upper limit result in a distorted EEG output. Flexible control of amplification within the dynamic range is achieved by manipulating the sensitivity switch. The sensitivity switch is connected to a series of voltage dividers that attenuate the amplified cerebral voltages sufficiently for the EEG record to be interpretable. Sensitivity is defined as the amount of voltage necessary to produce a prespecified output deflection. The usual units are microvolts per millimeter or millivolts per centimeter. In the past, studies were mostly recorded with analog systems, where sensitivity had to be adjusted by the technician as the study was being recorded and could not be manipulated by the polysomnographer at the time of interpretation. With

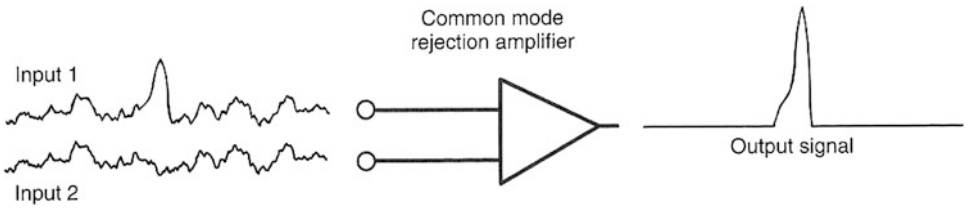

Fig. 18.5 A schematic representation of common mode rejection amplification. The potential difference between the electrodes connected to input 1 and input 2 results in a single amplified upwards deflection. The complex underlying waveform is common to both electrodes, is artifactual and not of biological interest, and represents "noise" that is canceled out by the common mode rejection amplifier. Reproduced and modified with permission from Libenson [5]

virtual replacement of analog with digital systems, the polysomnographer has the freedom to change sensitivity as best suited to the situation. Chapters 16 and 17 discuss analog and digital systems in greater detail.

Polarity Convention

Whereas the sensitivity settings determine the amplitude of waveforms, the positivity or negativity of cerebral activity determines their polarity. The differential amplifier compares relative positivity and negativity at the two electrodes. The resulting deflection is determined according to the polarity convention. If input 1 is negative relative to input 2, or if input 2 is positive relative to input 1, there is an upward, or negative deflection. On the other hand, if input 1 is positive relative to input 2, or if input 2 is negative relative to input 1, there is a downward, or positive deflection. When a number of inputs are connected together as channels in a bipolar EEG montage, the direction of the deflections produced according to the above polarity convention results in the deflections "meeting" at a common point, referred to as a *phase reversal*, which can be used to roughly localize the scalp distribution of those waveforms. Such a phase reversal is due to an area of cortical negativity, although the direction of deflection in any given channel depends on whether the first electrode in the channel is closer or further away from this area of cortical negativity in comparison to the second, resulting in a negative or positive deflection, respectively (Fig. 18.4).

An illustrative example of this concept is provided in Fig. 18.6, which represents a bipolar hypothetical left parasagittal chain. If one were to assume that there is an area

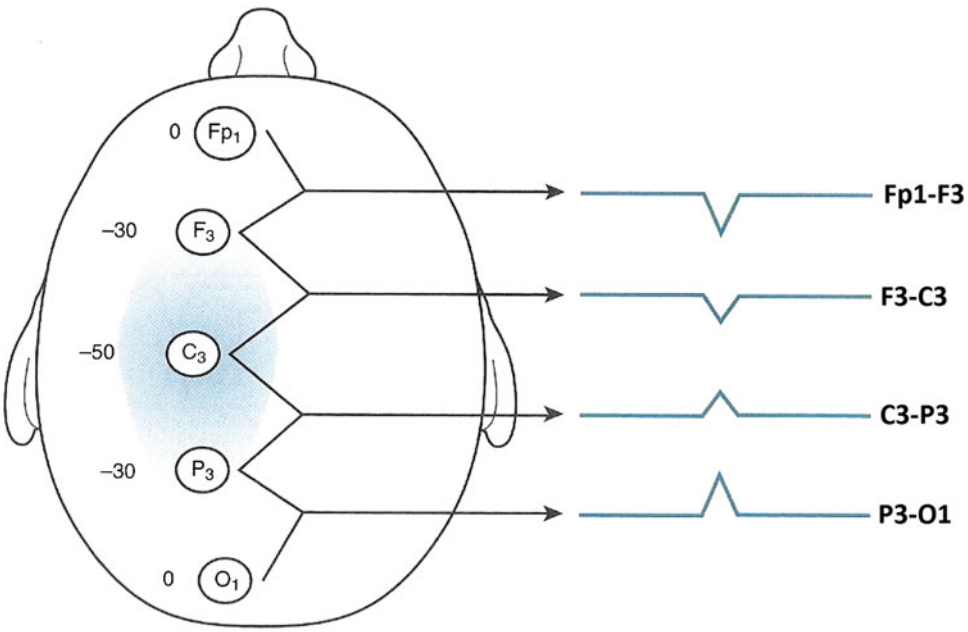

Fig. 18.6 Schematic representation of bipolar montage with an area of cortical negativity at the C3 electrode. There is a phase reversal at C3, the area of maximal cortical negativity. Note that while the maximum deflection is noted in the channels containing the phase reversal (F3-C3 and C3-P3), adjacent channels (FP1-F3 and P3-O1) also show defections predicted by the relative negativity of the individual electrodes, thereby producing a "field." Reproduced and modified with permission from Libenson [5]

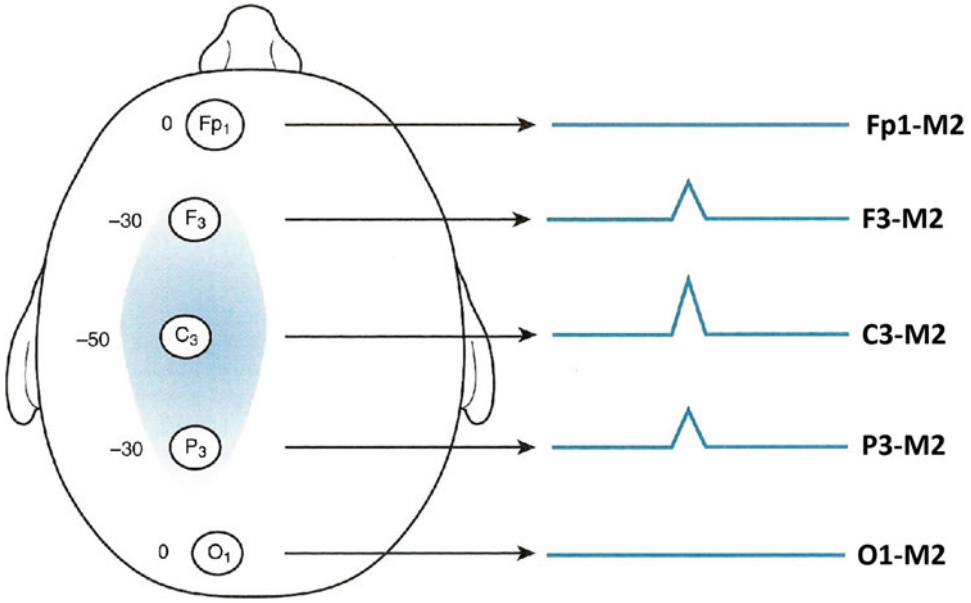

Fig. 18.7 Schematic representation of a referential montage with an area of cortical negativity at the C3 electrode. The montage has been created by connecting electrodes Fp1, C3, P3, and O1 to the contralateral mastoid (M2, not shown). All channels demonstrate negative (upward) deflections, with the waveform being of highest amplitude in the channel containing the electrode with the highest degree of cortical negativity (C3-M2). Adjacent channels demonstrate negative deflections of lower amplitudes, thereby producing a "field." Reproduced and modified with permission from Libenson [5]

of relative cortical negativity at C3 (as typically occurs in epileptogenic foci), then there would be a downward deflection in F3-C3 (because C3 is more negative than F3) and an upward deflection in C3-P3 (because P3 is less negative, or more positive, than C3). However, in practice, epileptogenic foci are rarely so precisely localized, and the area of cortical negativity generally extends beyond a single electrode, i.e., it usually has a "field". Thus, while C3 may be the most negative electrode, its adjacent electrodes, while less negative than C3 itself, are nevertheless more negative than the electrodes farther away from C3 in the montage. The result is that F3 is more negative than Fp1 (causing a positive or downward deflection in Fp1-F3), and P3 is more negative than O1 (causing a negative or upward deflection in P3-O1). Reviewing the entire montage, it is obvious that while a large portion of the left frontotemporal region is involved, the phase reversal is at C3, the area of maximum cortical negativity. The "meeting point" is between the F3-C3 and C3-P3 electrodes, and the common electrode between the two, the site of phase reversal, is C3.

In a referential montage, where each electrode is connected to a common relatively electrically inactive reference electrode (e.g., right mastoid, M2), the same epileptogenic focus would look different. Since every electrode recording from the area of cortical negativity would be more negative than the reference electrode, deflection would always be upwards in channels where M2 is connected to input 2 as is the convention. However, since the degree of deflection of the waveform is dependent on the potential differences between the two electrodes, the amplitude would be highest in that channel where the active electrode is the most negative. Thus, in the example above, the amplitude of the negative potential is highest at C3, the same electrode where a phase reversal occurred on the bipolar montage. But because the area of cortical negativity extends beyond C3 to involve the adjacent electrodes, although to a lesser degree, deflections occur in those channels as well, i.e., there is a field noted even on the referential montage (Fig. 18.7). Thus, while the channel containing the most negative electrode (C3-M2) demonstrates the negative wave with the highest amplitude, adjacent electrodes (F3-M2 and P3-M2) demonstrate negative waves with lower amplitudes, thus producing a field. The ability to view a suspicious waveform (e.g., a spike or sharp wave of potential epileptic significance) in multiple reformattable montages is a benefit of digital recordings.

To summarize, localization of an area of epileptogenic potential or an area showing a focal slow wave, as represented by cortical negativity, is by visualization of phase reversal on bipolar montages, and by maximum waveform amplitude on referential montages.

Filters

Once inputs are subtracted and amplified, the result is passed through a series of filters. The goal of filtering is to attenuate voltages occurring at undesirable frequencies (e.g., environmental noise) without disturbing frequencies found in the biological signal of interest. Filters are described in greater detail in Chap. 16. Briefly, however, a high-pass filter, (also known as a low-frequency filter), allows higher frequency activity to pass unchanged while progressively attenuating lower frequencies (see Fig. 16.12a). This is particularly useful to eliminate artifacts of low frequency such as sweat and respiratory artifact. A low-pass filter (also known as a high-frequency filter), allows lower frequencies to pass unchanged while progressively attenuating higher frequencies (see Fig. 16.12b). This is particularly useful to eliminate high-frequency artifacts such as muscle artifact. A 60-Hz or notch filter is also present in most polygraphic amplifiers. This filter is designed to specifically attenuate the 60-Hz artifact from electrical lines very harshly while attenuating activity of surrounding frequencies less extensively. A similar 50-Hz notch is available in European and certain other countries to match the current in those countries. The notch filter should be used sparingly for at least two reasons. Some biological signals of interest to the polysomnographer have waveforms with important components in the range of 40–80 Hz. Examples include myogenic activity and epileptiform spikes, both of which may be significantly attenuated by the notch filter. For example, use of the notch filter in the chin EMG channel may result in a false impression that tonic EMG has significantly decreased. In addition, the capability of the differential amplifier to reject common signals (see above) should be sufficient to suppress 60-Hz artifact in most cases. Thus, the appearance of 60-Hz artifact usually signals a problem somewhere in the polygraphic circuit that needs to be resolved. Most often the culprit is high impedance at the electrode–scalp interface. Less frequently, defects in the amplifier or grounding of the polygraph are responsible. In these cases, addressing the cause of the 60 Hz rather than using the notch filter is the appropriate course. There are circumstances in which a nearby source of 60 Hz (e.g., a critical piece of medical equipment that cannot be disconnected) renders the EEG uninterpretable. Use of the 60-Hz filter may be justified in these circumstances but must be clearly documented.

Analog and Digital Systems

Until digital PSG recording became the norm, analog systems were used. The analog PSG and EEG machines consisted of an oscillograph in the form of a galvanometer pen unit, with current flow from the amplifier entering a coil attached to the unit, inducing a magnetic field that interacted with the permanent magnetic field in which the coil was placed and causing the deflection of the pen. These have been virtually phased out at this time in favor of digital equipment and hence will not be discussed further.

Modern digital communications technology has allowed miniaturization of what had been much bulkier (if somewhat hardier) solid state components. It has also resulted in some reorganization of the functions of the polygraphic circuit. Digital polygraphs perform all of the functions of the analog polygraphic circuit. However, the ability to digitize the EEG signals allows easier manipulation, transmission, display, and storage that confers some distinct advantages. The ability of the polysomnographer to change sensitivities, montages, and filters while reviewing the study, rather than be limited by decisions taken by the technician at the time the study was recorded, is probably the biggest such benefit.

Recorded signals are still analog signals and need to be presented to the analog to digital converter (ADC). The ADC assesses the voltage of the continuous analog EEG, creates a numerical value corresponding to this voltage, and stores this value in memory. The ADC then repeats this process at a uniform interval (intersample interval). In this manner, a continuous (analog) EEG signal is converted into a series of numerical values representing the voltage of the signal at serial moments in time. Thus, the signal is commonly referred to as "digitized" or a "digital signal." As described in Chap. 16, the reliability of the digital signal is dependent on the sampling rate; if the digitized signal is to reflect the analog signal faithfully, the sampling rate must be at least twice the highest frequency in the analog signal to prevent aliasing (see Figs. 16.17 and 16.18).

The digitized signal is now passed to a computer for storage in memory and further manipulation by a software program. Software programs perform many of the functions of the solid state components of the analog polygraph.

Filtering is an important function performed by software on the digitized EEG signal. Digital filters are computer algorithms that transform digitized EEG by filtering out designated frequencies. Digital filtering [11] can be performed in the frequency domain by computing the Fourier transform of a segment of EEG, replacing coefficients at the frequency one wishes to eliminate by zero, and then reconstituting the EEG by computing the inverse Fourier transform (see further discussion of Fourier analysis below). Digital filtering can also be performed in the time domain by using a moving average method. Such finite impulse response filters are increasingly used in digital EEG machines and allow filtering without phase distortion, an advantage over traditional analog filters [12].

Software can manipulate and analyze digitized EEG signal in more sophisticated ways as well. Spectral analysis is a commonly employed technique relying on the Fourier

theorem and forms the basis of sleep stage scoring software. Pitfalls and limitations of this technique are discussed below. Algorithms designed to detect seizures and epileptiform abnormalities are also commercially available [13]. The clinical utility of these is variable and at present they do not replace a thorough analysis of the original record by a qualified interpreter.

Modified and organized digital signal can be directed from computer memory to a variety of destinations. Polygraphic data must be presented to the interpreter for visual inspection. Polygraphic data in digital systems is typically displayed on monitors. Monitor resolution must be sufficient so that the degree of resolution provided by the ADC is not significantly compromised. For example, if 1024 pixels (a common horizontal resolution in "off the shelf" computer monitors) is available to display 30 s of EEG, at most 1024/30 or 34 pixels can be devoted to display one second of EEG. This is far less than the 256 samples per second horizontal resolution provided by ADCs typically used in contemporary polygraphic systems. While this degree of horizontal resolution may be adequate for sleep stage scoring, it is not sufficient for analysis of epileptiform activity or electrographic seizures. Changing the timebase of the display so that 10 s epochs are displayed on the monitor will triple the horizontal resolution of the monitor in the above example and bring it more into line with the resolution provided by the ADC. Similar considerations pertain to the vertical resolution of the monitor though this is of less concern in polygraphy where less channels of polygraphic recording are typically presented at any time. In general, larger monitors with higher monitor resolution better reflect all the information present in the digitized signal.

Digitized polygraphic data can be transmitted to a printer to generate a "hard copy" polygraphic tracing of selected epochs. Printing an entire polygraph is rarely necessary with digital systems. Digitized data in computer memory must ultimately be transmitted to peripheral devices for storage. A variety of digital storage mediums are available, all of which are less expensive and more convenient than the paper and microfilm required for analog EEG. After security and privacy issues are addressed, digitized polygraphic data can be transmitted via network or the internet to other computers in the clinic, the interpreter's home, or on another continent.

Advantages and Limitations of Digital Recording Systems

Digital recording systems are now the norm and have rendered analog polygraph systems obsolete. With digital systems, there has been a revolution in techniques of data acquisition, display, and storage. Some of these have been alluded to in the discussion above, but to summarize, digital equipment is much less bulkier and conserves space. Previously recorded data can be manipulated retroactively and changes can be applied to the filter settings, sensitivities, and monitor speeds. As a result, artifacts can often be minimized and eliminated, data can be analyzed in multiple ways, and areas of interest can be more easily pinpointed and logged for future reference. Computerized recording makes the EEG paperless, conserving space, and being more environmentally friendly. Digital information is easier to store on inexpensive media such as DVDs, and the digital format translates more easily into databases. For these reasons, digital recording will undoubtedly continue to replace analog polygraphic systems over time.

Spectral Analysis

Spectral analysis is probably the most widely used computerized analysis of digitized EEG [14]. Spectral analysis is based on the Fourier theorem, which states that any waveform can be decomposed into a sum of sine waves at different frequencies with different amplitudes and different phase relationships. When summed, these waves reconstitute the original waveform. The Fourier transformation is a mathematical operation that provides the frequency, amplitude, and phase parameters of each of these component sine waves. Fourier coefficients represent the amplitude and phase relationship at each of the component sine-wave frequencies. Squaring and summing the Fourier coefficients at each frequency provides the power at that frequency. A plot of power at each of the component frequencies is called the power spectrum. The power spectrum allows determination of relative amounts of given frequencies in the waveform over the time segment analyzed.

The fast Fourier transform algorithm allows real-time spectral analysis with contemporary personal computers. Commercially available software packages offer straightforward presentation of the power contained in the traditional frequency bands during a set period of EEG. This allows detection and quantification of frequencies not detected with visual inspection. However, there are many potential pitfalls. Theoretically, the power spectrum is a faithful representation of the original signal only if the original signal is stationary (has stable statistical properties). The EEG signal is clearly not stationary over long periods, although it appears reasonably stationary over brief epochs. In practice, this means that the EEG segment selected for analysis should not include obvious changes such as those due to alerting or drowsiness. In addition, the Fourier theorem assumes that an infinitely long sample is available for analysis. Because, even long samples are clinically impractical, tapering, or "windowing" of the endpoints of the sample is necessary to attenuate the spurious frequencies

(leakage) arising from the segmentation of the signal. Windowing is never completely successful—some leakage is unavoidable. This may affect clinical interpretation when power is displayed in the traditional frequency bands; for example, a reasonable amount of alpha power may leak to the theta band or beta bands. Nonsinusoidal rhythms, such as "spiky alpha" are common in routine EEG. Fourier analysis of a nonsinusoidal rhythm of a set frequency often shows a large peak at that frequency with smaller peaks at harmonics of the frequency. These smaller, higher frequency peaks may lead the interpreter to conclude that cerebral activity at the higher frequency is actually present. The most common pitfall in interpreting power spectra is artifact. Artifact is ubiquitous, often subtle, and can take an almost infinite variety of forms. The computer cannot separate artifact from EEG and includes artifact in the computation of the power spectrum. This can lead to significant misinterpretation. Artifact is much more difficult to recognize in the power spectrum than in the unprocessed EEG. It is therefore very important to review EEG before spectral analysis or interpretation of the power spectrum to prevent analysis of segments contaminated by artifact [15, 16].

Despite these limitations, spectral analysis can play a useful role in the operating room and in routine scoring of sleep studies. A basic understanding of the principles of signal processing and thorough experience in the appearance of various cerebral activities after spectral analysis is necessary. Unprocessed "real" physiologic signal must always be reviewed. Spectral analysis has not demonstrated any consistent clinical utility in routine EEG despite almost two decades of active research. Because the potential for misinterpretation and abuse is high, the major neurologic and neurophysiologic professional organizations have taken strong positions against the use of spectral analysis during routine EEG.

Electro-oculography

Electro-oculography (EOG) recording is crucial to staging sleep accurately. Gold cup or silver–silver chloride electrodes can be used to monitor the EOG. The sensitivity and filter settings for EOG are similar to those used for EEG (see Table 18.3). The two recommended electrodes are labeled E1 (1 cm below the left outer canthus) and E2 (placed 1 cm above the right outer canthus) both referenced to the right mastoid [9]; this arrangement allows simultaneous recording of both vertical eye movements (such as blinking) and horizontal eye movements (both slow and rapid) (Fig. 18.8).

The underlying concept is that the eye is an electric dipole, with relative positivity at the cornea and a relative negativity at the retina. Any eye movement changes the orientation of the dipole, and it is the movement of the dipole that is recorded as a potential difference between the two electrodes used to record the EOG. In this arrangement, conjugate eye movements produce out-of-phase deflections in the two EOG channels whereas the EEG slow activities contaminating the eye electrodes are in phase. For example, when the eyes look to the right (see Fig. 18.8), the cornea of the right eye approaches electrode A in input 1 and electrode A becomes positive relative to the inactive ear. According to the polarity convention, amplifier 1 will register a downward deflection. Simultaneously, the retina of the left eye approaches electrode B connected to input 2. Consequently, electrode B becomes negative relative to the inactive ear and amplifier 2 registers an upward deflection. The out-of-phase deflections in the two adjacent channels indicate that a conjugate eye movement has occurred. Similarly, an upward eye movement results in a downward deflection in amplifier 1 and an upward deflection in amplifier 2. Eye blinks will produce an identical pattern because eye closure results in an upward rotation of the eyeball (Bell's phenomenon).

Table 18.3 Filter and sensitivity settings for polysomnographic studies

Characteristics	High–frequency filter (Hz)	Time-constant (s)	Low Frequency filter (Hz)	Sensitivity
Electroencephalogram	70 or 35	0.4	0.3	5–7 μV/mm
Electro-oculogram	70 or 35	0.4	0.3	5–7 μV/mm
Electromyogram	90	0.04	5.0	2–3 μV/mm
Electrocardiogram	15	0.12	1.0	1 mV/cm to start; adjust
Airflow and effort	15	1	0.1	5–7 μV/mm; adjust

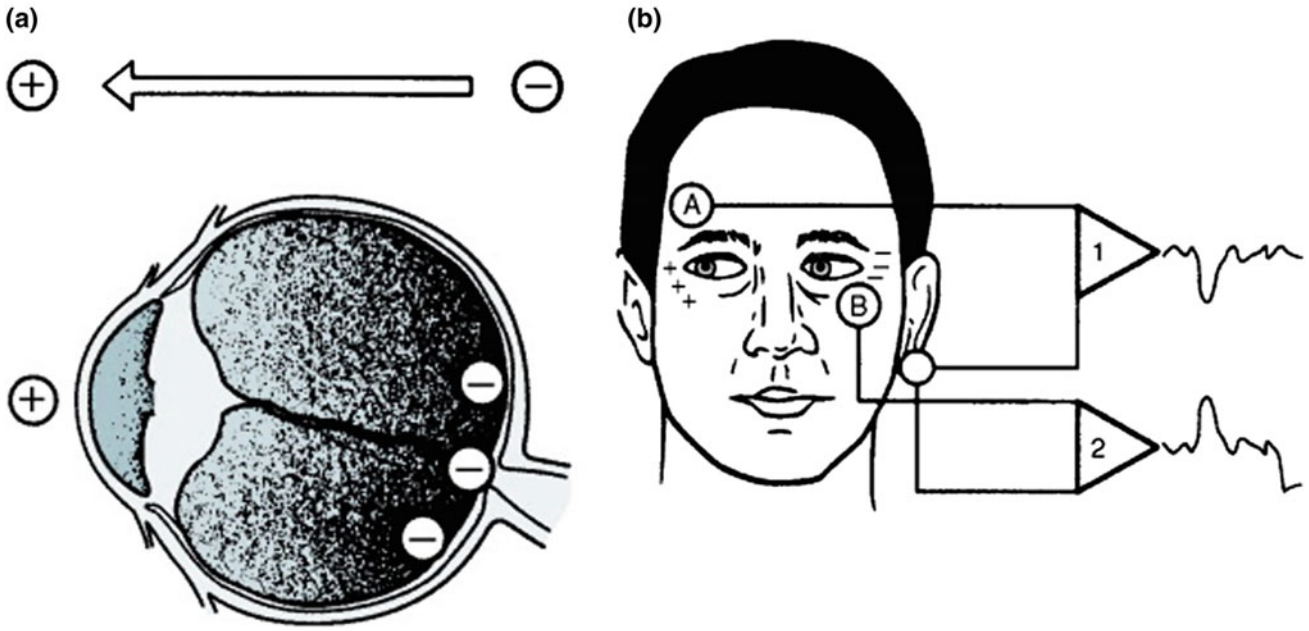

Fig. 18.8 **a** The voltage field generated by the eye can be represented by a simple dipole, the cornea being positive and the retina negative. **b** With the use of two polygraphic channels to detect conjugate eye movements according to the scheme suggested in the sleep scoring manual, eye movements result in out-of-phase potentials in the two channels

Eye movements are general characteristic of the sleep stage in which they occur and are an essential part of scoring. Eye blinks, seen only in wakefulness, are conjugate vertical eye movements occurring at 0.5–2 Hz with the eyes open or closed. REMs (conjugate, irregular, sharp eye movements with an initial deflection of less than half a second) occur in wakefulness along with high chin EMG tone, eye blinks and a posterior dominant rhythm, but also occur in REM sleep, especially in phasic REM where they occur in bursts seen in all directions (horizontal, oblique, and vertical) and are accompanied by low to absent chin EMG tone (interspersed with similar phasic bursting) and a desynchronized, amorphous EEG pattern. The frequency with which bursts of REMs occur in REM sleep, measured as REMs/minute, is called REM density. It typically increases in later REM cycles during the course of a normal PSG; this may be reversed in patients with depression. Slow lateral eye movements (SEMs or SLEMs) are seen in drowsiness and light sleep and are defined as conjugate, sinusoidal, and regular eye movements with an initial deflection of greater than half a second (Fig. 24.9). These eye movements are not under voluntary control and cannot be volitionally simulated. In patients, who do not generate a posterior dominant rhythm, their appearance heralds Stage N1 sleep. While they may persist into Stage N2 during the early part of the night, they generally disappear in Stage N3 and REM sleep. However, patients on antidepressants such as selective serotonin reuptake inhibitors (SSRIs such as fluoxetine and paroxetine) as well as serotonin–norepinephrine reuptake inhibitors (SNRI such as duloxetine) may have unusual eye movements that appear to be a mixture of rapid and slow eye movements occurring well into Stage N3 and often into REM sleep (colloquially referred to among polysomnographers as "Prozac eyes"); their presence makes sleep staging difficult (Fig. 18.9) and can render scoring of a multiple sleep latency testing (MSLT) equally frustrating. The role of EOG in sleep staging is further discussed in Chap. 24.

Santamaria and Chiappa [17] found two types of eye movements in drowsiness, not previously reported, by placing recording electrodes over the globe in addition to traditional EOG; they described small fast irregular eye movements in 60 % of normal subjects in early drowsiness, preceding slow eye movements, as well as small fast rhythmic eye movements in 30 % of normal subjects, usually associated with the traditional slow eye movements. The former did not appear in traditional EOG recordings, and when the latter occasionally did, they were of very low amplitude. These have yet to be validated by other authors.

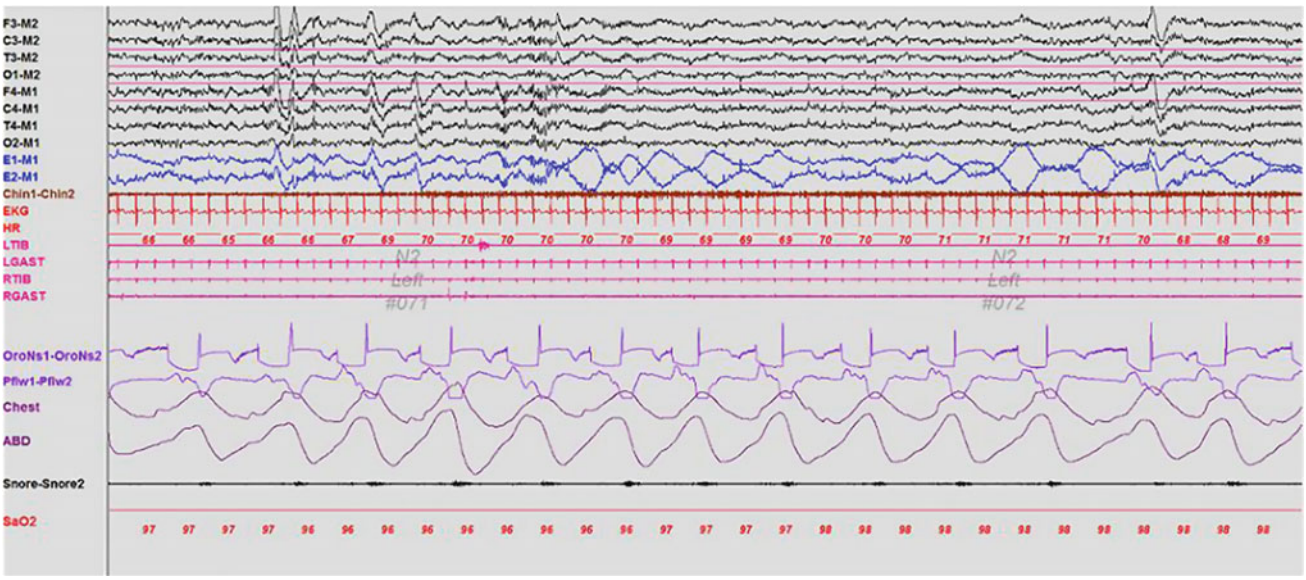

Fig. 18.9 A 60 s epoch from the overnight polysomnogram of a 35-year-old man complaining of excessive daytime sleepiness and with a prior diagnosis of obstructive sleep apnea. He also has a history of depression and is on citalopram, a selective serotonin reuptake inhibitor (SSRI). This epoch represents Stage N2 sleep, as evidenced by the presence of K complexes and sleep spindles. Note the presence of excessive eye movements, representing a combination of slow and rapid eye movements. Eye movements generally do not persist into Stage N2 and beyond but are often seen in patients on SSRIs (colloquially referred to as "Prozac eyes"). Top eight channels; EEG recording with electrodes placed according to the 10–20 international electrode placement system. Chin1-Chin2, submental electromyogram (EMG); ECG, electrcardiogram; HR, heart rate; LTIB; RTIB, left and right tibilais anterior EMG; LGAST; RGAST, left and right gastrocnemius EMG; OroNs1-OroNS2, oronasal airflow; Pflw1-Pflw2, nasal pressure transducer recording; Chest and ABD, effort belts; SaO2, arterial oxygen saturation by finger oximetry. Also included is a snore channel. Reproduced with permission from: Chokroverty and Thomas [65]

Electromyographic Recordings in Sleep Disorders

Electromyography (EMG) channels provide important physiological characteristics that help determine sleep stage, as well as aiding in the diagnosis and classification of a variety of parasomnias [18]. At a minimum, a PSG consists of chin EMG channels recording activity from the mentalis and submental muscles (the mylohyoid and anterior belly of the digastric, supplied by the motor fibers of the trigeminal nerve), and bilateral leg EMG channels recording activity from the tibialis anterior muscles. EMG is recorded using a gold cup or a silver–silver chloride electrode applied to a clean surface using tape or electrode glue. For chin EMG recordings, at least three EMG electrodes are applied so that in the event of a problem with one of the electrodes the additional backup electrode can be connected during the recording without disturbing the patient. The electrode impedance should be less than 5 K. The high- and low-frequency filter settings for the EMG recordings are different from those used for EEG and EOG and are listed in Table 18.3. The sensitivity should be at least 20 μV/cm for mental or submental EMG activity.

As recorded during a PSG, the EMG channels represent the surface recording of intracellular changes occurring as a result of muscle depolarization during contraction. Unlike needle EMG performed in patients with suspected neuromuscular disease in the neurophysiology laboratory, analysis of motor unit morphology and firing pattern is not the focus of these recordings. Rather, the EMG channels provide important information about overall muscle tone. EMG tone is seen to progressively decrease with sleep onset and continue to diminish through nonREM (NREM) sleep to a point where it is at its minimum and almost absent in REM sleep [19]. Phasic bursts (with short durations in the myoclonic range, 20–150 ms and sometimes up to 250 ms) in the chin EMG (as well as limb EMG) are seen in phasic REM sleep.

Lower limb EMGs are generally recorded with electrodes placed over the tibialis anterior muscles 2–2.5 cm apart. The main utility of these channels is to record limb EMGs in patients with periodic limb movements in sleep (PLMS). While generally seen in up to 80 % of patients with restless legs syndrome (RLS, recently renamed Willis-Ekbom disease), PLMS are often seen in normal patients with no daytime complaints, especially those above the age of 65 years. PLMS are also seen in those with a variety of sleep disorders (e.g., REM behavior disorder [RBD] and

narcolepsy, in which they may be abundant in REM sleep), those on antidepressants such as SSRIs and SNRIs. For this reason, a careful sleep history is essential while determining the clinical significance of PLMS. In many cases, PLMS occur in association with respiratory events as part of obstructive sleep apnea (OSA). These are referred to as respiratory related limb movements, and may respond to continuous positive airway pressure (CPAP) treatment. This recognition cannot be made without PSG that allows simultaneous analysis of respiratory and EMG channels, although the bedpartner may often complain of kicking leg movements or similar body flailing by the patient.

Many patients with a history of abnormal movements or behavior in sleep require a more extended EMG montage, which we term a multiple muscle montage (MMM), that includes extra channels recording from additional cranially innervated muscles (e.g., the sternocleidomastoideus, masseter, and other muscles), upper limb (e.g., biceps, triceps, extensor digitorum communis, and flexor digitorum subliminis), and lower limb muscles (e.g., quadriceps, hamstrings, gastrocnemius, and extensor digitorum brevis) and axial muscles (e.g., cervical, thoracic and lumbar paraspinals, rectus abdominis, and intercostal muscles) (Table 18.4). This additional muscle recording is of particular utility in patients with suspected RBD where REM without atonia (RWA) may be missed if an adequate number of muscles are not sampled. While a standard montage for RBD has not yet been agreed upon, Fraucher et al. found that simultaneous recording and quantitative analysis of the mentalis and flexor digitorum superficialis in three second mini-epochs was 100 % specific for RBD, when activity was present in more than 31.9 % of mini-epochs [20]. The heterogeneity of RBD appears to be expressed in the dissociated EMG findings in muscles innervated by the cranial nerves, as well as spinal nerves to the arms and the legs, requiring recording from multiple muscles. Multiple muscle montage recording may also be useful in patients with suspected RLS, as PLMS may also occur in the arm muscles or, rarely, in the axial or cranially innervated muscles (Fig. 18.10). EMG recordings are needed to score excessive fragmentary myoclonus, hypnagogic foot tremor, and alternating leg muscle activation (ALMA), as well as propriospinal myoclonus at sleep onset.

Additional EMG channels aid in the analysis of unusual movements in sleep, especially myoclonus, and help assess their propagation and location of their generators. A dystonic muscle burst refers to a tonic or prolonged EMG activity lasting for 500–1000 ms or longer. Myoclonic muscle bursts are phasic bursts, which are characteristically noted during REM sleep and also during NREM sleep as excessive fragmentary myoclonus. Myoclonic bursts refer to EMG activity lasting for a brief duration of generally 20–150 ms and sometimes up to 250 ms. In patients with tremor, EMG may record rhythmic activity in agonist–antagonist muscle pairs. Physiological analysis of a variety of movements in sleep, many of which are benign phenomena such as hypnic or intensified hypnic jerks [21] is possible when additional muscle electrodes are used.

Recording alae nasi muscle may pick up not only inspiratory activity, but also some expiratory activity [22]. Many upper airway muscles are secondary muscles of respiration. All the facial muscles, including the masseter muscles, show inspiratory bursts during the recordings (Fig. 18.10) [23]. It is often helpful to include intercostal and diaphragmatic EMG channels to record respiratory muscle activity. The intercostal EMG can be recorded from the seventh to ninth intercostal spaces with active electrodes on the anterior axillary line and the reference electrodes on the mid-axillary line. Diaphragmatic muscle activity may be recorded by placing surface electrodes over the right or left side of the umbilicus or over the anterior costal margin. However, these tend to cross-contaminate each other so that recordings from either sites are effectively a mixture of both diaphragmatic and external intercostal muscles. True diaphragmatic activity is typically recorded by intraesophageal recording. Spectral analysis of data from chest wall surface electrodes with simultaneous data obtained from a swallowed bipolar electrode with a double-balloon catheter suggests that the former (i.e., chest wall electrodes) do not accurately reflect diaphragmatic activity [24]. Intercostal EMG is particularly useful in the differentiation between central and obstructive apneas, especially when the respiratory channels are unreliable; continued bursts of activity in these channels during an apneic event would identify it as obstructive while the absence of such bursts would indicate a central event (Fig. 18.11). The 2012 update to the AASM Manual for the Scoring of Sleep and Associated Events [25] recommends the use of the intercostal/diaphragmatic EMG channel for scoring apneas/hypopneas when the airflow channels are unreliable.

In our laboratory, we have designed a hybrid seizure/multiple muscle montage for recording patients who have abnormal behaviors and events in sleep and in whom the differential diagnosis includes seizures and parasomnias. While most PSG machines have a limited number of inputs, precluding full seizure and multiple muscle recordings during the same study, we have found this hybrid montage useful in analyzing such events (Table 18.5).

Table 18.4 Multiple muscle montage (extended EMG channels for parasomnias and other movement disorders in sleep)

Channel number	Name

34	Heart rate

Channels 1–6 record electroencephalogram activity from bilateral cerebral hemispheres with referential parasagittal chains. Channels 10–26 record EMG activity, including from additional muscles not routinely studied on typical PSGs. Channels 27 and 28 record airflow ("flow channels"). Channels 29 and 30 record respiratory effort ("effort channels")

[a]In a CPAP titration study, flow channels are replaced by a CPAP signal (C-flow signal)

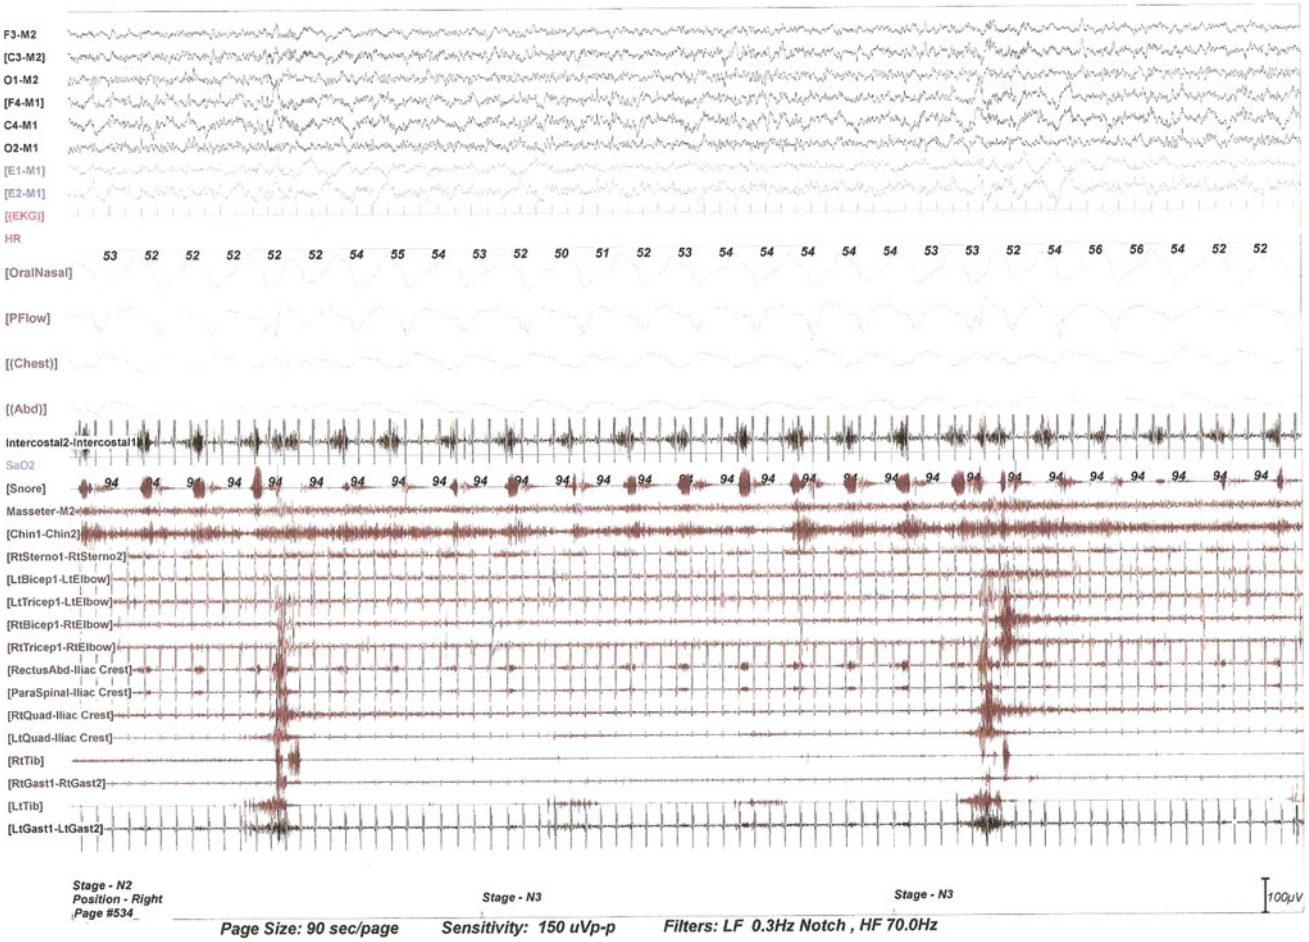

Fig. 18.10 Propriospinal propogation of periodic limb movements of sleep. This 90 s epoch of Stage N3 sleep is taken from the overnight PSG recording using multiple muscle montage in a 66-year-old man with a history of restless legs syndrome (Willis-Ekbom Disease) fulfilling all the essential diagnostic criteria for this. Note periodic limb movements in sleep (PLMS) originating first in the tibialis anterior and propagating up the spinal cord to the quadriceps muscle and subsequently to the rectus abdominis, paraspinals, and then to the biceps and triceps muscle at a very slow speed (note prolonged interburst intervals between the lower limb, trunk, and upper limb muscles). This suggests propagation along slowly conducting propriospinal pathways. It is not possible to measure exact interburst latencies using our PSG equipment. Note also the inspiratory muscle bursts in cranially innervated muscles (secondary respiratory muscles). The upper rectus abdominis and paraspinal muscles are picking up inspiratory bursts from neighboring intercostal and diaphragmatic muscles. Top 6 channels: EEGs (international nomenclature system); E1–M1 and E2–M1: Left and right electro-oculography, respectively; M1: left mastoid; ECG: Electrocardiogram; HR: Heart rate; OralNasal: oralnasal thermistor; PFlow: Nasal pressure transducer; chest and ABD: CHEST and abdominal respiratory effort channels; intercostals: Intercostal EMG from the Right 8th intercostal space; SaO2: oxygen saturation by finger oximetry; channels 18-32: EMGs from masseter, chin (mentalis muscle) sternomastoid, biceps, triceps, rectus abdominis (right), paraspinal (right thoracolumbar), quadriceps (Lt and Rt), gastrocnemius (Gast) (Lt and Rt), and tibialis anterior (Tib) (Lt and Rt), muscles. Reproduced with permission from: Chokroverty and Thomas [65]

Special Techniques for Physiological Characterization of Abnormal Movements

In addition to polymyographic recording to understand the onset and propagation of muscle bursts, other electrophysiological techniques may be needed to characterize the nature of propriospinal myoclonus at sleep onset and other nocturnal muscle jerks.

Propriospinal myoclonus at sleep onset [26] usually originates from a generator in the mid-thoracic region with propagation up and down the spinal cord at a very slow speed (3–5 m/s) using very slowly conducting propriospinal pathways. Surface EMG recording may be obtained for upper thoracic (e.g., second or third intercostal space), mid-thoracic (upper rectus abdominis muscle), lower thoracic (lower rectus abdominis muscle), and lumbar (e.g., quadriceps femoris muscle) regions. The onset of muscle burst, interburst duration in milliseconds and the distance in centimeter between the recordings should be measured. The motor conduction velocity is then computed to

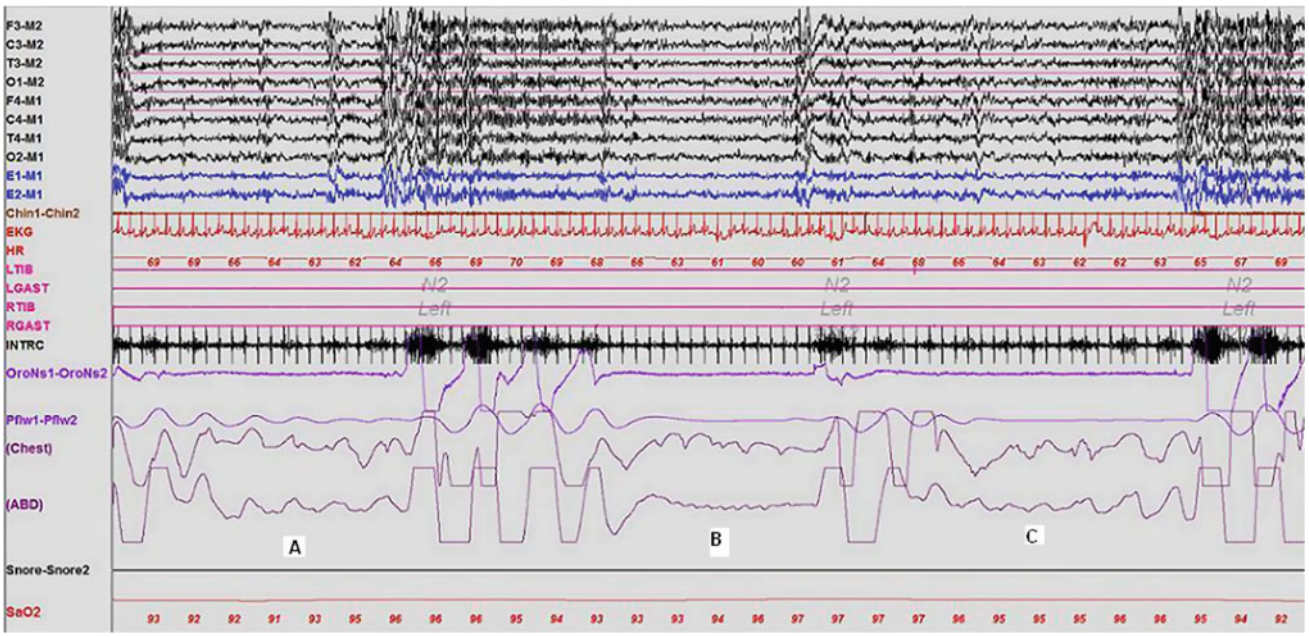

Fig. 18.11 A representative 90 s epoch from the overnight polysomnogram (PSG) of a 46-year-old man with a longstanding history of snoring, witnessed apneas, and excessive daytime sleepiness. Three respiratory events are depicted in this epoch. Note that during the second event (B), the chest lead shows artifacts making it difficult to determine whether it is central or obstructive in nature. However, the intercostal EMG channel (INTRC) shows the absence of inspiratory bursts during the event, confirming that it is a central apnea. Also noted is cardioballistic artifact in the abdomen (ABD) lead, another indicator of a central event. For comparison, the first and third events (A and C) are clearly obstructive apneas, and intercostal EMG bursts continue (albeit at a lower amplitude) throughout their duration. The intercostal EMG channel is often very helpful in distinguishing between obstructive and central apneas when effort channels are unreliable or show artifacts. Top eight channels; EEG recording with electrodes placed according to the 10–20 international electrode placement system. Chin1–Chin2, submental electromyogram (EMG); ECG, electrcardiogram; HR, heart rate; LTIB, RTIB: left and right tibilais anterior EMG; LGAST, RGAST: left and right gastrocnemius EMG; OroNs1-OroNS2, oronasal airflow;. Pflw1-Pflw2, nasal pressure transducer recording; SaO2, arterial oxygen saturation by finger oximetry. Also included is a snore channel. Reproduced with permission from: Chokroverty and Thomas [65]

(distance/interburst time interval) show conduction at a very slow speed. Propogation of muscle bursts up and down the spinal cord at a very slow speed will provide evidence for a propriospinal myolclonus [27].

For abnormal muscle jerks, the technique of back-averaging (EMG-EEG correlation) will tell if the jerks are voluntary or involuntary in nature [28]. A voluntary jerk will produce a Bereitschaftspotential (readiness potential), a characteristic slowly rising negative potential with onset about 500–1000 ms before the onset of the EMG activity from the jerking muscle which is a classic electrophysiologic signature of voluntary movement. A cortical prepotential will be recorded (about 20 ms before the onset from an upper limb muscle or 30–40 ms before the onset from a lower limb muscle) in case of cortical myoclonus whereas no prepotential will be recorded in case of brain stem or spinal myoclonus [29].

Interpreting the EEG

While the main purpose of recording the EEG in sleep studies is to stage sleep, it is vital that the polysomnographer be familiar with normal waking rhythms, be able to identify abnormalities, both epileptiform and nonepileptiform, as well as recognize artifacts that may contaminate a recording, and be a source of confusion. This is especially true since many epileptiform abnormalities become more pronounced during drowsiness and sleep (specifically NREM sleep), and the prolonged nature of sleep recordings (six hours or more over a night), in comparison to the relatively short recording time for routine EEGs (generally 20–30 min) increases the yield of finding abnormalities, giving the polysomnographer a unique opportunity to evaluate potential cerebral dysfunction. Incorporation of multiple EEG electrodes to cover both the temporal and parasagittal regions of the scalp is

Channels 1–8 record electroencephalogram activity from bilateral cerebral hemispheres in a bipolar montage. Channels 11-24 record EMG activity, including from some additional muscles not routinely studied on typical PSGs. Channels 25 and 26 record airflow ("flow channels"). Channels 27 and 28 record respiratory effort ("effort channels")

[a]In a CPAP titration study, flow channels are replaced by a CPAP signal (C-flow signal)

particularly important for a patient with suspected nocturnal seizure (see also Chap. 44).

Describing EEG Activity

EEG activity is described based on particular characteristics, summarized in Table 18.6 (see also Chap. 24). EEG frequency is measured in hertz (Hz, or cycles per second) and is commonly in the delta, theta, alpha, or beta range. EEG activity is also described on the basis of its distribution (whether localized, i.e., predominantly frontal, temporal, central, occipital, or generalized), amplitude, rhythmicity (whether the waves have a sinusoidal pattern and occur in a set pattern), morphology (e.g., monomorphic [all similar in appearance], or polymorphic [dissimilar]), synchronicity (i.e., occuring simultaneously in both hemispheres), symmetricity (equal amplitude on both sides), regularity (intermittent or continuous), and reactivity (whether the activity changes in response to stimulation).

Normal Waking Rhythms

A normal awake adult EEG has a characteristic posterior dominant rhythm (PDR) in the *alpha range*, generally between 8 and 13 Hz. As implied by its name, this rhythm is distributed over the parieto-occipital regions bilaterally, becoming less pronounced anteriorly (i.e., has an anterior-posterior gradient). It is synchronous and symmetric over the two hemispheres. Frequency of the rhythm should not vary by more than 1 Hz, and amplitude should not vary by more than 50 %, between the two hemispheres. The PDR is best seen during quiet alertness with eyes closed and attenuates with eye opening (i.e., it is reactive, see Chap. 24). The PDR may be suppressed in an anxious patient. Up to 10 % of normal adults will show no alpha rhythm during quiet wakefulness. The EEG in these subjects is characterized by low-amplitude (10–20 μV) poorly sustained beta (>13 Hz) and a small amount of theta frequencies. Occasionally, hyperventilation elicits a typical alpha rhythm in such patients. With drowsiness, the PDR slows into the theta range and may be better seen anteriorly before dropping out and being replaced by typical sleep background activities. A PDR slower than in the normal alpha range may be seen in patients with encephalopathies from various causes, both acute (e.g., toxic-metabolic) and chronic (e.g., dementia).

Non-alpha range rhythms may occasionally be seen in normal waking EEGs (e.g., beta rhythms). There are probably at least two beta rhythms, one distributed over the frontal and central regions and the other with a more diffuse distribution. Beta rhythms are present during wakefulness and drowsiness. They may appear more persistent during drowsiness, drop out during deeper sleep, and reappear during REM sleep. Amplitude over the two hemispheres should not vary by more than 50 %. Amplitude of beta activity is less than 20 μV in 98 % of normal drug-free subjects. A persistent beta rhythm with higher amplitude suggests use of sedative-hypnotic medications (generally benzodiazepines and barbiturates) because most such medications increase amplitude of beta activity.

It is important to bear in mind that the EEG in infants and children undergoes significant evolution with increasing brain maturity. A sustained PDR is not seen until approximately 3 months of age. At that time, reactive 3-Hz waves are recorded during wakefulness. Frequency of the parieto-occipital rhythm increases rapidly over the next several years, reaching at least 6 Hz by one year of age and adult values in most children by 8–9 years of age. Greater amounts of random frontocentral theta are seen in children than in adults, but this decreases as the child ages. Brief runs of more sustained low-amplitude (15 μV) frontal 6- to 7-Hz waves are seen in as many as 35 % of adolescents. This rhythm is present during quiet wakefulness with eyes open and may be related to affective arousal.

Whether slowing of the PDR is a natural consequence of aging remains controversial [30, 31]. However, an alpha rhythm with a dominant frequency of less than 8 Hz is always abnormal in adults. Focal temporal theta or delta is seen in as many as 35 % of asymptomatic individuals older than 50 years. Such activity is more commonly noted over the left temporal regions and should probably occupy no more than 5 % of the tracing. More persistent temporal slowing is considered abnormal by most electroencephalographers.

Normal Sleep EEG

This section provides a brief overview of normal EEG changes in sleep from the point of view of the electroencephalographer. Readers are referred to Chap. 24 for a detailed description of the implications of EEG changes for staging sleep while interpreting a PSG.

Stage 1 sleep (equivalent to N1 sleep on PSG) is a transitional stage between wakefulness and Stage 2 sleep, occupying a relatively small percentage of a normal night's sleep, generally less than 5 %. The term "drowsiness," while often used by electroencephalographers, is not a standard part of the polysomnographers' lexicon. Indeed, even within

the electroencephalographer community, the distinction between drowsiness and Stage 1 is often difficult and arbitrary. Drowsiness may be thought to occur with shifting of the posterior rhythms of wakefulness from the characteristic parieto-occipital distribution to the frontocentral or temporal regions. Amplitude of alpha activity may either increase or decrease and frequency of the alpha rhythm may slow. Slow lateral eye movements may appear (Fig. 24.8). Slower theta and delta frequencies may be superimposed in the central or temporal regions. In older patients especially, paroxysmal theta bursts may predominate in one temporal region. Eventually, the PDR disappears altogether. Vertex waves, high-voltage monophasic surface-negative sharp transients with a maximal voltage at the Cz electrode (often with extension of the field to Fz, or less frequently Pz) occur (Fig. 24.9) and may be particularly sharp and of high amplitude in children and young adults.

Stage 2 (equivalent to N2 sleep on PSG), which comprises the bulk of a normal night's sleep in an adult, is characterized by the presence of specific sleep architecture and a synchronized EEG background. Sleep spindles are prominent (see Figs. 24.13 and 24.14). There is a high degree of symmetry and synchrony between the two hemispheres in normal subjects older than one year. Some investigators have proposed a classification of spindles based on topography and frequency [32], but it is not clear that this has clinical utility at this time. K complexes (Fig. 24.12), another feature of N2 sleep, often accompanies sleep spindles. Slow-wave activity may be seen in this stage but does not meet the criteria for Stage 3.

Stage 3 sleep (equivalent to N3 sleep on PSG, see Chap. 24), commonly referred to as "slow-wave sleep," is present when 20 % or more of any epoch is occupied by waves slower than 2 Hz and greater than 75 μ (Fig. 24.16). Electroencephalographers (but not polysomnographers) recognize an additional sleep stage, Stage IV, when the slow waves occupy more than 50 % of the epoch. Vertex waves, sleep spindles, and K complexes may persist in this stage but are much less prominent. The percentage of Stage N3 tends to decrease with age.

REM sleep has very characteristic EEG, EMG, and EOG features. In contrast to Stages 2 through 3 sleep, the background EEG is desynchronised, meaning that it is comprised of low-voltage, mixed-frequency activity similar to Stage 1. Alpha frequencies are often present and may be more persistent than in Stage 1 but are usually 1–2 Hz less than the subject's waking rhythm [33]. Vertex waves, sleep spindles, and K complexes are generally absent, although may occasionally occur, especially in the earlier REM cycles. In fact, REM-spindle sleep (Fig. 18.12), where sleep spindles

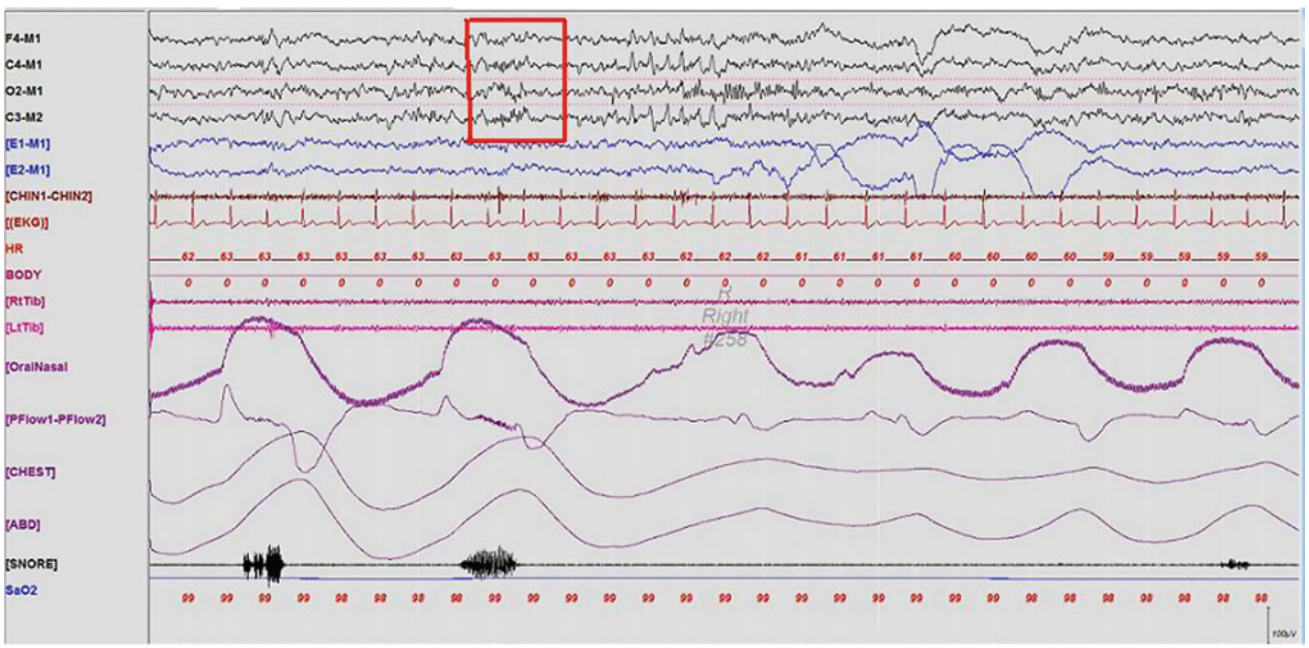

Fig. 18.12 A case of sleep spindles in REM sleep. Shown is a 30 s epoch from the overnight PSG of a 50-year-old woman with difficulty sleeping, loud snoring, and excessive daytime sleepiness for 5 years. Medical history is significant for chronic headaches and hypothyroidism. Nocturnal PSG showed the presence of mild sleep apnea (no respiratory events are occurring in this epoch) with an apnea–hypopnea index of 10/hr. Note the presence of sleep spindles (*box*) during REM sleep. Prominent sawtooth waves of REM sleep in C3- and C4-derived EEG channels, prominent phasic eye movements of REM sleep on electrooculogram channels and decreased chin muscle tone characteristic of REM atonia are seen. Sleep spindles, while characteristic of Stage N2 sleep, may be seen in REM, especially in the early cycles. Reproduced with permission from: Chokroverty and Thomas [65]

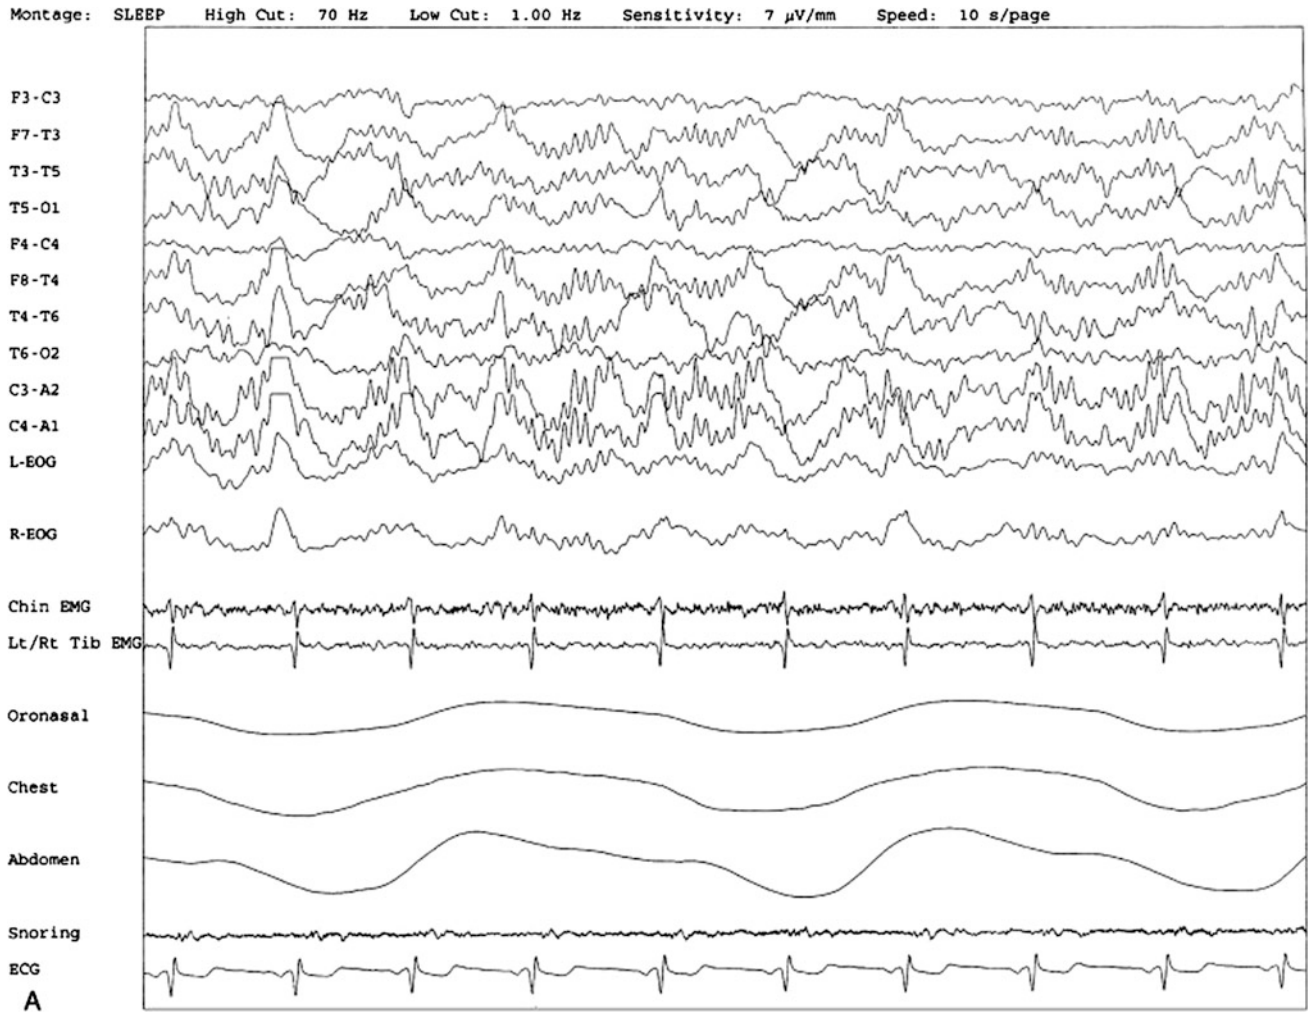

Fig. 18.13 A case of alpha-delta sleep. Ten- and 30-second excerpts from a nocturnal PSG showing alpha–delta sleep in a 30-year-old man with history of snoring for many years. He denied any history of joint or muscle aches and pains. The alpha frequency is intermixed with and superimposed on underlying delta activity. Alpha–delta sleep denotes a nonspecific sleep architectural change noted in many patients with complaints of muscle aches and fibromyalgia. It is also seen in other conditions and many normal individuals. EEG, Top 10 channels; Lt. and Rt. EOG, left and right electrooculograms; chin EMG, EMG of chin; Lt./Rt. Tib. (Figure 9 from Atlas 2nd edition)

intrude on what otherwise meets all the scoring criteria for REM sleep, may be seen in 1–7 % of normal subjects but is more common when sleep is disrupted and after the first night of continuous positive airway pressure treatment [34]. Characteristic sawtooth waves (Fig. 18.12), 2- to 7-Hz sharply contoured triangular waves usually occurring serially for several seconds with highest amplitude over the Cz and Fz electrodes are seen, which usually, but not always, precede a burst of REMs [35]. REM sleep occupies 20–25 % of a night's sleep in a normal adult subject.

An atypical variant is the so-called "alpha-delta sleep" pattern (Fig. 18.13) characterized by persistence of alpha activity overriding the slow waves of Stage N3. It may be seen in Stage N2 as well, obscuring spindles. Its clinical relevance is unknown at this time, but it appears to be associated with unrefreshing sleep and is seen in a variety of conditions associated with muscle aches and pains. Researchers have shown that it can be produced by depriving patients of slow-wave sleep, a process that also elicited complaints of diffuse arthralgias, myalgias, and fatigability, similar to the complaints of the fibromyalgia syndrome. These findings raise the intriguing question whether fibromyalgia is basically a sleep disorder causing musculoskeletal symptoms rather than the other way around, but clearly more research needs to be done in this regard [36–38].

Normal Sleep EEG in Pediatrics

The transition from neonatal to infantile EEG sleep patterns occurs between 1 and 3 months (see also Chap. 52).

The first recordable EEG activity begins at around 8 weeks conceptual age (CA), as a completely low voltage (>25 μV), completely discontinuous background (i.e., the periods of background activity ["burst interval"] are interspersed by periods of background suppression ["interburst interval"]). As the neonate ages, the burst interval increases and the interburst interval decreases; at 24 weeks CA, the interburst interval is approximately 6–12 s, but by 30 weeks CA, it decreases to about 5–8 s. This continuously discontinuous EEG persists between 8 and 12 weeks CA; after this age, it can be divided into three stages; wake, active sleep (a precursor of REM sleep), and quiet sleep (a precursor of NREM sleep). Between 30 and 36 weeks CA, the EEG is more continuous in wake and active sleep but still very discontinuous in quiet sleep (with an interburst interval amplitude of >25 μV, "tracé discontinu"). Between 36 and 42 weeks, the activity becomes nearly continuous in active sleep and wake ("activité moyenne") and remains discontinuous in quiet sleep, but with higher amplitudes of the interburst interval than seen in tracé discontinue (>25 μV). The tracé alternant pattern ("tracé alternant", Fig. 18.14) gradually matures into the "continuous slow-wave sleep pattern" and complete continuity of the EEG background in all stages of sleep is generally achieved between 42 and 46 weeks CA.

Even after the neonatal period, there is a great deal of change in the electroencephalographic patterns until the adult patterns are reached. Drowsiness in the pediatric age group differs from the adult patterns in several ways. Before eight months of age, drowsiness is marked by a progressive slowing of EEG frequencies until delta waves predominate. After eight months, the onset of drowsiness is marked by long runs of continuous, generalized, high-voltage rhythmic theta or delta waves, which have been called hypnagogic hypersynchrony (see Chap. 24). Three types have been described in normal subjects [39]. In the most common type, the rhythmic slow waves have highest amplitude in the frontal and central regions. The continuous rhythmic slowing may persist for several minutes. Less commonly, amplitude is highest in the parieto-occipital regions. Finally, a paroxysmal type occurs in approximately 10 % of normal children. With this pattern, the alpha rhythm is gradually replaced by mixed frequencies. Diffuse bursts of 2- to 5-Hz slow waves, a few seconds in duration, then appear intermittently. Occasionally, random, poorly developed, and sharply contoured waveforms are noted amidst the slow waves. These may be random, superimposed alpha transients and should not be confused with epileptiform spike and wave. The first two types of hypnagogic hypersynchrony are rarely recorded after age 10. The paroxysmal type persists into the mid-teens or, rarely, into adulthood. In infancy and early childhood, 20- to 25-Hz beta is also a prominent feature of drowsiness. The beta rhythm may have maximum

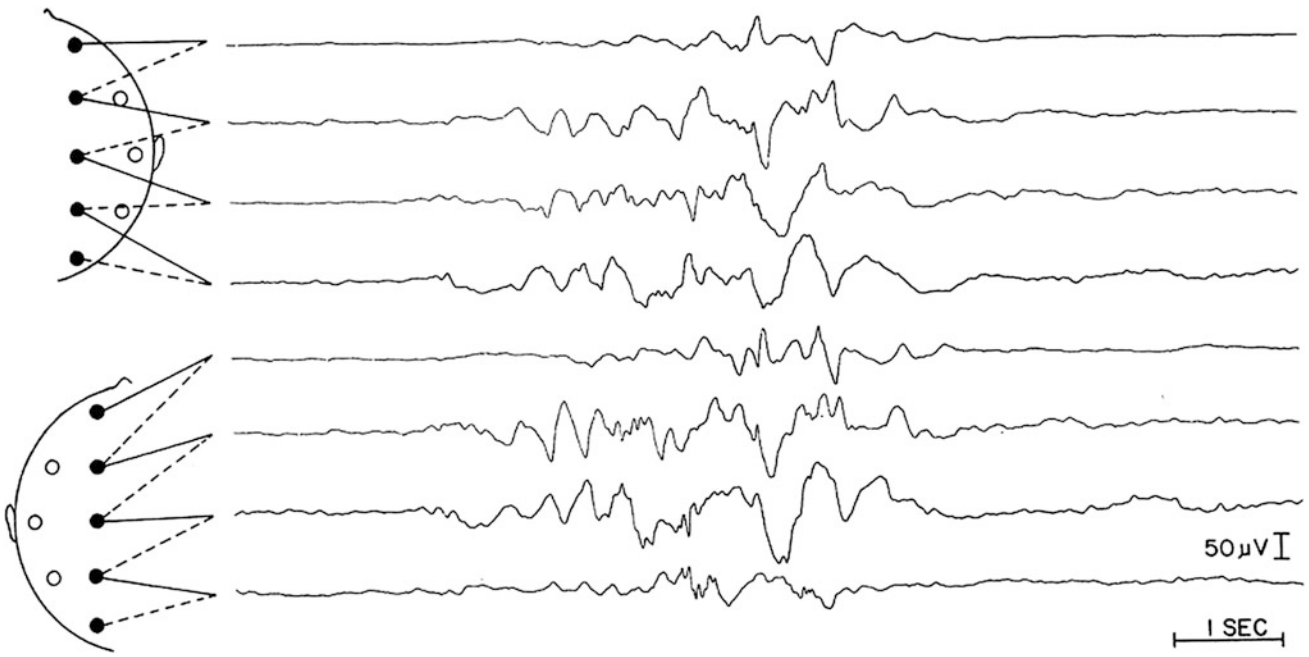

Fig. 18.14 Pattern of quiet sleep ("trace alternant") in a normal full-term infant, 4 days old. Reproduced with permission from: Fisch and Spehlmann's EEG Primer [70]

voltage anteriorly or posteriorly or have a diffuse distribution. The amplitude may reach 60 μV. This pattern appears at 6 months and is seen most frequently from 12 to 18 months. Prevalence decreases subsequently, and prominent beta rhythm during drowsiness is rarely seen after 7 years [40].

Vertex waves may be seen around three months, and K complexes appear at age six months. These potentials are rather blunt and may reach amplitudes exceeding 200 μV in infancy and early childhood. By age five years, both vertex waves and K complexes have an increasingly spiky configuration. Mild asymmetry is quite common. They may occur repetitively in brief bursts. Sleep spindles appear at approximately three months of age. Between three and nine months of age, spindles occur in wicket-like trains often exceeding several seconds. These potentials are common at this age, often occupying as much as 15 % of Stage N2 sleep. Asynchrony between the hemispheres is the rule, with only half of the trains demonstrating interhemispheric synchrony at six months. Interhemispheric synchrony increases to 70 % by 12 months and the duration and frequency of the spindle bursts gradually decrease. By two years of age, virtually all spindle trains are synchronous; however, spindles are much less frequent, occupying only 0.5 % of Stage II sleep. Spindles remain infrequent until approximately five years of age [41–43].

Stage N3 sleep is marked by slow activity, as in adults, but the amplitude of the slow activity is usually higher. An occipitofrontal gradient is often present with a very high amplitude, slower frequencies predominating posteriorly, and lower amplitude, faster frequencies predominating anteriorly. This gradient becomes less striking with age, so that by five years, the slow waves are distributed more diffusely.

EEG during REM sleep in infants and children is characterized by a greater amount of slow activity than in adults. The mature desynchronized EEG with scattered alpha emerges during the mid-teens. Neonates may have up to 50 % of sleep occupied by REM, and may often directly enter sleep through REM. The percentage of a normal night's sleep occupied by REM gradually decreases from 40 % at age 3–5 months to 30 % at age 12–24 months and then gradually assumes adult values by about six years. REM onset latency gradually lengthens over the first year of life as well [44, 45].

Abnormal EEG

While EEG abnormalities on PSG recordings are not very common, the polysomnographer must be familiar with the most frequently occurring findings of clinical significance. This section is not intended to be an exhaustive description of all possible EEG abnormalities but is meant to provide an introduction to the most frequently encountered findings. Readers are referred to several excellent volumes that deal with EEG abnormalities in depth [5, 46–48].

Slowing

Diffuse slowing of background activity (Fig. 18.15) is probably the most commonly recorded EEG abnormality. This may range from mild slowing, where the PDR is below the expected frequency, or the background may have excessive, diffuse theta and delta activity with a normal PDR. More moderate slowing occurs when there is no clear PDR or anteroposterior gradient, and the background is diffusely in the theta or delta ranges. The most severe slowing entails a nonreactive background, generally in the delta range. Specific patterns may have their own significance; for example, frontal intermittent rhythmic delta activity (FIRDA) is often seen with midline or diffuse lesions and triphasic waves (described in greater detail below) may be seen with a variety of toxic-metabolic encephalopathies. Before concluding that an EEG has excessive slowing of background frequencies, the polysomnographer must consider the patient's age and state of alertness. More diffuse theta is seen in normal children than is acceptable for adults. Frequency of background rhythms must be assessed while the patient is clearly awake. As noted earlier, both slowing of alpha rhythms and diffuse slower frequencies are commonly found in drowsiness in normal subjects. Consequently, the polysomnographer must be certain that the background frequencies are slow during wakefulness. Unfortunately, diffuse slowing of background frequencies is a very nonspecific pattern. It is commonly interpreted as being consistent with a variety of diffuse encephalopathies, including toxic, metabolic, and degenerative encephalopathies but is generally unable to distinguish between them.

Focal slowing (Fig. 18.16) refers to slow frequencies that predominate over one discrete region of the brain. Electrocerebral activity elsewhere is normal or generalized slowing is present but is relatively mild. A structural lesion must always be suspected when persistent focal slowing is recorded, although this may not always be reflected in brain imaging [49]. In epilepsy patients, this slowing may be due to an ongoing local ictal phenomenon (such as in patients with temporal intermittent rhythmic delta activity [TIRDA], see below) or may be a transient postictal finding.

Another important abnormality is background attenuation, where activity over one region or one hemisphere is of lower amplitude than the other. Any fluid collection between the cortex and the recording electrode attenuates the recorded EEG activity. Thus, subdural fluid collections and

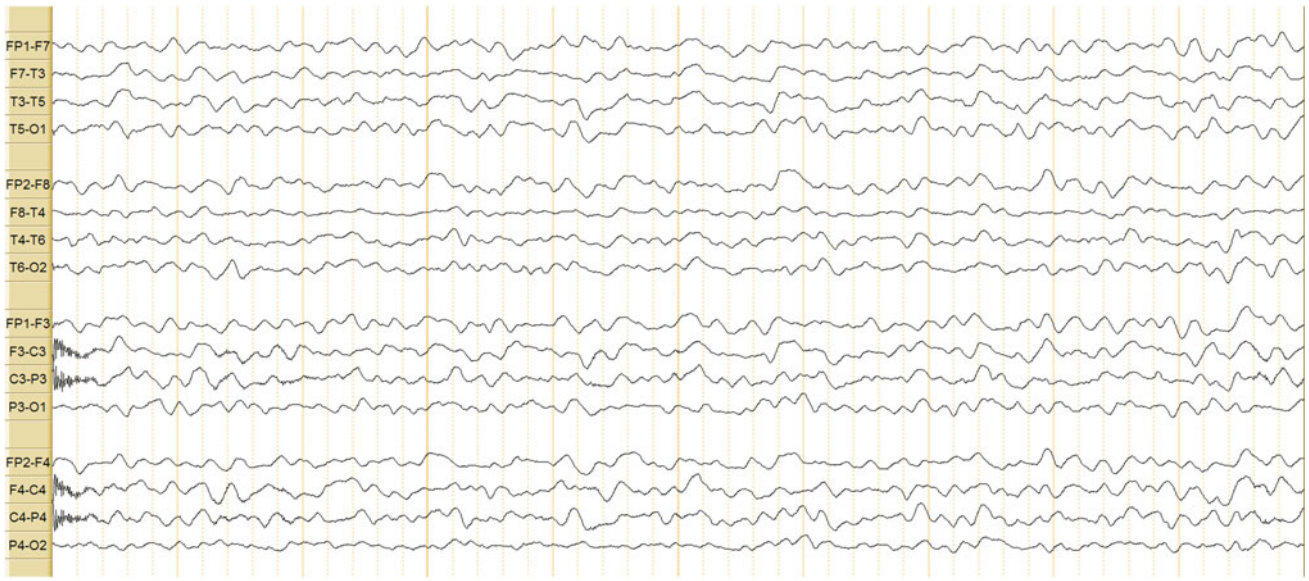

Fig. 18.15 10 s EEG epoch recorded from an 81-year-old woman with mild cognitive impairment. Note the slow, disorganized background and slow, ill-defined, and ill-sustained posterior dominant rhythm in the theta range (6–7 Hz). This is suggestive of a nonspecific toxic metabolic encephalopathy

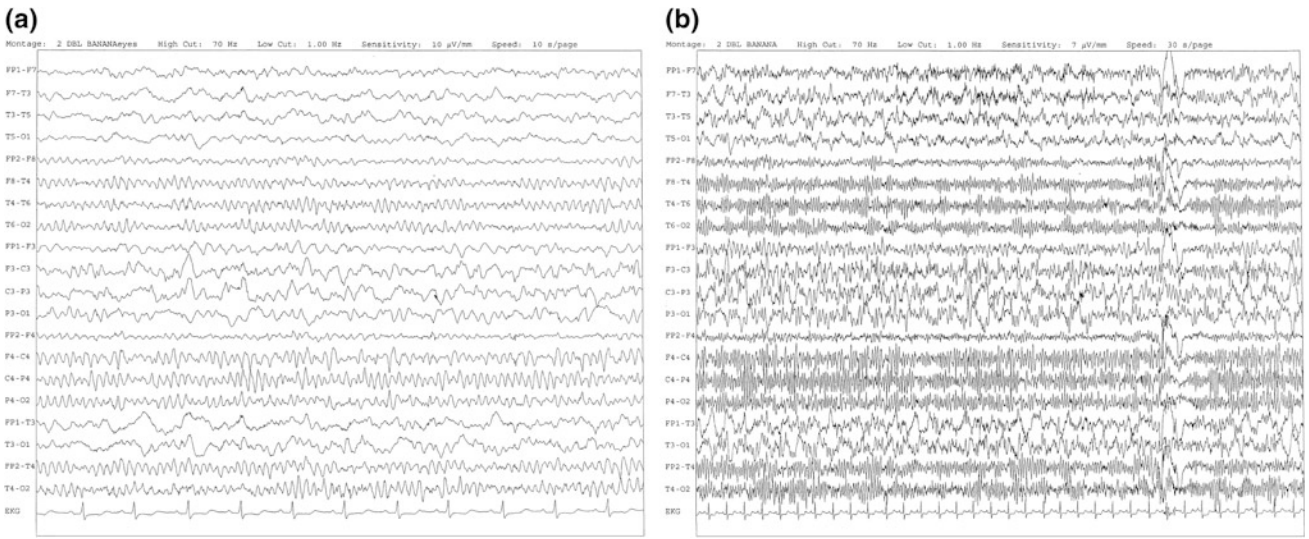

Fig. 18.16 **a** 10-s and **b** 30-s EEG epoch shows focal slowing at 3–6 Hz over the left temporoparietal region in an 85-year-old man with history of a stroke. Normal alpha rhythm at 10–11 Hz is noted on the right side. Reproduced with permission from: Chokroverty and Thomas [65]

subgaleal hematomas may result in a focal attenuation of background, although the cortex may not be damaged.

The converse situation exists when a section of skull is missing or the skull has a defect, which results in a breach rhythm. Without the attenuating effect of bone, local electrocerebral activity is of higher amplitude, more sharply contoured, and may display more fast frequencies than its counterpart in the other hemisphere. Such skull defects are generally a result of neurosurgical intervention to address an underlying brain lesion; hence, there is frequently slowing and possibly also sharp activity interspersed with breach rhythms. Determining the epileptogenic potential of such activity often poses a challenge to even the most experienced electroencephalographer.

Epileptiform Activity

EEGs cannot be interpreted in isolation; as the old adage goes, the clinician must treat the patient, not the EEG. Epilepsy is a clinical diagnosis. Therefore, history must be obtained from patients, relatives, witnesses, or medical personnel. The history must include descriptions of preictal, ictal, postictal, and interictal phenomena, family and drug histories, as well as history of any significant medical or surgical illnesses that might be responsible for triggering the seizures. A meticulous and thorough physical examination must be conducted to find any evidence of neurological or other medical disorders before ordering an EEG. EEG is the single most important diagnostic laboratory test for patients with suspected seizure disorder, when ordered appropriately in light of the patient's history and physical examination findings. Certain characteristic EEG waveforms correlate with a high percentage of patients with clinical seizures and therefore can be considered of potentially epileptogenic significance. These epileptiform patterns consist of spikes, sharp waves, spike and waves, sharp and slow-wave complexes, as well as evolving pattern of rhythmic focal activities, particularly in neonatal seizures. In addition, a pattern that correlates highly with complex partial seizure is temporal intermittent rhythmic delta activity (TIRDA) (Fig. 18.17). Another pattern that is considered a marker of the seizure onset zone is interictal scalp high-frequency oscillations (HFOs) consisting of gamma frequency activity (30–80 Hz), ripples (80–250 Hz), and fast ripples (250–1000 Hz), recorded noninvasively using amplifiers with appropriate filter settings (Fig. 18.18). Therefore, recording HFOs may help map epileptogenic zones.

Recognition of a spike or a sharp wave depends on the presence of certain characteristics [50]. A spike is defined as a waveform, which suddenly appears out of the background rhythm with a brief duration of 20–70 ms showing a field of distribution and is often followed by an after-going slow wave (Fig. 18.19a). It must also have a field, i.e., there must be some evidence of the area of cortical negativity over adjacent electrodes. A sharp wave fulfills all the criteria described for a spike except that the duration is 70–200 ms. Generally, spikes or sharp waves are surface negative (resulting in phase reversals in bipolar montages, see discussion above). The characteristic feature of a true epileptiform spike or sharp wave is a biphasic or triphasic appearance with a sharp ascending limb followed by a slow descending limb in contrast to augmented background rhythm of sharp contour, which is generally monophasic and has uniform ascending and descending limbs (Fig. 18.19b). The amplitude of a true epileptiform spike or sharp wave is at least 30 % higher than the background activity, and often there is a disturbance in the background rhythm in the neighboring region of the spikes or the sharp waves. Spike and waves, and sharp- and slow-wave complexes may be transient or may repeat for several seconds or longer, and in some patients these repeat in a rhythmic manner, such as may be seen in patients with absence seizure showing 3-Hz spike and wave complexes in the EEG (Fig. 44.1).

Fig. 18.17 10 s EEG epoch shows left temporal intermittent rhythmic delta activity (TIRDA) during wakefulness in a 30-year-old woman with partial complex seizures. Reproduced with permission from: Chokroverty and Thomas [65] (Figures 2–7 from Atlas 2nd edition)

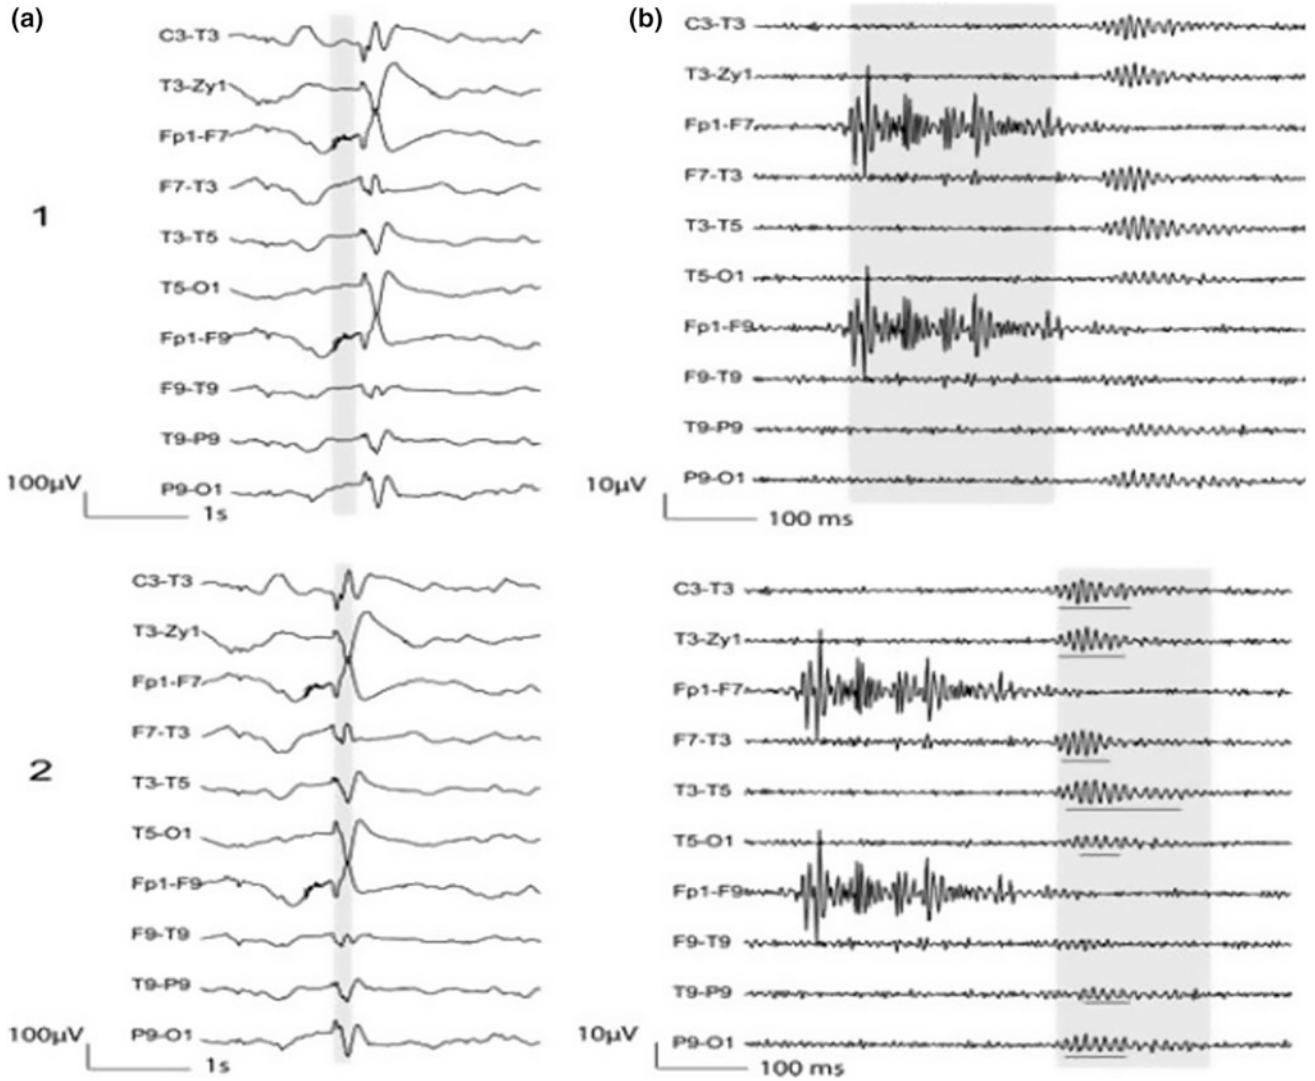

Fig. 18.18 *1* Short EMG burst, which could be mistaken for ripples but are actually artifactual oscillations. *2* Ripples co-occurring with sharp wave. **a** Raw EEG. **b** EEG filtered with high-pass filter of 80 Hz. Gray section in A is expanded in time and amplitude in B. Note that for this figure the calibration is different in the left and right part of the figure but is the same for the top and bottom parts. Ripple oscillations are underlined. The waveform morphology of nonartifactual fast oscillations is more rhythmic and regular in amplitude and frequency than artifactual oscillations. A basic distinction is made between generalized and focal epileptiform discharges. Generalized epileptiform discharges indicate that the patient's seizure is likely to start simultaneously throughout the brain. An example is the aforementioned generalized 3-Hz spike and wave that is characteristic of petit mal absence seizures. Focal epileptiform discharges indicate that the patient's seizure is likely to start in a restricted area of the brain, although it may subsequently spread. An example is the anterior temporal sharp wave that is characteristic of complex partial seizures of temporal lobe origin (Fig. 18.20). This is an important distinction because the treatment and prognosis in these two epilepsy syndromes are very different.

It is important to distinguish between epileptiform activity, which portends a potential propensity toward seizures, and an actual electrographic seizure. Many electroencephalographers liken this distinction to the difference between the weather being cloudy (epileptiform activity on an EEG) and it actually raining (an electrographic seizure). When spikes, sharp waves, or rhythmic slow waves increase in frequency and rhythmicity and evolve in location and distribution, a seizure is recorded. If there is a clinical correlate to this finding, it is called a clinical seizure, otherwise it remains an electrographic or nonconvulsive seizure. It is therefore crucial that the technician be ever vigilant during the recording and carefully document any abnormal behavior

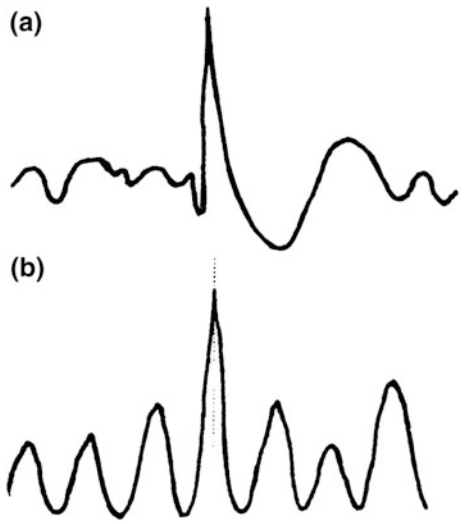

Fig. 18.19 Diagram of epileptic spike (**a**) and an augmented background sharp rhythm (**b**) (From Ajmone-Marsan [67], with permission)

on the patient's part. However, it is rare to observe the occurrence of a clinical seizure during an EEG recording (see Chap. 44). Therefore, a definitive statement about the diagnosis of epilepsy in a particular patient cannot be made even in the presence of the characteristic EEG signs of epilepsy. Approximately 90 % of adults with epileptiform discharges will have a history of seizures, and incidental epileptiform discharges are very uncommon in normal adults [51, 52].

In patients suspected of seizure disorder, it is advantageous to include activation procedures such as sleep, hyperventilation, and photic stimulation during routine EEG recording in the daytime in order to bring out the ictal or interictal epileptiform patterns. Special basal temporal electrodes (T1, T2 and sphenoidal electrodes) should be used in addition to the routine electrode placement in patients suspected of partial complex seizure. Many patients are referred to the sleep laboratory with suspected nocturnal seizures, and as described above, in such patients, the PSG study must include multiple EEG channels covering the parasagittal and temporal regions bilaterally.

Epileptiform Patterns in Sleep

Patients with focal or generalized seizures may sometimes present only during night. On the one hand, such nocturnal seizures may be mistaken for other motor disorders during sleep such as parasomnias. On the other hand, patients with a variety of sleep-related movement disorders (severe sleep apnea, periodic limb movements in sleep, hypnic jerks, confusional arousals, and night terrors) are misdiagnosed as having nocturnal seizures. It is, therefore, important for the sleep specialists to be familiar with the clinical and EEG patterns seen in primary generalized seizure (e.g., absence spells or generalized tonic–clonic seizures) and partial complex seizures of temporal or extratemporal (frontal) origin.

Patients with nocturnal frontal lobe epilepsy are often referred to the laboratory for PSG recording (see Chap. 44). The characteristic EEG pattern in the primary generalized epilepsy of the absence type is the presence of symmetrical and synchronous frontally dominant 3-Hz spike and wave discharges (Fig. 44.2) seen either as an ictal or as an interictal pattern. EEG immediately before and after this discharge remains normal. Patients with tonic–clonic seizures may show a sudden burst of spike and slow waves beginning at a rate of 4–6 Hz and then gradually slowing down and stopping before the postictal

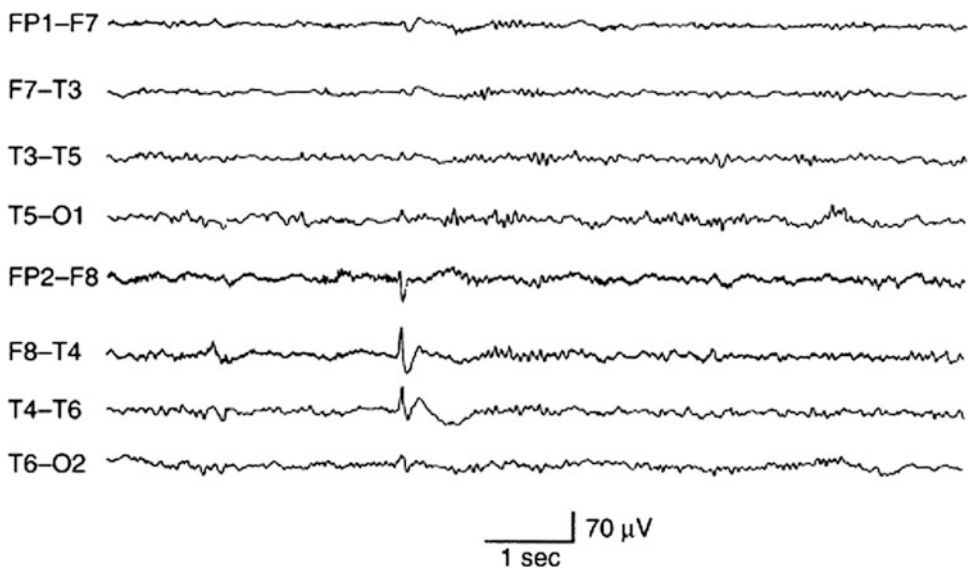

Fig. 18.20 Right temporal interictal epileptiform discharge in a 32-year-old patient with complex partial seizures. Calibration: *vertical bar* 70 µv, *horizontal bar* 1 s (Reproduced with permission from Emerson [71]

period. These discharges are seen in a bilaterally symmetrical and synchronous fashion. Postictal slow waves are followed by gradual recovery to the preictal normal background rhythm after several hours or sometimes after a day or two. Interictal EEG may show generalized synchronous and symmetrical 4- to 6-Hz spike- and slow-wave discharges or multiple spike and waves.

Some patients with generalized tonic–clonic and partial complex seizure may also have predominantly nocturnal seizures. It is well known that sleep deprivation can lower seizure threshold; indeed, sleep-deprived EEGs increase the yield of identifying epileptiform activity.

In addition, certain types of seizures are characteristically observed during sleep or at sleep–wake transition, and so it is important to differentiate nocturnal seizures from motor and behavioral parasomnias and other movement disorders persisting during sleep. Tonic seizures are typically activated by sleep, occur frequently during NREM sleep, and are never seen during REM sleep. A typical EEG shows interictal abnormality as slow spike and waves intermixed during sleep with trains of fast spikes. Benign focal epilepsy of childhood with centrotemporal spikes is characterized by the presence of centrotemporal or rolandic spikes or sharp waves (Fig. 44.7). Seizures generally resolve by the age of 15–20 years without any neurologic sequelae. Juvenile myoclonic epilepsy (Fig. 18.21) typically shows in the EEG synchronous and symmetrical multiple spikes and

Note the recording at 30 mm/sec (10 s epoch, conventional EEG speed) on the *left* (**a**) and at 10 mm/s (30 s epoch, conventional polysomnogram speed) on the *right* (**b**) (From Chokroverty and Montagna [72]) (Figures 2–30 from Atlas 2nd ed)

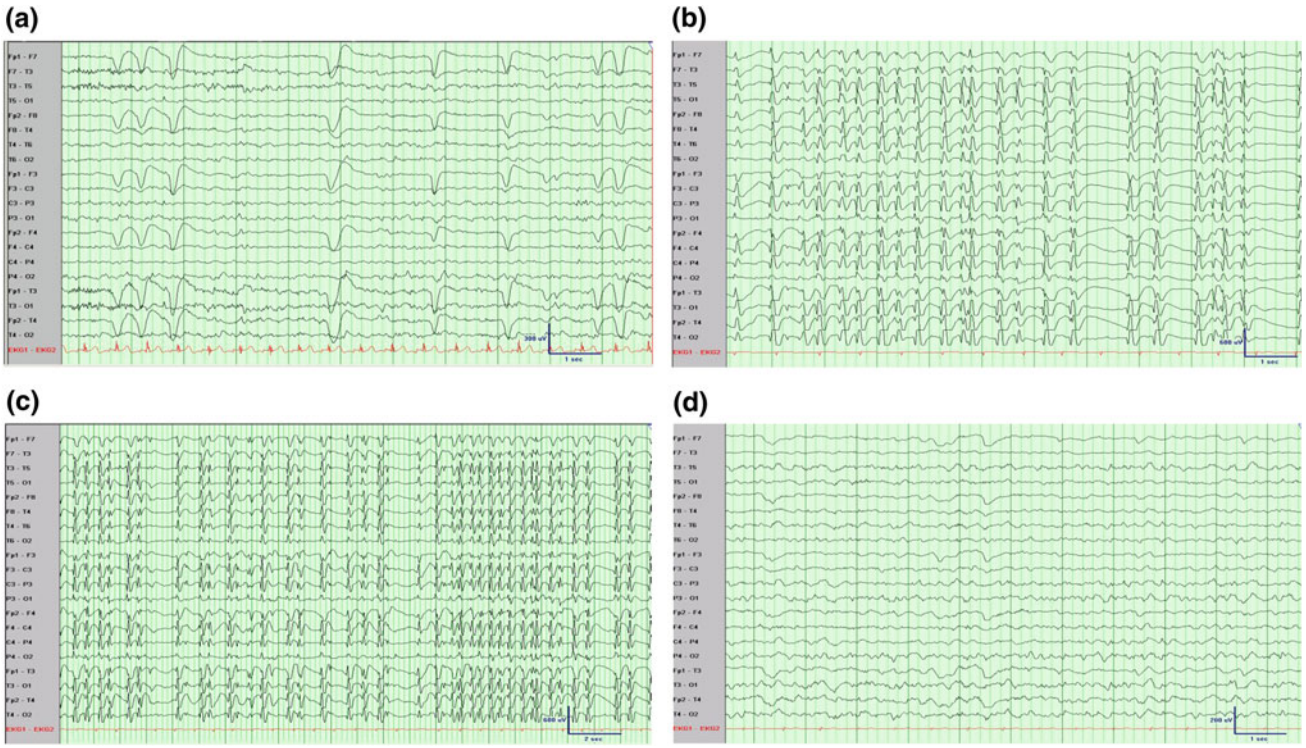

Fig. 18.22 EEG tracings from a 9–year-old boy with developmental delay and poor speech output and nocturnal events of uncertain etiology. **a**: 30 mm/s epoch of wakefulness showing eye blinks in the bilateral frontopolar leads with no evidence of epileptiform activity. **b**: 30 mm/s EEG epoch of Stage N3 sleep. The patient had 2–3.5 Hz continuous generalized spike and wave discharges with 1–2 s of electrocerebral decrement (continuos spike and wave in slow-wave sleep, CSWS). **c**: Same epoch as B, displayed at a speed of 10 mm/s (the usual speed at which polysomnograms are reviewed). **d**: 30 mm/s EEG epoch of rapid eye movement (REM) sleep in the same patient showing absence of epileptiform activity (Reproduced with permission from Neiman et al [68])

spike-wave discharges. The EEG in the entity of continuous spike and waves during NREM sleep consists of generalized 2- to 2.5-Hz spike and wave discharges occupying 85 % of slow-wave (CSWS) sleep and are suppressed during REM sleep (Fig. 18.22). This entity is generally seen in children and is associated with developmental regression; it may be mistaken for autism and illustrates the importance of capturing sleep even on daytime EEGs [53].

Chapter 44 discusses the relationship between clinical seizures and sleep in greater detail.

Nonepileptiform Patterns Mimicking Epileptiform Discharges

There are several nonepileptiform EEG patterns that may mimic epileptiform discharges but are not of epileptogenic significance. They are benign in nature, but the inexperienced electrencephalographer and polysomnographer may misread these completely normal variants as abnormal findings. Familiarity with them is the key to avoiding an erroneous report of epileptiform activity, which may lead to unnecessary further testing and unwarranted medication administration. Some commonly seen normal variants are described below.

Benign Sharp Transients Seen During Sleep and Wakefulness

A number of normal variants with sharply contoured morphology occur in sleep and wakefulness, and may perplex a polysomnographer unless they are identified correctly. However, they are all benign phenomena with no clinic significance.

Positive occipital sharp transients (POSTs) (Fig. 18.23) are diphasic or triphasic sharp waves with a predominant positive phase at the occipital electrodes and generally occur in drowsiness and early Stage N1. POSTs are noted synchronously over the two hemispheres and may occur singly or in runs. Occasional shifting amplitude asymmetry is noted in normal controls; however, persistent significant asymmetry should raise suspicion of a posterior lesion. Because, these potentials have a paroxysmal sharply contoured appearance, they may be confused with epileptiform discharges [54]

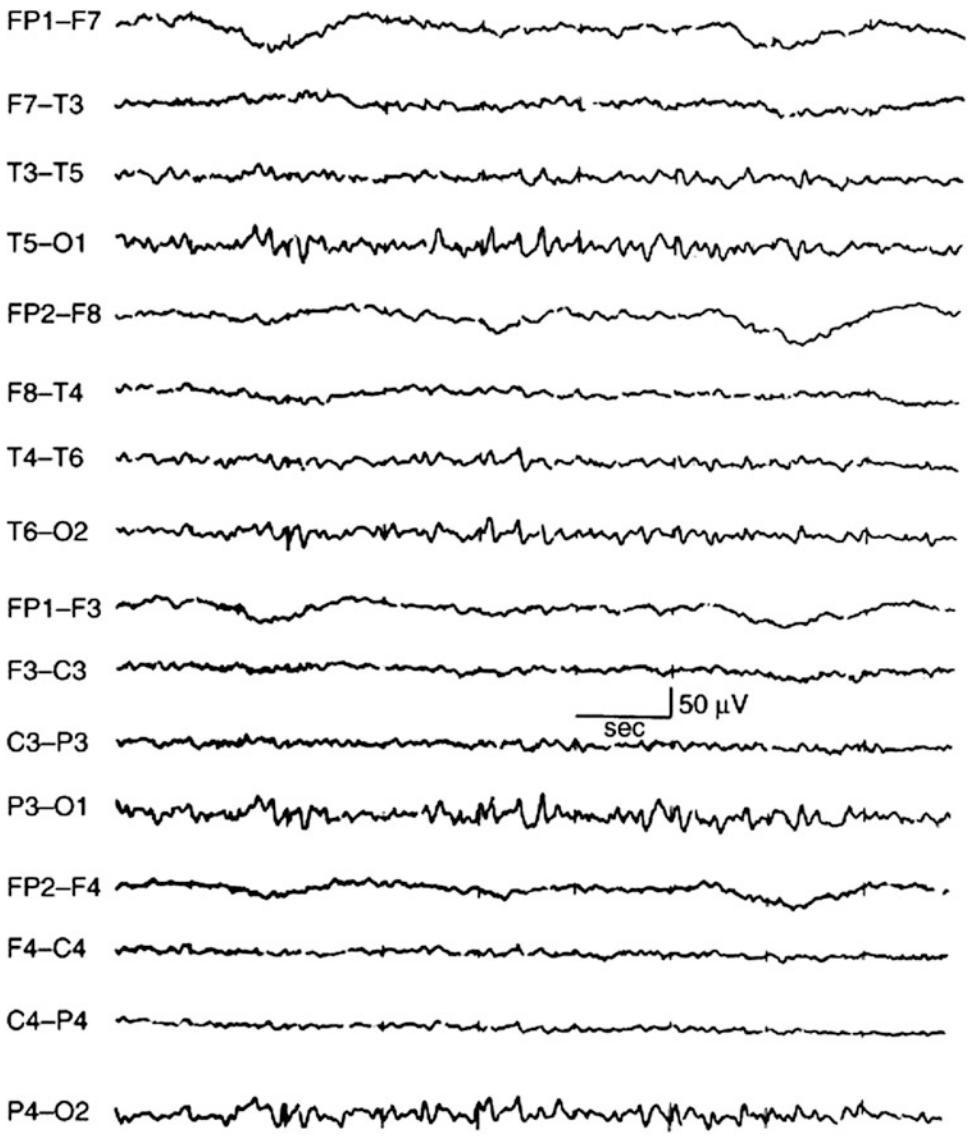

Fig. 18.23 **a** A 30-s epoch from nocturnal polysomnography recording. Positive occipital sharp transients of sleep (POSTs) are seen bilaterally in posterior temporal and occipital electrodes recorded during Stage II nonrapid eye movement sleep. **b** Same subject data as in A viewed at a 10-s epoch

Lambda waves (Fig. 18.24) are present in approximately 75 % of young adults and become somewhat less common as individuals age. Lambda waves assume a diphasic or triphasic waveform with the most prominent phase being positive at O1 or O2, morphologically similar to POSTs. The lambda wave is elicited by saccadic eye movements and appears to be an evoked response. It is present only during wakefulness with eyes open and scanning, in contradistinction to POSTs with which they may otherwise be confused.

Mu rhythms, seen in approximately 20 % of routine daytime EEGs, most commonly in young adults, consist of brief trains of 7–11 Hz waves over the central regions. The waves have a wicket or arciform shape (Fig. 18.25). Mu may occur synchronously or independently over the two hemispheres. This rhythm shows a characteristic reactivity. Active or passive movement of the contralateral limbs or even an intention to move the limb attenuates mu activity. Mu is seen during wakefulness and may become more prominent during stages N1 and N2. It typically disappears in slow-wave sleep and may reappear during REM sleep [55]. This has led to the conclusion that mu is an "ubiquitous rhythm of the sensorimotor cortex at rest."

Posterior slow waves of youth (Fig. 18.26) are found in the occipital regions bilaterally after 2 years in as many as 10 % of normal subjects. Prevalence is highest at approximately age 10 and gradually decreases afterwards. These waveforms rarely occupy more than 25 % of the record, and they do not significantly exceed amplitude of other background rhythms. They react to eye opening in the same manner as the alpha rhythm; these waves are in fact considered a variant of the alpha rhythm.

Benign epileptiform transients of sleep (BETS), also known as small sharp spikes (SSS) (Fig. 44.8), is seen in 5–24 % of normal subjects. These are spiky, often diphasic

Fig. 18.24 10 s EEG epoch showing lambda waves (in *red box*) recorded from a 16-year-old female with a history of a syncopal spell. She was scanning ceiling tiles at the time of the recording. Note the surface positive, occipitally predominant activity occurring simultaneously with rapid eye movements recorded in the frontal channels. Reproduced with permission from: Chokroverty and Thomas [65]

transients with a broad field of distribution, usually involving both hemispheres. They typically shift from side to side and become less frequent during deeper sleep stages. Although BETS may superficially resemble epileptiform spikes, they are not associated with seizure disorders [56, 57].

The 6-Hz *spike and wave* (Fig. 18.27) may be noted in either the frontal or temporal regions. The spike component usually has a relatively low amplitude, whereas the following slow wave is more prominent. For this reason, it is also known as phantom spike and wave, with the "phantom" referring to the subtle spike component (perhaps less confusingly, it may be referred to as "wave-and-phantom spike.") Paroxysms of such activity rarely last longer than 3 s, have an evanescent quality, and are less common during deeper sleep. It occurs in two variants with descriptive acronyms, the WHAM (wake, high amplitude, anterior, men) and FOLD (female, occipital, low amplitude, drowsy). Despite their paroxysmal quality, they are not associated with epilepsy [58].

The *Ciganek rhythm* (Fig. 18.28) is a 4–7 Hz, midline, somewhat sharply contoured waveform seen in drowsiness and early NREM sleep [59], but occasionally in REM sleep as well. Its field is generally maximal at Cz and while it may have a waxing and waning amplitude, it generally does not evolve or spread to other locations. While in the past it was thought to have epileptogenic significance, it is now considered a normal variant.

Epileptiform-like Patterns Without Epileptogenic Significance

While the typical polysomnographer is unlikely to encounter most of the following patterns during a PSG, they all have specific clinical significance and are important to be able to identify.

Triphasic waves (Fig. 18.29) have an initial positive deflection and characteristic distribution. These are seen synchronously and symmetrically with frontal dominance of the amplitude with anteroposterior phase shift. Triphasic waves are not of epileptiform significance. The pattern has classically been described in hepatic encephalopathy and correlates with serum ammonia level. Triphasic waves may also be seen in other metabolic or toxic encephalopathies (e.g., renal or respiratory failure). Sometimes these are also seen in anoxic encephalopathies. Their presence suggests a rather severe degree of encephalopathy.

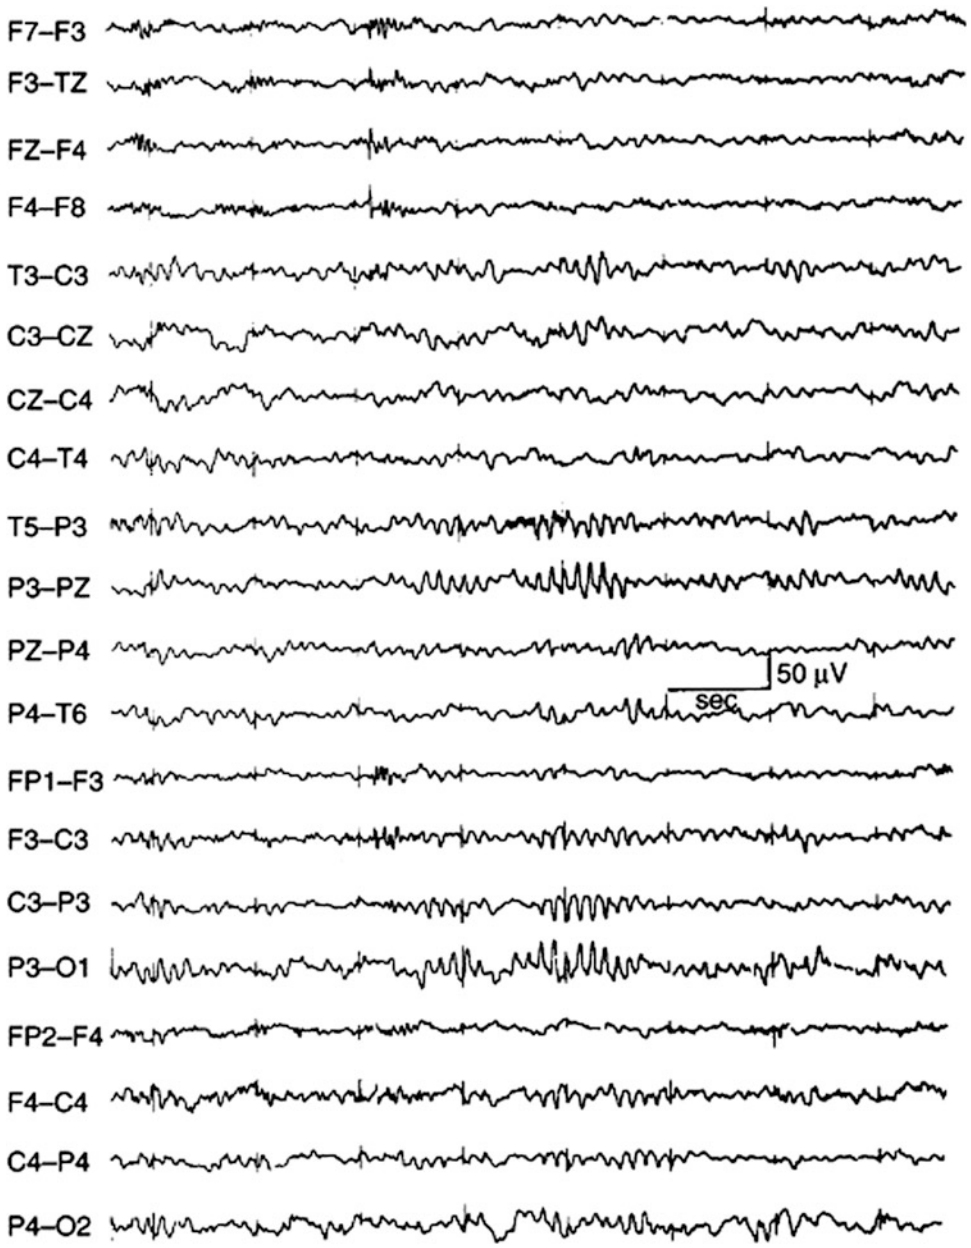

Fig. 18.25 Mu rhythm in the left parietal region (P3). Note phase reversal of the 7- to 8-Hz comb-like rhythm at P3 with spread of activity to C3

Periodic lateralized epileptiform discharges (PLEDs) are another important pattern to recognize. In this pattern, stereotyped sharply contoured discharges are recorded continuously over a given region (Fig. 18.30). They occur at regular intervals, usually every 1–2 s, and are thus labeled periodic. Background activity is usually significantly attenuated on the side with the discharges, and excessive slow frequencies are often seen bilaterally. This pattern is usually associated with an acute focal cerebral insult, most commonly an acute cerebral infarction, infection, anoxia, or other causes. Clinically, PLEDs are associated with obtundation, seizures, and focal neurologic deficits. Whether PLEDs themselves are ictal or interictal waveforms remains controversial. However, certain specific PLEDs patterns, known as PLEDs-plus, characterized by PLEDs with high-frequency, low-amplitude multispikes have a stronger

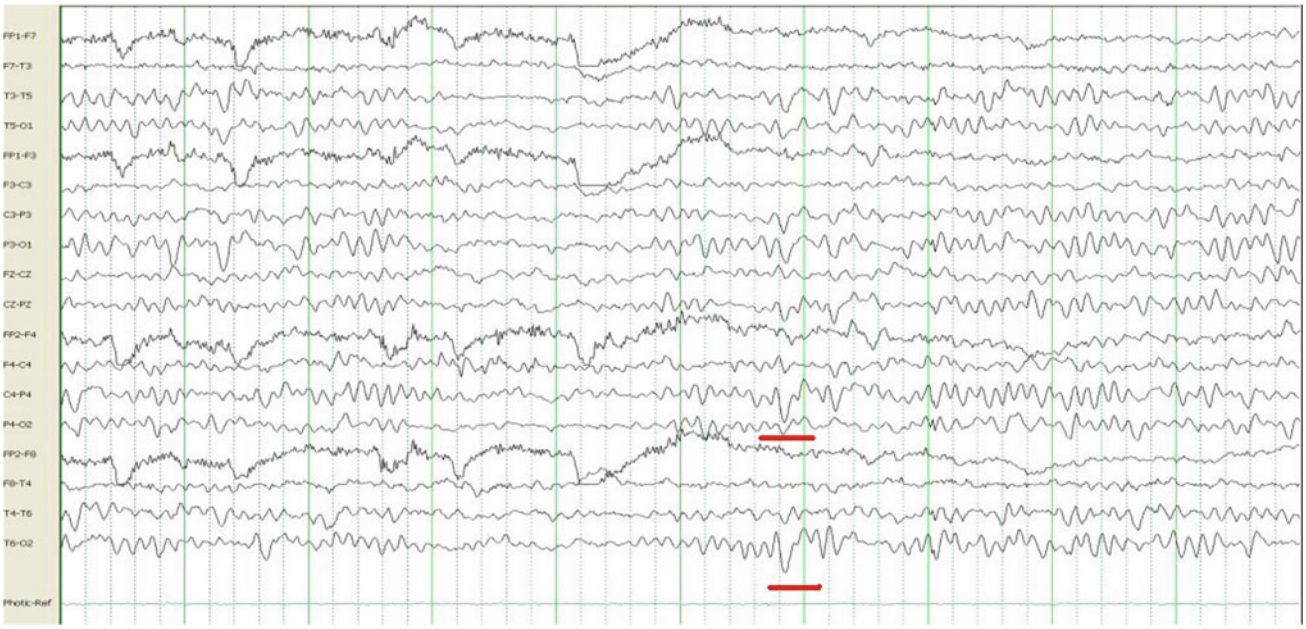

Fig. 18.26 A 15-year-old female patient with history of new onset of seizures. The EEG in wakefulness shows slow waves of youth (*underlined in red*) at 2 to 3 Hz superimposed intermittently on occipital alpha rhythm at 9 to 10 Hz bilaterally. This is a normal finding between ages 2 and 21 years of age, most commonly occurring between 8 and 14 years of age, and attenuates with eye opening. Reproduced with permission from: Chokroverty and Thomas [65]

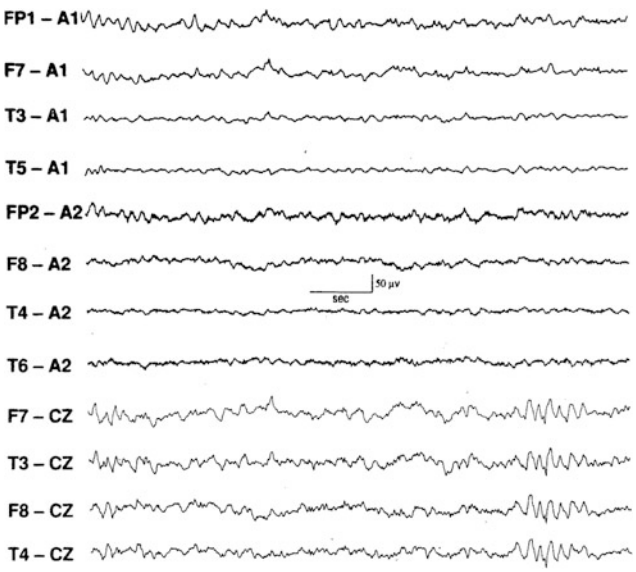

Fig. 18.27 Six-hertz spike and wave pattern seen in the last four channels. (From: Walczak T, Chokroverty S (2009). correlation with clinical seizures than simple PLEDs [60]. Of note, PLEDs can occur independently over the two hemispheres (known as BiPLEDs) or the discharges may be generalized (generalized periodic epileptiform discharges, GPEDs) [61–63, 64].

Artifacts

Given the relatively small voltages that the EEG, EOG, EMG, and ECG channels are intended to record, it is not surprising that artifacts from extraneous electrical activity, though not of clinical relevance, may obscure the biological signals of interest in these channels. Nevertheless, making the distinction between the signal of interest and artifact is a central task for the polysomnographer. Artifacts may come from the environment (50 or 60-Hz artifact, telephone or pager artifact, intravenous drip artifacts), the patient (ECG artifact in non-ECG channels, artifacts from deep brain stimulators, vagus nerve stimulators and pacemakers, movement, sweat and respiratory artifacts), or from the equipment (electrode artifacts and pops from

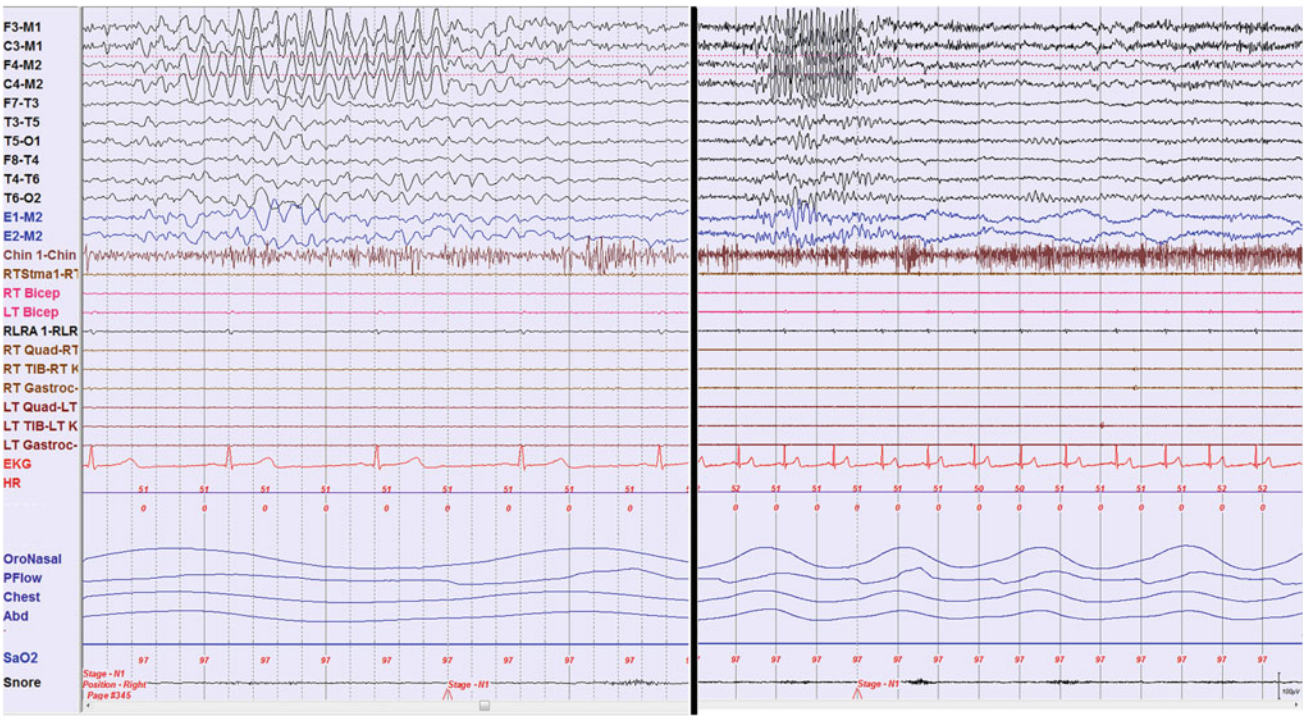

Fig. 18.28 10-s (*left*) and 30-s right epochs of Stage N1 sleep from the overnight PSG of a 35-year-old woman referred to the sleep laboratory for abnormal movements in sleep, later diagnosed to be intensified hypnic jerks. Note the occurrence of a burst of 6–7 Hz theta range slowing in the bilateral parasagittal leads (F3-M1, C3-M1; F4-M2, C4-M2), not evident in the bitemporal leads (F7-T3, T3-T5, T5-O1; F8-T4, T4-T6, T6-O2). This rhythm, known as a midline theta of drowsiness or Ciganek's rhythm, is a variant usually occurring in drowsiness or light sleep. It is considered to be benign but may be mistaken for epileptiform discharges. Chin1-Chin2, submental electromyogram (EMG); RT Stma1, right sternomastoideus EMG; RT Bicep; LT Bicep, right and left biceps brachii EMG; RLRA, right lateral rectus EMG; RT Quad; LT Quad, right and left quadratus femoris EMG; RTIB; LTIB, left and right tibilais anterior EMG; LGAST; RGAST, left and right gastrocnemius EMG; ECG, electrocardiogram; HR, heart rate; OroNasal, oronasal airflow; Pflow, nasal pressure transducer recording; SaO2, arterial oxygen saturation by finger oximetry. Also included is a snore channel

improperly placed or loose electrodes or poor impedence). An ever-vigilant, alert, and experienced technician is the first and best defense against artifact. The technician must strive to eliminate the artifact during the recording; if this is not possible, the source of the artifact must be meticulously recorded and the interpreter must identify the artifact as such. Artifacts are dealt with in great detail in Chap. 17.

Summary

The EEG plays a central role in the interpretation of a PSG. While unfortunately, the limited number of inputs available on standard PSG equipment results in a suboptimal number of channels available for EEG recording, the use of multiple channels dedicated to the EEG allows the polysomnographer to better determine whether a suspicious waveform is artifact, a normal variant, or of clinical significance. Polysomnographers require a thorough knowledge of the fundamentals of EEG recording and interpretation. This includes the nature of physiological changes that generate EEG potentials, basics of electronics such as differential amplification, filters and sensitivities, and the ability to identify common artifacts and benign waveforms.

Electrocardiography: Principles and Applications in Sleep Medicine

19

Daniel M. Shindler and John B. Kostis

A wealth of information is available about cardiac rate and rhythm disturbances during sleep. Twenty-four-hour ambulatory electrocardiography (ECG) has made it possible to study cardiac rhythm in both awake and sleeping subjects. For most practical purposes, it is possible to think about cardiac rhythm during sleep in the same way as during wakefulness, although the average heart rate is slower during sleep. As a result, escape-type arrhythmias may appear or become more frequent. One should first be familiar with the normal behavior of the heart and subsequently become familiar with a simple classification of cardiac arrhythmias.

Normal Cardiac Rhythm

The normal cardiac rhythm is defined as a normal sinus rhythm —that is, the cardiac rate is between 60 and 100 bpm and the cardiac impulse originates in the sinus node. This is best confirmed by identifying a normal-looking P wave that is followed by a normal and constant PR interval and is always succeeded by a single QRS complex. It is quite normal for cardiac cycle length (R–R interval) in a given patient to be somewhat variable. This is referred to as *sinus arrhythmia* (Fig. 19.1) [1–3]. The heart rate of children and infants is faster than the heart rate of adults. The rate of the sinus node is influenced by the autonomic nervous system.

Cardiac Arrhythmias

Arrhythmias are due to disturbances of impulse formation, impulse conduction, or a combination of the two. Arrhythmias can be separated into two large groups. Those that originate in the sinus node, atria, or atrioventricular (AV) node are referred to as *supraventricular arrhythmias*; those that originate in the ventricles are classified as *ventricular arrhythmias*. Figures 19.2, 19.3, 19.4, 19.5, 19.6, 19.7, 19.8, 19.9, 19.10, 19.11, 19.12, 19.13, 19.14, 19.15, 19.16, 19.17, and 19.18 illustrate a variety of cardiac arrhythmias.

Supraventricular Arrhythmias

When the QRS complex is narrow, the arrhythmia is, with few exceptions, supraventricular. Unfortunately, when the QRS complex is wide, it is often impossible to determine conclusively whether an arrhythmia is supraventricular or ventricular. Inspection of the ECG is the first step in evaluating an arrhythmia. If the arrhythmia is considered potentially life threatening, a specialized electrophysiologic study may be required to further assess its significance.

Sinus Tachycardia

The most common rhythm disturbance (which may not be abnormal), sinus tachycardia, is an acceleration of the sinus heart rate above 100 bpm [4]. In most cases, sinus tachycardia does not exceed 180 bpm. Sinus tachycardia is best diagnosed by identifying P waves, determining that they are of normal morphology, subsequently establishing that the PR interval is normal and constant, and determining that each QRS complex is preceded by the P wave and each P wave is followed by a normal QRS. In the course of normal daily activity, the heart rate rises in a gradual fashion and subsides in a gradual fashion [5]. Sinus tachycardia can

occur during rapid eye movement (REM) sleep. Yet, patients suffering from REM sleep behavior disorder can have violent body movements without an increase in the heart rate due to the absence of autonomic arousal.

Sinus Bradycardia

The opposite boundary of normal heart rate is sinus bradycardia. Sinus bradycardia is defined as a rate slower than 60 bpm [6]. Again, it is manifested by a normal P-wave appearance, a normal and constant PR interval, and a normal relationship of the P wave to the QRS complex, with a 1:1 sequence similar to that of sinus tachycardia. One observational

Fig. 19.17 Aberrant conduction

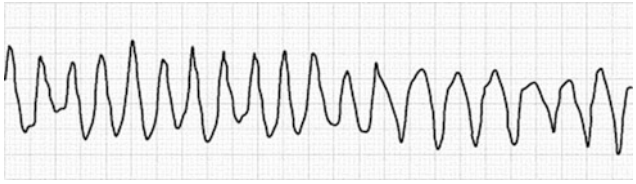

Fig. 19.18 Torsades de pointes

pitfall in the patient with sinus bradycardia is the fact that, at times, U waves become very prominent and can easily be confused with P waves. As a result, blocked premature atrial contractions can be misdiagnosed. Use of β blockers can slow the heart rate as well as cause nightmares and sleep disruption.

Sinus Arrhythmia

Sinus arrhythmia is especially easy to notice with slowing of the heart rate during sleep. The P-wave morphology usually does not change. If it does change, the changes are phasic and the P-waves do not appear retrograde. There should be a 10 % difference between the maximum and minimum cardiac cycle length. Atrioventricular conduction is normal. This is manifested as a PR interval greater than 120 ms. A shorter PR interval with an abnormal P wave would indicate that the beats are not of sinus origin. The variations in sinus cycle length may be phasic, with respiration becoming shorter with inspiration due to reflex inhibition of vagal tone. This form of sinus arrhythmia disappears with apnea.

Premature Atrial Contractions

Premature atrial contractions are observed frequently in normal subjects and patients with a variety of diseases. They are manifested as an interruption in the heart rhythm with a premature beat having a narrow QRS complex. Because the origin of the atrial impulse is ectopic, the appearance of the P wave is abnormal, denoting its abnormal early origin. There is quite a wide spectrum in the incidence and frequency of premature atrial contractions. Their nature is classified as follows: If the premature atrial contractions occur singly, they are classified according to their incidence per period of time. Therefore, an ambulatory ECG report commonly describes how many premature atrial contractions were observed in a given time, such as an hour, a minute, or 24 h, according to how common they are. When premature atrial contractions are frequent, it is customary to further describe their nature (cyclic or noncyclic) and rate. For example, when premature atrial contractions occur cyclically, they may show a bigeminal pattern.

Multifocal Atrial Tachycardia

A variant of frequent premature atrial contractions is tachycardia, which is called *multiform atrial tachycardia* or *chaotic atrial tachycardia* [7]. This is a rhythm disturbance with definite clinical significance. It is identified by an irregular heart rhythm with narrow QRS complexes and rates in excess of 100 bpm. As the name implies, it is multifocal: The atrial beats originate in multiple sites in the atria. Consequently, the appearance of the P waves varies with the point of origin. There is variability in both the P-wave morphology and the PR interval. Multifocal atrial tachycardia is an arrhythmia that may have significant consequences. It is particularly common in patients with significant lung disease. These same patients often suffer sleep disorders. When analyzing ECG recordings, multifocal atrial tachycardia should not be confused with atrial fibrillation.

Atrial Fibrillation

Atrial fibrillation is a very common rhythm disturbance that is important to diagnose, as the initial heart rate can be quite fast and drug therapy may be required to slow it down. Patients with chronic atrial fibrillation are at increased risk for thromboembolic phenomena and are therefore often admitted to the hospital for further management when this rhythm is diagnosed [8]. Management may be either rate control or attempted cardio version. Both approaches are typically accompanied by chronic antithrombotic therapy. The ECG hallmark of atrial fibrillation is a completely random and irregular heart rhythm with no reproducible R–R interval. Because the atria are fibrillating at a rate of 500 bpm, there are no P waves. The ECG baseline may appear irregular and erratic. This should not be confused with the variable P waves of chaotic atrial tachycardia or with U waves, as mentioned earlier. The ventricular rate in patients with atrial fibrillation tends to be fast when it first occurs. The rate may range around 150 bpm. A clue to underlying conduction system disease is a slow ventricular rate. In this case, caution needs to be exercised with therapeutic modalities, because of possible undesirable AV conduction problems [9, 10].

Atrial Flutter

A variant of atrial fibrillation is a rhythm disturbance known as *atrial flutter* [11]. Atrial flutter differs in that atrial activity can be diagnosed as occurring 300 times per minute. At this rate, the ECG hallmark is a characteristic sawtooth pattern at a rate of 300 bpm. The usual presentation of atrial flutter is an atrial rate of 300 bpm with some degree of block between the atria and ventricles (the usual block is 2:1). Therefore, it is quite typical to recognize atrial flutter by the presence of a sawtooth baseline with a ventricular response of 150 bpm. The therapeutic goal in atrial flutter (similar to atrial fibrillation) is to slow down the ventricular response when it is fast. Again, caution is exercised when the initial ventricular response (with no medication) is an unduly slow rate with a

conduction block of 4:1 or greater. Patients may benefit from radiofrequency catheter ablation.

Automatic Versus Re-entrant Tachycardia

The rhythm disturbances referred to earlier are classified as automatic rhythm disturbances. If properly diagnosed, they can be classified as disorders of cardiac automaticity. The warm-up phenomenon (gradual, nonabrupt increase in heart rate) is a hallmark of automatic tachycardia. Usually, an automatic tachycardia requires a search for its cause, which is then treated. For example, multifocal atrial tachycardia is typically seen in patients with lung disease, and improvement of hypoxemia often results in the return of the cardiac rhythm to normal. Sinus tachycardia frequently indicates a metabolic disturbance such as fever, thyrotoxicosis, or hypovolemia. Again, therapy of the cause is the proper approach rather than addressing the mechanism of the rhythm disturbance itself [12, 13]. Conversely, a group of tachycardias referred to as *re-entrant* are treated by addressing the mechanism of reentry. When this is corrected, the rhythm is restored to normal.

Paroxysmal Atrial Tachycardia

Paroxysmal atrial tachycardia is the classical re-entrant tachycardia treated with medications that interrupt the mechanism of reentry [14]. As the name implies, a paroxysmal atrial tachycardia begins abruptly. There is no warm-up phenomenon, and the heart rate instantly increases to between 140 and 180 bpm. It may cease spontaneously and, just as abruptly, return to sinus rhythm. It is quite common to observe these salvos of atrial tachycardia in patients, whether they are awake or asleep. When paroxysmal atrial tachycardia is persistent, it warrants treatment because of the unduly fast heart rate. Several maneuvers that increase vagal tone, such as a Valsalva maneuver or carotid sinus massage, can break the arrhythmia [15]. When these are ineffective, it becomes necessary to use medication. The calcium channel blocker verapamil was quite useful for this purpose. Subsequently, adenosine, an agent that causes complete but very transient AV block, has emerged as the modality of choice [16]. Long-term management consists of catheter ablation of the AV node.

Sick Sinus Syndrome

Various combinations of tachycardia with bradycardia may suggest the diagnosis of sick sinus syndrome. Ambulatory ECG monitoring may be required to demonstrate the presence of sinus node dysfunction [17–20]

Aberrant Supraventricular Conduction

A transient delay in intraventricular conduction can be seen in patients with supraventricular tachycardias. If the P waves are not clearly identifiable, the rhythm may be misdiagnosed as ventricular tachycardia (see *Ventricular Tachycardia* later). QRS complex morphology may be useful in making the correct diagnosis. The initial aberrant conduction occurs in the QRS complex, which terminates a short cardiac cycle immediately preceded by a long cardiac cycle [21, 22].

Ventricular Arrhythmias

The next group of rhythm disturbances, the ventricular arrhythmias, may be more hemodynamically significant and can be associated with clinically important heart disease. They can also be seen in normal patients.

Premature Ventricular Contractions

A very common rhythm disturbance often felt by patients is the premature ventricular contraction. It is most commonly an early beat that is easily recognized on the ECG as a wide QRS complex with abnormal repolarization [23]. The incidence on 24-h ECG monitoring can be reported according to how often this finding is present; therefore, premature ventricular contractions are reported as occurring a certain number of times per hour. If rare, they are classified by how many times they occur in 24 h; if very common, they may be classified in terms of occurrence per minute [24].

Ventricular Bigeminy

A very common rhythm disturbance is a sustained rhythm, especially at night, consisting of an alternating normally conducted QRS complex with a premature ventricular contraction followed by a pause and a resumption of the sequence. This is referred to as *ventricular bigeminy*. It is benign for most practical purposes, but it has some clinical implications. For example, a clinician taking a pulse may notice only the normally conducted beats. The pulse deficit might then result in a mistaken diagnosis of bradycardia.

Ventricular Tachycardia

The finding of three or more premature ventricular contractions in a row (at a heart rate faster than 100 bpm) is referred to as *ventricular tachycardia* [25], and it may be brief or sustained [26]. The most important distinction that needs to be made when ventricular tachycardia is suspected is the alternate diagnosis of supraventricular tachycardia with aberrant ventricular conduction. The diagnostic approach to this critical differential diagnosis is multifaceted. The diagnosis begins at the bedside. If the patient is hemodynamically decompensated, it is necessary to act rapidly [27, 28]. Multiple ECG leads should be used to identify P waves that mark atrial activity. Atrial P waves that are unrelated to ventricular QRS complexes make ventricular tachycardia more likely than aberrant conduction. The appearance of the QRS complex has been useful in the

recognition of a ventricular origin for tachycardia. Sustained ventricular tachycardia often degenerates into ventricular fibrillation, resulting in death [29].

Ventricular Fibrillation

Ventricular fibrillation is a lethal terminal dysrhythmia that requires immediate electrical defibrillation. There are no identifiable QRS complexes. It may begin on a T wave (this is referred to as *R on T*). It may also be seen in association with a unique ventricular tachyarrhythmia called *torsades de pointes*.

Torsades de Pointes

The morphology of torsades de pointes is unique. The points of the ventricular complexes vary in their height, appearing to turn around a central axis, the baseline of the ECG tracing. It is important to measure the QT interval. QT prolongation can be caused by electrolyte disturbances, antiarrhythmic drugs, or central nervous system or congenital disease [30–34].

Accelerated Idioventricular Rhythm

The law of the heart states that the fastest pacemaker is the one that governs the heart. Accelerated idioventricular rhythm (AIVR) is a slow ventricular rhythm that captures the heart because the sinus rate is even slower. The rate of AIVR is less than 100 bpm. It is usually faster than the typical 40-bpm ventricular escape rate (thus the term *accelerated*). This is typically an escape rhythm that should not be suppressed with antiarrhythmic agents such as lidocaine. AIVR is often short lived and has no hemodynamic consequences. In this setting, it does not require treatment. When AIVR is sustained and hypotension is observed, an agent such as atropine may be useful in overdriving the AIVR by accelerating the sinus node. The ECG diagnosis of AIVR consists of establishing the ventricular origin of the rhythm.

Brugada Syndrome

Patients with a structurally normal heart may have syncopal episodes and/or sudden cardiac death due to Brugada syndrome. This genetically determined syndrome is rare. There may be a family history of sudden death. Ventricular fibrillation may occur during sleep and may be related to nighttime bradycardia [35]. The ECG hallmark of the Brugada syndrome is a combination of right bundle branch block and ST-segment elevation in leads V_1 to V_3 (Fig. 19.19). This diagnostic ECG pattern can be evanescent and may not be present in patients at all times.

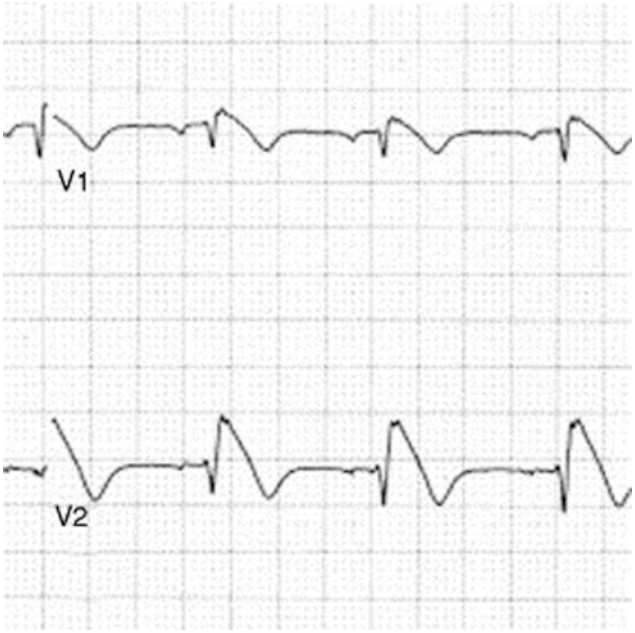

Fig. 19.19 Brugada syndrome: leads V1 and V2 show an rSR' QRS complex with ST-segment elevation in both leads

Pacemaker Rhythm

Pacemaker rhythms are identified by the pacemaker spike preceding the wide QRS complex. It is necessary to determine proper capture as well as proper sensing. Dual-chamber pacemakers are designed to restore the normal sequence of AV contraction. They are also associated with pacemaker-induced arrhythmias [36]. Some patients may have a pacemaker or defibrillator implanted to treat life-threatening ventricular arrhythmias [37, 38].

Intracardiac Recordings

Certain patients may be referred for electrophysiologic study to further evaluate their arrhythmia. The tracings obtained during those studies may demonstrate ECG information about the heart that is unobtainable from surface ECG studies. It is possible to record the electrical activity of the bundle of His. This may help decide which patients require a permanent pacemaker. The sinus node recovery time can be measured in patients with sick sinus syndrome. Ventricular arrhythmias can be induced to assess efficacy of antiarrhythmic therapy [39].

Signal-Averaged Electrocardiogram

It is possible to amplify the ECG complex by as much as 1000 times with the use of signal averaging. The signal-averaged ECG can demonstrate the presence of late potentials (high-frequency, low-amplitude signals). Their absence is associated with a more favorable prognosis after myocardial infarction.

Management of Arrhythmias Detected During Sleep

The sophisticated monitoring equipment available today permits detection of cardiac arrhythmias and conduction disturbances as they occur during sleep. Sustained ventricular arrhythmias require immediate attention. The patient needs to be awakened, and blood pressure and mental status must be determined. If the ventricular arrhythmia causes hypotension or the patient is unarousable, emergency measures may be required, but this is extremely rare. Nonsustained ventricular arrhythmias are a more common finding. Typically, by the time the patient is aroused, blood pressure is normal. The patient needs to be monitored, however, for recurrence of the arrhythmia. Conduction disturbances can also be detected. Sinus arrest is manifested by the disappearance of P waves and an area other than the sinus node taking over the cardiac rhythm. This can be a junctional, ectopic atrial, or ventricular rhythm. It is important to ascertain by ECG whether arrhythmias are, as mentioned, sustained or nonsustained. It is also worthwhile to determine whether a newly detected rhythm disturbance is a consequence of a conduction abnormality followed by an escape mechanism, rather than a premature mechanism for arrhythmia initiation such as a premature ventricular contraction. The hemodynamics, as measured by blood pressure, are the most important indicators of the significance of an arrhythmia as it is occurring. It is also important to take into account the underlying cardiac status of the particular patient in whom the arrhythmia is observed.

Evaluation and Monitoring of Respiratory Function

20

Reena Mehra and Harneet K. Walia

Evaluation of Baseline Pulmonary Function and Physiology

With increasing recognition and awareness of sleep-disordered breathing (SDB), a high proportion of patients are referred to the sleep clinic for evaluation, many of whom have comorbid factors including those that are pulmonary specific. Although some patients may carry previously diagnosed or recognized pulmonary disorders, in many situations these remain undiagnosed, and therefore, there is an opportunity to utilize the sleep evaluation to uncover concomitant pulmonary disease either through clinical evaluation or via sleep testing. It is crucial to perform a comprehensive assessment of the patient's baseline pulmonary status by obtaining a thorough medical history and performing a complete physical examination geared toward pulmonary-based issues. Medical history should focus particularly on symptoms of dyspnea on exertion or at rest, cough, sputum production, stridor, and wheezing; extensive smoking history/illicit drug use; occupational exposures; and family history of pulmonary disorders/sleep apnea and other sleep disorders. Physical examination should include a strategic assessment of the airway (e.g., Friedman classification, nasal valve incompetence, nasal septum examination, tonsillar hypertrophy, retrognathia, micrognathia, thyromegaly, macroglossia), lung auscultation (including with forced expiration) and percussion, evaluation of clubbing/cyanosis, along with comprehensive evaluation of other organ systems. A resting baseline oxygen saturation, the so-called fifth vital sign [1] should also be obtained in the clinic setting, which allows the ability to detect baseline hypoxia prior to sleep testing and prepare accordingly. If clinical suspicion of impaired pulmonary function is suspected based on initial evaluation, then testing to assess the type and severity of limitation is warranted.

Testing of Baseline Respiratory Function and Physiology

Although the testing discussed in this section is not warranted in the routine evaluation of pulmonary disorders, if a provocative history of baseline pulmonary abnormality is elicited in the context of a sleep disorder evaluation, then further pulmonary disorder diagnostic workup is indicated.

Chest X-ray/CT Chest

Radiographic assessment of the lung fields may be helpful in the context of a concerning pulmonary symptoms or examination findings particularly in the context of a smoking history of greater than 20 pack years. Radiographic review of enlarged pulmonary arteries, reticulonodular densities, lung mass, mediastinal lymphadenopathy, and interstitial/alveolar processes can be made.

Spirometry/Pulmonary Function Testing

Spirometry

Pulmonary function testing allows for the ascertainment of lung physiology and mechanics. Spirometry, or the measuring of breath, is performed with flow-volume loops and assesses the mechanical properties of the respiratory system by measuring expiratory volumes and flow rates. This test requires the patient to make a maximal inspiratory and expiratory effort. The patient in a sitting position breathes into a mouthpiece, and nose clips are placed to prevent air leak. At least three tests of acceptable

effort are performed to ensure reproducibility of results. Spirometric standards are derived from population-based epidemiologic data with the most commonly used standards from NHANES III to derive prediction equations for normative values based upon age, gender, and race/ethnicity [2]. The following are some of the measured values gleaned from spirometry:

Forced Vital Capacity (FVC): After a deep inhalation, this is the volume of air which can be forcibly and maximally exhaled out of the lungs until no more can be expired. FVC is expressed in liters.

Forced Expiratory Volume in One Second (FEV1): *After a deep inhalation, this is* the volume of air which can be forcibly exhaled from the lungs in the first second of a forced expiratory maneuver measured in liters.

FEV1/FVC: This is the ratio of FEV1 to FVC and indicates what percentage of the total FVC was expelled from the lungs during the first second of forced exhalation.

The general approach to interpretation of spirometry involves evaluation of the FEV1/FVC; a reduction is consistent with obstructive lung disease physiology, and to gauge the severity, the FEV1 percentage of predicted provides a sense of the degree of obstruction. If the FEV1/FVC is normal, then the patient either has normal or restrictive pulmonary physiology; in this context if the FVC is reduced, then this is suggestive of restrictive lung disease. Lung volumes and diffusion capacity may be helpful in the latter circumstance to ascertain severity grade and whether the restriction is intra or extrathoracic (Fig. 20.1).

The flow-volume loop is another aspect of data generated from spirometry characterized by a graphic illustration of inspiratory and expiratory flow (on the vertical axis) against volume (on the horizontal axis) during the performance of maximally forced inspiratory and expiratory maneuvers. Flow is plotted against volume to display a continuous loop from inspiration to expiration. The overall shape and the contour of the flow-volume loop are important in interpreting spirometric results (Fig. 20.2). In healthy subjects, maximal expiratory flow is highest at total lung capacity and progressively is reduced until residual volume is reached, while inspiratory flow is more even throughout the maximal effort of breathing in from residual volume to total lung capacity. In addition, the flow patterns are smooth during expiration or inspiration.

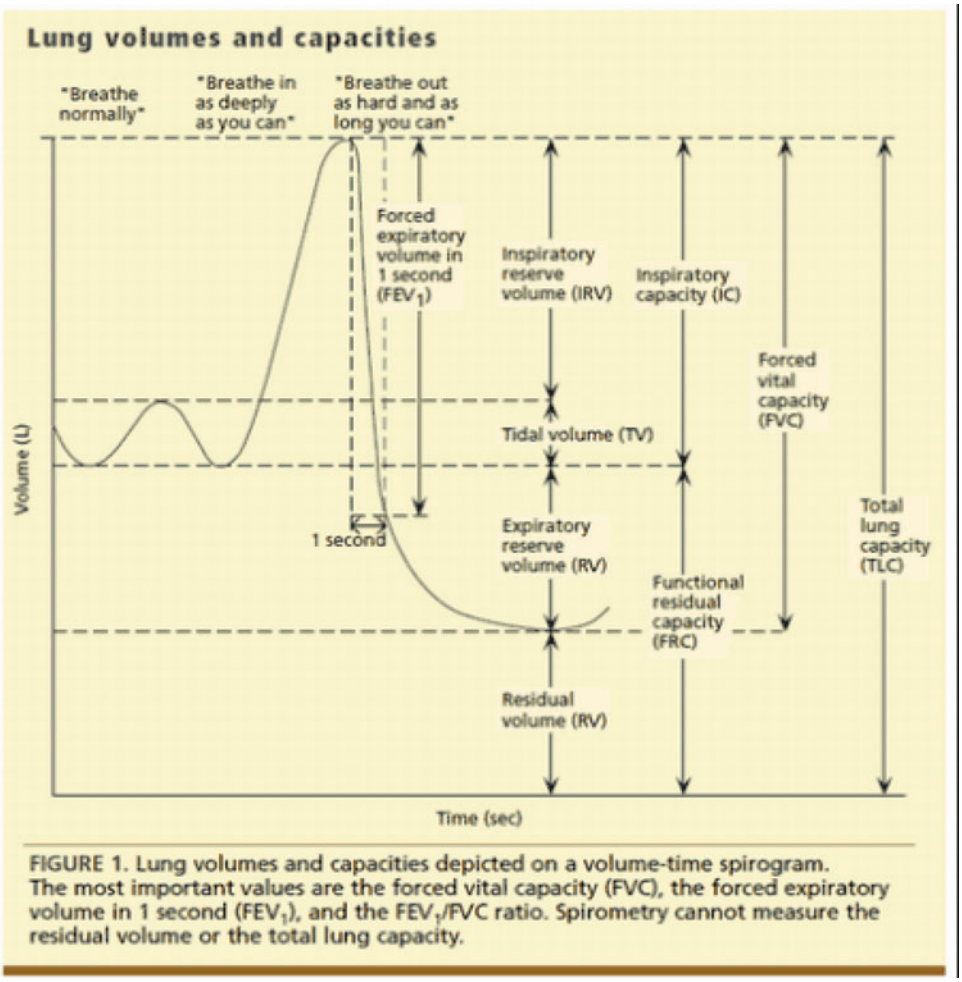

Fig. 20.1 This figure obtained from Cleveland Clinic Journal of Medicine with permission 2003 Oct; 70(10):866, 868, 871–873

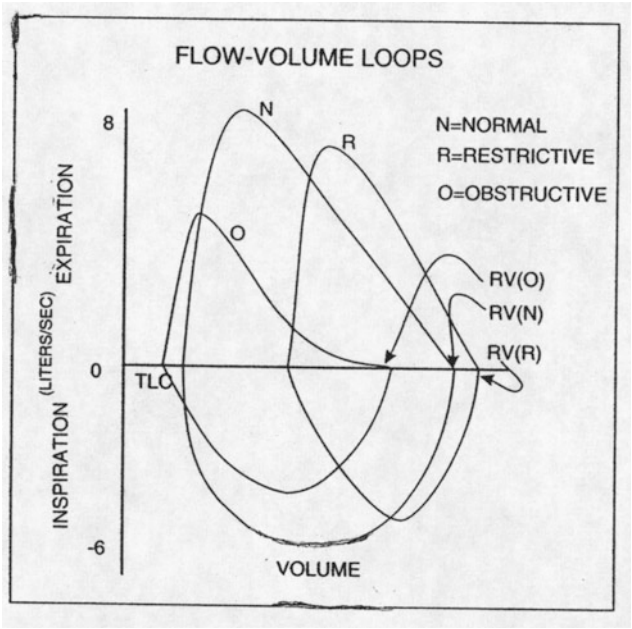

Fig. 20.2 Flow-volume loops

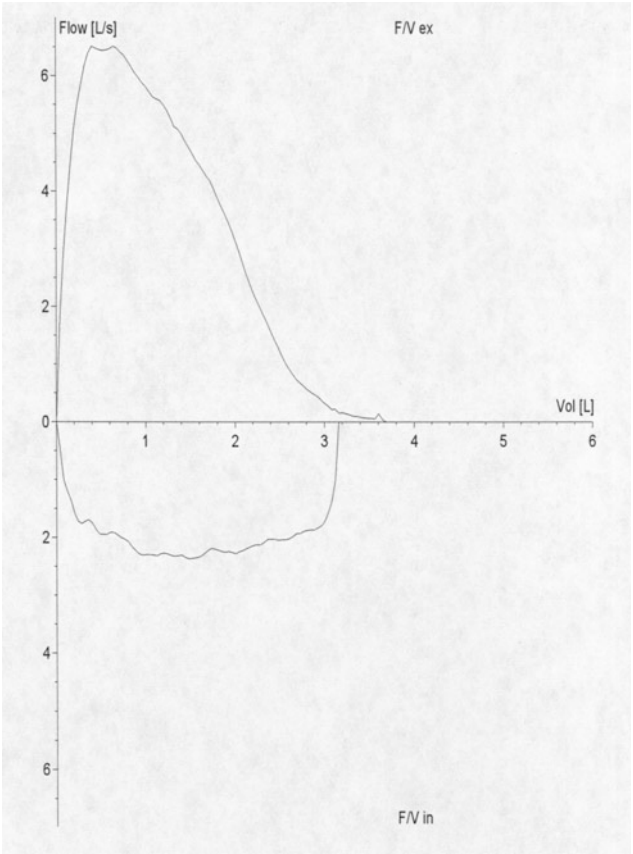

Fig. 20.3 Example of variable extrathoracic obstruction: note the "squaring" of the inspiratory limb of the flow-volume loop

Obstructive Lung Disease: Another feature is the proportion of flow between inspiration and expiration, especially at mid-lung volumes, halfway between residual volume and total lung capacity. At this point, expiratory flow is less than inspiratory flow in those diseases in which there is intrathoracic airway disease, such as asthma, chronic obstructive pulmonary disease (COPD), or tracheomalacia. Patients with airflow limitation due to obstructive lung disease often have a concave upward pattern on the expiratory portion of the flow-volume loop.

Restrictive Lung Disease: The characteristic flow-volume loop pattern of restrictive disease is a decrease in vital capacity combined with supernormal expiratory flows when corrected for lung volume. The resulting shape of the flow-volume curve is a tall appearance with a steep descending limb.

Fixed Airway Obstruction: If flows are equal and reduced, there is a possibility of a fixed upper airway obstruction, such as tracheal damage from prior surgery or airway tumor/foreign body.

Variable extrathoracic obstruction: If inspiratory flow exceeds expiratory flow at mid-lung volume, this physiology is one of a variable extrathoracic obstruction, seen in people with tracheal injury, vocal cord paralysis, and other conditions where the act of breathing in restricts the size and flow of inspiration, while breathing out opens the segment that has dynamic collapse during inspiration (Fig. 20.3).

Variable Intrathoracic Obstruction: Flow limitation is encountered during forced expiration, when the pleural pressure becomes positive relative to airway pressure, and the effect of any obstructive lesion becomes pronounced.

One feature of the loop that was thought to represent sleep apnea was a saw-tooth pattern on inspiration as well as on expiration believed to represent unstable upper airway structures (saw-tooth sign) [3] (Fig. 20.4). Although the precise mechanism may differ among individuals, fluttering on inspiration is not routinely seen in sleep apnea and can be present in those with motor disease like Parkinson's disease and may also be seen in normal patients due to artifact [4]. Reversibility of airways obstruction can be assessed with the use of bronchodilators. After spirometry is completed, the patient is given an inhaled bronchodilator and the test is repeated. The purpose of this is to assess whether a patient's pulmonary process is bronchodilator responsive by looking for improvement in the expired volumes and flow rates. In upper airway obstruction an increase in >12 % increase in the FEV1 (an absolute improvement in FEV1 of at least 200 ml) or the FVC after inhaling a beta agonist is considered a significant response. Spirometry is typically reported

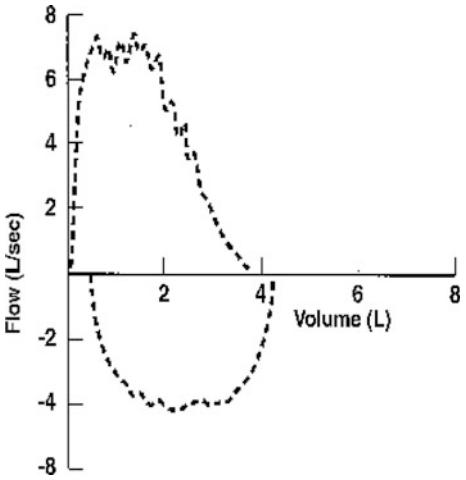

Fig. 20.4 Saw-tooth pattern of flow-volume loop: this finding may be observed in the setting of an individual at increased risk of sleep apnea or a patient with neuromuscular disease. Alternatively, this finding also may simply reflect artifact

in both absolute values and as a predicted percentage of normal. Normal values vary depending on sex, race, age, and height.

Lung Volumes

In contrast to spirometry, a dynamic test of airflow function, measurement of lung volumes is designed to collect values relating to the size of the lung as a gas-exchanging unit. These volumes are indirectly calculated from measures of a slow inspiration (or expiration) and a direct measure of thoracic gas volume (TGV) at functional residual capacity (FRC), with a subsequent derivation of a number of values. FRC is usually measured by a gas dilution technique or body plethysmography. Gas dilution techniques are based on a simple principle, are widely used, and provide a good measurement of all air in the lungs that communicates with the airways.

Body plethysmography is a second method of measuring lung volume that takes advantage of the principle of Boyle's law, which states that the volume of gas at a constant temperature varies inversely with the pressure applied to it. The primary advantage of body plethysmography is that it can measure the total volume of air in the chest, including gas trapped in bullae. Another advantage is that this test can be performed quickly. Drawbacks include the complexity of the equipment as well as the need for a patient to sit in a small enclosed space. From the FRC, the patient pants against a closed shutter to produce changes in the box pressure proportionate to the volume of air in the chest. The volume measured by this technique is referred to as TGV and represents the lung volume at which the shutter was closed, typically FRC.

After measurement of FRC, the patient would exhale fully and then take a large breath to total lung capacity. The difference between FRC and residual volume is called the expiratory reserve volume (ERV), and the difference between the total lung capacity and FRC is called the inspiratory capacity. The ERV is reduced in obesity where the chest wall mass makes for a smaller FRC (Fig. 20.1).

The interpretation of lung volumes is coordinated with that of spirometry to allow one to distinguish between obstructive lung physiology and a mixed picture (Fig. 20.2). An obstructed pattern may be seen most commonly if there is narrowing of the airways due to bronchial smooth muscle contraction (i.e., asthma), narrowing of the airways due to inflammation and swelling of bronchial mucosa and the hypertrophy and hyperplasia of bronchial glands (i.e., bronchitis).

In some patients, obstructive sleep apnea may co-exist with COPD, which has been coined the "overlap syndrome" given that this is a clinically distinct entity compared with each disease in isolation [5]. Patients with the overlap syndrome have been shown to have a higher frequency of breathing and lower tidal volume compared with patients with sleep apnea [6]. In COPD, the oxygen saturation falls approximately 2–4 % from the awake baseline value with minor fluctuations until a more substantial reduction is noted in REM sleep, and therefore, nocturnal oxygen desaturation is a commonplace finding in the setting of obstructive lung disease (Fig. 20.5). A more pronounced degree of hypoxia occurs in the setting of COPD due to starting on a steeper portion of the oxyhemoglobin curve, alveolar hypoventilation due to reduction in chemosensitivity and reduction in

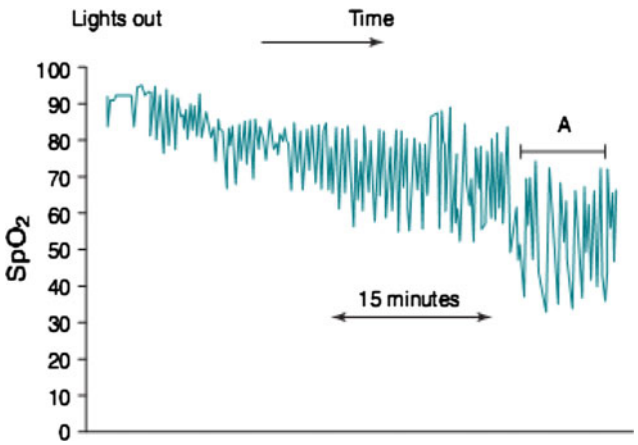

Fig. 20.5 In a patient with both snoring and moderate COPD, the baseline is reduced during sleep but the saw-tooth pattern is suggestive of obstructive sleep apnea. *A* period of REM sleep

end-expiratory lung volumes. The importance of the identification of overlap syndrome is highlighted by the observed association with increased risk of death and hospitalization because of COPD exacerbation [7]. Overlap syndrome has been associated with more pronounced sleep-related hypoxemia and hypercapnia compared with patients with COPD or OSA alone, which may explain the above findings [8]. The presence of OSA has also been demonstrated to result in increased COPD exacerbations and accelerated lung function decline [9].

Restriction can be applied to patients whose total lung capacity has been measured and found to be significantly reduced. Total lung capacity is the volume of air in the lungs when the patient has taken a full inspiration. There are a variety of restrictive disorders such as intrinsic lung disease (sarcoidosis, interstitial lung disease), extrinsic restrictive lung disorders (morbid obesity, kyphosis/scoliosis), and neuromuscular restrictive disorders (myasthenia gravis, muscular dystrophy, post-polio syndrome, amyotrophic lateral sclerosis). Although preliminary findings appear to support reduced REM sleep and increased sleep fragmentation, overall there are limited data characterizing relationships of sleep and sleep apnea with restrictive parenchymal lung disease [10].

Measurement of maximal inspiratory and expiratory pressures is indicated whenever there is an unexplained decrease in vital capacity or respiratory muscle weakness is suspected clinically. Maximal inspiratory pressure (MIP) is the maximal pressure that can be produced by the patient trying to inhale through a blocked mouthpiece. Maximal expiratory pressure (MEP) is the maximal pressure measured during forced expiration (with cheeks bulging) through a blocked mouthpiece after a full inhalation. Repeated measurements of MIP and MEP are useful in following the course of patients with neuromuscular disorders.

Diffusing Capacity

Diffusing capacity measures the features at work involving movement of oxygen from the alveolar surface through to the hemoglobin molecule. The clinical test diffusing capacity of the lung (DL) most commonly uses carbon monoxide (CO) as the tracer gas for measurement because of its high affinity for binding to the hemoglobin molecule. This property allows a better measurement of pure diffusion, such that the movement of the CO is in essence only dependent on the properties of the diffusion barrier and the amount of hemoglobin. The properties of oxygen and its relatively lower affinity for hemoglobin compared with CO also make it more perfusion dependent; thus, cardiac output may influence actual measurement of oxygen diffusion measurements.

Diffusing capacity for CO (DLCO) is the measure of CO transfer. DLCO is a measure of the interaction of alveolar surface area, alveolar capillary perfusion, the physical properties of the alveolar capillary interface, capillary volume, hemoglobin concentration, and the reaction rate of CO and hemoglobin. The most widely used and standardized technique is referred to as the single-breath breath-holding technique. This technique relies on a subject inhaling a known volume of test gas, the patient inhales the test gas and holds his or her breath for 10 s and then exhales to "wash out" mechanical and anatomic dead space. DLCO is calculated from the total volume of the lung, breath-hold time, and the initial and final alveolar concentrations of CO. Alveolar volume is estimated by the helium dilution and the initial alveolar concentration of CO. The driving pressure is assumed to be the initial alveolar pressure of CO.

Because the level of hemoglobin present in the blood and diffusing capacity are directly related, a correction for anemic patients (DLCOc) is used to further delineate whether a DLCO is decreased due to anemia or due to parenchymal or interface limitation. Diseases such as interstitial pulmonary fibrosis or any interstitial lung disease may make the DLCO abnormal long before spirometry or volume abnormalities are present. Low DLCO is not only an abnormality of restrictive interstitial lung disease but may also occur in the presence of emphysema. On the other end of the spectrum, alveolar hemorrhage or congested capillary beds may actually increase the DLCO. Similar to spirometry, predicted formulas have been established for DLCO and DLCO corrected for alveolar volume. It is important to note, however, that differences in race have been observed in normal subjects, and a race correction of 7 % is allowed for African American patients [11]. The diffusing capacity, if reduced, may be a reason for oxygen levels to be low even when there are relatively normal values on spirometry or lung volumes. Such a circumstance is found with pulmonary vascular disease [12]. To the extent that a reduced diffusing capacity affects oxygen levels, it can be one reason for excess hypoxemia during sleep, even in the absence of apneas or hypopneas.

Arterial Blood Gas

A sample of arterial blood is drawn anaerobically from a peripheral artery (typically radial, however, brachial, axillary, or femoral routes may be considered) via a single

percutaneous needle puncture, or from an indwelling arterial cannula or catheter for multiple samples. A resting arterial blood gas may be considered in the setting of hypoxia out of proportion to the degree of sleep-disordered breathing, thereby suggesting underlying possible cardiopulmonary disease or to obtain a sense of resting hypercapnia if underlying obesity hypoventilation, obstructive lung disease, or neuromuscular disease is known or suspected.

The arterial blood gas allows for the measurement of partial pressures of carbon dioxide ($PaCO_2$) and oxygen (PaO_2), acidity (pH), total hemoglobin (Hbtotal), oxyhemoglobin saturation (HbO_2), carboxyhemoglobin (COHb), and methemoglobin (MetHb). Refer to Table 20.1 for the approach to acid–base determination. Arterial blood gases permit another assessment of gas exchange and of ventilation. One can derive a value of the A–a gradient to determine a problem in gas exchange at the alveolar level:

$$P(A-a)O_2 = [FiO_2(P_B - P_{H_2O}) - PaCO_2/RQ] - PaO_2$$

- $P(A–a)O_2$ = Alveolar-Arterial O_2 Gradient. It is the difference between the amount of oxygen in the alveoli and the amount of oxygen dissolved in plasma.
- FiO_2 = Inspired Oxygen. It is the fraction of the inspired oxygen (0.21 at room air)
- P_B = Atmospheric Pressure of O_2
- P_{H_2O} = Partial Pressure of H_2O
- $PaCO_2$ = Partial Pressure of CO_2 in the Arterial Blood
- PaO_2 = Partial Pressure of O_2 in the Arterial Blood
- RQ: The Respiratory Quotient is the amount of CO_2 relative to the amount of O_2 consumed (in normal situations, this is approximately 0.8)

An increased A–a gradient would cause a reduction in arterial blood oxygen levels and be the result of a ventilation-perfusion mismatch (most common and most commonly observed in obstructive diseases such as COPD or asthma) or by an anatomic shunt (as in liver disease resulting in hepatopulmonary syndrome). A second pattern seen is a normal A–a gradient with the hypoxemia explained by hypoventilation of lung units, retention of carbon dioxide, and elevated arterial $PaCO_2$. Hypoxemia due to pure hypoventilation (e.g., in obesity hypoventilation syndrome, neuromuscular disease resulting in CNS depression and impaired neural conduction) corrects with increase in fraction of inspired oxygen. A process resulting in hypoxemia during wakefulness is likely to produce lower oxygen saturation levels during sleep as the latter is associated with a

Table 20.1 Determination of acid–base status

Step I. Determine primary acid–base status disorder	
(*A*) *Determine acidosis versus alkalosis*	
1. pH < 7.36: Acidosis	2. pH > 7.44: Alkalosis
(*B*) *Determine metabolic versus respiratory*	
1. Primary metabolic disorder (a) pH changes in same direction as bicarbonate, $PaCO_2$ (b) Metabolic acidosis (i) Serum pH decreased (ii) Serum bicarbonate and PaCO2 decreased (c) Metabolic alkalosis (i) Serum pH increased (ii) Serum bicarbonate and $PaCO_2$ increased	2. Primary respiratory disorder (a) pH changes in the opposite direction of bicarbonate, $PaCO_2$ (b) Respiratory acidosis (i) Serum pH decreased (ii) Serum bicarbonate and $PaCO_2$ increased (c) Respiratory alkalosis (i) Serum pH increased (ii) Serum bicarbonate and $PaCO_2$ decreased
Step II. Determine compensation	
(A) Metabolic acidosis: $PaCO_2$ decreases 1.2 mmHg per each 1 meq/L bicarbonate fall	*(A) Acute respiratory acidosis*: Bicarbonate increases 1 meq/L per 10 mmHg $PaCO_2$ rise
(B) Metabolic alkalosis: $PaCO_2$ increases 6 mmHg per 10 meq/L bicarbonate rise	*(B) Chronic respiratory acidosis*: Bicarbonate increases 4 meq/L per 10 mmHg $PaCO_2$ rise
	(C) Acute respiratory alkalosis: Bicarbonate decreases 2 meq/L per 10 mmHg $PaCO_2$ fall
	(D) Chronic respiratory alkalosis: Bicarbonate decreases 4 meq/L per 10 mmHg $PaCO_2$ fall

Normal range of values can vary among different laboratories. Normal pH is from 7.35 to 7.45, normal PCO_2 is 35–45 mm Hg, and normal HCO_3 is from 21 to 27 meq/L

reduction in the FRC and also reduced ventilation. Therefore, the presence of hypoxemia or hypoventilation in an awake resting arterial blood gas is predictive of greater hypoxemia during a sleep study.

Monitoring of Respiratory Function During Sleep

Updates have been put forth by the American Academy of Sleep Medicine (AASM) regarding scoring rules for respiratory events [13]. The goal of these updates was to revise the rules to reflect changes in our understanding of the predictiveness of various levels of hypoxia and flow reduction relative to adverse outcomes and also to address knowledge gaps in terms of specification of the sensor for detection of apnea and hypopnea during the positive airway pressure (PAP) titration given that PAP devices have the ability to output an analog or digital signal from the internal flow sensor. The updated rules also sought to overcome confusion caused by the endorsement of two hypopnea rules in the prior manual and to make more consistent the adult and pediatric respiratory event scoring rules. New evidence has emerged since 2007 showing the impact of the scoring rules in diagnosis of OSA [14, 15]. Below represents a description of the sensors that may be used for respiratory physiologic monitoring and also an overview of definitions recommended to be used for the scoring of respiratory events.

Airflow Monitoring

Most airflow sensors detect apneas reliably, but the detection and quantification of decreased flow needed to diagnose hypopneas depends on the type of sensor used. Hypopnea comprises the majority of obstructive respiratory events and therefore its measurement needs to be reliable.

The 2013 task force recommends thermistors, thermocouples, or polyvinylidene fluoride (PVDF) sensors for the detection of airflow. PVDF sensors have been included in the definition of thermal sensors for the detection of airflow given data demonstrating that the PVDF sum signal provides comparable detection of events independent of direct airflow monitoring with thermistry or nasal pressure. The PVDF sensor also performed as well as the pneumotachograph in the detection of the number of respiratory events [16, 17]. For identification of an apnea during the diagnostic study, the oronasal thermal airflow sensor is recommended to monitor airflow. If the oronasal sensor is not functioning or the signal is not reliable, then the use of nasal pressure transducer, respiratory inductance plethysmography (RIP) flow, or RIP sum is suggested. The nasal pressure signal is not the recommended sensor for apnea detection as the signal can show decreased amplitude during mouth breathing [18].

Pneumotachometer

This method of airflow monitoring provides a direct quantitative measurement of airflow or tidal volume and, however, requires connection to a sealed mask placed over the nose or mouth. It is considered the reference standard for obstructive apnea and hypopnea detection. Although its use provides a beneficial and accurate research tool, in the clinical setting this technique is somewhat cumbersome and therefore not standardly utilized. This method measures the flow rate of gases during breathing. The breath is passed through a short tube in which there is a fine mesh, which presents a small resistance to the flow. Flow (V′) is derived from the pressure difference over a small, fixed resistance, offered by a fine metal mesh. The pressure drop across the resistance relates linearly to flow at relatively low flows, when the flow pattern is laminar. Accurate measurements are best performed when the flow pattern is laminar and flow is linearly related to pressure drop.

Nasal Thermocouple/Thermistor

Oronasal thermocouple sensor assesses airflow via indirect semiquantitative assessment detecting increased temperature of expired air with only directional changes providing reliable results. Oronasal sensors can detect both nasal and oral airflow. Thermocouples are commonly used for temperature measurement as they are highly accurate and operate over a broad range of temperatures. Thermistors consist of an electronic component (semiconductor material) that exhibits a large change in resistance in proportion to a small change in temperature. In comparison with thermocouples, thermistors have a limited (smaller) temperature range; however, they are highly sensitive within this range. The resistance of these devices often changes in a nonlinear fashion and additional instruments are required to linearize the reading. In laboratory models that have compared thermistors and thermocouples to the pneumotachograph, the thermal sensors have been shown to be nonlinearly related to airflow, generally providing an overestimation of ventilation [19].

Intranasal Pressure/Transducer

This technique provides an indirect measurement of airflow by detecting pressure changes with an excellent response to airflow profile and is capable of detecting airflow limitation. Changing pressures require a transducer, which can respond to rapid changes. Nasal pressure transducers provide a significantly more sensitive measure of airflow than temperature-based sensors and many believe that the pressure transducers may provide a measure of upper airway resistance as inspiration and expiration provide transducer signal fluctuations similar to airflow [20, 21]. In one study, the nasal cannula/pressure transducer has been found to serve as a noninvasive reproducible detector of all events in SDB; in particular, it detects the same events as esophageal manometry (respiratory effort-related arousals, RERAs) with an intraclass correlation coefficient of 0.96 [22]. The nasal pressure transducer provides additional information for scoring hypopneas compared with themistry. If used for evaluation of sleep-related breathing disorders, the improved level of sensitivity offered by the nasal pressure transducer may lead to scoring of many more events than are typically scored with other methods of airflow detection. Nasal pressure monitoring is not recommended for patients who are predominantly mouth breathers or have nasal obstruction in which case airflow may be underestimated [23]. Square root linearization of nasal pressure more accurately approximates flow and greatly increases the accuracy for quantifying hypopneas and detecting flow limitation [24, 25]. Features of the signal such as flattening of the inspiratory portion of the waveform serve as a surrogate for flow limitation; however, reliable detection of flow limitation requires the use of a DC signal or an AC signal with an appropriately low frequency filter setting [26].

Respiratory Inductance Plethysmography

The literature supports that RIP is acceptable for the semiquantitative measurement of ventilation assessed by thoracic and abdominal pressure changes. The 2013 task force includes the available dual RIP belt signals, RIP sum signal (sum of the thorax and abdomen belt signals), and RIP flow (time derivative of the RIP sum signal) [13] unlike the previous manual, which did not clearly differentiate the utility of these RIP signal subtypes. With this technique, transducers are placed at the level of the nipples and at the umbilicus to monitor cross-sectional changes reflected by changes in inductance or resistance to change in flow of the transducers. The sum of the signals may provide an estimate of tidal volume and respiratory pattern during sleep [27]. Measurement inaccuracies may occur due to slippage (displacement of transducer bands) and position changes. RIP detects changes in the volume of the chest and abdomen during inspiration and expiration and, when properly calibrated, the sum of the two signals can provide an estimate of tidal volume [28]. However, calibration may be difficult to maintain throughout the night [29]. In uncalibrated RIP, deflections in the RIP sum signal allow detection of relative change in tidal volume compared with baseline breathing; however, when calibrated, it provides a more accurate estimate of tidal volume. RIP flow is the time derivative of the RIP sum signal and serves as a semiquantitative estimate of airflow in calibrated RIP [30, 31].

Snore Monitoring

The microphone is used to detect snoring during polysomnography (PSG), providing an output signal with easily identifiable waveforms. This tracing in conjunction with sleep technician comments may assist in the diagnosis of primary snoring when there is lacking evidence for SDB. The piezoelectric sensor or nasal pressure transducer can also be used for monitoring snoring. In addition, snoring may be detected as superimposed oscillations on the airflow waveform. Unfiltered nasal pressure signal, piezoelectric sensors, or acoustic sensors can be used to record the sound of the snoring. High-frequency oscillations may be seen in the nasal pressure signal but may not be observed on the PAP device flow signal.

Esophageal Balloon Manometry

The measurement of esophageal pressure with continuous overnight monitoring is the reference standard for measuring respiratory effort during PSG and, however, carries intrinsic practical issues that obviate its use clinically. Respiratory efforts are associated with changes in pleural pressure which can be accurately measured using esophageal manometry. This method is useful when distinguishing central versus obstructive apneas, and is useful for detecting RERAs in the setting of upper airway resistance syndrome during which there is increasingly more negative esophageal pressures immediately preceding an arousal, subsequent to which the esophageal pressure fairly rapidly returns to normal levels [32, 33].

Pulse Oximetry Monitoring

Pulse oximetry monitoring may be performed at baseline in the clinical setting and is recommended to be included in standard sleep study monitoring including portable sleep monitoring. Pulse oximetry may also be performed during

sleep to assess the residual degree of hypoxia after someone has been placed on treatment with PAP for sleep apnea in order to assess the need for concomitant supplemental oxygen. Although the AASM clinical guidelines and practice parameters do not specify the location of the probe (e.g., ear, finger, forehead), it is generally agreed that finger oximetry probes be utilized. In order to maximize ability to extract data in a meaningful way and to ensure capturing desaturations in synchrony with respiratory events, AASM guidelines recommend a maximum signal averaging time of ≤3 s at a heart rate of >80 beats per minute even in the setting of portable sleep monitoring [34].

The fundamental physical property that allows the measurement of arterial oxygen saturation is that blood changes color with saturation. Hemoglobin, in its reduced form or oxygenated state, absorbs light at wavelengths below approximately 630 nm, which includes the entire part of the visible spectrum aside from the red region. The opposite situation occurs in the near-infrared region (810–1000 nm), where hemoglobin absorbs more light when it is desaturated. Pulse oximeters usually are designed with two emitters (usually light-emitting diodes); one designed to emit light in the red region (~660 nm), and the other in the near-infrared region (~925 or 940 nm). In order to measure absorption of arterial blood only, without interference from venous blood, skin, bone, and to minimize scatter effect, a differential absorption is calculated by dividing the small change in intensity by the total intensity of the output light. Chromophores other than oxyhemoglobin and reduced hemoglobin, such as carboxyhemoglobin and methemoglobin, may cause falsely elevated readings for the arterial oxygen saturation. Of note, oximeters may be calibrated using functional or fractional oxygen saturation with the former reading slightly higher (1–3 %). Oximeters may be prone to artifact such as during states of poor perfusion, hypothermia, profound anemia, excessive patient motion (particularly at the probe site), and electrical noise and may also be affected by changes in heart rate and circulation time [35].

It is also important to note that while oxygen saturation from pulse oximetry allows a convenient and noninvasive means of assessing arterial oxygenation, it does not in and of itself allow for assessment of ventilation. Moreover, due to the sigmoidal shape of the oxyhemoglobin dissociation curve, a large reduction in arterial PO_2 will not result in a substantial decline in the oxygen saturation until the steeper portion of the curve is approached. Overall, pulse oximetry is easy to use, inexpensive, readily available, and noninvasive and permits continuous monitoring of oxygen saturation. Pulse oximetry sensitivity is improved with shorter sampling intervals, and minimal filtering in order to achieve the most rapid response. During scoring of sleep study data, the oxygen desaturation associated with the respiratory event is defined as drop in baseline SpO_2 preceding the event to the nadir in the SpO_2 following the event.

Carbon Dioxide Monitoring

Expired End-tidal CO_2 Monitoring

Arterial partial pressure of carbon dioxide is the gold standard method for determining hypoventilation; however, it is difficult to obtain. Therefore, other surrogate sensors are commonly used during PSG such as end-tidal CO_2 monitoring. This modality works by a drawing a stream of air from the nose or the mouth to a chamber in which a light is shone through the air (side stream method). The degree of absorption at a certain frequency of infrared light is proportional to the concentration of CO_2. Continuous measurement of CO_2 reflects the excretion pattern of carbon dioxide from the lung. Values for CO_2 are near or at zero on inspiration and show an abrupt rise until the end of expiration when there is a plateau in the CO_2 level. The end-expiratory value is correlated with arterial PCO_2 provided that there is complete gas emptying to FRC, and little effect of ventilation-perfusion mismatch. The arterial partial pressure of CO_2 and end-tidal CO_2 difference is usually 2–7 mmHg with overall trends of capnography CO_2 values underestimating the arterial PCO_2 values [36] and in general is higher in patients with lung disease [37].

End-tidal CO_2 monitoring may help in identifying hypoventilation in obesity hypoventilation syndrome, as well as COPD, congestive heart failure, and neurologic diseases that produce neuromuscular weakness. In addition, end-tidal CO_2 values can be helpful in assessing disorders of chronic hyperventilation, distinguishing pathophysiologic from psychogenic causes by the persistence or resolution of hypocapnia during sleep.

A limitation of end-tidal CO_2 monitoring includes the inability to accurately measure levels in the setting of continuous positive airway pressure (CPAP) or bilevel pressure therapy in order to assess response to treatment. The values are also inaccurate during application of supplemental oxygen as the supplemental oxygen dilutes the exhaled gas sample [38].

The value of capnography (breath-by-breath CO_2 measurements) is twofold as described below, but limited in scope compared with direct measures of airflow.

The first is that capnography may detect absence of expiratory airflow and signal an apnea. There are no established criteria, but an apnea event is considered to occur

when there is a failure for end-expiratory CO_2 to fall after expiration with subsequent decline in CO_2 over the next 10 s to values at or near zero. The end of the apnea is heralded by the occurrence of a rapid rise in CO_2 with expiration; the length of an event is from the peak of the last CO_2 rise to the peak of the next CO_2 rise if greater than 10 s. A cardiac oscillation in the capnography signal indicates a patent airway during a central apnea (but the frequency of this is only recorded at an anecdotal level of evidence). There can be expiratory puffs after an obstructed inspiratory effort, but again the frequency of this is only recorded at an anecdotal level of evidence. Second, capnography can be used to identify obstructive hypopneas. In this instance, there are persistent efforts characterized by asynchronous chest wall movements of the ribcage and abdomen with a rising end-tidal CO_2 over time. The frequency of this kind of pattern is only recorded at an anecdotal level of evidence.

Scoring of events from the CO_2 monitor should be directed at apneas, and to the extent possibly correlated with ribcage/abdominal movements and CO_2 fluctuation in synchrony with EKG (central event) or in synchrony with respiratory efforts (expiratory puffs signaling an obstructive event). The length of an event is from the peak of the last CO_2 rise to the peak of the next CO_2 rise, if greater than 10 s. Obstructive hypopneas would be detected by a series of breaths with asynchronous ribcage/abdominal motion associated with an increasing end-expiratory CO_2 level.

Transcutaneous CO_2 Monitoring

There are two methods that may be employed in transcutaneous CO_2 monitoring: the first uses a silver electrode which measures CO_2 that has diffused from the skin through a gas-permeable membrane into solution (response time less than one minute), and the other uses an infrared capnometer that analyzes CO_2 in the gas phase (response time more than 2 min).

Transcutaneous CO_2, unlike end-tidal CO_2, remains accurate with mouth breathing, supplemental oxygen, or mask ventilation. Transcutaneous CO_2 may overestimate the arterial CO_2. In a study involving severe obese individuals, the difference between arterial CO_2 and transcutaneous CO_2 was −1.4 mm Hg (SD 1.3 mm Hg) [39] and another study demonstrated consistent findings with $TcCO_2$ measurement serving as an overestimate of arterial PCO_2 values during hypercapnia [40]. End-tidal CO_2 and transcutaneous CO_2 are surrogates of $PaCO_2$ during diagnostic studies. It is important to carefully review the tracings to determine whether artifacts are present that may compromise the integrity of the data. If there is a discrepancy in the readings in reference to the clinical picture, recalibration of a change in the sensor site may be required [38, 41].

Classification and Scoring of Respiratory Events

Obstructive Apneas: As per the latest AASM recommendations [26], obstructive apneas are defined as a drop in the peak signal excursion (defined as ≥ 90 %) from pre-event baseline in the amplitude of a valid measure of breathing that is oronasal thermal sensor (diagnostic study) or an alternative apnea sensor (diagnostic study), PAP device flow (titration study) during sleep lasting at least 10 s associated with continued or increased thoracoabdominal respiratory effort throughout the entire period of absent airflow. Recommended airflow sensors include oronasal thermal sensor or PVDF sensor. Of note, based upon consensus and clinical evidence, it is recommended that the PAP device flow signal be used to score apneas or hypopneas during the PAP titration with the caveat that the magnitude of oral airflow if present is not accurately estimated by the PAP flow signal.

Baseline is described as the mean amplitude of stable breathing and oxygenation in the preceding two minutes prior to the event in individuals who have a stable breathing pattern during sleep or the mean amplitude of the three largest breaths in the two minutes preceding the onset of the event in individuals without a stable breathing pattern.

Central Apneas: A drop in the peak signal excursion (defined as ≥ 90 %) from pre-event baseline in the amplitude of a valid measure of breathing that is oronasal thermal sensor (diagnostic study) or an alternative apnea sensor (diagnostic study), PAP device flow (titration study) during sleep lasting at least 10 s associated with absent inspiratory effort throughout the entire period of absent airflow.

Mixed Apneas: A drop in the peak signal excursion (defined as ≥ 90 %) from pre-event baseline in the amplitude of a valid measure of breathing that is oronasal thermal sensor (diagnostic study) or an alternative apnea sensor (diagnostic study), PAP device flow (titration study) during sleep lasting at least 10 s is associated with absent inspiratory events in the initial portion of the event, followed by redemption of inspiratory effort in the second portion of the event.

Hypopneas: Hypopnea is scored as a respiratory event when all the following criteria are met: The peak signal excursions drop by $\geq$30 % of prevent baseline using nasal pressure (diagnostic study), PAP device flow (titration study), or an alternative hypopnea sensor (diagnostic study). (A) The duration of >30 % drop in signal excursion is $\geq$10 s. (B) There is a $\geq$3 % oxygen desaturation from pre-event baseline or the event is associated with an arousal. The

recommended airflow sensor for hypopnea detection is nasal pressure transducer with or without square root transformation.

There has been a change in the definition of the hypopnea scoring criteria from 2007 scoring manual. The basis for incorporation of the 3 % oxygen desaturation in reference to the hypopnea definition is based upon accrued data demonstrating associations of SDB defined by the apnea hypopnea index including hypopneas accompanied by ≥3 % oxygen desaturations with adverse cardiovascular outcomes. Analysis of Wisconsin Sleep Cohort and Sleep Heart Health Data showed that the use of the AHI incorporating hypopnea defined by ≥3 % oxygen desaturation criteria was as predictive of adverse outcomes as utilizing the AHI based on ≥4 % hypopnea oxygen desaturation criteria [42, 43]. Several epidemiologic studies have determined that SDB defined by the AHI utilizing the 3 % oxygen desaturation hypopnea rule is significantly associated with increased atrial fibrillation and ventricular arrhythmia [44] as well as insulin resistance [45]. Moreover, use of the 3 % hypopnea rule has been longitudinally associated with an increased risk of stroke [46]. The use of greater than 30 versus 50 % reduction in airflow to define hypopnea was based upon the logic that irrespective of a 30 % or a 50 % reduction in flow is the presence of a significant physiologic consequence, i.e. hypoxia or arousal.

Given the need for identification of central respiratory events to characterize degree of central SDB burden clinically, there are now guidelines providing the option of differentiating obstructive versus central hypopneas based upon polysomnogram-identified features as follows:

Obstructive Hypopnea is scored if **any** of the following criteria are met:

(a) Snoring during the event
(b) Increased inspiratory flattening of the nasal pressure or PAP device flow signal compared with baseline breathing
(c) Associated thoracoabdominal paradox occurs during the event but not during the pre-event breathing (Fig. 20.6).

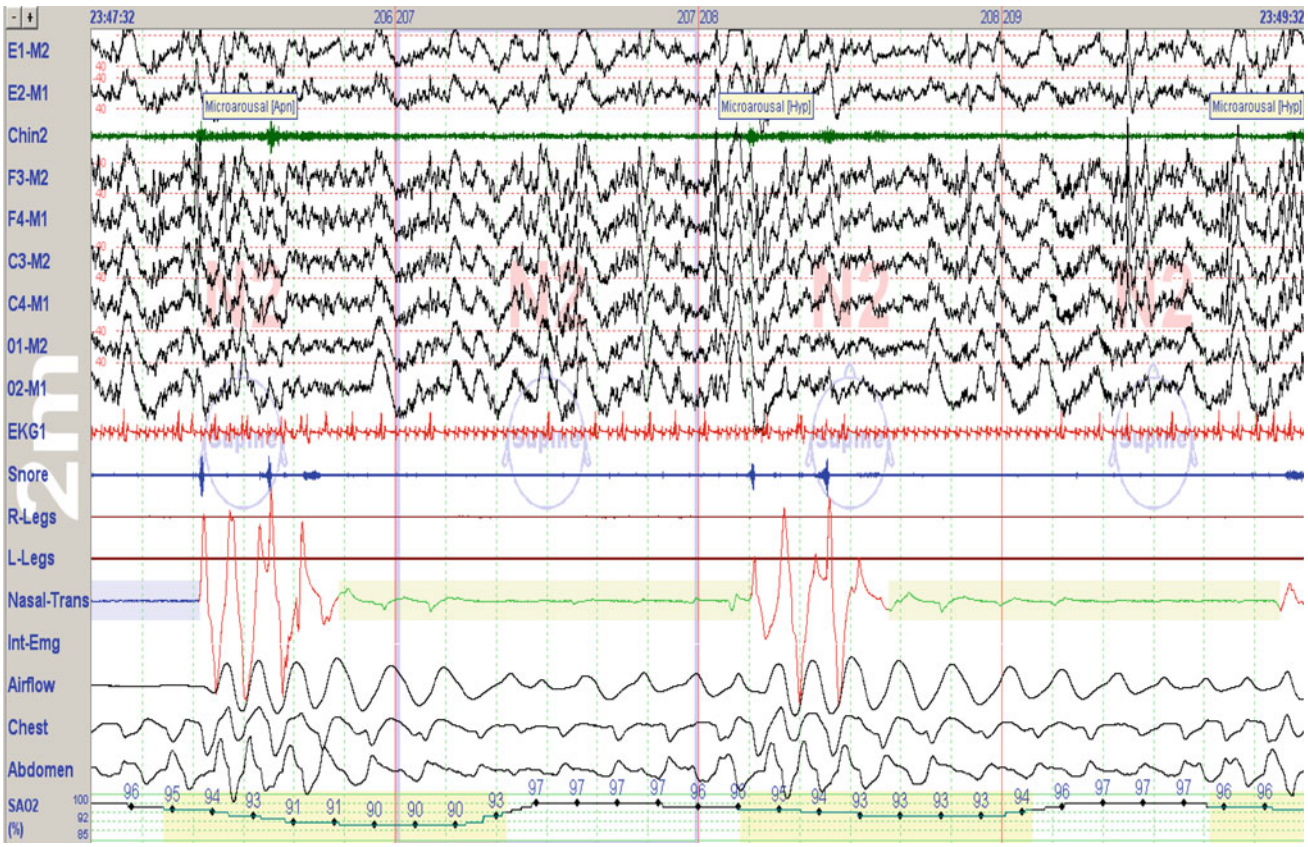

Fig. 20.6 Obstructive hypopneas: these events are associated with snoring, oxygen desaturation, and arousal accompanied by thoracoabdominal paradox

Central hypopneas can be scored if none of the following criteria are met:

(a) Snoring during the event
(b) Increased inspiratory flattening of the nasal pressure or PAP device flow signal compared with baseline breathing
(c) Associated thoracoabdominal paradox occurs during the event but not during pre-event breathing (Fig. 20.7)
(d) **Cheyne–Stokes Respirations**: Respiratory monitoring indicates at least three consecutive central apneas and/or central hypopneas separated by crescendo and decrescendo change in breathing pattern with cycle length of more than or equal to 40 s, and there are five or more central apneas or hypopneas per hour of sleep, associated with the crescendo/decrescendo breathing pattern recorded over ≥2 h of monitoring [26] (Fig. 20.8)
(e) **Sleep-Related Hypoventilation**: This is defined as one or both of the following: (1) an increase in arterial PCO_2 (surrogate) to a value ≥55 mm Hg for more >10 min and/or (2) there is ≥10 mm Hg increase in arterial PCO_2 (or surrogate) during sleep (in comparison with an awake supine value) to a value exceeding 50 mm Hg for >10 min [26] (Fig. 20.9)

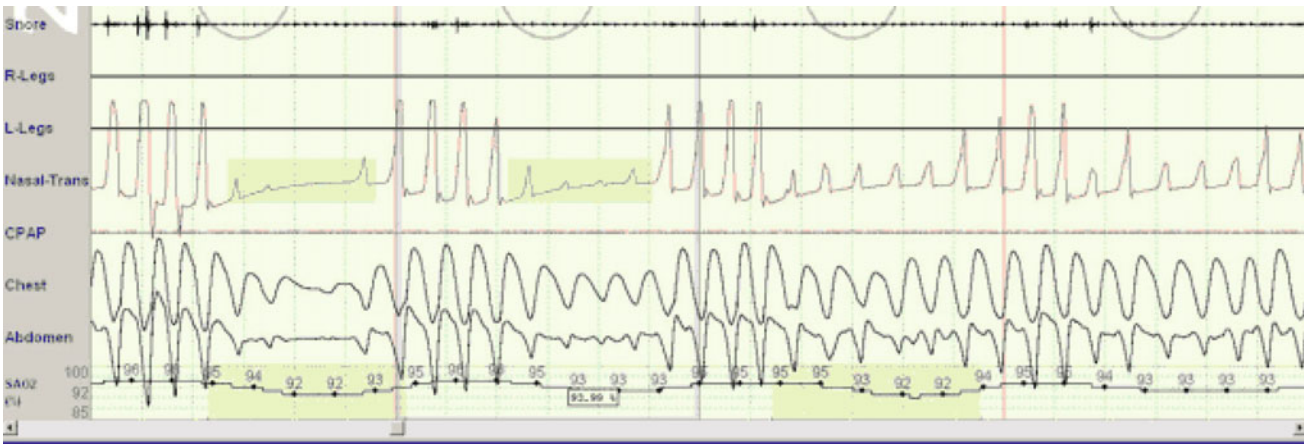

Fig. 20.7 Central hypopneas: these events are associated with absence of snoring, oxygen desaturation (albeit less substantive than that noted in obstructive events), and lack of thoracoabdominal paradox

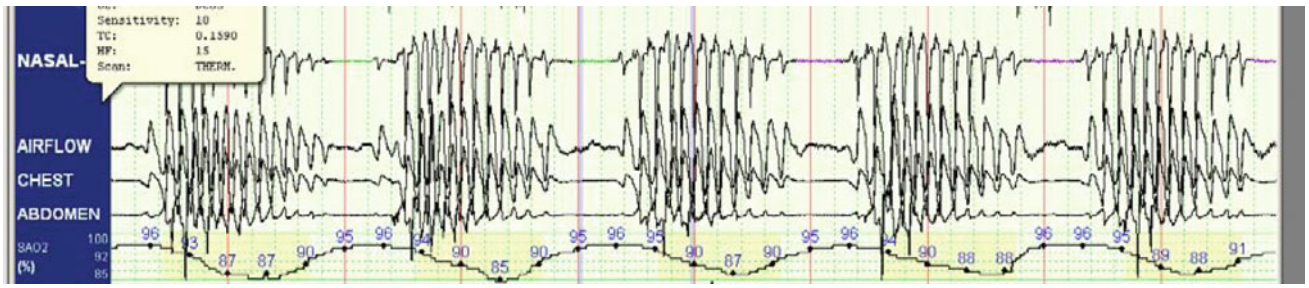

Fig. 20.8 Cheyne–Stokes respiration. Periodic breathing is characterized by crescendo-decrescendo change in breathing amplitude which separates at least three consecutive central apneas and/or central hypopneas

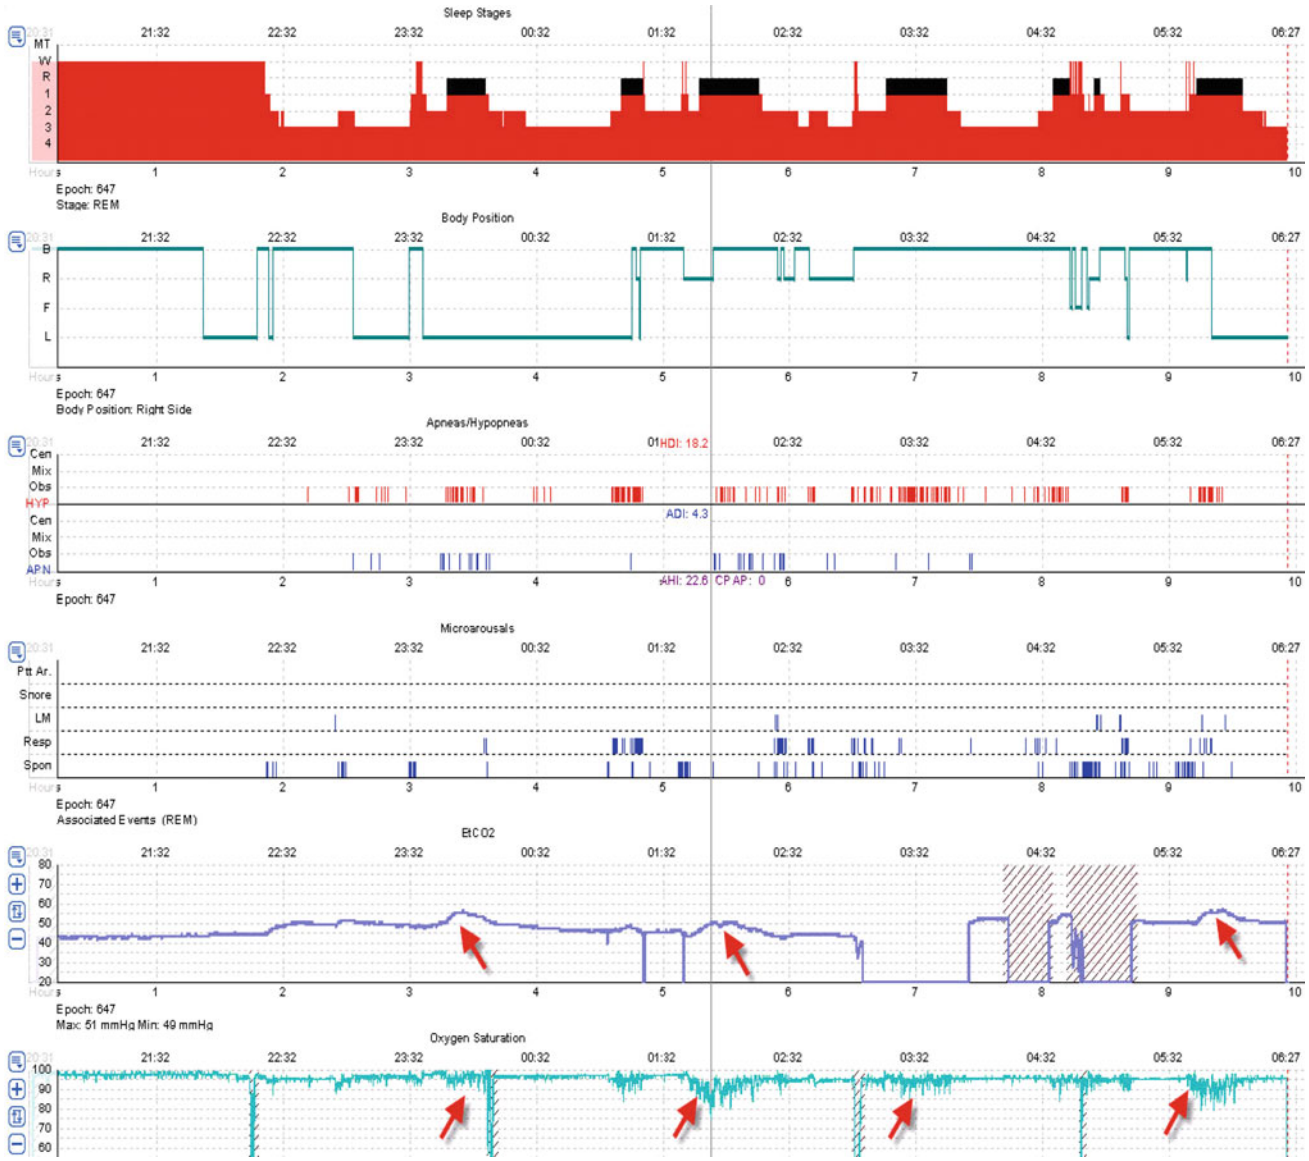

Fig. 20.9 Sleep-related hypoventilation. The *leftward slanting arrows* point toward the rise in CO_2 level with accompanying drop in oxygen saturation as indicated by the *rightward slanting arrows*. Note the increase in the CO_2 level with the sleep onset

Neuroimaging in Normal and Abnormal Sleep

21

Thien Thanh Dang-Vu, Jordan O'Byrne, Victoria Zhang, Audrée Arcelin, Sophie Schwartz, Philippe Peigneux, Pierre Maquet, and Martin Desseilles

Introduction

Functional neuroimaging is a powerful tool to explore regional brain activity in humans. It includes a variety of metabolic and hemodynamic techniques such as positron emission tomography (PET), single-photon emission computed tomography (SPECT), functional magnetic resonance imaging (fMRI), and near-infrared spectroscopy. Neurophysiologic techniques such as electroencephalography (EEG) and magnetoencephalography (MEG) are not reviewed here.

Neuroimaging in patients suffering from sleep disorders may serve several purposes. First, it can help characterize the cerebral consequences of sleep disruption due to intrinsic sleep disorders and extrinsic environmental or medical causes. For instance, neuroimaging studies have shown that chronic sleep fragmentation in sleep-disordered patients [e.g., patients with obstructive sleep apnea syndrome (OSAS)] [1] or acute sleep deprivation in normal subjects [2–4] eventually leads to impaired cognitive functioning associated with significant changes in the underlying pattern of regional brain activity.

Second, neuroimaging may serve to better characterize the pathogenic mechanisms of sleep disorders, or at least their cerebral correlates [5]. This endeavor is hindered by the fact that, from the practical and methodological points of view, scanning patients during their sleep is not easy. However, alternative approaches are available, as the functional and structural consequences of these sleep disorders can also be assessed during wakefulness. For instance, voxel-based morphometry (VBM) analysis can be used to detect structural brain changes typical of specific sleep disorders. Likewise, cardiovascular regulation can be assessed by probing important reflexes (e.g., during the Valsalva maneuver).

Third, neuroimaging might help to establish the nosography of sleep disorders. For instance, neuroimaging could help classify different subtypes of insomnia in terms of their underlying characteristic patterns of regional brain activity, an approach that may prove complementary to clinical observation.

This chapter reviews attempts made in these various directions. To set the stage for the study of sleep disorders, we first describe recent contributions of neuroimaging techniques to the functional neuroanatomy of normal sleep in humans.

Neuroimaging in Normal Human Sleep

Sleep profoundly impacts the activity of numerous physiologic systems (see, e.g., Kryger et al. [6]). PET, SPECT, or fMRI studies reviewed in this section have demonstrated that global and regional patterns of brain activity during sleep are remarkably different from those during wakefulness. These studies have also shown the persistence of brain responses to external stimuli during sleep, and plastic changes in brain activity related to previous waking experience.

Functional Neuroimaging of Normal Human Sleep

Noninvasive functional neuroimaging with PET brought an original description of the functional neuroanatomy of human sleep. These studies described a reproducible regional distribution of brain activity during sleep stages (rapid eye movement [REM] and non-REM [NREM] sleep) that largely differs from wakefulness, as expected from animal data. More recent data, using event-related fMRI, have also assessed the brain activity related to spontaneous neural events within sleep stages, such as sleep spindles.

NREM Sleep

In mammals, the neuronal activity observed during NREM sleep is sculpted by a cortical slow oscillation that alternates short bursts of firing ("up" states) and long periods of hyperpolarization ("down" states) [7]. Slow oscillations organize the synchronization of other NREM sleep rhythms (spindles and delta waves) [8] and should also have a major impact on regional cerebral blood flow (rCBF), which when averaged over time decreases in the areas where they prevail. Taking into account that PET measurements average cerebral activity over 45–90 s, decreases in cerebral blood flow (CBF) and cerebral glucose metabolism during NREM sleep are thought to underlie a change in firing pattern, reflected by the slow oscillation and characterized by synchronized bursting activity followed by long hyperpolarization periods [8]. Accordingly, as compared to wakefulness, the average cerebral metabolism and global blood flow levels begin to decrease in light (stage 1 and stage 2) NREM sleep [9–11], and reach their nadir in deep (stage 3) NREM sleep, also named slow-wave sleep (SWS) [12, 13].

In animals, the cascade of events that generates NREM sleep oscillations by thalamo-neocortical networks is induced by a decreased firing in the activating structures of the brainstem tegmentum [7]. In agreement with animal data, humans' PET studies show that brainstem blood flow is decreased during light NREM sleep [14] as well as during SWS [14–17]. During light NREM sleep, the pontine tegmentum appears specifically deactivated, whereas the mesencephalon seems to retain an activity that is not significantly different from wakefulness [14]. In SWS, both pontine and mesencephalic tegmenta are deactivated [16].

The thalamus occupies a central position in the generation of NREM sleep rhythms, due to the intrinsic oscillating properties of its neurons and the intrathalamic and thalamo-corticothalamic connectivity. As expected, in humans, regional activity decreases have been found in the thalamus during both light and deep NREM sleep in PET [14–16] and block-design fMRI [16] studies; rCBF decreases in the thalamus have also been evidenced in proportion to the power density of the EEG signal in the spindle and delta frequency range [18] (see Dang-Vu et al. [19] for a critical discussion of these findings).

The role of the cortex in the generation of NREM sleep oscillations is equally important but not yet fully understood [20], especially at the neuronal level. Electroencephalographic power density maps have revealed a relatively typical predominance of the delta frequency band in the frontal regions, whereas sigma power predominated over the vertex [21]. Human PET data similarly showed that the pattern of cortical deactivation was not homogeneously distributed throughout the cortex. As compared to wakefulness, the least active areas in SWS were observed in various associative cortices of the frontal (in particular the dorsolateral and orbital prefrontal cortex) and parietal, and to a lesser extent in the temporal and insular cortices [14, 15, 16, 22]. In contrast, the primary cortices were the least deactivated cortical areas [15]. Finally, a meta-analysis of our own data [19] showed a linear (inverse) relationship between EEG spectral power within the delta frequency band and rCBF in ventromedial prefrontal regions during NREM sleep in non-sleep-deprived normal subjects. This result suggests an important role of medial prefrontal cortices in the modulation of delta waves.

The reasons for this heterogeneous cortical distribution remain unclear. One hypothesis is that, since polymodal association cortices are the most active cerebral areas during wakefulness, and because sleep intensity is homeostatically related to prior waking activity at the regional level [23], these cortices might be more profoundly influenced by SWS rhythms than primary cortices [8].

The predominance of rCBF decreases in prefrontal regions may be functionally important since these cortical

regions are involved in mood regulation and in various cognitive functions (e.g., planning or probability matching) [24] that help adaptation of individual behaviors. Studies of the deleterious effects of sleep deprivation on human cognition also pointed to a high sensitivity of these association cortices to sleep deprivation (see later).

The previous functional brain imaging studies have compared periods or "blocks" of brain activity averaged over several tens of seconds or minutes between NREM sleep and wakefulness. Because hyperpolarization phases may predominate over these periods, the resulting picture emerging from these studies is decreasing brain activity during NREM sleep in the areas where slow oscillations are most prevalent. While NREM sleep is consistently characterized by a global and regional net decrease of brain activity over several seconds or minutes, the concept of NREM sleep as a stage of brain quiescence is not accurate, as we know from animal studies that NREM sleep is also characterized by transient bursts of neuronal discharge ("up" states) organized by NREM sleep oscillations. We conducted an event-related fMRI study during NREM sleep in normal non-sleep-deprived human volunteers and showed that the occurrence of the phasic sleep spindles was associated with increases of brain activity in a specific set of cortical and subcortical structures, including the thalamus, paralimbic areas, and superior temporal gyri [25]. Moreover, beyond this general activation pattern, we also demonstrated that slow and fast spindles could be differentiated in terms of their macroscopic hemodynamic responses: slow spindles were specifically associated with activation of the superior temporal gyrus, and fast spindles preferentially recruited hippocampal and sensorimotor cortical areas. Besides bringing further evidence that spindles can be divided in two biologically distinct subtypes, this study demonstrates that NREM sleep cannot be reduced to a state of sustained brain deactivation but is characterized by phasic increases in brain activity triggered by NREM sleep oscillations, such as spindles, in agreement with animal data.

Further support for this notion was obtained from another study from our group, this one evaluating brain activation in response to slow waves during NREM sleep [26]. Compared with baseline activation during deep sleep, slow waves were associated with significant activation in the inferior frontal gyrus, parahippocampal gyrus, precuneus, posterior cingulate cortex, brain stem (pons), and cerebellum. Higher amplitude slow waves (>140 μV) were more consistently associated with parahippocampal and brainstem activation [26]. This specificity of slow-wave regional recruitment, particularly in parahippocampal and prefrontal regions, may subserve a role of slow waves in sleep-dependent memory consolidation. In addition, the activation of pontine structures with slow waves suggests a change of firing rate—from a tonic to a phasic mode—in specific brainstem nuclei during NREM sleep, in agreement with recent animal data [27].

REM Sleep

REM sleep is characterized by desynchronized neuronal activity [28, 29] and, correspondingly, by high cerebral energy requirements [12] and blood flow [13, 30]. In this active but sleeping brain, some areas are particularly active, even more than during wakefulness, while others have lower than average regional activity.

PET studies have shown significant rCBF increases during REM sleep in the pontine tegmentum, thalamic nuclei, limbic and paralimbic areas, amygdaloid complexes [31, 32], hippocampal formation [15, 32], anterior cingulate cortex [15, 31, 32], and orbitofrontal and insular cortices [32] (Fig. 21.1). Posterior cortices in temporo-occipital areas were also found to be activated [15], although less consistently. In contrast, the inferior and middle dorsolateral prefrontal gyri, the inferior parietal cortex, and the posterior cingulate cortex and precuneus were the least active brain regions [15, 31].

Regional brain activity in subcortical mesopontine and thalamic regions during human REM sleep [14, 31] is in keeping with our current understanding of sleep generation in animals. REM sleep is generated by neuronal populations of the mesopontine reticular formation that activates the thalamic nuclei, which in turn activate the cortex [28].

Functional connectivity between remote brain areas is also modified during human REM sleep. The functional relationship between striate and extrastriate cortices, usually excitatory, is reversed during REM sleep [15, 33]. Likewise, the functional relationship between the amygdala and the temporal and occipital cortices is different during REM sleep than during wakefulness or NREM sleep [34]. This pattern suggests that functional interactions between neuronal populations are different during REM sleep than during wakefulness. A recent resting-state fMRI study demonstrated that REM sleep connectivity is also different from NREM sleep connectivity, specifically in the set of brain areas known as the default-mode network [35]. The default-mode network consists of regions activated when the brain is not engaged in externally oriented behavior [36]. The functional connectivity within the default-mode network is diminished in NREM sleep, but in REM sleep, it is comparable to that in wakefulness [35]. Moreover, in REM sleep, the higher-order association cortices (encompassing the default-mode network) engage in a rapid oscillatory fluctuation of anticorrelated activation with the sensorimotor areas [35]. These characteristic patterns of activation may underlie neuroplastic and phenomenal aspects of REM sleep.

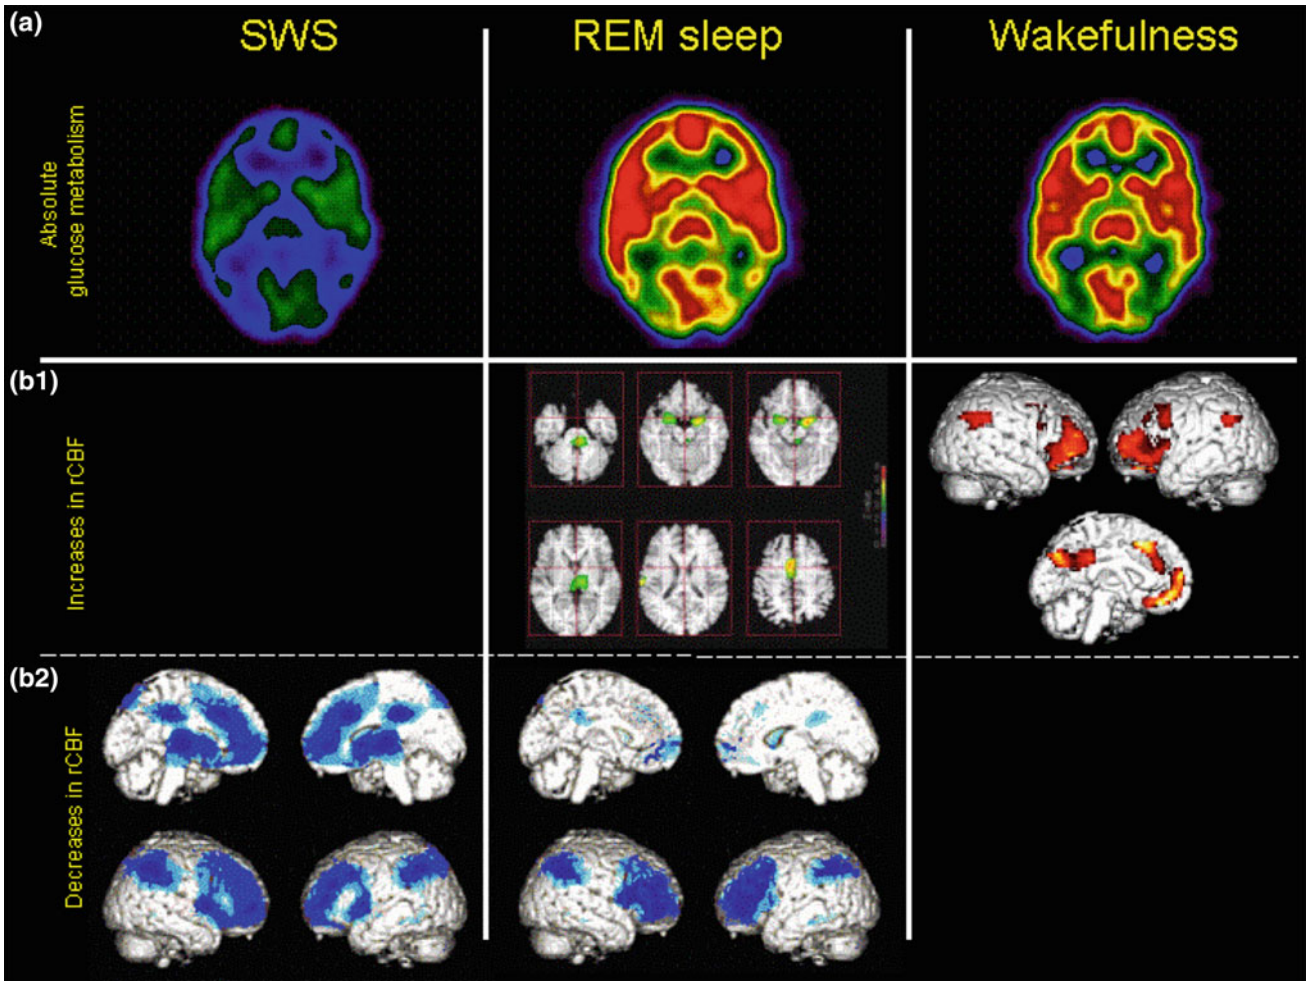

Fig. 21.1 Cerebral glucose metabolism (*CGM*) and regional cerebral blood flow (*CBF*) during deep NREM sleep (*first column*), REM sleep (*second column*), and wakefulness (*third column*). Row **a** CGM quantified in the same individual at 1-week interval, using FDG and PET. The three images are displayed at the same brain level using the same color scale. The average CGM during deep NREM sleep (versus wakefulness) is significantly decreased. During REM sleep, the CGM is as high as during wakefulness. Row **b1** Distribution of the *highest* regional brain activity, as assessed by CBF measurement using PET, during wakefulness and REM sleep. The most active regions during *wakefulness* are located in the polymodal associative cortices in the prefrontal and parietal lobes (both on the medial wall and convexity). During REM sleep, the most active areas are located in the pontine tegmentum, thalami, amygdaloid complexes, and anterior cingulate cortex. Other data (not shown) have shown a large activity in the occipital cortices, insula, and hippocampus [15]. Row **b2** Distribution of the *lowest* regional brain activity, as assessed by CBF measurement using PET, during NREM and REM sleep. In both sleep stages, the least active regions are located in the polymodal associative cortices in the prefrontal and parietal lobes (convexity). During NREM sleep, the brainstem and thalami are also particularly deactivated

Pontine waves, or ponto-geniculo-occipital (PGO) waves, are also primary features of REM sleep. In rats, the generator of the pontine waves projects to a set of brain areas shown to be active in human REM sleep: the occipital cortex, the entorhinal cortex, the hippocampus, and the amygdala as well as brainstem structures participating in the generation of REM sleep [37]. Although most easily recorded in the pons [38], the lateral geniculate bodies [39], and the occipital cortex in cats [40], PGO waves are also observed in many parts of the brain, including limbic areas (amygdala, hippocampus, cingulate gyrus) [41]. Several observations suggest that PGO waves also occur during human sleep. In epileptic patients, direct intracerebral recordings in the striate cortex showed monophasic or diphasic potentials during REM sleep, isolated or in bursts [42]. In normal subjects, surface EEG revealed transient occipital and/or parietal potentials time-locked to the REMs [43]. Source dipoles of MEG signal were localized in the brainstem, thalamus, hippocampus, and occipital cortex during REM sleep [44, 45]. Using PET, we showed that the rCBF in the lateral geniculate bodies and the occipital cortex is tightly coupled to spontaneous eye movements during REM sleep, but not during wakefulness [46]. This finding has been confirmed by fMRI studies [47, 48]. Although fully conclusive

components are still awaited, these elements support the hypothesis that PGO-like activities participate in shaping the distribution of regional brain activity during human REM sleep.

Many subjective aspects of dreams may be related to changes in brain activation during REM sleep [49], as evidenced by a series of PET studies. Increased perfusion in the occipital and temporal lobes, in the absence of afferent sensory input, may relate to the visual and auditory experiences that characterize dreams [33]. Indeed, lesions in the occipital cortex are associated with suppressed visual mentation during dreams. Increased perfusion in the motor and premotor areas during REM sleep may relate to movement perception in dreams [8, 15]. These intended movements are not physically enacted because efferent motor signals are suppressed in REM sleep by muscle atonia. This suppression can be inhibited by pontomedullary lesion, as has been shown in cats. Lesioned cats then engage in coordinated movement during REM sleep, ostensibly acting out their dreams. Similar behavior is also observed in humans with REM sleep behavior disorder (RBD) (see section below). The amygdala is particularly active during REM sleep [15, 31], perhaps underlying the potent emotions experienced in dreams. Regional deactivations during REM sleep are also related to certain elements of dreams. The lateral prefrontal cortex, an area involved in the monitoring of complex cognitive processes during waking, shows marked hypoperfusion during REM sleep [8]. Accordingly, dreams are often characterized by a bizarreness and incoherence of which the dreamer is unaware. The failure to coherently access episodic memory during dreams is also attributable to lateral prefrontal deactivation. In contrast, the medial prefrontal cortex remains activated in REM sleep. The representation of others' minds, known as theory of mind, is a function thought to be subserved by this area, and indeed, dreams contain characters with thoughts, emotions, and intentions of their own. However, the delimitation of the dreamer's mind is less distinct. Dreamers commonly move between first-person and third-person perspectives over the course of a dream. The inability to differentiate first- and third-person perspective may be associated with decreased perfusion in the inferior parietal cortex [50].

Recently, Dresler et al. [51, 52] were able to image lucid dreaming, a rare and intriguing feature of REM sleep. Unlike in normal dreams, lucid dreamers can gain awareness of the fact that they are dreaming, can access long-term memory stores, and can willingly control the events of their dream. Moreover, lucid dreamers can, to a slight extent, control their real eye and hand movements while maintaining polysomnographic sleep. By instructing the dreamer to provide gestural signals at the onset of a lucid dream, researchers determined that several areas normally deactivated in normal dreaming become activated during lucid dreaming, including the dorsolateral prefrontal cortex [51]. In a related experiment, Dresler et al. [52] asked participants to perform a pretrained motor task during lucid dreaming. They found that similar areas were activated during the dreamed mentation of a motor task and during its execution in wakefulness. It should be noted that both of these studies are limited by very small samples of 1 or 2 participants, owing to the rarity of lucid dreaming.

Brain Reactivity to External Stimulation During Sleep

Electrophysiologic studies have demonstrated that sleep is not a state of complete unresponsiveness to external stimuli (e.g., Perrin et al. [53]). Early studies have shown that external stimuli can induce an autonomic or electrophysiologic response during human sleep, in particular after a relevant or meaningful stimulus presentation [54]. Available PET and fMRI data globally suggest that the processing of external stimuli can proceed beyond the primary cortices during NREM sleep. However, the mechanisms by which salient stimuli can recruit associative cerebral areas during sleep remain unclear. A pioneering fMRI study found that, during NREM sleep as during wakefulness, several areas continue to be activated by external auditory stimulation: the thalamic nuclei, the auditory cortices, and the caudate nucleus [55]. Moreover, the left amygdala and the left prefrontal cortex were found to be more activated by subjects' own names than by pure tones, suggesting the persistence during sleep of specific responses for meaningful or emotionally laden stimuli.

Other groups observed that auditory stimulation induced a decreased response in the auditory cortex [56, 57]. Intriguingly, visual stimulation during SWS in adults elicited a decrease in activity in the occipital cortex [58]. This decrease was more rostral and dorsal compared to the relative rCBF increase along the calcarine sulcus found during visual stimulation in the awake state. The origin of this negative blood oxygenation level is still unclear [59]. One fMRI study investigated responsiveness to sounds during REM sleep, and detected auditory cortex activation during tonic but not phasic REM sleep. The non-responsiveness observed in phasic REM sleep was interpreted as a state of functional isolation [60].

Processing of external stimuli during sleep may be dependent on spontaneous brain activity, such as sleep spindles. In order to explore this interaction, we conducted an EEG/fMRI study involving the presentation of pure tones

to participants sleeping in the scanner [61]. When comparing blood-oxygen-level-dependent (BOLD) activation from tones presented during and outside of sleep spindles, we found a stark difference in global activation. Whereas tones played outside of spindles elicited activation in the thalamus and auditory cortex, replicating earlier results [55], tones played during spindles produced no significant activation, save for a small area in the brainstem [61]. These results show that sleep spindles effectively hinder the transmission of external auditory stimulation to the cortex during NREM sleep. This finding may explain variable susceptibility to noise disturbance during sleep, within and between subjects. Indeed, in another study, sleep stability in the presence of auditory disturbance was correlated with spindle density [62]. The "noise-canceling" function of sleep spindles is also consistent with its hypothesized role in sleep-dependent memory consolidation, in that it may contribute to brain functional isolation necessary for endogenous information processing in the absence of contaminating inputs. In support of this notion, hippocampal connectivity with neocortical areas was increased during sleep spindles, suggesting information transfer akin to systems consolidation [63]. In the same EEG/fMRI study, we also investigated the interaction between incoming auditory stimulation and K-complexes. It was found that sound-induced K-complexes were associated with increasing activation in the auditory cortex [61]. This finding suggests that K-complexes reflect a facilitated processing of sensory information at the cortical level during NREM sleep. Finally, in a complementary study, we examined the effect of slow-wave phase on the processing of auditory stimulation in NREM sleep [64]. We found a larger activation of the superior temporal gyrus with sounds presented during the up state of the slow wave compared to those presented during the down state. Therefore, the processing of sensory stimulation during NREM sleep is closely regulated by the underlying state of neural synchronization and firing, as reflected by slow waves and spindles.

Sleep and Brain Plasticity

Evidence accumulates suggesting that sleep participates in the consolidation of recent memory traces [65]. Accordingly, PET studies have shown that waking experience influences regional brain activity during subsequent REM and NREM sleep. Several brain areas, activated during procedural motor sequence learning (using a serial reaction time task) during wakefulness, have been found to be significantly more activated during subsequent REM sleep in subjects previously trained on the task than in non-trained subjects [66]. Furthermore, this effect is not observed in subjects trained to a task with similar practice requirements but devoid of any sequential content [67]. These findings speak against use-dependent changes in regional brain activations. Additionally, functional coupling between learning-related areas was found to be enhanced during post-training REM sleep [68]. Another PET study demonstrated that hippocampal and parahippocampal areas, which are activated during a spatial memory task, can be reactivated during post-training NREM sleep and that the amount of hippocampal activity during SWS positively correlated with overnight improvement in the memory for spatial locations [69]. Collectively, these findings suggest that reactivations of regional activity and modifications of functional connectivity during post-training sleep reflect the off-line processing of recent memory, which eventually leads to improved performance the next day. Moreover, these results are in line with behavioral data suggesting that NREM sleep and REM sleep differentially modulate the consolidation of declarative and non-declarative memories, respectively [70, 71]. However, they do not rule out an alternative hypothesis that natural succession of NREM sleep and REM sleep is also mandatory for memory consolidation.

Functional MRI studies demonstrated that sleep deprivation hinders the plastic changes that normally would occur during post-training sleep [72]. In this study, the effects of normal sleep or sleep deprivation on learning-dependent changes in regional brain activity were assessed after the subjects were trained on a pursuit task, in which they had to hold a joystick position as close as possible to a moving target, whose trajectory was predictable on the horizontal axis but not on the vertical axis. The time on target was used as the behavioral performance parameter. In the first group, subjects were totally sleep-deprived during the first post-training night, while in the second group, they were allowed to sleep. Both groups were then retested after 2 more nights of normal sleep in order to recover a similar state of arousal across the two groups and between the training and retest sessions. The fMRI scanning session was recorded during the retest, while subjects were exposed to the previously learned trajectory and also to a new one in which the predictable axis was vertical. Behavioral results showed that the time on target was larger for the learned trajectory than for the new one in both groups during the retest and that this performance gain was greater in the sleeping group than in the sleep deprivation group. The fMRI data showed a significant effect of learning, irrespective of the group, in two regions: the left supplementary eye field and the right dentate nucleus. A region of the right superior temporal sulcus, close to regions coding for motion processing (biologic motion, smooth pursuit, etc.), was found to be more active for the learned than for the new trajectory, and more so in the sleeping group than in the sleep deprivation group. The functional connectivity also showed that the dentate nucleus was more closely linked to the superior temporal sulcus, and the

supplementary eye field to the frontal eye field, for the learned than for the new trajectory, and more so in the sleeping group. Moreover, interactions between the temporal cortex and cerebellum, as well as between the frontal eye field and the supplementary eye field, are both known to be implicated in the standard pursuit eye movement pathways [73]. These results therefore suggest that the performance on the pursuit task relies on the subject's ability to learn the motion characteristics of trajectory in order to program optimal motor pursuit execution. Sleep deprivation during the first post-training night would disturb the slow processes that lead to the acquisition of this procedural skill and alter related changes in functional connectivity that were reinforced in subjects allowed to sleep [72].

Orban et al. [74] used fMRI in order to map regional cerebral activity during place-finding navigation in a virtual town, immediately after learning and 3 days later, in subjects either allowed regular sleep (RS) or totally sleep-deprived (SD) on the first post-training night. Results showed that, at immediate and delayed retrieval, place-finding navigation elicited increased brain activity in an extended hippocampo-neocortical network in both RS and SD subjects. Moreover, behavioral performance was equivalent between groups. However, striatal navigation-related activity increased more at delayed retrieval in RS than in SD subjects. Furthermore, correlations between striatal response and behavioral performance, as well as functional connectivity between the striatum and the hippocampus, were modulated by post-training sleep. Overall, these data suggest that brain activity is restructured during sleep in such a way that navigation in the virtual environment, initially related to a hippocampus-dependent spatial strategy, becomes progressively contingent in part on a response-based strategy mediated by the striatum. Interestingly, both neural strategies eventually relate to equivalent performance levels, indicating that covert reorganization of brain patterns underlying navigation after sleep is not necessarily accompanied by overt changes in behavior [74]. Further studies have also evidenced a reorganization of brain activity when post-training sleep is allowed both for neutral [75] and emotional [76] verbal material, as well as for visual face-to-location associations [77]. In addition, exposure to an odor during SWS that had been presented as context during prior learning improved the retention of hippocampus-dependent declarative memories and elicited a significant hippocampal activation during SWS [78]. In a similar experiment using sounds to cue object-location memory, it was also shown that functional connectivity between the parahippocampal region and the visual cortices was enhanced upon sound presentation during SWS [79].

In addition, EEG and MEG studies have provided robust evidence for the "sleep and memory consolidation" hypothesis by focusing on more specific sleep features and mechanisms that are regarded as important for different types of memory, including sleep spindles [80–83], slow waves [84], or the actual number of rapid eye movements [85]. For instance, sleep homeostasis has a local synaptic component, which can be triggered by a learning task involving specific brain regions. The local increase in slow-wave activity after learning correlated with improved performance of the task after sleep [84]. Moreover, the induction of slow oscillation-like potential fields by transcranial application of slowly oscillating potentials (0.75 Hz) during early nocturnal NREM sleep (i.e., a period of emerging SWS) enhanced the retention of hippocampus-dependent declarative memories in healthy humans. This stimulation induced an immediate increase in SWS, cortical slow oscillations, and slow spindle activity in the frontal cortex [86].

Sleep spindles appear to play a central role in NREM sleep-dependent memory consolidation. Specifically, spindles appear to organize the concerted reactivation of neocortical areas involved in a memory with its hippocampal trace. In this way, spindles are believed to facilitate the transfer of newly consolidated memories from the hippocampus to the neocortex. Accordingly, Bergmann et al. [87] demonstrated in an EEG-fMRI study that sleep spindles were temporally coupled with concurrent activation in the hippocampus and neocortical areas relevant to a previously learned declarative memory task. Notably, this spindle-hippocampo-neocortical synchrony was greater after declarative learning than after a visuomotor control task and was correlated with performance on the declarative task. Furthermore, the magnitude of hippocampo-neocortical activation was proportional to variations in spindle amplitude. The key role of sleep spindles in memory consolidation is consistent with its aforementioned ability to block out external stimulation during NREM sleep [61].

Alertness, Performance, and Sleep Deprivation

Sleep deprivation or fragmentation is increasingly common in industrialized societies (noisy environments, shift work). Likewise, many sleep disorders are common in the general population (e.g., insomnia, anxiety disorders). The considerable proportion of vehicle accidents related to sleep loss is now viewed as a serious concern for public health [88]. The impact of sleep deprivation on cognition and brain functions has been assessed mainly in healthy subjects. By comparison, studies on the consequences of sleep disorders on behavior and cerebral activity remain scarce.

Cognitive Challenges

Sleep deprivation is known to alter alertness and performance in a series of cognitive tasks. Several neuroimaging studies have tried to determine the underlying patterns of cerebral activity during different cognitive tasks. The cerebral responses to sleep deprivation seem to depend on the type of task and also on its level of difficulty. Both decreases and increases in responses were reported. The former were interpreted as metabolic impairments related to sleep deprivation, whereas the latter were viewed as compensatory responses.

An early PET study with [^{18}F]2-fluoro-2-deoxy-D-glucose (^{18}FDG) investigated the effect of total sleep deprivation (about 32 h) on brain metabolism [89]. Although global brain metabolism was not affected by sleep deprivation, regional glucose metabolism significantly decreased in the thalamus, basal ganglia, and cerebellum. A significant reorganization of regional activity was observed after sleep deprivation, with relative decreases in the cerebral metabolic rate of glucose (CMRglu) within the temporal lobes and relative increases in the visual cortex [89]. Additionally, sleep deprivation significantly reduced performance in an attentional continuous performance test, and this decrease was significantly correlated with reduced metabolic rate in thalamic, basal ganglia, and limbic regions [89].

One study showed that, even after as little as 24 h of continuous wakefulness, significant decreases in global CMRglu are observed with ^{18}FDG PET [2]. When subjects performed a sleep deprivation-sensitive serial addition/subtraction task (which combines arithmetic processing and working memory), significant decreases in absolute regional CMRglu were found in several cortical and subcortical structures, whereas no areas of the brain showed any significant increase in regional metabolism. Alertness and cognitive performance scores declined in parallel with deactivations in the thalamus and in the prefrontal and posterior parietal cortices [2].

The same group of researchers characterized the cerebral effects of 24, 48, and 72 h of sleep deprivation during the same task performance in 17 healthy subjects using correlations with performance measures outside of the scanner and metabolism during resting state assessed by ^{18}FDG PET [90]. Results showed that absolute CMRglu and relative regional CMRglu decreased further at 48 and 72 h of sleep deprivation primarily in the prefrontal and parietal cortices and in the thalamus, the same areas that showed decreases at 24 h of sleep deprivation. The authors proposed that the decreases in CMRglu induced in the prefrontal-thalamic network by sleep deprivation underlie the progressive impairment in cognitive performance and alertness and the progression toward sleep onset. In contrast, increased activity in visual and motor areas would reflect voluntary attempts to remain awake and perform despite a continuing decline in prefrontal-thalamic network activity [90].

In these PET CMRglu studies, metabolism during resting state was correlated with performance measures obtained outside of the scanner. However, a different picture emerges when subjects are scanned during task performance using fMRI.

Drummond and colleagues used fMRI on normal subjects while those subjects performed different cognitive tasks after a normal night of sleep or following 35 h of sleep deprivation. In a first report [4], the study used a serial subtraction task. Bilateral activations in the prefrontal, parietal, and premotor cortices were found during task practice after a normal night of sleep, whereas activity in these regions declined markedly after sleep deprivation, mainly in the prefrontal cortex [4], which is in agreement with the hypothesis of prefrontal cortex vulnerability to sleep deprivation [91]. Likewise, Mu et al. [92] found reduced activations in several frontal and parietal regions (left dorsolateral prefrontal cortex, right ventrolateral prefrontal cortex, supplementary motor area, Broca's area, and bilateral posterior parietal cortices) during practice of the Sternberg working memory task after 30 h of sleep deprivation compared to normal sleep. However, a very different pattern emerged when using other types of tasks. For example, the effects of 35 h of continuous wakefulness on cerebral activation during verbal learning (memorizing a list of words) were also investigated using fMRI [93]. The authors found that the prefrontal cortex and parietal lobes were more activated during verbal learning after 1 night of sleep deprivation than after normal sleep. In addition, increased subjective sleepiness in SD subjects correlated significantly with the amount of prefrontal cortex activation, while stronger parietal lobe activation was linked to less impairment in the free recall of words. Neurobehavioral (fMRI) effects of 24 h of continuous wakefulness were assessed using two verbal working memory tasks of different difficulty levels, known to induce responses in frontal-parietal networks in normal, non-sleep-deprived conditions. After sleep deprivation, activity was reduced in the medial parietal, anterior medial frontal, and posterior cingulate regions in both tasks, and disproportionately greater activation of the left dorsolateral prefrontal cortex and bilateral thalamus was observed when additional manipulation of information in working memory was required [94] (see also [95]). It has been suggested that these results reflect dynamic, compensatory changes in cerebral activation during verbal learning after sleep deprivation [93]. Compensatory mechanisms may lead to stronger responses within regions typically underlying task performance, as well as to activation in regions that do not show significant responses to task demands in the well-rested condition [96]. Indeed, the thalamus was also found to be

hyperactivated in sleep deprivation during a visual attention task, in the absence of performance deficits [97]. In another fMRI study, performance on a higher-order attention task was unaltered by sleep deprivation, while greater thalamic activation was recruited in the SD group [98]. The thalamus may thus play an important role in cognitive compensation in SD states.

These data suggest that decreases in regional brain activity could contribute to cognitive impairment after sleep deprivation and that increased prefrontal and thalamic activation may represent compensatory adaptation. In a similar attempt to better understand how sleep deprivation might interact with task difficulty, an fMRI study found stronger correlation between difficulty in a logical reasoning task and increased activity in the bilateral inferior parietal lobes, bilateral temporal cortex, and left inferior and dorsolateral prefrontal cortex following 35 h of continuous wakefulness than after normal sleep [96]. In a second study by the same group, the effects of normal sleep and 36 h of total sleep deprivation were assessed by fMRI during a verbal learning task with two levels of difficulty (easy and difficult words) [99]. A set of regions showed increased response to difficult words after sleep deprivation compared with normal sleep (inferior frontal gyrus, dorsolateral prefrontal cortex, and inferior parietal lobe, bilaterally). While better free recall performance on the difficult words following sleep deprivation was positively related to activation within the left inferior and superior parietal lobes and left inferior frontal gyrus, it was negatively related to activation within the right inferior frontal gyrus. Consequently, the performance relationships are thought to be both beneficial (as a compensatory function) and deleterious (as an interference with task performance), depending on the brain regions implicated. In addition, these studies suggest that increased recruitment of compensatory brain regions is yoked to rising task difficulty.

The default-mode network appears to be compromised by sleep deprivation. Disengagement of these brain regions is thought to be necessary for optimal externally oriented cognitive performance, and disturbances in default-mode function are observed in mental disorders [100]. According to a few recent studies, typical task-related default-mode network suppression was disrupted after sleep deprivation [101] and functional connectivity between default-mode areas was compromised [102, 103]. Furthermore, the anti-correlation between the default-mode network and its externally oriented counterpart was weakened in the SD condition [102].

Other cognitive domains seem to be impaired by sleep deprivation. For instance, competent decision making was impaired after sleep deprivation, which induced a modulation of activation in the nucleus accumbens and insula, brain regions associated with risky decision making and emotional processing [104]. Likewise, SD healthy adults were more likely to adopt risky strategies in a gambling task, and this change correlated with ventromedial prefrontal activation and anterior insular deactivation [105]. Furthermore, the ventromedial prefrontal and ventral striatum showed greater activation during wins, and the anterior cingulate displayed smaller deactivation during losses. These data indicate that the pursuit of gain is amplified in sleep deprivation, while losses are perceived more optimistically. Another fMRI study deprived participants of REM sleep only or NREM sleep only and evaluated emotional reactivity in a visual emotional reactivity task [106]. They found emotional reactivity to be enhanced in the REM-deprived group only, concurrently with increased activity in occipital and temporal areas, compared to NREM-deprived controls. The authors conclude that emotional reactivity is modulated by REM sleep.

Since prefrontal cortex functioning appears to be affected by sleep loss, processes mediated by this region should be altered after sleep deprivation (e.g., attention, emotion, motivation, feeding, and olfaction). In order to assess the effects of sleep deprivation on olfaction, which is mediated by the orbitofrontal cortex, a region known to have decreased activity after sleep deprivation [2], Killgore and McBride [107] studied 38 healthy subjects at rest and after 24 h of sleep deprivation. Relative to rested baseline performance, SD subjects showed a significant decline in the ability to identify specific odors on the Smell Identification Test. In relation to effects on feeding, an fMRI study examined BOLD response to the presentation of images of food items after a night of sleep deprivation [108]. Activation of the anterior cingulate cortex in response to food was increased in sleep-deprived participants with respect to non-sleep-deprived controls, independent of prescan blood-glucose levels. Moreover, this activation correlated significantly with increased post-scan hunger ratings. Sleep deprivation thus seems to enhance hedonic response to food stimuli.

Changes in dopamine neurotransmission may underlie the cognitive challenges observed in sleep deprivation. Dopamine's involvement in sleep/wake regulation remains unclear, but degeneration of dopamine pathways is associated with sleep disorders such as REM sleep behavior disorder and excessive daytime sleepiness in Parkinson's disease (PD) [109, 110]. In a series of studies, Volkow et al. [111–113] studied the effect of sleep deprivation on dopamine using PET with ^{11}C-raclopride, a dopamine D_2/D_3 receptor radioligand. They found dopamine receptor occupancy to be increased in the ventral striatum. Furthermore, this increase does not seem to be due to changes in dopamine transporter (DAT) density [114]. Increases in dopaminergic activity were associated with worse performance on a visual attention task, concurrent with BOLD changes in known dopamine-modulated areas (smaller

deactivation of anterior cingulate cortex and insula) as well as in other areas (greater deactivation of inferior occipital cortex and cerebellum) [112]. These findings suggest that striatal dopamine hyperactivity may interfere with attentional processes, or instead, may represent a compensatory mechanism in order to maintain arousal after sleep deprivation.

Personal Vulnerability to Sleep Deprivation

People may be differently affected by the same sleep-depriving environmental conditions. Studies suggest that brain responses to sleep deprivation for a given task are modulated by individual vulnerability to sleep deprivation [115]. For example, in one fMRI study, subjects were divided into two groups, a sleep deprivation-resilient group and a sleep deprivation-vulnerable group, according to their performance on a working memory task after sleep deprivation. In the sleep deprivation-resilient group, significant activations were found in several cortical areas (left dorsolateral prefrontal cortex, left ventrolateral prefrontal cortex, left supplementary motor area, and left posterior parietal cortex) during practice of the working memory task after sleep deprivation. By contrast, in the sleep deprivation-vulnerable group, only the left dorsolateral prefrontal cortex was activated after sleep deprivation. The patterns of brain activation after sleep deprivation may therefore differ as a function of the subjects' individual vulnerability to sleep deprivation [115]. The same group conducted another fMRI study on fatigue vulnerability in military pilots. Pilots were scanned during the working memory task under non-sleep-deprived conditions, and individual fatigue vulnerability was quantified using performance on a flight simulation during 37 h of continuous wakefulness. Analyses revealed that global cortical activation during the working memory task was positively correlated with fatigue resistance in flight-simulator performance. The authors therefore proposed that baseline fMRI activation during the working memory task may provide a good index of individual fatigue susceptibility [116].

Individual differences in the effect of sleep deprivation on working memory performance were assessed by fMRI in 26 healthy volunteers, in a rested condition and after 24 and 36 h of sustained wakefulness [117]. In both sleep deprivation conditions, task-related activation was significantly decreased with respect to the rested condition in the superior parietal regions and left thalamus. There was also an inverse correlation between activation of left parietal and left frontal regions during the rested condition, and individual decline in working memory performance from the rested condition to the 24-h sleep deprivation condition. In this way, frontoparietal activation in the rested state may distinguish individual cognitive vulnerability to sleep deprivation. Similarly, another fMRI study showed that lower task-related activation of the ventral prefrontal cortex during rested wakefulness was predictive of greater individual ability to maintain inhibitory efficiency in a go/no-go task [118]. Low-vulnerability individuals also showed reduced activation in this region as well as in the right insula after sleep deprivation, compared to highly vulnerable individuals.

In addition to functional imaging, structural neuroimaging techniques were also used to investigate interindividual differences in responses to sleep deprivation. For instance, studies of white matter anatomy with fractional anisotropy (FA) may provide one such physiologic marker of vulnerability to sleep deprivation [119]. In that study, West Point cadets first completed a simple visual-motor task before and after 24-h sleep deprivation and their change in performance was assessed. Taking these change scores as indices of sleep deprivation vulnerability, cadets were separated into a more vulnerable and a less vulnerable group by median split. They were then scanned with MRI using diffusion tensor imaging (DTI), and FA was calculated for each cadet as an indicator of fiber number, density, and myelination in white matter tracts. FA values were significantly greater in the low-vulnerability group than in the high-vulnerability group, predominantly in ascending and longitudinal pathways of the right hemisphere and the genu of the corpus callosum. Furthermore, greater FA values correlated significantly with smaller decreases in the performance on the task. These findings are consistent with those of aging studies linking greater white matter integrity to improved cognitive performance [120].

Sleep Deprivation in Depression

Sleep deprivation has profound effects on brain metabolism in both normal and depressed subjects. When used therapeutically (i.e., wake therapy), sleep deprivation relieves acute depressive symptoms in 60 % of patients. In depressed patients responding favorably to sleep deprivation, ^{18}FDG PET [121–123], technetium-99m–labeled hexamethylene-propyleneamine oxime (^{99m}Tc-HMPAO) SPECT [124, 125], and fMRI [126] revealed greater baseline brain activity during wakefulness in responders than in non-responders in the anterior cingulate cortex and/or the nearby mesial frontal cortex. This activity was significantly decreased after sleep deprivation. A similar profile of brain metabolism was observed with ^{18}FDG PET in elderly depressed patients, including normalization after total sleep deprivation associated with antidepressant treatment [127]. Moreover, the normalization of anterior cingulate metabolism persisted even after recovery sleep. However, these results were not replicated with placebo control [128].

MRI spectroscopic studies have shown glutamate [129, 130] and serotonin [131] levels to be globally increased after sleep deprivation in depressed patients. These neurotransmitters may then underlie the antidepressant effect of sleep

deprivation. This is consistent, in the case of serotonin, with the widespread use of selective serotonin reuptake inhibitors as antidepressants. With PET and SPECT, it was also shown that sleep deprivation responders exhibit a significant decrease in relative basal ganglia D_2 receptor occupancy after sleep deprivation, as compared to non-responders [132]. Sleep deprivation also resulted in lower binding of ^{11}C-raclopride, a D_2/D_3 receptor radioligand, in the striatum and thalamus of healthy subjects [111]. These results suggest that the antidepressant benefits of sleep deprivation are correlated with enhanced endogenous dopamine release in responders, although a later study suggests DAT downregulation may instead be responsible for observed increases in dopamine receptor occupancy [113]. Nonetheless, these results corroborate previous hypotheses about the role of dopaminergic response in the therapeutic action of sleep deprivation and indirectly support a dopamine hypothesis of depression [132]. In relation to this hypothesis, sleep-deprived healthy subjects reacted more intensely to pleasure-evoking stimuli in dopaminergic mesolimbic brain networks associated with reward [133]. In addition, gains produced higher ventromedial prefrontal and ventrostriatal activation in healthy subjects, and losses produced less anterior cingulate deactivation [105]. Together, these findings suggest that the antidepressant effect of sleep deprivation may operate through reward-enhancing increases in dopaminergic activity.

^{31}Phosphorous magnetic resonance spectroscopy (^{31}P-MRS) has also been applied to healthy SD participants to understand the metabolic and bioenergetic changes that may underlie the antidepressant effect of wake therapy. Within-subject designs with healthy participants showed no change in phosphate brain chemistry after a night of sleep deprivation [134, 135], although one study found elevated β-nucleoside triphosphate and reduced phospholipid catabolism after a subsequent recovery night [134]. In a sample of depressed women, higher baseline levels of choline compounds in the pons were associated with the improvement in mood after sleep deprivation, indicating a role of pontine choline metabolism in the antidepressant response to sleep deprivation [136]. Further studies are needed scanning both depressed patients and healthy controls before and after sleep deprivation.

Sleep deprivation data suggest a tight link between mood alteration and activity in limbic and paralimbic structures. The data suggest that anterior cingulate hyperactivity in depressed patients during wakefulness may hinder further increases during REM sleep. Hence, sleep deprivation may alleviate depression symptoms by decreasing abnormally elevated activity in the anterior cingulate cortex during wakefulness. However, further studies are needed to understand the causes and consequences of these mesial frontal metabolic disturbances.

Instrumental Manipulation of Sleep Deprivation Effects

Repetitive transcranial magnetic stimulation (rTMS) can be used to artificially stimulate cortical brain areas, enabling true experimental designs in human neuropsychology. Luber et al. [137] used rTMS to artificially relieve impairments in working memory performance from sleep deprivation. Fifteen participants were first scanned with fMRI before and after sleep deprivation, while completing a working memory task. The brain areas that showed deactivation under sleep deprivation were then used as guides for rTMS application after a second night of sleep deprivation, two weeks later. Of the three identified sites, stimulation of the upper middle occipital site produced improvements in performance, whereas no improvement was accrued from the other sites or from sham rTMS. Furthermore, the degree of performance enhancement was directly proportional to the magnitude of each participant's sleep-deprivation-induced deactivations. Hence, cognitive deficits from sleep deprivation can be corrected with rTMS by targeting the affected brain area. The authors replicated these findings in a recent experiment [138].

Summary

There is a marked heterogeneity in the functional findings relating to the cognitive effects of sleep deprivation. Deficits in cognitive function after sleep deprivation have been correlated with both activations and deactivations in several brain regions. Hypotheses explaining these findings range from compensatory mechanisms in order to maintain cognitive function, to homeostatic pressure diverting energy from certain regions, resulting in cognitive deficits. These hypotheses remain speculative. The wide range of tasks employed in these studies may in part explain the variability in results. Nonetheless, some interesting markers of individual vulnerability to sleep deprivation have been identified, including white matter integrity. In addition, the study of the therapeutic effect of sleep deprivation in depression has yielded some promising findings, particularly in relation to the dopaminergic system. Lastly, sleep deprivation effects can seemingly be rectified by the targeted use of rTMS.

Neuroimaging in Sleep Disorders

Sleep may be disrupted in a number of conditions ranging from medical diseases (e.g., endocrine disorders, chronic pain, brain lesions, and sleep apnea) and psychiatric disorders (e.g., anxiety, depression, and schizophrenia) to environmental situations (e.g., jet lag, shift work, and noisy environment).

In this section, we consider several primary sleep disorders (narcolepsy, periodic limb movement disorder, idiopathic insomnia, recurrent hypersomnia, and obstructive sleep apnea) as well as specific parasomnia syndromes

Fig. 21.2 Findings from PET, SPECT, fMRI and MRI studies in sleep disorders. **a1** Brain areas showing metabolic changes in idiopathic insomnia. Most studies show hypermetabolism in cortical and subcortical areas during NREM sleep, as well as smaller decreases in metabolism in the transition from wake to sleep. These results are consistent with the hyperarousal theory of insomnia. During wake, insomnia patients show decreased prefrontal activity. **a2** Neuroanatomical alterations in idiopathic insomnia. While many studies found no anatomic changes in insomnia patients, some reported cortical gray matter loss or changes in hippocampal or rostral anterior cingulate volume. **b1** Areas showing functional abnormalities in narcolepsy. All metabolic and hemodynamic changes are shown during wake, and one study imaged hypoperfusions during a cataplectic episode. Abnormalities in narcoleptics were reliably observed in the hypothalamus, consistent with a hypocretinergic dysfunction. **b2** Neuroanatomical alterations in narcolepsy. Hypothalamic gray matter loss may relate to hypocretinergic dysfunction. Limbic and neocortical alterations may underlie mood disturbances in narcoleptic patients. **c1** Functional studies on OSAS have focused mainly on activity changes during cognitive tasks and have mostly detected deactivations. A few resting-state studies using PET and SPECT have found decreases in activity during resting wakefulness. **c2** Neuroanatomical alterations in OSAS. Gray matter loss in the hippocampus, parietal, and prefrontal cortices may underlie various neuropsychological deficits observed in OSAS, only some of which seem to be reversible by CPAP. **d** Brain areas showing structural or functional changes in RLS. Iron deficiencies in several areas, notably the SN, may contribute to RLS, possibly via dysregulation of the closely associated dopaminergic system. These changes may in turn sensitize sensorimotor pain sensation. **e** Areas showing functional and structural abnormalities in RBD. Changes have most consistently been shown in the pons, hippocampus, and superior frontal cortex. Adapted from Desseilles et al. [5], and from illustrations by Patrick J. Lynch and C. Carl Jaffe.

(sleepwalking and RBD). We do not review sleep disorders due to disturbances from external environmental sources.

Idiopathic Insomnia

Idiopathic insomnia is a lifelong inability to obtain adequate sleep that is presumably due to an abnormality in the neurologic control of sleep–wake regulation systems [139]. This disorder is thought to reflect an imbalance between the arousal system and the various sleep-inducing and sleep-maintaining systems. Neuroanatomic, neurophysiologic, or neurochemical dysfunctions or lesions within the sleep–wake systems are suspected in some of these patients [139].

Theoretically, either hyperactivity within the arousal system or hypoactivity within the sleep system may cause idiopathic insomnia, but hyperarousal is believed to be the final common pathway of the disorder [139]. Increased arousal might be of a physiologic, cognitive, or affective nature; it is likely that these categories overlap [6, 140], since several studies have reported increased alertness on the Multiple Sleep Latency Test, increased heart rate during the sleep period, increased anxiety on rating scales, and increased tension during wakefulness [140–142]. In addition, poor sleep leads to altered mood and motivation, decreased attention and vigilance, low levels of energy and concentration, and increased daytime fatigue [139].

Quantitative EEG recordings suggest an overall cortical hyperarousal in insomnia [143]. However, hyperarousal in primary insomnia was also found to be associated with greater increase in beta/gamma activity at sleep onset, followed by a decline of high-frequency EEG activity leading to a period of hypoarousal [143]. This could explain why some neuroimaging studies showed a cortical hyperarousal pattern in insomnia while others reported a decrease in cortical functions. In the latter case, decreased metabolism might originate from time-window coincidence of the cortical hypoarousal period to neuroimaging acquisition and therefore does not discard the hyperaousal hypothesis of primary insomnia.

Only a few studies tried to characterize the functional neuroanatomy of idiopathic insomnia disorder during sleep (referred to as primary insomnia in these reports) (Fig. 21.2a1). rCBF was estimated using ^{99m}Tc-HMPAO, a gamma-emitting radionuclide imaging agent used in the evaluation of rCBF, in five insomniacs and four normal sleepers. Patients with insomnia showed major rCBF decrease in the basal ganglia, medial frontal cortex, occipital cortex, and parietal cortex. These results suggest that idiopathic insomnia is associated with an abnormal pattern of regional brain activity during NREM sleep that particularly involves a dysfunction in the basal ganglia [144]. Four of the insomnia patients from the Smith et al. study [144] were rescanned after they had been treated with cognitive behavioral therapy [145]. After this treatment, sleep latency was reduced by at least 43 % and there was a global 24 % increase in CBF, with significant increases in the basal ganglia. Smith and collaborators proposed that such increase in brain activity might reflect the normalization of sleep homeostatic processes.

^{18}FDG PET was used to measure regional CMRglu of 7 patients with idiopathic insomnia and 20 healthy age- and gender-matched subjects during waking and NREM sleep [146]. Insomniac patients showed increased global CMRglu during sleep as compared to healthy subjects, suggesting an overall cortical hyperarousal in insomnia. Moreover, insomniac patients had a smaller decline, compared to healthy subjects, in relative CMRglu from waking to sleep states in the ascending reticular activating system, hypothalamus, thalamus, insular cortex, amygdala, hippocampus, anterior cingulate, and medial prefrontal cortices (Fig. 21.3). During wakefulness, reduced relative metabolism, as compared to healthy subjects, was found in the prefrontal cortex bilaterally, in the left temporal, parietal, and occipital cortices, and in the thalamus, hypothalamus, and

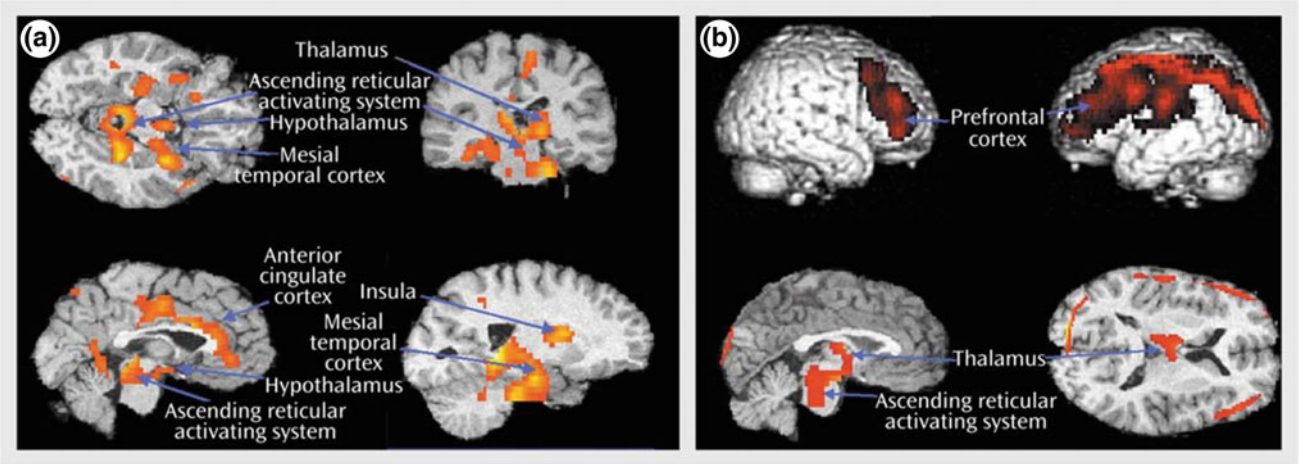

Fig. 21.3 CMRglu assessed by ^{18}FDG PET in insomniacs (versus healthy subjects) during waking and NREM sleep. **a** Brain structures that did not show decreased cerebral metabolic rate of glucose (CMRglu) from waking to sleep states in patients with idiopathic insomnia. **b** Brain structures where relative metabolism while awake was higher in healthy subjects than in patients with insomnia. Differences in all regions shown reached statistical significance ($p < 0.05$), corrected at the cluster level (Reproduced with permission from Nofzinger et al. [146]. Copyright 2004, American Psychiatric Association)

brainstem reticular formation. These findings confirm that regional brain activity does not normally progress from waking to sleep states in patients with insomnia. Additionally, it was proposed that daytime fatigue resulting from inefficient sleep may be reflected by decreased activity in the prefrontal cortex [146]. In another ^{18}FDG PET study by the same group [147] examining 15 insomniac patients, CMRglu in the pontine tegmentum and thalamo-cortical networks during NREM sleep was found to be significantly correlated with self-reported wake time after sleep onset (WASO), based on a 7-day sleep diary. Hence, elevated cortical arousal during sleep is associated with insomnia symptom severity, lending support to the hyperarousal theory of insomnia.

Additional studies have imaged idiopathic insomniacs during wakefulness, using fMRI (Fig. 21.2a1). In a first study [148], 21-year-old adult insomnia patients showed reduced medial and inferior prefrontal activation during the completion of a verbal fluency task, compared to 12 age-matched controls. In a second phase of the study after 8 weeks of non-pharmacological therapy, insomnia patients showed partial recovery of activation in these areas. These results corroborated similar findings by Nofzinger et al. [146] indicating prefrontal hypoactivation during wakefulness in insomnia. Another recent fMRI study [149] imaged 25 idiopathic insomnia patients and 25 age- and sex-matched controls during the performance of a working memory task. Interestingly, insomniacs failed both to recruit typical task-specific brain areas and to deactivate irrelevant, default-mode network regions. The authors suggested that the observed alteration in task-specific activation reflects compromised cognitive processing in insomnia, even though task performance in insomniacs was not different from controls. They attributed this to a masking effect of high perfectionism, a trait associated with insomnia.

Insomnia has been associated with high emotional reactivity [150]. An fMRI study investigated resting-state functional connectivity in the emotional system of 10 idiopathic insomnia patients and 10 matched controls [151]. Abnormalities were detected in functional connectivity between the amygdala and several cortical and subcortical areas in insomnia patients. While decreased connectivity was found for the striatum, insula, and thalamus, elevated connectivity was observed between the amygdala and the premotor cortex, sensorimotor cortex, a pathway associated with threat response. Increased motor activation is consistent with global cortical hyperarousal in insomnia.

Some recent efforts have been made to identify structural brain alterations in idiopathic insomnia, with the use of magnetic resonance imaging (MRI) (Fig. 21.2a2). While an early study found reduced hippocampal volumes in idiopathic insomnia patients compared to controls [152], subsequent studies were unable to replicate the finding [153–156]. One study found significant negative correlations between hippocampal volume and insomnia duration, as well as with a polysomnography-based index of arousal [154]. Consistent with these findings, significant inverse correlations have been reported between hippocampal volume and actigraphic WASO and sleep efficiency [153]. In one retrospective study, rostral anterior cingulate volumes were significantly greater in insomniacs [157]. The role of the anterior cingulate in insomnia is corroborated by earlier

findings in insomniacs of attenuated deactivation in this area during the transition from waking to sleep [146], and of reduced levels of inhibitory neurotransmitters in this area [158]. Additional structural studies have inspected small-scale brain modifications using VBM. VBM is a neuroimaging analysis technique that allows the investigation of focal differences in tissue composition (gray and white matter) based on high-resolution MRI scans. Prefrontal gray matter concentrations were smaller in insomniacs than in good sleepers, specifically in the orbitofrontal [156, 159] and dorsolateral prefrontal cortices [159], but these findings were not replicated in a later study [155].

Magnetic resonance spectroscopy (MRS) has been applied to the study of idiopathic insomnia. According to proton MRS (^{1}H-MRS) studies, relative concentrations of gamma-aminobutyric acid (GABA) appear to be reduced in insomniacs relative to good sleepers, globally (single-voxel) [160] and locally, in the occipital and anterior cingulate [158], although another study found occipital GABA levels to be increased instead [161]. This latter study also detected a significant inverse correlation between global GABA levels and polysomnography-based WASO. A ^{31}P-MRS study investigating gray and white matter phosphocreatine levels found this cell metabolite in lower concentrations in the gray matter of insomniac patients relative to controls, indicating a possible increase in cortical energy demand in insomnia [162].

Together, neuroimaging studies of insomnia tend to support hyperarousal theory. Diminished inhibition in the transition from waking to sleep [146], increased connectivity in the emotional and threat response systems [151], decreased ability to inhibit irrelevant cognitive processes [149], depletion of inhibitory neurotransmission [158, 160], and increased cortical energy demands [162] all are consistent with an incapacity to modulate cortical arousal across the sleep–wake cycle. In addition, evidence of reduced hippocampal volume [152], reduced prefrontal gray matter concentrations [156, 159], and increased rostral anterior cingulate volume [157] provide possible neural correlates of cognitive and emotional dysfunctions experienced in insomnia. Still, these findings require replication in larger, clinically homogeneous samples.

Narcolepsy

Narcolepsy is a disorder characterized by excessive sleepiness that is typically associated with several manifestations of so-called dissociated or isolated REM sleep features, such as muscle atonia (i.e., cataplexy), sleep paralysis, and hallucinations [139, 163]. Human narcolepsy has been found to be associated with reduction in or loss of the hypothalamic peptide hypocretin (also called orexin) implicated in arousal systems [164–167].

Anatomic Neuroimaging Studies of Narcolepsy

Structural abnormalities in narcolepsy have been examined extensively (Fig. 21.2b2). The pontine tegmentum controls transitions between sleep states and was therefore first proposed as a possible main site of anatomic or functional impairments in narcolepsy. While Plazzi and coworkers had reported pontine tegmentum abnormalities in three narcoleptic patients [167], two other structural MRI studies [168, 169] found no pontine abnormalities (except in 2 of 12 patients who had long-standing hypertension [169]. The MRI abnormalities found in Plazzi et al.'s study could reflect non-specific age-related pontine vascular changes rather than a narcolepsy-related phenomenon [167].

VBM has been employed to find evidence for hypothalamic abnormalities in narcoleptic patients, reporting equivocal results. An early study found no structural change in brains of patients with hypocretin-deficient narcolepsy [170]. Subsequent studies did find cortical gray matter reduction predominantly in frontal brain regions [171–174], as well as in inferior temporal regions [175]. Interestingly, relative global gray matter loss was independent of disease duration or medication history, and there were no significant subcortical gray matter alterations [175]. Significant gray matter concentration decreases were found in the hypothalamus, cerebellum (vermis), superior temporal gyrus, and right nucleus accumbens in 29 narcoleptic patients relative to unaffected healthy controls [176] (Fig. 21.4). Given the widespread projection sites of hypocretin, the decreases in gray matter could thus reflect secondary neuronal losses due to the destruction of specific hypocretin projections. The results of this study were later corroborated by two other VBM studies [171, 177]. More recent MRI studies in narcolepsy with cataplexy identified volumetric decreases in the bilateral hippocampus [178] and amygdala [179]. Notably, amygdalar deficits may underlie emotional dysregulation in narcolepsy.

Anatomic alterations have also been described using MRI cortical thickness measurements. A localized thinning of the cortex was detected in the prefrontal, cingulate, inferior parietal, and temporal areas in narcoleptic-cataplectic individuals [180]. Another study measured increased cortical volume and thickness in the dorsolateral prefrontal cortex of narcoleptic patients [181]. Furthermore, early-onset narcoleptic patients exhibited thinner cortex than late-onset narcoleptics in the precentral gyrus, inferior parietal cortex, and temporal regions. These results were interpreted as reflecting distinct pathological subtypes [181].

Recent studies have used DTI to detect alterations in fiber tract integrity, based on water diffusion in the brain. Using FA and mean diffusivity measures, it was shown that white matter tracts were disrupted in frontal, temporal, and anterior cingulate regions in narcolepsy [173]. Another DTI study found similar results, in addition to white matter

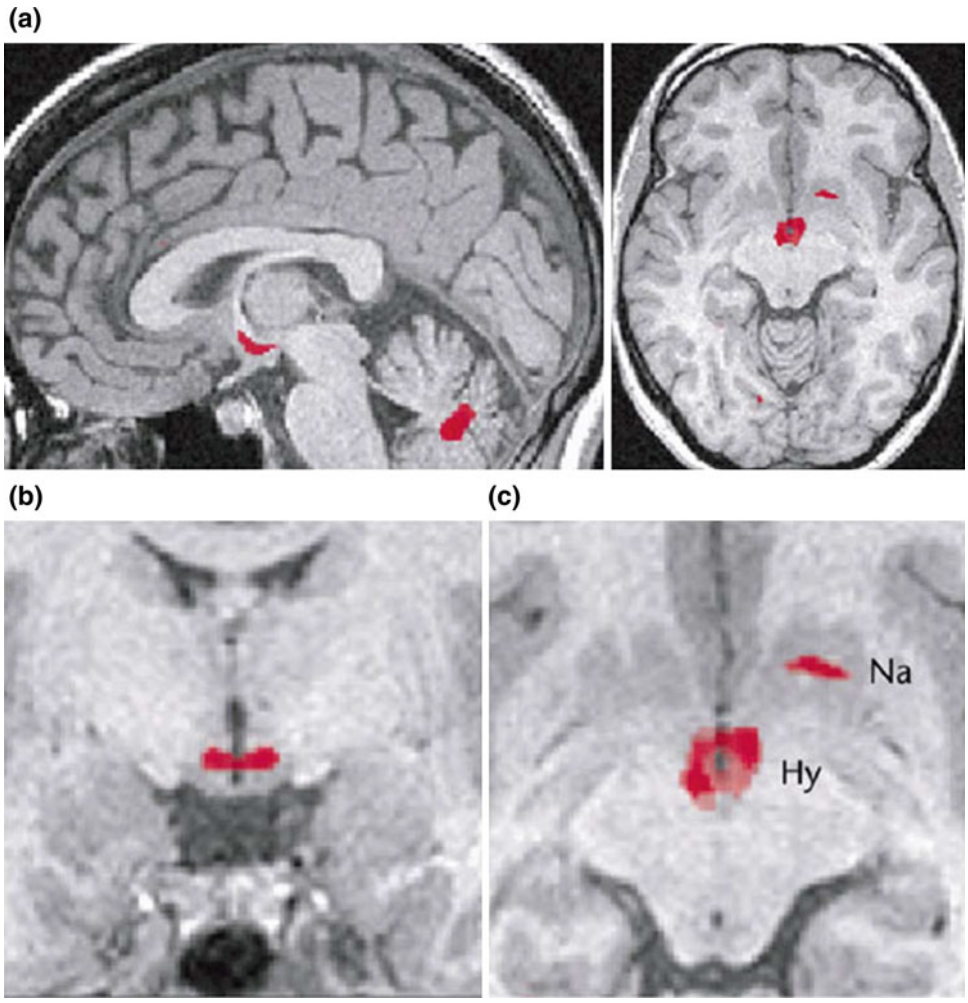

Fig. 21.4 Statistical parametric maps demonstrating the structural difference in *gray* matter between narcolepsy patients and healthy control subjects. Differences are shown superimposed in *red* on a normalized image of a healthy control subject. The *left panel* in A is the *left side* of the brain. A significant decrease in *gray* matter concentration was found in the hypothalamus (Hy) (**a**–**c**) and in the area of the *right* nucleus accumbens (Na) (**a** and **c**) (Reproduced with permission from Draganski et al. [176]. Copyright 2002, Nature Publishing Group)

abnormalities in the pons, right hypothalamus and left mesencephalon, consistent with a dysfunction in the hypothalamic hypocretin system in narcolepsy [182].

Proton MRS was also used to assess the *N*-acetylaspartate (NAA) and creatinine plus phosphocreatinine (Cr + PCr) content in specific brain areas of narcoleptic patients. A reduced NAA/Cr + PCr ratio indicates reduced neuronal function, which could reflect neuronal loss (i.e., fewer neurons) but could also be due to reduced activity of existing neurons. An analysis of spectral peak area ratios revealed a decrease in the NAA/Cr + PCr ratio in the hypothalamus [183] and the ventral pontine areas [184] of narcoleptic patients compared with control subjects. These results may indicate structural damage to these areas in narcolepsy.

Several factors can explain equivocal results across structural neuroimaging studies, such as inhomogeneous patient groups, history of treatment, or, for VBM, prestatistical image processing and limited sensitivity of this technique. VBM studies with larger samples of drug-naive patients are required to identify reliable structural abnormalities in narcolepsy.

Functional Neuroimaging Studies of Narcolepsy

A number of studies have examined brain metabolic differences in narcoleptic patients in the waking state (Fig. 21.2 b1). Early functional observations using ^{133}Xe inhalation showed that, during wakefulness, CBF in the brainstem was lower in narcoleptic patients than in normal subjects. However, after sleep onset (3 of 13 cases in REM sleep), the CBF increased in all regions, particularly in temporoparietal regions. This pattern was supposedly attributed to dreaming activity, in line with prior reports showing increased regional blood flow in temporoparietal areas during visual dreaming and hypnagogic hallucinations [185, 186].

A ^{99m}Tc-HMPAO SPECT study in six narcoleptic patients found similar HMPAO uptake in the waking state and REM sleep [187], suggesting a similar overall cortical activity. Data analysis using regions of interest additionally indicated an activation of parietal regions during REM sleep [187]. The latter result is intriguing given the parietal deactivation usually observed by PET studies during normal REM sleep [8]. Further studies during REM sleep are needed to confirm these results in a larger population.

Two ^{18}FDG PET studies were conducted in the waking state to examine differences in narcoleptic brain activation. In the first study, a sample of 24 narcoleptic patients had reduced CMRglu in the bilateral posterior hypothalami, mediodorsal thalamic nuclei, and frontal and parietal cortices, compared to controls [188]. The second study instead found a CMRglu increase in the cingulate and visual association cortices in 21 narcoleptic patients also suffering from cataplexy [189]. A SPECT study revealed hypoperfusion during wakefulness in several areas including the bilateral anterior hypothalami, caudate nuclei, pulvinar, parahippocampal gyri, cingulate gyri, and prefrontal cortices [190].

There are very few data describing the neural correlates of cataplexy in narcoleptic patients (Fig. 21.2b1). One SPECT study was conducted on two patients during a cataplexy episode compared to REM sleep or a baseline waking period [191]. During cataplexy, perfusion increased in limbic areas (including the amygdala) and the basal ganglia, thalami, premotor cortices, sensorimotor cortices, and brain stem, whereas perfusion decreased in the prefrontal cortex and occipital lobe. Increased cingulate and amygdala activity may relate to concomitant emotional processing that is usually reported as a powerful trigger of cataplexy. However, such hyperperfusion in the pons, thalami, and amygdaloid complexes was not found in two subsequent studies [189, 192]. A more recent PET study imaged two patients during a cataplectic attack and found a large decrease in glucose metabolism in the hypothalamus, as well as increased metabolism in pre-postcentral gyri and somatosensory cortex [189].

Based on the clinical observation that cataplexy episodes are often triggered by positive emotions (e.g., hearing or telling jokes), an fMRI study was performed on narcoleptic patients and controls while they watched sequences of humorous pictures [193]. Group comparisons revealed that humorous pictures elicited reduced hypothalamic response together with enhanced amygdala response in the narcoleptic patients. These results suggest that hypothalamic hypocretin activity physiologically modulates the processing of emotional inputs within the amygdala and that suprapontine mechanisms of cataplexy might involve a dysfunction of hypothalamic–amygdala interactions triggered by positive emotions [193, 194]. Another fMRI study examined amygdalar response to emotional stimuli, by pairing visual stimuli with painful electric shock. Whereas healthy controls showed enhancement of amygdalar response to conditioned aversive stimuli, no such enhancement was observed in narcoleptic subjects [195]. In addition to this abnormal emotional circuitry, abnormal reward circuitry was evident in another report by the same group [196].

Neurotransmission in Narcolepsy

Given the role of acetylcholine as an important neurotransmitter in the generation of REM sleep [28, 197], it was hypothesized that disturbances in the cholinergic system might underlie narcolepsy. However, a PET study with ^{11}C-*N*-methyl-4-piperidylbenzilate found no evidence for a change in muscarinic cholinergic receptors in narcoleptic patients [198].

Likewise, the dopamine system has been probed by PET and SPECT in narcoleptic patients because increased dopamine D_2 receptor binding was shown in the brains of deceased narcoleptic patients [199, 200]. The results from these neuroimaging studies remain mostly inconsistent. One SPECT study showed elevated D_2 receptor binding in the striatal dopaminergic system, correlating with the frequency of cataplectic and sleep attacks in seven patients with narcolepsy [201]. However, other PET [202–204] or SPECT [205, 206] ligand studies did not find such change in D_2 receptor binding. A potential explanation for this discrepancy might be related to the drug treatment of narcoleptic patients. Indeed, considerable increase in the uptake of ^{11}C-raclopride, a specific D_2 receptor ligand, was observed in the putamens of narcoleptic subjects older than 31 years who underwent various regimens of prolonged treatment [207]. Likewise, despite the fact that the binding of iodobenzamide (IBZM, a highly selective CNS dopamine D_2 receptor ligand), was similar in narcoleptic patients and normal controls, treatment by stimulants and/or antidepressants for 3 months significantly changed ligand uptake in four of five patients [206]. Therefore, elevated postmortem dopamine binding might be due to the long-term effect of prior treatment rather than intrinsic modifications.

Brain Response to Drug Probe in Narcolepsy

The effects of stimulant drugs on cerebral function in narcoleptic patients were assessed using functional imaging. The effect of amphetamines was evaluated using fMRI in two patients with narcoleptic syndrome [208]. The extent of the brain response to auditory and visual stimulation decreased after amphetamine administration in normal subjects. The reverse pattern was observed in the narcoleptic patients. These findings remain difficult to interpret, and larger samples of patients should be studied.

Modafinil is a wakefulness-promoting psychostimulant used to treat narcoleptic patients. Two fMRI studies have evaluated its effect on brain perfusion responses. A first study found that normal subjects showed larger brain responses to a multiplexed visual and auditory stimulation paradigm at 10:00 A.M. than at 3:00 P.M. in visual areas, but not in auditory areas, suggesting time-of-day influences [209]. Surprisingly, the reverse pattern of activity was

observed in a group of 12 narcoleptic patients, with greater perfusion at 3:00 P.M. than 10:00 A.M.. Critically, modafinil administration did not modify the average level of activity either in normal subjects or in narcoleptics ($n = 8$), but post-drug activity level was inversely proportional to the predrug activity level. These findings are not easy to interpret but might suggest that modafinil can modulate brain activation in response to external stimuli. The second fMRI study tested the effect of modafinil on brain activation during a working memory task in healthy subjects, following a night of sleep deprivation. Modafinil at once improved working memory performance and enhanced activation in the executive network, specifically in the prefrontal and anterior cingulate cortices [210].

The metabolic effect of modafinil was studied in healthy individuals using ^{99m}Tc-ethylcysteinate dimer (^{99m}Tc-ECD) SPECT before and after the administration of the stimulant or a placebo [211]. Modafinil increased wakefulness and rCBF to areas in the brain associated with arousal, emotions and executive function, including the prefrontal, insular, cingulate, middle/inferior temporal and parahippocampal cortices and the pons. An ^{18}FDG PET study imaged baseline CMRglu in awake patients and controls before and after treatment with modafinil. Decreased CMRglu was observed in the brainstem, hypothalamus, thalamus, and mesio-temporal areas in narcoleptics compared to controls. When comparing pre- and post-treatment conditions in narcoleptic patients, an increase in CMRglu was found in the left hippocampus post-modafinil [212]. A second ^{18}FDG PET study compared CMRglu levels in 14 narcolepsy-cataplexy patients treated with psychostimulants and anticataplectics, and 7 narcolepsy-cataplexy patients that were not treated with drugs. Treated narcoleptic had higher levels of CMRglu in their cerebellum and primary sensory motor cortex. However, these results were hard to interpret due to sample heterogeneity [189].

Summary

Structural and functional neuroimaging studies in narcolepsy with cataplexy show remarkable convergence. Primarily, the hypothalamus displays consistent abnormalities in narcoleptic patients, both structural and functional. Hypothalamic involvement in narcoleptic psychopathology is consistent with the characteristic loss of hypocretinergic neurons in this disorder. The limbic system also shows abnormal responding, including the amygdala, which may reflect emotional dysregulation seen in the disorder and triggering cataplectic episodes. Structural abnormalities were equally found in the hippocampus and various cortical areas, perhaps underlying dysfunctions in cognitive processing. Sparse imaging data acquired during cataplexy itself suggest a possible role of the hypothalamus and somatosensory cortex. As for treatment response, modafinil seems to alter metabolism in a variety of areas, but none have stood out from the few studies to date. Despite recent breakthroughs in the pathophysiology of narcolepsy, more studies using state-of-the-art technology of acquisition and analysis of functional neuroimaging data are needed to better characterize the functional organization of the narcoleptic brain during wakefulness and sleep.

Recurrent Hypersomnia

Recurrent hypersomnia is a disorder characterized by recurrent episodes of hypersomnia that typically occur weeks or months apart [139]. One SPECT study in a 24-year-old male with recurrent hypersomnia showed decreased blood flow in the left thalamus during the hypersomnolent period, but failed to report any abnormal activation during recovery or remission periods [213]. This case report neuroimaging study provides only limited information about possible pathophysiologic mechanisms of this disorder. By contrast, other clinical and electrophysiologic studies clearly point toward a hypothalamic rather than a thalamic dysfunction [214, 215].

A typical form of recurrent hypersomnia, KLS, is characterized by periodic hypersomnia as well as behavioral and cognitive abnormalities, mainly in male adolescents [216]. Neuroimaging studies of KLS patients have revealed normal brain anatomy [216–218]; however, functional abnormalities were observed in SPECT. In an early SPECT study with ^{99m}Tc-ECD, unilateral hypoperfusion of both thalami was found in a sample of 27 KLS patients. These hypoperfusions consistently occurred during the symptomatic period [218] and were confirmed in later studies using both SPECT and ^{1}H-MRS [219–221]. During asymptomatic periods, perfusion of thalami returned to normal levels in all subjects, while other abnormalities in hypoperfusion persisted, mainly in the temporal lobe [218]. Other studies corroborated that hypoperfusion of the temporal lobe persists in asymptomatic patients [220]. Hypoperfusion of both thalami and basal ganglia [217, 220], as well as the frontal [222–224] and temporal lobe [216, 218, 220, 222, 225, 226], may provide insight to the pathophysiology of KLS, but the roles of the brain structures are not yet clear.

Obstructive Sleep Apnea Syndrome (OSAS)

OSAS is characterized by repetitive episodes of upper airway obstruction that occur during sleep, usually associated with a reduction in blood oxygen saturation [139]. Population-based epidemiologic studies have revealed a high prevalence (1–5 % of adult men) of OSAS. They also associate OSAS with significant morbidity, such as hypertension, cardiovascular disease, stroke, and motor vehicle accidents [227]. OSAS may lead to functional and structural brain alterations. Functional alterations such as sleep

fragmentation are often associated with neuropsychological deficits that can be reversible after treatment of OSAS. Structural alterations may indicate irreversible consequences on brain integrity and suggest permanent cognitive impairment, although this proposal remains a matter of debate in the literature, especially given recent structural imaging data showing a reversibility after treatment [228].

The pathophysiology of OSAS is complex and not yet completely understood. Several studies suggest that OSAS across all age groups is due to a combination of both anatomic airway narrowing and abnormal upper airway neuromotor tone. Notwithstanding the known anatomic factors, such as craniofacial anomalies, obesity, and adenotonsillar hypertrophy, that contribute to OSAS, clear anatomic contributing factors cannot always be identified [139]. This suggests that alterations in upper airway neuromuscular tone also play an important role in the etiology of OSAS [229]. The pathophysiology of OSAS also includes enhanced chemoreflex sensitivity and an exaggerated sympathetic response during hypoxemic episodes [230].

Apnea episodes in OSAS patients have considerable hemodynamic consequences, which are mediated by a complex cascade of physiologic events. Repetitive episodes of apnea trigger marked fluctuations in both blood pressure and heart rate, with consequent effects on the estimates of cardiovascular variability [6]. Several important regulatory mechanisms in cardiovascular homeostasis seem to be impaired in OSAS patients. Specific chemoreceptors seem to be implicated in the pathophysiology of OSAS [231]. For instance, the ventilatory response to carbon dioxide is elevated in OSAS patients [231] due to an elevation of the partial pressure of carbon dioxide that delimits carbon dioxide ventilatory recruitment threshold. An altered autonomic balance has been suggested as one possible pathogenic factor. This autonomic dysfunction has been thought to be implicated in the subsequent development of cardiovascular diseases in patients with OSAS.

Functional Neuroimaging Studies of OSAS

Several fMRI studies have been conducted in OSAS patients to characterize the neural correlates of integrated afferent airway signals with autonomic outflow and airway motor response [232–234]. For instance, altered response after a Valsalva maneuver involves cerebellar, limbic, and motor area deactivation. Enhanced sympathetic outflow after a forehead cold pressor challenge results in both diminished response in the thalamus, hippocampus, and insula, and exaggerated response in the cingulate cortex, cerebellum, and frontal cortex. Mandibular advancement led to decreased fMRI response in the left cingulate gyrus and the bilateral prefrontal cortices in 12 healthy subjects during induced respiratory stress [235]. Simultaneously, the subjective effects of this treatment were assessed by a visual analog scale that confirmed successful reduction of respiratory stress.

OSAS has been associated with distinctive cognitive alterations in various domains. Both hypoxemia and fragmented sleep are proposed as the main factor leading to neurocognitive impairments during wakefulness [236–243]. Several studies emphasized the deterioration of executive functions in OSAS patients, including the inability to initiate new mental processes [244, 245] and deficits in working memory [244, 246], analysis and synthesis [244, 246], contextual memory [247], selective attention [248], and continuous attention [248]. A meta-analysis showed that untreated patients with OSAS had a negligible impairment of intellectual and verbal functioning but a substantial impairment of vigilance and executive functioning [249].

A number of functional imaging studies of OSAS patients have used fMRI to evaluate BOLD contrasts during performance on cognitive tasks (Fig. 21.2c1). Generally, these studies have found deactivations in various regions [250–254], while some instead showed increases in activation [255] or mixed results [252, 256, 257]. For example, Ayalon et al. [253] compared 14 OSAS patients with 14 healthy controls on a sustained attention task and found task-related reductions in activation in OSAS patients across parietal, cingulate, and frontal regions typically recruited in attention tasks. Archbold et al. [256] found that OSAS severity correlated with increased activation of the right parietal lobe during a working memory task, in a sample of 9 treatment-naïve male OSAS patients. Deactivations are consistent with OSAS-related structural deterioration (described below), whereas activation increases may represent compensatory recruitment. More recent studies have focused on resting-state functional connectivity changes and have found regional reductions in connectivity in the medial and dorsolateral prefrontal cortices, which make up part of the default-mode network [258, 259]. Concordantly, default-mode network deactivation was compromised in OSAS patients during a visuospatial N-back task, in parallel with performance deficits [252, 260].

Aside from fMRI studies during cognitive performance, functional correlates of OSAS have also been studied during restful wakefulness, using PET and SPECT. A ^{99m}Tc-ECD SPECT study observed decreased baseline rCBF in the parahippocampal and lingual gyri of OSAS patients compared to healthy volunteers [261]. Using ^{18}FDG PET, another group found reduced CMRglu in the prefrontal, parieto-occipital, and cingulate gyri of OSAS patients, compared to healthy controls [262].

Long-term consequences of OSAS have been rarely assessed after nasal continuous positive airway pressure (CPAP) treatment. An early ^{99m}Tc-HMPAO SPECT study in 14 adult OSAS patients reported a marked frontal hyperperfusion in 5 patients [263]. In contrast, regional analysis showed reduced perfusion in the left parietal region. All these changes were reversed by effective CPAP therapy, suggesting that the main deleterious effects of OSAS on

brain activity are reversible. According to the authors, there might be an apnea-associated effect of local vascular autoregulation mechanisms acting to compensate systemic blood flow alterations or blood gas changes in OSAS. Similar findings were obtained in an fMRI study, where hyperactivation of prefrontal and hippocampal areas was reversed with 3 months of CPAP treatment [257]. In a recent study, 2 months of CPAP treatment improved task-related default-mode network deactivation, concomitantly with improvements in behavioral performance [260].

Anatomic Neuroimaging Studies of OSAS

Structural modifications of brain morphology in OSAS have been studied extensively in several modalities (Fig. 21.2c2). In an early study, structural changes were assessed using VBM in 21 patients with OSAS and in 21 control subjects [264]. Gray matter loss was apparent in patients with OSAS in multiple brain sites involved in motor regulation of the upper airway as well as in various cognitive functions, including the frontal and parietal cortices, temporal lobes, anterior cingulate, hippocampus, and cerebellum. Additional VBM studies found gray matter loss in similar regions, mainly in the prefrontal, anterior cingulate, parietal, and hippocampus [228, 258, 262, 265, 266, 267, 268]. These anatomic changes were often [228, 266, 267] but not always [262] associated with cognitive deficits, notably memory impairment. Female gender [269] and depressive symptoms [270] were associated with exacerbated neural damage and neurocognitive symptoms from OSAS. Another MRI study compared both neuroanatomical and neuropsychological effects of hypoxia in patients with either carbon monoxide poisoning or OSAS and found a hippocampal atrophy in both groups [266]. Of note, a linear relationship between hippocampal volume and memory performance selectively in the OSAS group was found for a subset of tests (the delayed recall or the Rey-Osterrieth Complex Figure Design and Trail 6 of the Rey Auditory Verbal Learning Test among others). Moreover, hippocampal volume was related to performance on nonverbal information processing (Wechsler Adult Intelligence Scale–Revised Block Design) in both groups. In a more recent study, hippocampal volume was also negatively correlated with excessive daytime sleepiness [268]. Further investigation will be necessary to better delineate the specificity and contribution of hippocampal atrophy in OSAS. A set of interesting correlations between indices of OSAS severity and prefrontal cortex changes were observed with MRI. Apnea–hypopnea index was negatively correlated with frontal gray matter volumes [228]. Also in the frontal regions, prolonged arterial oxygen desaturation correlated with gray matter decreases [228], deactivations during working memory tasks [251, 252], and decreased cortical connectivity [259]. In one of these studies, 3 months of CPAP treatment in 17 treatment-naïve OSAS patients resulted in the recovery of gray matter concentrations in the hippocampus and frontal regions, alongside significant improvements in neurocognitive performance [228]. These findings underline the effectiveness of CPAP treatment in both physiologic and cognitive recovery from OSAS-related neural damage.

Single-voxel ^{1}H-MRS has also been used to assess whether OSAS can induce axonal loss or dysfunction, or myelin metabolism impairment. An early study using this technique showed that the NAA/Cr ratio in cerebral white matter was significantly lower in patients with moderate to severe OSAS than in patients with mild OSAS and healthy subjects [271]. A series of studies followed which compared OSAS patients to controls and found significantly lower NAA/Cr [272, 273], NAA/choline (Cho) [273, 274], and Cho/Cr [275] ratios in frontal white matter, as well as greater Cho/Cr ratios in the thalamus [273] and temporal regions [272]. In addition, apnea–hypopnea index was negatively correlated with NAA/Cr ratios [272]. These findings may explain some of the deficits in executive function associated with OSAS. Consistent with the VBM results noted previously, decreases in absolute and relative creatine-containing compounds in the left hippocampal area correlated with increased OSAS severity [274, 276, 277, 278] and worse neurocognitive performance [277]. Together, VBM and spectroscopy studies point to an atrophy and/or dysfunction of hippocampal regions in OSAS. In a ^{1}H-MRS study of the effects of CPAP on OSAS severity, NAA in the parieto-occipital cortex was significantly lower in 14 OSAS patients than in controls, but this reduction persisted after CPAP therapy despite clinical, neuropsychological, and neurophysiologic normalization [279]. Accordingly, a later MRS study found no significant differences in creatine-containing compounds after 6 months of CPAP treatment [274].

Summary

Altogether, these findings suggest that neuropsychological deficits in OSAS might relate to various alterations in the prefrontal cortex, hippocampus, and parietal cortex. In particular, volumetric decreases may provide a useful biomarker of OSAS severity [280]. Reduced functional connectivity of the default-mode network may also relate to cognitive deficits in OSAS. Even if abnormal brain activations and even structural changes seem reversible under CPAP, several studies have suggested that not all neuropsychological impairments disappear after the treatment [245, 281, 282]. Although the basic pathophysiologic mechanisms of OSAS are not completely understood, a dysregulation in autonomic control seems to play an important role [232–234].

Restless Legs Syndrome and Periodic Limb Movements

Periodic limb movements (PLM) during sleep and restless legs syndrome (RLS) are distinct but overlapping disorders. RLS is typified by an irresistible urge to move the legs (and less often, the arms), especially during sleep onset. The compulsion is associated with relentless feelings of discomfort from deep inside the limbs [283, 284]. PLM is characterized by periodic episodes of repetitive and highly stereotyped limb movements that occur during sleep [284]. While these movements disturbed sleep and can result in awakening, patients are mostly unaware of the movements or even that their sleep has been disturbed. Diagnosis requires a polysomnographic recording along with a complaint such as "unrefreshing" sleep [284, 285].

RLS and PLM commonly co-occur. However, PLM is non-specific, occurring in isolation in healthy individuals or comorbid with other sleep disorders such as narcolepsy, RBD, and sleep apnea [285]. Given their close association, few neuroimaging studies have investigated PLM alone and instead RLS and PLM are most often considered in concert. The present section will first cover neuroimaging studies focused on RLS (Fig. 21.2d) and will end by covering the few studies of PLM alone.

Restless Legs Syndrome

An early ^{18}FDG PET study found no differences in glucose metabolism between six RLS patients and six age-matched controls, albeit when measured outside the symptomatic period [286]. An fMRI study also attempted to localize some cerebral generators of leg discomfort and PLM in RLS [287]. During RLS leg discomfort, the study showed a bilateral activation of the cerebellum and contralateral activation of the thalamus in patients. A later fMRI study examined brain activation in concert with electromyography measures of tonic activity in the legs, in 7 RLS patients [288]. Tonic activity was inversely correlated with reported discomfort in the legs and with cerebellar activation and positively correlated with activation in the sensorimotor cortex, cingulate gyrus, precuneus, and occipital cortex.

An inhibition of descending inhibitory pathways implicating dopaminergic, adrenergic, and opiate systems is thought to be involved in RLS pathogenesis [289]. Patients' condition worsens when dopamine antagonists are given [290], whereas dopaminergic drugs have been shown to relieve RLS [291–293].

Dopamine research in RLS has centered mainly on the striatum, probing both presynaptic DAT and postsynaptic D_2 receptor occupancy. Striatal DAT can be taken as a measure of dopaminergic neuron density in the substantia nigra (SN). Some PET studies found reduced presynaptic dopamine activity in the striatum of RLS patients compared to controls, using either ^{11}C-methylphenidate [294] or ^{18}F-dopa [295, 296], although an early study using ^{18}F-dopa found no such difference in a small sample [297]. Additionally, some SPECT studies found no change in DAT in RLS compared to controls, using ^{123}I-2β-carbomethoxy-3β-(4-iodophenyl) tropane (^{123}I-β-CIT) [298, 299] or ^{123}I-N-(3-iodopropen-2-yl)-2β-carbomethoxy-3β -(4-chlorophenyl) tropane (^{123}I-IPT) [300, 301]. Variable pharmacokinetic properties of radioligands may contribute to explain the discrepancy in these findings. DAT binding seems independent of clinical severity and time of day [294]. An additional SPECT study employed SPECT with ^{123}I-β-CIT and ^{123}I-IBZM, and contrarily to previous presynaptic dopamine studies, DAT density showed an increase in the striatum, as well as the caudate and posterior putamen [302]. The authors concluded that DAT dysregulation may be responsible for RLS pathogenesis, rather than DAT upregulation or downregulation specifically.

Results of postsynaptic D_2 receptor binding studies are also ambivalent. Among SPECT studies using ^{123}I-IBZM, some found no difference [300, 303, 304], and others detected a reduction in striatal D_2 receptor binding in RLS patients compared to controls [298, 305, 306, 307, 308]. In one of these studies, treating patients with dopamine replacement therapy increased the IBZM binding and improved sleep quality in these patients [305]. Two PET studies with ^{11}C-raclopride found conflicting results, with one showing an increase [295] and the other a decrease [309] in striatal D_2 receptor binding. Different pharmacological histories may explain this discrepancy; only the latter study used drug-naïve patients. Indeed, it has been shown that chronic drug treatment can downregulate D_2 receptors, thus decreasing ligand binding [310]. Another study using ^{11}C-FLB457 found increased binding potential in the striatum as well as in the insula, thalamus, and anterior cingulate cortex, all of which are components of the medial nociceptive system [309]. Upregulation of D_2 receptors in this area may be the consequence of endogenous dopamine depletion. Similar to presynaptic dopamine findings, clinical severity, and time of day had no effect on D_2 binding potential. [309]. A recent PET study using ^{11}C-raclopride found that RLS patients had reduced D_2 receptor binding potential in the putamen and caudate but not ventral striatum [311]. Altogether, pre- and postsynaptic dopamine studies remain inconclusive.

The role of dopamine in RLS pathophysiology may be better understood by taking into account studies implicating the cerebral metabolism of iron [312] (Fig. 21.2d). Iron and the dopaminergic system are linked since iron is an important cofactor for tyrosine hydroxylase, the step-limiting enzyme in dopamine synthesis, and also plays a major role

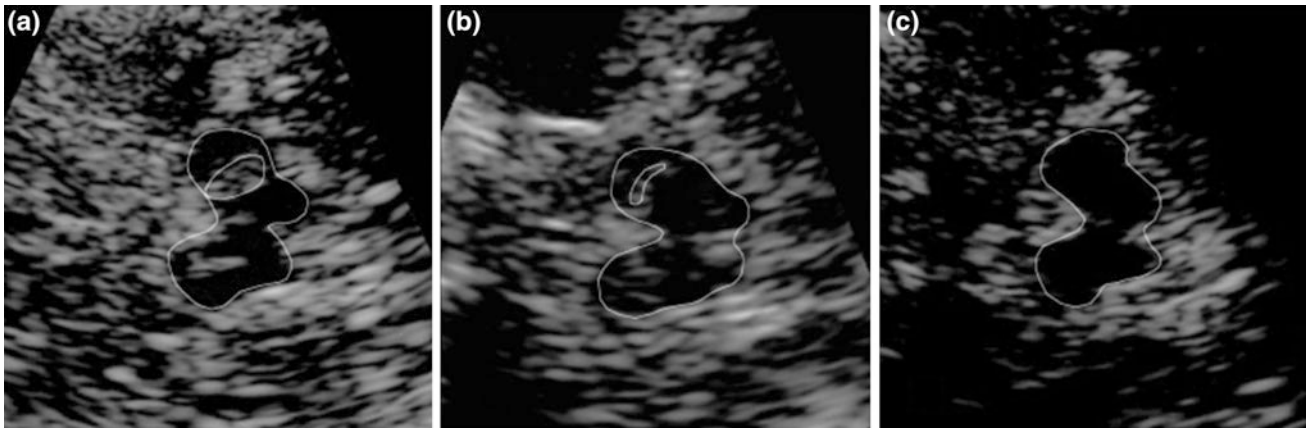

Fig. 21.5 Transcranial ultrasound images (axial plane) in three patients. **a** Patient with Parkinson's disease (PD). **b** Control subject. **c** Patient with restless legs syndrome (RLS). Midbrain is *encircled* and areas of hyperechogenicity are *encircled* in (**a**) and (**b**). There is a progression of decreased echogenicity from PD to healthy control to RLS (Reproduced with permission from Schmidauer et al. [319]. Copyright 2005, American Neurological Association)

in the functioning of postsynaptic D_2 receptors [6]. Notably, increased iron concentrations in the midbrain are a reliable biomarker in PD [313, 314]. Consistent with a link between the dopaminergic system and iron, Allen et al. [315] found decreased regional iron concentrations in the SN and putamens of five patients with RLS, both in proportion to RLS severity. In addition, Earley et al. [316] found diminished iron concentration across 10 brain regions in early-onset RLS patients but not in late-onset RLS patients when compared to controls. Transcranial ultrasound has also been used to measure decreased iron levels in the SN, capitalizing on iron's echogenic effect [317–319]. Of note, midbrain iron concentrations in RLS patients were significantly reduced relative to control subjects and showed an even more pronounced reduction relative to PD patients (Fig. 21.5) [319]. Iron depletion was also found in other areas than the SN, such as the thalamus and caudate, suggesting RLS is a multiregional disorder [317].

Opioid receptor agonists improve RLS symptoms [320], consistent with RLS as a disorder of the nociceptive system. This effect may be mediated by dopamine and may not necessarily reflect a endogenous opioids deficiency [321]. In support of this, one PET study examined opioids in RLS, using ^{11}C-diprenorphine (a non-selective opioid receptor ligand), and found no differences between patients and controls, although some correlations were detected between RLS severity or pain scores and decreased opioid binding in several brain areas [322]. These decreases in opioid receptor availability likely result from the endogenous release of opioids in response to RLS-related pain and discomfort.

Structural cerebral abnormalities have been reported in patients with idiopathic RLS [323]. High-resolution T1-weighted MRI of 51 patients and 51 controls analyzed using VBM revealed a bilateral gray matter increase in the pulvinar in patients with idiopathic RLS. These authors suggest that changes in thalamic structures are either involved in the pathogenesis of RLS or may reflect a consequence of chronic increase in afferent input of behaviorally relevant information. A number of VBM and DTI studies followed. Two studies by a same research group found gray matter decreases in the primary sensorimotor cortex using VBM (63 RLS patients, 40 controls) [324] and white matter alterations near this area and near the thalamus, using DTI (45 patients, 30 controls) [325]. These changes may, however, have been due to patient pharmacological treatment history. Indeed, four subsequent studies examining unmedicated patients detected no neuroanatomical differences using VBM [326–329] and DTI [329], except for a slight gray matter increase in the orbitofrontal gyrus and hippocampus [328]. However, these studies had possessed lower power due to smaller samples (from 15 to 20 patients). A recent multimodal study using ^{1}H-MRS found a significant reduction of *N*-acetylaspartate concentration and *N*-acetylaspartate to creatine ratio in the medial thalamus in RLS patients versus controls [330]. These results lend support to a role of thalamic dysfunction in RLS pathophysiology, although concurrent fMRI and DTI in this same study did not reveal thalamic alterations. It remains unclear whether RLS is associated with any consistent neuroanatomical changes.

A recent ^{1}H-MRS study demonstrated that thalamic glutamate/glutamine (Glx)/Cr levels were augmented in RLS patients, with respect to controls [331]. Furthermore, correlations were observed between Glx/Cr and WASO, a sleep variable related to RLS, but no correlation was found with PLM rate. This is interesting given that dopamine, to the contrary, has been correlated strongly with PLMs and not with WASO. The authors propose two dichotomous systems involved in RLS pathology, namely a glutamatergic arousal system and a dopaminergic motor system. Hence, the

glutamatergic system may be an important target for further pathophysiologic studies of RLS.

Periodic Limb Movements

A few studies have focused specifically on PLM. An fMRI study combining PLM and sensory leg discomfort showed activity in the cerebellum and thalamus with additional activation in the red nuclei and brainstem close to the reticular formation [287]. Notably, when subjects were asked to voluntarily imitate PLM, there was no activation in the brainstem, but rather additional activation in the globus pallidus and motor cortex. These results suggest an involuntary mechanism of induction and a subcortical origin for PLM.

Dopaminergic transmission has been studied in relation to PLM. Presynaptic dopamine transmission was measured in 11 patients with PD using SPECT with ^{123}I-β-CIT [308]. Patients with PD showed a large decrease in striatal binding relative to controls, as predicted. A negative correlation was detected between the number of polysomnography-based PLMs and striatal dopamine binding values. This indicates a potential role of presynaptic dopamine deficiency in PD-induced PLM. A few studies found reduced D_2 receptor occupancy in the striatum of PLM patients using SPECT and ^{123}I-IBZM [306, 307]. Dopamine replacement therapy can reverse this pattern and restore sleep quality [305].

Summary

Studies on RLS seem to indicate iron depletion in several brain regions, especially in the SN, which may interact with dopamine metabolism to unbalance the sensorimotor control of pain. Functional studies on opioids and glutamate are few, but may shed further light on the disorder. Meanwhile, structural studies have not revealed any consistent changes in brain structure in RLS. The thalamus stands out as a potentially important area in RLS pathology, having shown functional and structural abnormalities. Further research into RLS and PLM brain activation during sleep is needed to better understand these disorders.

Sleepwalking

Sleepwalking, also known as somnambulism, is an arousal parasomnia consisting of a series of complex behaviors that result in large movements during sleep [332]. It is perceived as a dissociation state whereby most of the brain exhibits non-REM sleep patterns, except motor-related areas. One

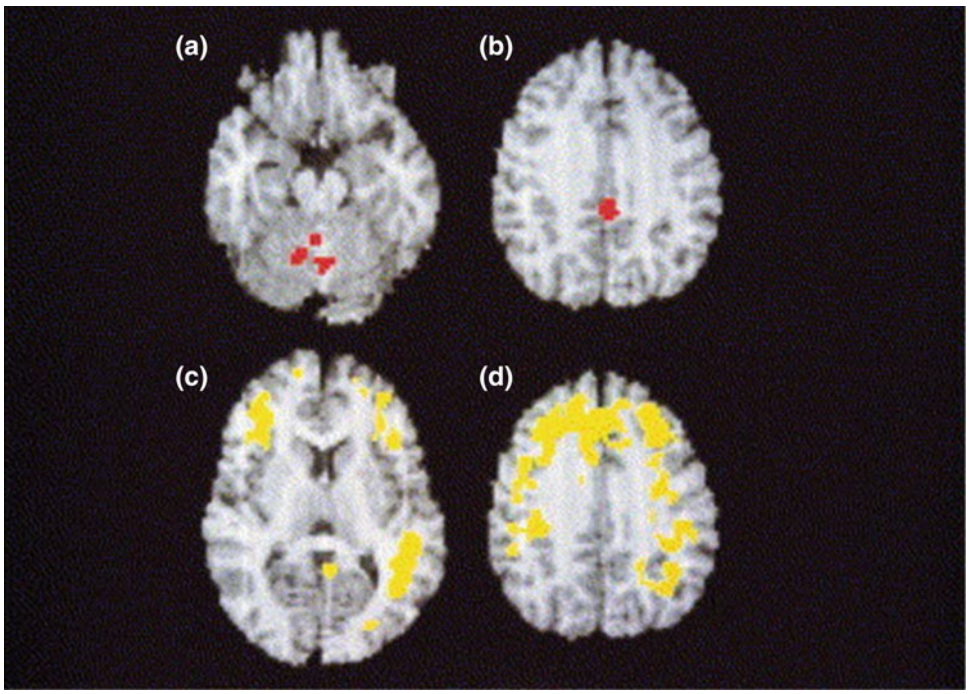

Fig. 21.6 SPECT findings during sleepwalking after integration into the appropriate anatomic magnetic resonance image. The highest increases of regional CBF (>25 %) during sleepwalking compared with quiet stage 3–4 NREM sleep are found in the anterior cerebellum (i.e., vermis) (**a**), and in the posterior cingulate cortex (**b**). However, as compared to data from normal volunteers during wakefulness, large areas of frontal and parietal association cortices remain deactivated during sleepwalking, as shown in the corresponding parametric maps. Note the inclusion of the dorsolateral prefrontal cortex (**c**), mesial frontal cortex (**d**), and left angular gyrus (**e**) within these areas (Reproduced with permission from Bassetti et al. [333]. Copyright 2000, The Lancet)

16-year-old male subject was studied during sleepwalking using ^{99m}Tc-ECD SPECT [333]. Compared to awake normal volunteers (n = 24), a decrease in rCBF in the frontoparietal associative cortices was found. Additionally, the posterior cingulate cortex showed increased rCBF during the sleepwalking episode, with respect to the patient's baseline activity. These results suggest that this state dissociation arose from combined activation of thalamo-cingulate pathways and persisting deactivation of other thalamo-cortical arousal systems (Fig. 21.6). Since only one patient has ever been studied while sleepwalking, further studies with larger sample sizes are needed to confirm these findings.

REM Sleep Behavior Disorder

This condition, initially described by Schenck et al. [334], is characterized by brisk movements of the body associated with dream mentation during REM sleep that usually disturbs sleep continuity. During the nocturnal spells, patients behave as if they were acting out their dream, in the absence of muscle atonia [139]. This disease may be idiopathic (up to 20 %) but mostly associated with neurodegenerative disorders. A sizeable proportion of patients with RBD will develop extrapyramidal disorders [335–337], Lewy body dementia (LBD) [338], and multiple system atrophy (MSA) [339, 340]. More recently, a strong association between RBD and α-synucleinopathies has been observed, with the parasomnia often preceding the clinical onset of the neurodegenerative disease [338]. It is notable that, an early experimental model of RBD in the cat has shown that lesions in the mesopontine tegmentum can lead to the disappearance of muscle atonia during REM sleep together with dream-enactment behavior [341].

Functional Neuroimaging Studies of RBD

Changes in perfusion to various brain regions have been shown in a number of studies (Fig. 21.2e). A SPECT study in 8 RBD patients during waking rest showed decreased activity in the frontal and temporoparietal cortices but found increased activity in the pons, putamen, and right hippocampus [342]. These results have been verified in later studies with larger sample sizes [343, 344]. In another SPECT study, 24 idiopathic RBD patients showed decreased rCBF in cerebellar, parietal, occipital, and limbic regions [345].

A recent longitudinal study followed 20 idiopathic RBD patients over an average period of 3 years. At the study's outset, patients were scanned during wakefulness with ^{99m}Tc-ECD SPECT. After the three-year period, 10 of the patients had developed PD or LBD. Regression analysis revealed that hyperperfusion in the hippocampus predicted

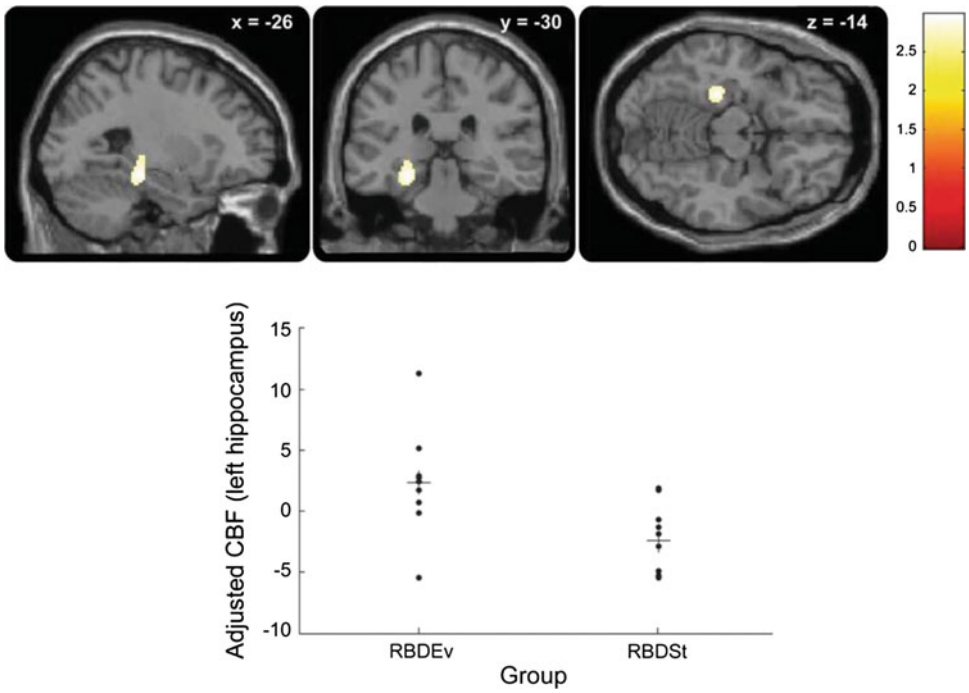

Fig. 21.7 Hippocampal hyperperfusion in REM sleep behavior disorder patients who did (RBDEv) and did not (RBDSt) develop synucleinopathy. Peak hypoperfusion of the left hippocampus at study outset is shown in sagittal, coronal, and transverse sections (p< 0.05 corrected). The range of t values for this contrast is shown in the *color scale* on the *right*. The coordinates are given at the *top right* corner of each panel. *Below*, the plot displays the adjusted regional cerebral blood flow in the left hippocampus, showing distinct distributions for RBDEv and RBDSt groups. Each subject is represented by a *black dot*. *Horizontal bars* represent group means (Reproduced with permission from Dang-Vu et al. [344]. Copyright 2012, American Academy of Neurology)

the subsequent development of LBD or PD in RBD patients (Fig. 21.7) [344]. Hippocampal perfusion across RBD patients was also correlated with motor and color vision scores, which are markers of neurodegeneration. This demonstrates the involvement of hippocampal perfusion as a consistent biomarker of the neurodegenerative evolution in RBD. Studies of brain perfusion with SPECT thus provide useful prognostic tools predicting the onset of neurodegenerative diseases in RBD patients.

One ^{99m}Tc-ECD SPECT study was able to capture an episode of RBD in an MSA patient [346]. Notably, perfusion to the supplementary motor area increased compared to wakefulness, while no such pattern was found during REM sleep in two healthy controls. However, REM sleep outside the episode was not imaged in the MSA patient, thus limiting conclusions about the specificity of supplementary motor area activation to dream enactment in RBD. Replication in larger samples, along with baseline REM sleep assessment, may determine whether this area plays a role in RBD pathophysiology.

Neurotransmission in RBD

Findings of RBD comorbidity with dopaminergic disorders, such as PD and LBD [344], have driven forward research into the nigrostriatal dopaminergic system in RBD patients. Presynaptic DAT densities have been probed in two SPECT studies with the DAT ligand ^{123}IPT [109, 347]. Together, they trace a spectrum of decreasing striatal DAT density from healthy subjects, to subclinical RBD patients showing muscle atonia with no dream enactment, to full-blown RBD patients, and finally to PD patients, who showed the lowest presynaptic DAT density. A similar spectrum was described by a third SPECT study using another presynaptic DAT ligand, ^{123}I-2β carbomethoxy-3 (4-iodophenyl)-*N*-(3-fluoropropyl)-nortropane (^{123}I-FP-CIT) [348]. In contrast, four more studies using this ligand reported striatal DAT decreases in only a minority of RBD patients (2 out of 11 [349], 2 out of 5 [350] and 3 out of 14 [348]). PET studies have also found striatal DAT decreases in RBD, using ^{11}C-dihydrotetrabenazine (^{11}C-DTBZ), an in vivo marker for dopaminergic nerve terminals. Significant reductions in striatal ^{11}C-DTBZ binding characterized 6 elderly subjects with chronic idiopathic RBD, as compared to 19 age-matched controls, particularly in the posterior putamen [351].

Two longitudinal ^{123}I-FP-CIT SPECT studies, from the same research group, examined the relationship between striatal DAT and incident neurodegenerative disease over the course of several years [352, 353]. The first study followed 43 idiopathic RBD patients and 18 controls [352]. At the outset, 40 % of RBD patients showed reduced striatal DAT. Patients were followed up 2.5 years later and 8 of them had developed a neurodegenerative disorder (PD, LBD, or MSA). Six of these eight patients had shown reduced striatal DAT at the outset of the study. This measure may then provide a useful tool early on for identifying RBD patients at high risk for developing neurodegenerative disease. The second longitudinal study followed 44 idiopathic RBD patients over the course of 7 years [353]. At follow-up, 82 % of patients had developed a neurodegenerative disease. The 4 patients showing no sign of disease had reduced striatal DAT at follow-up, placing them at high risk of developing a neurodegenerative disease later on. Both studies buttressed the association between RBD and reduced presynaptic DAT in the SN, and provided additional evidence that idiopathic RBD presents an early stage of neurodegeneration. The deterioration of presynaptic dopamine dysfunction was monitored in a longitudinal case report of a 73-year-old male suffering from RBD over 3.5 years. ^{11}C-CFT with PET was used to show a significant decrease (about 4–6 % per year) in dopamine binding in the striatum, similar to decreases observed in PD [354]. It remains to be shown whether these dopaminergic alterations play a causal role in the pathophysiology of RBD or reflect functional consequences and adaptations to the pathologic conditions.

Lastly, postsynaptic D_2 receptor density was also assessed in RBD in two previously cited ^{123}I-IBZM SPECT studies from the same group [109, 347]. There were no significant differences detected between RBD, PD, and healthy control groups, indicating that postsynaptic dopaminergic function is unaltered in RBD.

Anatomic Neuroimaging Studies of RBD

Neuroanatomical abnormalities in RBD have been revealed by structural neuroimaging (Fig. 21.2e). One study, employing MRI and VBM, demonstrated decreased bilateral putamen volumes in RBD patients compared to healthy controls, as well as in comparison with patients with early PD [355]. A later study conducted through DTI whole-brain scans showed white matter microstructural changes in 12 patients with idiopathic RBD compared with age-matched healthy controls [356]. These significant changes occurred in multiple brain regions known to be involved in REM sleep regulation. Notably, changes were found in the pons. A combined DTI-VBM study [357] found white matter decreases in the pontine region, as well as significant bilateral gray matter increase in the hippocampus of RBD patients. Structural alterations in the pons and hippocampus are in accord with findings from functional studies described above [342, 344, 358, 359].

In addition, an increased Cho/Cr ratio in the brain stem suggesting local neural abnormalities was revealed by ^{1}H-MRS in a 69-year-old man with idiopathic RBD as compared with healthy adults [360]. In contrast, one ^{1}H-MRS study, conducted in 15 patients with idiopathic RBD and 15 matched control subjects, failed to reveal any difference in metabolic peaks of NAA/Cr, Cho/Cr, and myoinositol/creatine ratios in the pontine tegmentum and the midbrain [361]. Similarly, a ^{1}H-MRS study examining pontine metabolic ratios in 15 PD patients with RBD and 15 PD patients without RBD detected no group difference [362]. Whether

idiopathic RBD involves mesopontine neuronal loss or ^{1}H-MRS–detectable metabolic disturbances therefore remains unsettled.

Transcranial ultrasound has been employed to measure SN iron levels in RBD based on midbrain echogenicity. Since increased nigral iron concentrations are a reliable biomarker of PD, as evidenced by ultrasound hyperechogenicity, Iranzo et al. hypothesized that transcranial ultrasound measures of nigral iron in RBD may predict the later onset of PD and other synucleinopathies. In their aforementioned longitudinal study [352], they measured nigral iron levels in 39 idiopathic RBD patients and 149 controls, and found hyperechogenicity in 36 % of RBD patients and 11 % of controls. Two and a half years later, 8 of 43 RBD patients had developed synucleinopathies, 5 of which had shown hyperechogenicity at the study's outset. In combination with DAT concentration measures from ^{123}I-FP-CIT SPECT, this study was able to use transcranial ultrasound to predict the conversion from idiopathic RBD to synucleinopathy with 100 % sensitivity and 55 % specificity. Similar to the decreasing DAT spectrum described earlier, this study provides evidence for a spectrum of increasing iron concentrations in the SN, from normal levels, to RBD, and ending in synucleinopathy.

Summary

Structural and functional neuroimaging studies in RBD agree with involvement of the pons in the pathophysiology of RBD. In addition, presynaptic dopamine dysfunction in nigrostriatal pathways seems related to the progression of RBD severity, with subclinical RBD showing the least reduction in DAT density, followed by a greater reduction in manifest RBD, and the greatest reduction in neurodegenerative disease, particularly in synucleinopathies (PD, LBD, and MSA). Whether dopaminergic dysfunction is a cause or consequence of RBD remains unclear. Similar to the spectrum of decreasing striatal DAT density, transcranial ultrasound data suggest a spectrum of increasing iron concentrations in the SN from normal levels, to RBD, and ending in synucleinopathy. Early biomarkers seem available to identify RBD patients at high risk of developing a synucleinopathy, using transcranial ultrasound of the SN combined with SPECT assessing presynaptic striatal DAT density or hippocampal hyperperfusion. Future studies would do well to investigate hippocampal involvement in RBD, as well as provide additional functional data during sleep, particularly during RBD dream-enactment episodes.

Conclusions

The relatively new field of neuroimaging has already yielded valuable insights into disorders of sleep. Functional anomalies in brain activation in insomnia patients support hyperarousal theory, whereas structural alterations in the hippocampus, rACC and prefrontal cortex may underlie cognitive and emotional deficits in insomnia. Hypothalamic abnormalities in narcolepsy, both functional and structural, are consistent with a dysfunction of the hypocretinergic system. Altered response of the limbic system and anatomic alterations of the hippocampus and cortical areas may relate to emotional dysregulation in narcolepsy. Thalamic hypoperfusion pervades the few recurrent hypersomnia studies. A dysregulation of autonomic control seems to underlie OSAS, and cognitive deficits may be reflected in structural alterations of the prefrontal cortex, parietal cortex, hippocampus, and white matter tracts. Functional alterations also occur in OSAS, notably in the reduced connectivity of the default-mode network. While functional and structural changes seem partially reversible by CPAP, some cognitive deficits may be more permanent. Turning to movement disorders, RLS may be due to an imbalance in the sensorimotor control of pain, which itself may be due to dopaminergic dysfunction and iron depletion in the SN. The single case report of a sleepwalking episode showed prefrontal hypoperfusion and posterior cingulate hyperperfusion. Lastly, RBD seems to be related to pontine abnormalities, as evidenced by structural and functional studies. Presynaptic dopamine dysfunction in the striatum is also a reliable feature of RBD, correlating with the degradation from subclinical RBD, through full-blown RBD, and eventually to synucleinopathy. Neuroimaging may provide a valuable tool in identifying RBD patients at greatest risk of neurodegenerative disease, by relying on biomarkers such as DAT density, nigral hyperechogenicity, and hippocampal hyperperfusion.

Functional neuroimaging provides unprecedented possibilities to explore brain function during normal and pathologic sleep. Nevertheless, neuroimaging in sleep is still in its infancy, at present mostly restricted to research purposes. A major research effort should be developed in order to better characterize pathophysiologic mechanisms of sleep disorders, teasing apart functional causes from consequences. These efforts should benefit from advanced multimodal neuroimaging and improved experimental designs.

Multiple Sleep Latency Test

22

Thomas Roth and Timothy A. Roehrs

Introduction

Daytime sleepiness as a consequence of inadequate sleep the previous night is a common experience for most adults. Because of the universality of the acute experience of daytime sleepiness, it is typically minimized as a health problem within the general population; in a 1997 Gallup Poll of Americans, only 6 % of those reporting impairing sleepiness considered it medically serious [1]. Although minimized by laypeople, increasingly chronic excessive daytime sleepiness is recognized as an important and significant symptom in medicine and public health. Furthermore, excessive daytime sleepiness can and should be distinguished from fatigue, tiredness, and lassitude, although many patients may not make such distinctions themselves unless they are carefully queried.

Representative surveys of the populations of industrialized countries have found that between 11 and 32 % of respondents report that sleepiness interferes with activities almost daily [1–5]. Sleepiness is associated with a number of medical, behavioral, and pharmacologic causes, and, regardless of its cause, has serious social and medical consequences. Nearly half of the patients with excessive sleepiness seen at sleep disorders centers report automobile accidents; more than half report occupational accidents, some life threatening; many have lost jobs because of their sleepiness; and the impact of sleepiness has a disruptive effect on family life [6]. Information on traffic and industrial accidents in the general population suggests a link between sleepiness and life-threatening events. For example, the highest rate of self-reported automobile accidents occurs between 2 and 6 am, which is remarkable because fewer automobiles are on the road during these hours [7]. A population-based study related Department of Motor Vehicle (DMV)-verified automobile accidents to excessive sleepiness as measured by the MSLT and a commonly used subjective sleepiness questionnaire, the Epworth Sleepiness Scale (ESS) [8]. Those with the lowest MSLT scores had the highest accident rates, while the ESS was not predictive (see discussion below). Shift workers, a particularly sleepy subpopulation, have the poorest job performance and the highest rate of industrial accidents among all workers [9].

Problems in assessing sleepiness became evident during early research on the daytime consequences of sleep loss before the clinical significance of sleepiness was recognized. Sleep loss compromises daytime functions. Virtually all individuals experience dysphoria and reduced performance when they do not sleep adequately. The majority of performance tasks are insensitive to the effects of sleep loss [10], but long and monotonous tasks are reliably sensitive to the changes in the quantity and quality of nocturnal sleep. Using various measures of mood, including factor analytic scales, the most consistent and systematic response to sleep loss is increased sleepiness. Among the various subjective measures of sleepiness, the Stanford Sleepiness Scale (SSS) is the best validated [11]. Yet clinicians have found that patients may rate themselves alert on the SSS even as they are falling asleep [12]. The likely reason for such discrepancies is that subjective daytime sleepiness has multiple dimensions [13].

Normal and pathologic variations in daytime sleepiness and alertness can now be directly assessed and quantified by the multiple sleep latency test (MSLT), a test of the rapidity with which a subject falls asleep in a standardized, sleep-conducive setting, repeated at 2-h intervals throughout the day. The MSLT uses standard sleep recording methods to document both the rate of sleep onset and the appearance of rapid eye movement (REM) episodes at sleep onset. Other procedures that have been used to quantify sleepiness and alertness (but because of a variety of shortcomings are not

widely used), including pupillometry, subjective rating scales, and tests of vigilance or reaction time, are all correlated to some extent with the MSLT. The MSLT has become the standard method in clinical sleep disorders medicine for documenting the complaints of excessive daytime sleepiness and to document treatment success. It is also used to document sleep-onset REM periods, a diagnostic sign of narcolepsy. The American Academy of Sleep Medicine has indicated that the MSLT should be used as part of an evaluation of suspected narcolepsy and may be helpful in the evaluation of suspected idiopathic hypersomnia [14]. Since the development of the MSLT by Carskadon and Dement [15] in the late 1970s, enormous progress has been made in the scientific investigation and understanding of both normal and pathologic variations in sleepiness and alertness. The original R–K method of recording and scoring has recently been slightly modified (see Chap. 6).

Multiple Sleep Latency Test Methods

Recording Montage

General and specific technical guidelines for the administration of the MSLT have been published [16]. Briefly, the guidelines require that the standard Rechtschaffen and Kales (R-K) recording montage be used in performing the MSLT [16]. The montage includes the referential electroencephalogram (EEG) from a central (C3 or C4) placement, two horizontal referential electrooculograms (EOGs) from right and left outer canthi, and a mental or submental electromyogram. Also helpful in the determination of sleep onset is a referential occipital EEG lead, which shows alpha activity in relaxed wakefulness with eyes closed and is followed by a characteristic change to mixed-frequency EEG activity at the onset of sleep. An EOG recording with filters set to allow visualization of slow rolling eye movements (e.g., 250 ms) is another sign of sleep onset.

General Procedures

As indicated in the guidelines, to ensure a reliable and valid MSLT, a number of general procedures are necessary [16]. A 1- or 2-week sleep diary recorded before the test that includes information on usual bedtime, time of arising, napping, and drug use (i.e., caffeine, alcohol, and illicit and licit drugs) is very helpful. Deviations from the subject's habitual sleep behavior should be noted, because sleep time accumulated or lost over the week before an MSLT can significantly affect the result. Some controversy has arisen regarding what defines adequate sleep prior to the MSLT [17, 18]. The critical point is that the sleep prior to the MSLT represents a patient's habitual sleep at home. Central nervous system (CNS)-active drugs, as well as their discontinuation, can alter sleep and REM latencies and therefore should be discontinued sufficiently well in advance of the test. The sleep of the night preceding an MSLT should be documented with a standard nocturnal sleep recording. This nocturnal sleep recording should be scheduled to coincide with the timing and amount of the subject's usual sleep, as revealed in the diary.

The reliability of the MSLT is based on multiple determinations of sleep latency, as the studies discussed in the following sections have shown. Consequently, as indicated in the guidelines, four or five tests of sleep latency at 2-h intervals throughout the day should be conducted [16]. Testing should be initiated from 1.5 to 3 h after the nocturnal sleep period has been terminated, typically at 9:30 or 10:00 AM. The MSLT should be conducted in a sleep-conducive environment that is quiet, dark, and controlled at a comfortable temperature. Any potentially arousing stimuli should be removed from the test area.

Specific Procedures

The following procedures are specified by the guidelines for conducting the MSLT [16]. After arising from nocturnal sleep, the subject should toilet, dress in street clothes, and eat the usual breakfast (avoiding caffeinated beverages). Between the latency tests, the subject should be kept out of the bed and monitored by technical staff to assure that no napping occurs. A small retrospective study of patients being evaluated for excessive daytime sleepiness monitored the patients telemetrically between tests and brief inadvertent napping did occur [19]. But, the naps occurred among the sleepiest patients and did not alter the clinical results appreciably. Preparations before each latency test include smoking cessation 30 min before lights out, bedtime preparation (removing shoes and restrictive clothes such as belts or neckties) at 10 min before lights out, all electrode connections and calibrations completed at 5 min before lights out, and the instructions to relax and fall asleep given 5 s before lights out.

Ending a Test

According to the guidelines, if sleep does not occur, each test is concluded 20 min after lights out [16]. For the clinical version of the MSLT, in which the occurrence of REM sleep is at question, the test is concluded 15 min after the first 30-s epoch of sleep. In a research version of the MSLT, the test is concluded after three consecutive 30-s epochs of stage I sleep or one 30-s epoch of another sleep stage. When the

recording is equivocal, it is safer to allow clearer signs of sleep (i.e., spindles and K-complexes) to emerge rather than to terminate the test prematurely.

Scoring and Interpretation

Criteria for scoring sleep onset differ from criteria for test termination [16]. There has been some confusion in the MSLT literature in this regard. Furthermore, it should be noted that the MSLT sleep latency criteria differ from the typical definition of nocturnal sleep onset (stage II sleep or 10 continuous minutes of sleep) in much of the all-night sleep literature. MSLT sleep latency is the elapsed time in minutes from lights out to the first 30-s epoch scored as sleep. According to the scoring criteria of Rechtschaffen and Kales [20], this implies that 16 s of sleep (i.e., >50 % on a given epoch of the recording) is sufficient to score a sleep onset. REM sleep latency in a clinical test is scored as minutes from sleep onset (as defined earlier) to the first epoch of REM sleep.

Average sleep latency (in minutes) for the four or five latency tests is the parameter typically used to express the level of sleepiness. In some of the clinical literature, the MSLT result is expressed as a median sleep latency or a sleepiness index, which is merely the average latency subtracted from 100 and multiplied by 100 % (and corrected if fewer than five tests are conducted). In population studies, survival analyzes have been used to examine the predictors of sleep onset during the MSLT [21]. The occurrence of REM sleep within 15 min of sleep onset is generally defined as a sleep-onset REM period (SOREMP), and the frequency of such SOREMPs is also tabulated.

Sources of Error

The level of sleepiness (defined as the average sleep latency) observed on the MSLT is affected by the sleep of the previous night and weeks. Any deviation from the subject's habitual sleep schedule (as revealed in the sleep diary) and sleep quality (as seen in the nocturnal sleep recording and the individual's estimate of its consistency with usual sleep) is likely to overestimate or underestimate the usual level of daytime sleepiness. Similarly, the timing of the nocturnal sleep and daytime MSLT assessment relative to the subject's circadian phase is a potential source of error, that is, an issue in studying shift and night workers. Out-of-phase sleep is likely to be disturbed and associated with shorter MSLT latencies. Moreover, sleep latency itself varies as a function of circadian phase.

Sedating or alerting effects of drugs or discontinuation of long-term drug use can also be a source of error in documenting sleepiness. For some patients, a urine drug screen may be necessary to confirm the absence of drugs. A noisy, bright, or stimulating test environment invalidates the MSLT result. In addition, stimulating activity immediately prior to a latency test will increase sleep latency on the subsequent test [22]. Instructions given to the subject at the initiation of the test are also important. Subjects should be aware that they are to close their eyes, lie still, and allow sleep to occur. Excessive tossing and turning are to be avoided. It should be recognized that the instruction "relax and fall asleep" may be emotionally loaded for patients with insomnia. This issue is discussed under the Determinants of Sleepiness section.

Finally, a "last test" effect might be observed (this has not yet been systematically studied). In anticipation of going home for the day, subjects may remain awake for the 20 min of the last latency test. This last test effect could elevate the average sleep latency for the day. It can be avoided by scheduling other non-arousing activities after the last latency test. Patient-feedback sessions with the clinician either before or after the last test can be disruptive to that test and should be avoided.

REM sleep can occur on latency tests of the MSLT as a result of a number of factors. Many drugs suppress REM sleep, and discontinuing them increases the likelihood of SOREMPs on an MSLT. For example, a study of cocaine addicts found an average of 2.8 SOREMPs on five-test MSLTs conducted on the first two days after discontinuing the cocaine use [23]. By days 13 and 14 of discontinuation, the average number had dropped to 0.2 SOREMPs. The circadian-phase timing of the MSLT is also important with respect to the occurrence of REM sleep. REM sleep can occur on early morning latency tests in a person who is a late-morning sleeper. Excessive disturbance of the sleep of the previous night also has the potential to result in REM sleep on early morning latency tests. For example, it has been suggested that apnea patients with highly fragmented sleep may have more SOREMPs than the general population. SOREMPs should be re-evaluated in patients suspected of narcolepsy, but who show apneas in the nocturnal sleep recording. It is rare for sleep restriction the week previous to an MSLT to alter REM occurrence on the MSLT.

Reliability and Validity

Reliability

Several studies of the reliability of the MSLT have been conducted. In healthy controls who maintained consistent sleep–wake schedules, the test–retest reliability of a four-test MSLT was 0.97 over a 4- to 14-month test–retest interval [24]. The test–retest interval ($\sim$6 months vs. >6 months)

and the level of sleepiness (average latency of ~5 min vs. 2 min) did not affect this MSLT reliability. The *number* of latency tests did alter MSLT reliability: The coefficient dropped to 0.85 for three tests and 0.65 for two tests. Another study of patients with insomnia over an interval of 3–90 weeks found a test–retest correlation of 0.65 on a five-test MSLT [25].

There has also been interest in the test–retest reliability of SOREMPs in patients with narcolepsy. The current criteria require two or more SOREMPs out of five possible sleep onsets. In the only one study done to date, 28 of 30 patients had two or more SOREMPs when retested ($K = 0.93$, $P < 0.05$). Of particular interest is the finding that the REM latency on SOREMPs during the initial evaluation was also correlated with that during retesting ($r == 0.64$, $P < 0.02$) [26].

Strength of test–retest reliability for mean sleep latency and SOREMPs on the MSLT is dependent on test–retest scoring reliability. Several studies have demonstrated strong scoring reliability in clinical populations. The intra-rater scoring reliability for mean sleep latency on MSLTs from 200 patients was 0.87, and the inter-rater coefficient was 0.90 [27]. The intra-rater and inter-rater scoring reliabilities for one or more SOREMPs were 0.78 and 0.91, respectively.

Validity

The MSLT measures the speed of falling asleep on repeated tests conducted in a sleep-conducive setting, as described above. The validity of the MSLT as a measure of sleepiness rests on its response characteristics to known determinants of sleepiness, which are discussed in the following section. Additionally, in evaluating its validity, the parametric limits of average sleep latency as measured on the MSLT must be discussed. The first issue is the two anchors of the scale. By scoring definition (i.e., sleep onset is scored in 30 s epochs) one cannot fall asleep in less than 30 s, often referred to as a "floor" effect. Thus, a brief <15 s attention lapse or micro-sleep, which emerges in continuous performance assessments of excessively sleepy individuals [28], is not scored on the MSLT. Similarly, by the standard MSLT procedure, the test is terminated after 20 min of continuous wake. Thus, average sleep latencies can be no longer than 20 min, which has been referred to as a "ceiling" effect. Consequently, alerting drug effects in non-sleepy individuals can be difficult to detect, although as discussed below studies have shown alerting drug effects in volunteers whose basal average sleep latency is within a standard deviation of population norms.

Secondly, the linearity of average sleep latency across the 0.5–20 min range of the MSLT cannot be assumed, an issue that has received little investigation. A study in healthy controls compared the alerting effects of caffeine 0, 75, and 150 mg after 8 h or 5 h time-in-bed (TIB) the previous night [29]. Average sleep latency was increased by 2 min with 75 mg and 4 min with 150 mg regardless of the placebo baseline, which was 6 min and 10 min, respectively, for the 5 and 8 h TIBs. On the other hand, in patients with excessive sleepiness and MSLT scores of <6 min, an increase due to treatment in average sleep latency from 2 to 6 min may be quite different than that from 6 to 10 min.

The validity and clinical utility of the MSLT were recently reviewed [30]. It was concluded that average sleep latency and multiple SOREMPs "do not discriminate well between patients with sleep disorders and normal populations." As the next section indicates, a number of factors cause sleepiness and multiple SOREMPs in both patients and controls. Furthermore, the excessive sleepiness of a given patient may have multiple causes. Thus, the MSLT would not be expected to have good diagnostic specificity. As to sensitivity, the review suggested that most patients with complaints of excessive sleepiness do show short average sleep latencies, although establishing the limits of normal and pathological is complex (see the section on Norms).

Determinants of Daytime Sleepiness

Quantity and Continuity of Sleep

A number of different causes of sleepiness have been identified. The degree of daytime sleepiness is directly related to the amount of nocturnal sleep. Habitual bedtime is predictive of median sleep latency on the MSLT with short bedtimes predictive of short latencies [31]. Partial or total sleep deprivation in normal subjects is followed by increased sleepiness the following day, which can reach pathologic levels [32]. Furthermore, modest sleep deprivation (as little as 1 h per night) accumulates over time to progressively increase daytime sleepiness, again to pathologic levels [33]. In normal young adults, however, increased sleep time extending TIB beyond the usual 7 or 8 h per night produces increased alertness (i.e., reduction in sleepiness) [34]. Daytime sleepiness also relates to the quality and continuity of a previous night's sleep. Sleep in patients with a number of sleep disorders is punctuated by frequent, brief arousals of 3–15 s duration. The arousals typically do not result in awakening, as judged by Rechtschaffen and Kales sleep staging criteria [20] or by behavioral indicators, and the arousals recur in some conditions as often as one to four times per minute. The arousing stimulus differs in various disorders and can be identified in some cases (e.g., apneas, leg movements, and pain). The critical point is that the arousals generally do not result in shorter sleep, but rather in fragmented or discontinuous sleep, and this fragmentation produces daytime sleepiness [35].

Correlational evidence suggests a relationship between sleep fragmentation and daytime sleepiness. Fragmentation, as indexed by the number of brief EEG arousals, number of shifts from other sleep stages to stage 1 sleep or wake, and the percentage of stage 1 sleep, correlates with excessive sleepiness in various patient groups [35]. Fragmentation of the sleep of healthy controls has been produced by inducing 3–15 s arousals with an auditory stimulus. Studies have shown that subjects aroused at various intervals during the night demonstrate the performance decrements and increased sleepiness on the following day [36–39] and that fragmented sleep is non-recuperative [40].

CNS Acting Drugs

CNS-depressant drugs, as might be expected, increase sleepiness. The benzodiazepine hypnotics hasten sleep onset at bedtime and shorten the latency to return to sleep after an awakening during the night, as demonstrated in a number of objective studies [41, 42]. If taken at bedtime, long-acting benzodiazepines continue to shorten sleep latency on the MSLT the next day [43]. Ethanol administered at bedtime and during the day reduces sleep latency as measured by the MSLT [44, 45]. One of the most commonly reported side effects associated with the use of H_1 antihistamines is daytime sleepiness, and studies with objective measurement of sleepiness have confirmed the effect [46, 47].

CNS-stimulant drugs reduce sleepiness. In healthy volunteers, caffeine, 75–300 mg, compared to placebo increased average sleep latency on the MSLT by 2–4 min during a simulated night shift or during the day after 4 h TIB the previous night [48]. Even after a night of "normal" sleep, average sleep latency was increased from 10.7 to 17.8 min by caffeine 400 mg t.i.d. [49]. Methylphenidate 20 mg in healthy volunteers increased average sleep latency after both 8 and 0 h TIBs, and methylphenidate 10 mg similarly increased average sleep latency after both 8 and 4 h TIBs [50, 51]. In patients with narcolepsy, methylphenidate 60 mg increased average sleep latency [52]. Finally, in three studies of patients with excessive sleepiness associated with narcolepsy, sleep apnea, and muscular dystrophy modafinil as well as armodafinil increased average sleep latency [53–55].

Sleep Disorders

Disorders of the CNS are assumed to be another determinant of daytime sleepiness. A deficiency in the hypothalamic hypocretin system is the putative cause of excessive sleepiness in patients with narcolepsy [56]. Another sleep disorder associated with excessive sleepiness and thought to be due to an unknown disorder of the CNS is idiopathic CNS hypersomnolence [57]. In both conditions, excessive sleepiness has been well documented, although the pathophysiology for idiopathic CNS hypersomnolence has not been definitively established.

Several case series have presented MSLT results in patients with complaints of excessive daytime sleepiness [58, 59]. These series have clearly shown that patients experiencing difficulties with excessive sleepiness show MSLT average sleep latencies of 8 min or less, although questions regarding the degree to which their diagnoses were based on the MSLT result have to be raised [26]. As noted above in the validity discussion, short average sleep latencies on the MSLT do not differentiate controls from patients (norms and deviations from the norm in healthy adults are discussed later). On the other hand, multiple SOREMPs are infrequent (i.e., rates of 5–10 % in population-based [60, 61]) in normal individuals, whereas the occurrence of two or more is considered suggestive of narcolepsy [26]. Furthermore, the data have shown that the differences in the severity of some sleep disorders are reflected in different levels of sleepiness on the MSLT. For example, patients with obstructive sleep apnea syndrome who have 40 or more apneas per hour of nocturnal sleep usually have average sleep latencies of 5 min or less, whereas those with fewer apneas per hour (20–40) have average latencies of 5–8 min and sometimes higher.

Among sleep disorders associated with excessive daytime sleepiness, a differentiation in the levels of sleepiness and the frequency of SOREMPs can be seen. Patients with chronic insufficient sleep usually have a more moderate level of sleepiness (5–8 min) than do patients with narcolepsy or severe obstructive sleep apnea syndrome (no more than 5 min) [26]. Among sleep disorders patients, only those with narcolepsy show two or more SOREMPs. Shift work disorder (SWD) patients complain of insomnia, sleepiness, or both and those with specific excessive sleepiness complaints compared to insomnia complaints and shift workers without SWD showed significantly lower MSLT scores that are in the pathologic range [62].

The relationship between nocturnal sleep and daytime sleepiness (i.e., MSLT scores) in insomnia patients appears to be the reverse of that in healthy controls. Insomnia patients do not generally complain of daytime sleepiness as the consequence of their perceived inadequate nocturnal sleep. Often the complaint is fatigue, tiredness, and dysphoria. In fact, some data suggest that insomnia patients may be "hyperalert." Although showing shortened and fragmented nocturnal sleep compared to age-matched, healthy controls, a majority of insomnia patients have unusually high average sleep latencies (i.e., $\geq$ 15 min) [63]. Most think of the MSLT as a measure of sleepiness, but elevations in the MSLT latency, particularly associated with short sleep, may also have clinical significance. A large study of the MSLT in

insomnia found MSLT latencies of ≥15 min (1 min above the population mean) in the majority of insomnia patients, and these high latencies were reliable across eight months [64]. In addition, the high MSLT latencies were associated with elevated urinary norepinephrine levels [65]. An interesting question is what is the MSLT in other disorders of arousal (e.g., generalized anxiety disorder, post-traumatic stress disorder, and mania).

Evaluation of Therapeutic Interventions

A number of studies have shown that the MSLT levels in various sleep disorders are improved after appropriate therapeutic intervention. Two current treatments for obstructive sleep apnea syndrome are continuous positive airway pressure (CPAP) and uvulopalatopharyngoplasty (UPPP). CPAP provides a pneumatic splint of the airway, eliminating the upper airway obstructions and thus the brief arousals that fragment sleep. This improved sleep is associated with normalization of the MSLT [66, 67], and the duration of nightly use predicts the degree of sleepiness on the MSLT [66, 67]. UPPP, a surgical treatment aimed at removing excess upper airway tissue and thus establishing a patent airway, is less consistently successful. In those patients who benefit from the surgery, apneas are reduced, sleep is improved, and the MSLT level of sleepiness is normalized [68]; but in patients whose apnea does not improve, the MSLT result remains at presurgery levels, even though patients perceive a subjective improvement in alertness. This once again indicates the inaccuracy of subjective assessments of sleepiness and alertness.

Modifications of the Multiple Sleep Latency Test

The basic MSLT procedure has been modified in various ways, with no clear improvement. The first such modification was a change in the instructions to "try and stay awake" while lying in bed in a quiet, dark room [69]. The instruction does produce longer sleep latencies, but the change did not increase sensitivity of the MSLT [69]. A subsequent variation, the maintenance of wakefulness test (MWT), instructs the subject to stay awake while seated in a chair [70]. Again, longer sleep latencies result from the change, but improvement in sensitivity over the MSLT has not been documented. Finally, the modified assessment of sleepiness test (MAST) has been offered as an alternative to the MSLT [71]. It consists of three standard sleep latency tests (with a "try to sleep" instruction) alternating with two tests of the subject's ability to remain awake while seated in a chair reading a book. As indicated above, MSLT reliability begins to decline as the number of tests is reduced; this is also found with the MAST. Improved sensitivity has not been established for the MAST.

The intent of the MSLT modifications is to measure a subject's ability to remain awake. It is argued that, clinically, the patient's problem is remaining awake (which adds a certain face validity to the instruction to remain awake). The ability to stay awake is a function of many factors that can momentarily override the underlying physiologic state, including the motivation to remain awake, the presence of competing motives, the environment, and the time of day. Consequently, the ability to maintain wakefulness varies significantly between individuals and hour to hour within an individual. No single laboratory test is generalizable to the variety of circumstances under which wakefulness is to be maintained. The MSLT attempts to remove the confounding factors and measure the underlying physiologic state, thus defining the patient's maximal risk.

Correlations among the standard MSLTs and these modified versions of the MSLT and also with two widely used subjective measures of sleepiness, the ESS and the Sleep-Wake Activity Inventory, are relatively weak [72, 73]. This has led some to argue that there are different types of or dimensions to sleepiness. A more parsimonious and valid explanation, however, is that the methodologies differ in sensitivity. Another more plausible explanation is that rather than different kinds of sleepiness, there are different levels of ability to detect sleepiness, different environmental demands for alertness, and different abilities to counteract sleepiness. Additional constructs have utility and become meaningful when the same variable affects the constructs in different ways. This has not been demonstrated for the various versions of the MSLT.

Multiple Sleep Latency Test Norms

Enough data on the MSLT have now been collected to describe the range of values. The previously described 2005 review of the MSLT calculated a weighted mean across a total of 27 studies that presented control or healthy normal data [14]. Across studies the mean daily sleep latency for studies presenting four-test MSLT data was 10.4 ± 4.3 min and for those studies presenting five-test MSLT data it was 11.6 ± 5.2 min. These studies selected their participants as healthy controls. From a representative US population-based sample of 1648 adults, 157 randomly chosen volunteers with a 68 % response rate underwent a five-test MSLT conducted on the day after an 8.5 h overnight polysomnogram [74]. The population mean daily sleep latency was 11.3 ± 4.5 min. These data, both selected and unselected, suggest that the population mean for a five-test MSLT is about 11 min with an approximate 5 min standard deviation.

Clinically, evidence of pathologic sleepiness is considered to be an average daily sleep latency of 5 min or less. An

average latency of 6–8 min is considered borderline pathologic and latencies of 9 min and greater are considered normal. In the samples of healthy, normal individuals, some have latencies in the pathologic range (not more than 5 min) [75]. These normative data (in a statistical sense) do not help in differentiating controls without complaints from sleep disorders patients with excessive sleepiness. What appears to be the critical difference is that the sleepiness in the controls is not persistent. With adequate sleep over a number of nights, the average daily sleep latency increases, reaching the population norm (see the discussion of sleep time determinants of daytime sleepiness). In the latest American Academy of Sleep Medicine, practice parameters of pathological sleepiness are considered to be a mean sleep latency of 8 min or less; an average sleep latency of 10 min or more is considered normal; latencies between these two means are considered borderline pathologic [76].

A final issue is the degree to which average sleep latency changes as a function of age. In several reports of healthy, non-complaining adults using a four-test MSLT, younger subjects aged 21–35 years had an average daily sleep latency of 10 min, adults aged 30–49 years had an average latency of 11–12 min, and subjects aged 50–59 years had an average latency of 9 min [77]. For the older subjects, nocturnal sleep efficiency was lower than that of the other age groups, and periodic leg movements during sleep were observed in 50 % of the sample. In the 2005 MSLT review, just the opposite age effect on MSLT values was found. With age average, daily sleep latency increased. The difference probably relates to the fact that those participants were selected for their normal nocturnal sleep. Finally, preadolescent children rarely fall asleep on a sleep latency test, and hence the average sleep latencies are close to 20 min [78].

Maintenance of Wakefulness Test

23

Cathy Goldstein and Ronald Chervin

Introduction

Excessive daytime sleepiness is defined as the inability to maintain alertness during the day, resulting in unintentional intrusion of drowsiness or sleep into the major waking period [1]. Excessive daytime sleepiness can impair performance and increase propensity for accidents [2, 3]. Public safety becomes a concern as almost one-third of survey respondents report sleepiness that interferes with their daily activities at least a few days a month [4]. In fact, 36 % of drivers polled report nodding off or falling asleep while operating a motor vehicle [4]. Historically, sleepiness has been implicated in disasters such as the nuclear accidents at Chernobyl and Three Mile Island, and the Exxon Valdez oil spill. Sleep disorders such as obstructive sleep apnea, narcolepsy, or circadian rhythm alteration may be the source of sleepiness. However, the symptom often results from sleep deprivation and may be associated with certain medical conditions or pharmacotherapy.

Multiple measures exist to quantify excessive daytime sleepiness. The Epworth Sleepiness Scale (ESS) is one of the most commonly used subjective assessments [5–7]. Factors apart from the ability to maintain alertness may impact the score on subjective scales, which therefore must be interpreted carefully [5]. Objective tools to assess sleepiness include the multiple sleep latency test (MSLT) and maintenance of wakefulness test (MWT). The Oxford Sleep Resistance (OSLER) Test and pupillometry also objectively evaluate sleepiness but are not typically used in clinical settings [8, 9]. The MWT, the subject of this chapter, seeks to assess an individual's ability to remain awake in an environment lacking stimulation, whereas the MSLT focuses on an individual's propensity to fall asleep.

The American Academy of Sleep Medicine (AASM) cites two specific situations in which the MWT may be beneficial [10]. The MWT is indicated to evaluate sleepiness when failure to maintain wakefulness may threaten the safety of the individual or public [10]. For example, the MWT may provide valuable data for patients employed in public transportation or aviation. However, mean sleep latency values that fall into normal ranges by no means guarantee optimal alertness and performance in a real-life environment. Limitations of the MWT will be discussed later in this chapter. The second indication for the MWT is to assess treatment response of patients who receive therapy for excessive daytime sleepiness [10].

History and Development

The need for improved objective testing to assess sleepiness became evident in the late 1970s when inconsistencies were seen in subjective sleepiness ratings among patients whose sleepiness did not result from acute sleep deprivation [11]. For example, some patients with chronic sleepiness described themselves as alert on the Stanford Sleepiness Scale, while they were visibly falling asleep [11]. Although performance testing and pupillography were available, performance testing was confounded by motivation, fatigue, and skill. Furthermore, neither test could reveal sleep-onset rapid eye movement (REM) periods which are the polysomnographic hallmark of narcolepsy [12]. The MSLT was developed in 1977 and recorded electroencephalogram (EEG), electro-oculogram (EOG), and electromyogram (EMG) to determine latency to sleep onset and distinguish sleep stages [13]. As the MSLT became widely used for the assessment of physiological sleep tendency, investigators began to use the test to assess treatment response [5]. Mean sleep latency, as measured by the MSLT, did not demonstrate improvements in line with reduced sleepiness reported by patients [14]. In this setting, the MWT was developed in

S. Chokroverty (ed.), *Sleep Disorders Medicine*, DOI 10.1007/978-1-4939-6578-6_23

1982 to measure the ability to remain awake as opposed to the MSLT's measure of the propensity to fall asleep [15].

The MWT recorded EEG, EOG, and EMG during five 20-min trials in which subjects remained in a chair in a dark room and were instructed "to stay awake as long as possible" [15]. This instruction was the most important difference from the MSLT, in which subjects were instructed to try to fall asleep. Sleep onset was defined as three consecutive epochs of stage N1 sleep or one epoch of any other sleep stage [15]. If no sleep occurred by minute twenty, the trial was concluded. If the patient did fall asleep prior to minute twenty, the trial was terminated after either 10 min of continuous sleep or when the patient awoke spontaneously after minute twenty (even if sleep duration was less than 10 min) [15]. Of note, in patients with untreated narcolepsy, mean sleep latency increased by threefold when it was derived from the MWT as opposed to the MSLT [15]. This is an extension of the previous work by Hartse, which demonstrated an increase in mean sleep latency on the MSLT simply by changing the instructions from "try to sleep" to "try to stay awake" [16]. These findings highlight the different physiological tendencies measured by the MSLT and MWT.

In the initial investigation by Mitler et al., contrary to the findings in patients with narcolepsy, control subjects displayed no difference between mean sleep latency derived from the MSLT and mean sleep latency derived from the MWT [15]. This may reflect a "ceiling effect" of the 20-min MWT protocol such that many of the control subjects could easily remain awake for the entire 20 min trial [15]. In subsequent studies, extending the MWT trials to 40 min diminished the "ceiling effect" [10, 13, 17, 18]. Both the 20- and 40-min protocols were used prior to the American Academy of Sleep Medicine's (AASM) practice parameter for clinical use of the MSLT and the MWT [10]. Normative data vary based on the protocol used as average mean sleep latencies in healthy subjects are much shorter when derived from the 20-min as opposed to 40-min protocols [18]. The AASM now recommends the 40-min nap trial MWT to standardize the test and minimize the "ceiling effect" [10].

Protocol

The 2005 practice parameters for use of the MSLT and MWT made recommendations on how to conduct the MWT [10]. The MWT should consist of four 40-min trials with the first trial one and a half to three hours after the patient's usual wake time, and at two-hour intervals thereafter. During these trials, central (C3-A2, C4-A1) and occipital (O1-A2, O2-A1) EEG derivations, bilateral EOG, chin EMG, and electrocardiogram should be recorded. The environment should be shielded from external light; however, a light should be situated behind the patient's head such that an illuminance of 0.10–0.13 lx is achieved at the cornea. The patient should be seated in bed, in a semi-recumbent position, with a bolster pillow to support the head and back. Room temperature may be adjusted for the patient's comfort. A light meal should be offered one hour before the first trial and immediately after the noontime trial. Biocalibrations prior to each trial should include eye opening, eye closure, lateral eye movement, blinking, and teeth clenching. The following instructions should be given to the patient at the start of each trial: "Please sit still and remain awake as long as possible. Look directly ahead of you, and do not look directly at the light." Slapping the face, singing, and other extraordinary measures to promote wakefulness are not permitted. If sleep occurs, the trial is terminated after either three consecutive epochs of stage one sleep or one epoch of any other sleep stage. If no sleep occurs, the trial is concluded after 40 min. The technician should document the following parameters for each trial: start and stop times, sleep latency, total sleep time, and sleep stages recorded. Mean sleep latency should be calculated. Recording sleep logs or conducting an overnight polysomnogram prior to the MWT is at the discretion of the ordering sleep physician based on the clinical scenario. In addition, the clinician may make his/her own determination in regard to the use of medications, caffeine, and tobacco prior to and during the MWT. Drug screening on the morning of the test should be considered [10]. Table 23.1 highlights the differences between the MWT and MSLT protocols.

Interpretation

Mean sleep latency is determined from the MWT by calculating the average sleep-onset latency from all four trials. Like the MSLT and overnight polysomnogram, sleep onset is defined as the start of the first thirty-second epoch scored as sleep [19]. Normative data guide interpretation of mean sleep latency. In 64 healthy controls, when defining sleep onset as at least ten seconds of sleep or the first epoch scored as sleep, mean sleep latency was 32.6 $\pm$ 9.9 min and 42 % of subjects remained awake for the entirety of all four 40-min trials of the MWT [20]. When a more stringent definition of sleep onset was used (three continuous epochs of N1 sleep, or one epoch of another sleep stage), mean sleep latency was 35.2 $\pm$ 7.9 min and 59 % of subjects remained awake for the entirety of all four trials [20]. Additionally, 97.5 % of normal subjects had a mean sleep latency $\geq$ 8 min [10]. Based on these data and a subsequent investigation in normal controls, the AASM recommends interpretation of mean sleep latency less than 8 min as abnormal and mean sleep latency between 8 and 40 min as a

Table 23.1 Protocols for conducting the maintenance of wakefulness test and multiple sleep latency test

	Maintenance of wakefulness test	Multiple sleep latency test
Overnight polysomnogram required prior to test	No	Yes
Recording montage	EEG (C3-A2,C4-A1,01-A2,02-A1), EOG (left and right), EMG (submetal), EKG	EEG (C3-A2,C4-A1,01-A2,02-A1), EOG (left and right), EMG (submetal), EKG
Environment	Seated in bed in a dimly lit room	Lying down in a dark quiet room
Patient instructions	Please sit still and remain awake for as long as possible. Look directly ahead of you, and do not look directly at the light	Please lie quietly, assume a comfortable position, keep your eyes closed, and try to go to sleep
Nap trials	4	5
Sleep-onset latency	The start of the first epoch of sleep	The start of the first epoch of sleep
Trial terminated	40 min if no sleep occurs or after 3 consecutive epochs of N1 sleep or 1 epoch of any other sleep stage	20 min if no sleep occurs or 15 min after the first epoch of sleep
Mean sleep latency of controls[a]	30.4 ± 11.2 min	11.6 ± 5.2 min

[a]Pooled from literature describing normative data. Adapted from Littner et al. [10]

value of uncertain significance [21, 10]. Remaining awake for the full 40 min on each trial provides the greatest objective evidence to support an individual's ability to maintain alertness [10].

Mean sleep latency may be affected by multiple factors. A significant, positive correlation between age and mean sleep latency is seen with the 40-min but not 20-min MWT protocol. This suggests that the ability to remain awake after the first 20 min of an MWT trial may be age-dependent [20]. Furthermore, medications, caffeine, prior total sleep time, sleep fragmentation, circadian phase, anxiety, depression, and motivation have all been shown to affect MWT results [22–35]. Even playing background music can increase mean sleep latency on the MWT [36]. Contrary to what may be expected, napping between MWT trials did not significantly impact the results in one investigation [37].

Special Populations

At this time, the MWT is not recommended in the pediatric population secondary to lack of data in this group including undefined normative values. However, a recent study did demonstrate that the MWT may be beneficial in assessing treatment responses of pediatric patients with narcolepsy [38]. The MWT has been evaluated in other specific patient populations, for example, patients with retinitis pigmentosa, myotonic dystrophy, and more extensively individuals with Parkinson's disease [22, 39, 40, 41]. The MWT may be a valuable assessment tool in patients with Parkinson's disease, particularly to assess the ability to maintain alertness in the setting of dopaminergic medication use [22, 41].

Utility for Specific Indications

The MWT is recommended as a tool to assess treatment response in individuals receiving therapy for hypersomnolence. The magnitude of change that represents adequate treatment is not defined, but the direction of change may be valuable when combined with clinical assessment [10]. Studies of patients with narcolepsy, idiopathic hypersomnia, obstructive sleep apnea, and shift work disorder have shown varying degrees of increased mean sleep latency on the MWT after treatment.

Additionally, the MWT may be used to evaluate individuals in whom impaired alertness could create risk to personal or public safety [10]. Studies have used driving simulators to investigate the relationship of mean sleep latency with performance, and their results are as follows. Subjects with disorders that cause hypersomnolence demonstrate significant negative correlations between mean sleep latency and the following measures of driving impairment: lane-position variability, crash frequency, inappropriate line crossing, and standard deviation from the center of the road [42–44]. Some studies have shown the greatest driving impairments in those with mean sleep latencies below 19 min [42]. Conversely, untreated obstructive sleep apnea patients with mean sleep latencies above 30 minutes perform similar to healthy controls on measures of vehicle control and vigilance [43]. Notably, in one investigation, driving simulator performance showed significant improvements when obstructive sleep apnea was treated with continuous positive airway pressure (CPAP) [45]. However, this did not correlate with increases in mean sleep latency [45]. Furthermore, in a group of subjects

undergoing partial sleep loss, only those who were also impaired by alcohol demonstrated a significant inverse correlation between simulator car crashes and mean sleep latency on the MWT [46]. Mean sleep latencies derived from the MWT show correlations with simulated driving performance that are superior to the MSLT [43, 44].

Significant limitations arise in evaluation of sleepiness in real drivers on actual roadways. A study that did examine actual highway driving showed a significant increase in inappropriate line crossings among very sleepy (mean sleep latency 0–19 min) and sleepy (mean sleep latency 20–33 min) untreated obstructive sleep apnea patients, as compared to alert patients and controls (mean sleep latency > 33 min) (Fig. 23.1, [47]. However, line crossings may not necessarily translate directly to automobile crashes. Another study found that drivers who had been in a motor vehicle accident, in comparison with those who had not, did not show significantly different MWT results [48]. Due to the paucity of data that address real-life fitness for operating a motor vehicle, the MWT is not generally required for commercial vehicle drivers with sleep disorders [49]. Furthermore, in contrast to the MWT findings on simulated driving performance, mean sleep latency derived from the MSLT has been associated with motor vehicle accidents, as demonstrated by an increased risk of car crashes in individuals with mean sleep latencies less than or equal to 5 min on MSLT [50].

Data on performance in aviators are scarce, but two pilots with hypersomnolence and short sleep latencies on MSLTs were successfully returned to duty after they demonstrated the ability to stay awake on all naps of the MWT [51]. Currently, the Federal Aviation Administration (FAA) does employ the MWT to ensure alertness in pilots with obstructive sleep apnea (www.faa.gov).

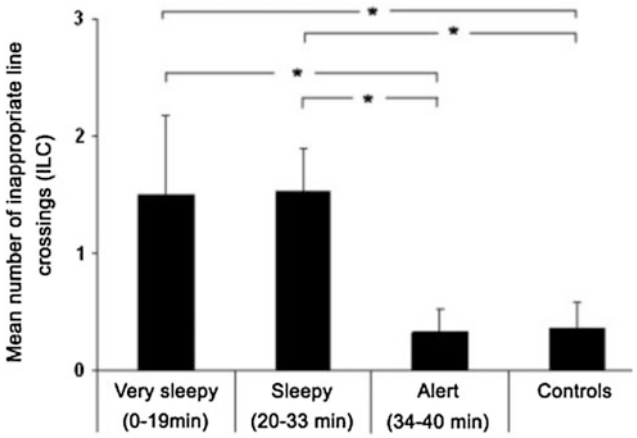

Fig. 23.1 Mean number of inappropriate line crossings (ILCs) during real driving (mean ± standard error) in the three mean sleep latency groups on the maintenance of wakefulness test (MWT) and in healthy control subjects. *$p < 0.05$. Limitations

In addition to limitations in assessment of safety and performance, the MWT has other shortcomings. Compared to MSLT, less validity data exist for the MWT and clinicians tend to have less experience with this test. Although highly sensitive to sleepiness produced by acute, severe sleep deprivation, the linear relationship of mean sleep latency with sleep loss is attenuated in the setting of less severe, more chronic sleep deprivation [24]. Also, microsleep episodes, which are associated with performance decrements, are not typically reported in the interpretation of the MWT [52]. The MWT is not designed to aid in the diagnosis of narcolepsy. Sleep-onset REM periods are significantly decreased on the MWT compared to the MSLT, and use of the MWT in patients with suspected narcolepsy would lead to false-negative results [53]. The range of mean sleep latencies in the category of unclear clinical significance (between 8 and 40 min) is large, with the potential for overlap of normal individuals, those with sleep disorders, and patients with treated and untreated conditions. Furthermore, the ability to remain awake for all trials on the MWT may not reflect alertness in real-life situations where confounding factors such as prior sleep duration and circadian phase contribute to sleepiness, and motivation to stay awake may differ from that experienced during a laboratory test. For the MWT, as with the MSLT, the lack of prospective data to show prediction of future crashes and morbidity remains a significant limitation and area for further research.

Summary

The maintenance of wakefulness test is a tool designed to assess the ability to sustain alertness rather than the tendency to the fall asleep. This test may be beneficial to evaluate response to therapy in individuals with hypersomnolence. In addition, the maintenance of wakefulness test may provide valuable information when performed in patients whose occupations require constant alertness to ensure safety. However, like all diagnostic modalities, careful clinical correlation is required with interpretation of this test as results that fall into normal ranges may not guarantee alertness under other conditions.

Introduction to Sleep Stage Scoring

Continuous recordings of electroencephalographic (EEG), electrooculographic (EOG), and electromyographic (EMG) activity are required to classify the different stages of sleep and wakefulness. The original Rechtschaffen and Kales sleep scoring manual of 1968 [1], commonly known as the "R and K" rules, was used until 2007 at which point the American Academy of Sleep Medicine (AASM) created a new scoring manual known as the *AASM Manual for the Scoring of Sleep and Associated Events: Rules, Terminology, and Technical Specifications* [2]. Each scoring rule and subsequent revision is formed by consensus based on extensive literature review and analysis. At this time, the AASM scoring manual is updated continuously and is accessed online in its most updated version [3]. The *Rechtschaffen and Kales* method divides sleep into five distinct stages: non-rapid eye movement (non-REM) stages 1, 2, 3, and 4 and stage REM sleep. The most recent AASM scoring manual recognizes four sleep stages: stage N1 (formerly stage 1 sleep), stage N2 (formerly stage 2 sleep), stage N3 (formerly stages 3 and 4 sleep), and stage R sleep (formerly stage REM sleep). Sleep stages do not exist as single distinct entities, but should be viewed as gradual transition of a waveform. The scoring rules were devised to allow for standardization between sleep laboratories and offer a conceptual simplicity rather than a rigid structure.

Fig. 24.1 10–20 electrode placement. The 10–20 system assigns a number to further specify the location in the left or right hemisphere. Location "z" is used to indicate that the location of the electrode is in the midline or "zero" meaning that it is neither left hemisphere nor right hemisphere. The electrode placed at Cz is said to be the "Vertex" meaning that it is the mid central or at the top of the head. Fpz and Oz are used in achieving the other measurements and can be used as additional electrode placements for localization of activity. Fpz may be used as the location of the COM (common) or ground electrode placement. Copyrighted to Alon Y. Avidan, MD, MPH

Technical Specifications

Electroencephalogram (EEG) is recorded using the International 10–20 recording system as depicted in Fig. 24.1. The recommended derivations are F4-M1, C4-M1, and O2-M1 as demonstrated in Fig. 24.2. Backup electrodes should be placed at F3, C3, and O1 (all referenced to M2). An alternative acceptable derivation is Fz-Cz, Cz-Oz, and C4-M1 with backup electrodes at Fpz, C3, and O1. EEG recording criterion includes a minimum paper speed of 10 mm/sec. One page equates 30 s and is defined as one epoch. Time constant (TC) is 0.4 s (or low frequency filter of 0.3 Hz). Electrode impedances should not exceed 5K Ω.

The electrooculogram (EOG) signals measure changes in the electric potential of the positive anterior aspect of the eye, the cornea, relative to the negative posterior aspect, the retina. The "Recommended" EOG derivations are E1-M2 and E2-M2 with E1 placed 1 cm below the outer canthus of the left eye and E2 placed 1 cm above the outer canthus of the right eye. An alternative "Acceptable" derivation is placing E1 1 cm below and lateral to the outer canthus of the left eye and E2 1 cm above and lateral the outer canthus of the right eye as demonstrated in Fig. 24.3. During any eye movement, the cornea moves toward one electrode, while the retina moves away. When the eye is not moving, the change in relative position is zero, and the eye leads do not record a signal. Slow rolling eye movements (SREM) occur during drowsiness and light sleep and are recorded as long gentle waves with the initial deflection lasting longer than 500 ms (Table 24.1). In contrast, rapid jerking eye

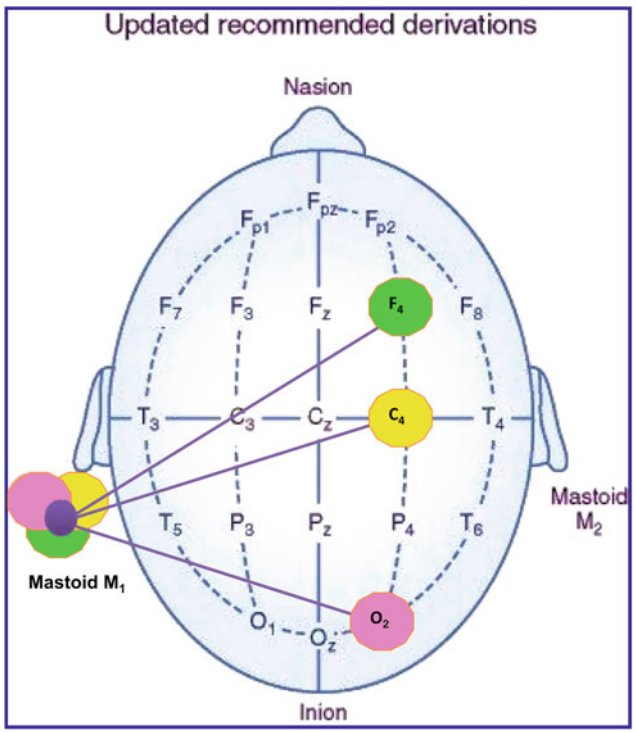

Fig. 24.2 Updated AASM-recommended derivations for recording the EEG. Electrode locations as recommended in 2007 by the American Academy of Sleep Medicine. Key: *Fp* frontopolar or prefrontal, *F* frontal, *C* central, *T* temporal, *P* parietal, *O* occipital, *A* ear or mastoid, *F3* left mid-frontal, *P3* left parietal, *T4* right temporal, *A1* right ear, and *Cz* vertex. Modified from Kryger [8]

movements are represented by sharply contoured fast waves with the initial deflection lasting less than 500 ms. Blinking of the eyes produces rapid vertical movements.

The electromyographic (EMG) signals are muscle twitch potentials, which are used in sleep studies to distinguish between sleep stages based on the fact that electromyographic activity progressively diminishes during deepening stages of sleep. Specifically, during rapid eye movement (REM) sleep, muscle activity is minimal. There are occasional intrusions of EMG artifact into the record, some of which may be expressed as yawns, swallows, and teeth grinding (bruxism). Three electrodes are placed to record chin EMG: (1) midline 1 cm above the inferior edge of the mandible, (2) 2 cm below the inferior edge of the mandible and 2 cm right of midline, and (3) 2 cm below the mandible and 2 cm left of the midline. The standard chin EMG derivation utilizes one electrode below the mandible referred to the electrode above the mandible.

Scoring Stages of Sleep

Epochs of polysomnography are broken into 30-second sequential epochs with a sleep stage assigned to each epoch based on scoring rules that will be discussed below. If two or more stages coexist during a single epoch, the stage occupying the greatest portion of the epoch will be assigned. When scoring a record for stage of sleep, it may be helpful to scroll through the entire record quickly to evaluate the quality of the recording. He or she should observe the specific shape of the features that represent the stages in that particular individual and to gain an overall picture of the cycles for that record. Specifically observe for sleep spindles, K complexes, slow waves, and rapid eye movements.

EEG cortical activity can be characterized by their specific frequencies. Frequency is defined as the number of times a repetitive wave recurs in a specific time period (typically one second). Frequency is noted as cycles per second (i.e., Hertz, Hz). EEG activity has been divided into four bands based on the frequency and amplitude of the waveform and are assigned Greek letters (alpha, beta, theta, and delta) and is summarized in Tables 24.1 and 24.2.

The following convention is used to define EEG frequencies as per the AASM scoring manual:

- Beta is greater than 13 Hz;
- Alpha is between 8 and 13 Hz;
- Theta is between 4 and less than 8 Hz; and
- Delta is the slowest activity at less than 4 Hz.

Beta activity originates from the frontal and central regions and can be present during wakefulness or drowsiness. Beta activity typically declines during deeper stages of sleep but may reemerge during REM sleep. Use of sedative hypnotics (such as benzodiazepines) may cause enhanced beta activity (termed pseudo-spindles or drug-spindles) as depicted in Fig. 24.4, with frequencies faster than true bona fide physiological spindle activity (Table 24.3).

Alpha activity, also known as the posterior dominant rhythm, originates in the parieto-occipital regions bilaterally and is normally symmetric over both cerebral hemispheres. The alpha rhythm is noted during quiet alertness with the eyes closed and disappears or decreases in amplitude when the eyes open (reactivity) (Fig. 24.5).

Stage Wake

Typically, the first several minutes of recording will consist of wake (W) stage. Stage W is scored when more than 50 % of the epoch has scorable alpha EEG activity over the occipital region. Submental EMG is relatively high tone and will reflect the high-amplitude muscle contractions and movement artifacts. The EOG channels will show eye blinks (0.5–2 Hz) (Fig. 24.6) or possibly reading eye movements if the eyes are open (Fig. 24.7). As the patient becomes drowsy, with the eyes closed, the EEG will show predominant alpha activity, while the EMG activity will become less prominent. The EOG channels may show slow rolling eye movements.

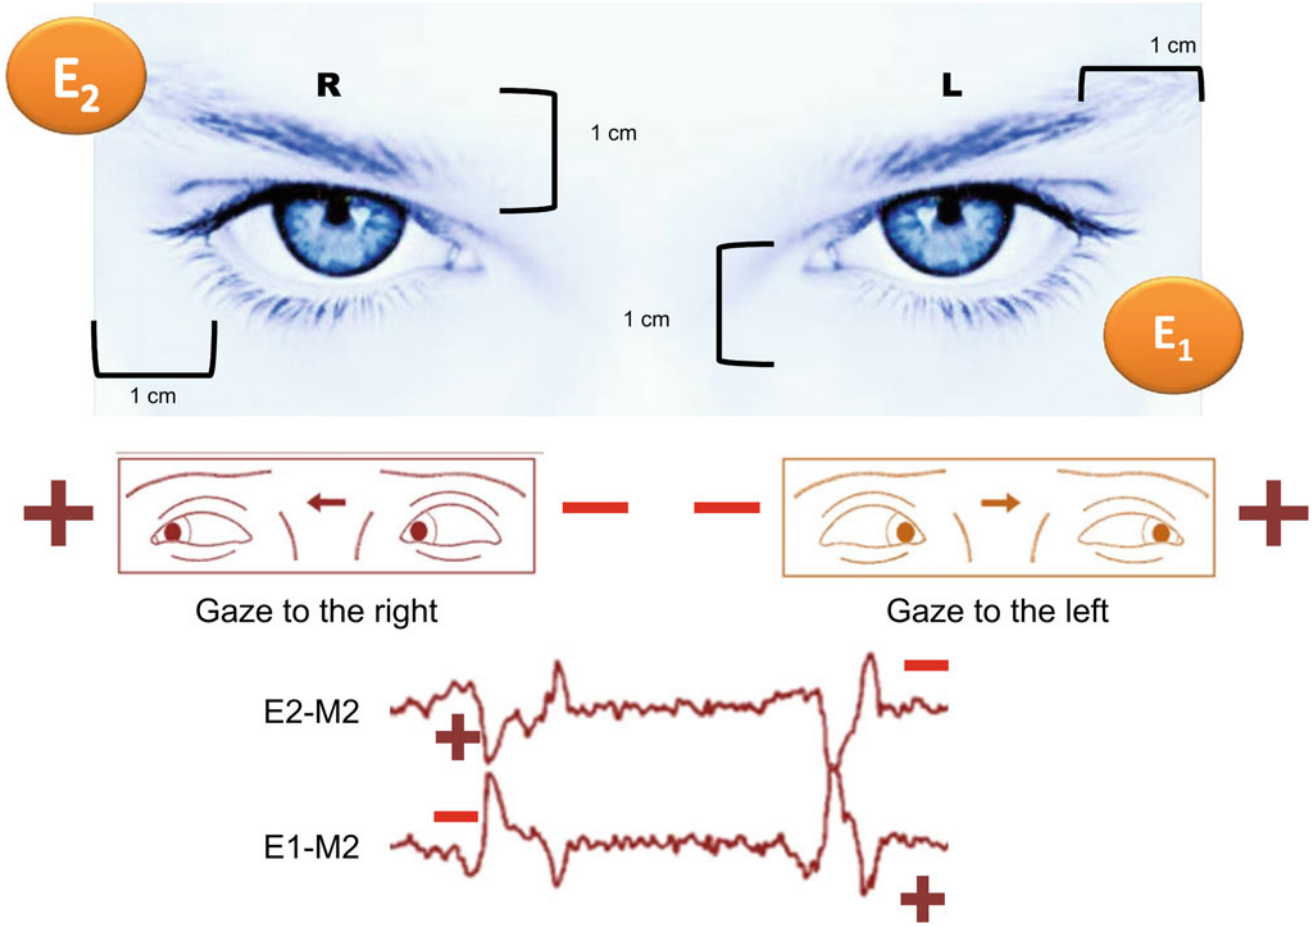

Fig. 24.3 Derivation of eye movements. *E1* Left outer canthus eye electrode (previously LOC). *E2* Right outer canthus eye electrode (previously ROC). *M1* Left mastoid electrode location. M2 Right mastoid electrode location. The eye can be envisioned like a battery with the positive pole at the cornea and the negative pole at the retina. The EOG consists of a bipolar linkage from the ROC electrode 1 cm lateral and 1 cm superior to one outer canthus to the LOC electrode 1 cm lateral and 1 cm inferior to the other outer canthus. The electrode toward which the eyes move becomes relatively positive, the other relatively negative. As the eyes move during sleep, they produce corresponding changes in the electrical field producing a correlating potential change in the EEG electrodes. This can be verified by noting corresponding movements in the EOG channels. From: Avidan and Barkoukis [9]. Copyrighted to Alon Y. Avidan, MD, MPH

Table 24.1 Key brain wave frequencies and landmarks used in sleep staging

Sample	Label	Definition
	Alpha activity	8–13 Hz rhythm, usually most prominent in occipital leads. Thought to be generated by cortex, possibly via dipole located in layers 4 and 5. Used as a marker for relaxed wakefulness and CNS arousals
	Theta activity	4–8 Hz waves, typically prominent in central and temporal leads. Sawtooth activity is a unique variant of theta activity (containing waveforms with a notched or *sawtooth-shaped* appearance) frequently seen during REM sleep
	Vertex sharp waves	Sharply contoured, negative-going bursts that stand out from the background activity and appear most often in central leads placed near the midline
	Sleep spindle	A phasic burst of 11–16 Hz activity, prominent in central scalp leads; typically last for 0.5–1.5 s. Spindles are a scalp representation of thalamocortical discharges; the name derives from their shape (which is spindle-like)
	K complex	Recently redefined in the AASM manual as an EEG event consisting of a well-delineated negative sharp wave immediately followed by a positive component standing out from the background EEG with total duration $\geq$0.5 s, usually maximal in amplitude over the frontal regions

(continued)

Table 24.1 (continued)

Sample	Label	Definition
	Slow waves	High-amplitude ($\geq$75 μV) and low-frequency ($\leq$2 Hz) variants of delta (1–4 Hz) activity. Slow waves are the defining characteristics of stage N3 sleep
	REM	Rapid eye movements are conjugate saccades occurring during REM sleep correlated with the dreamer's attempt to look at the dream sensorium. They are sharply peaked with an initial deflection usually <1/2 s in duration
	SEM	Slow eye movements are conjugate, usually rhythmic, rolling eye movements with an initial deflection usually $\geq$1/2 s in duration

Modified from Kryger [8]

Table 24.2 Definitions and examples of sleep figures encountered on an EEG

EEG rhythm	Characteristics	Best seen	Examples
Posterior dominant rhythm (PDR)	8–13 Hz	Occipital	Slow waves	0.5–2 Hz; amplitude $\geq$75 μV	Frontal	Spindle	11–16 Hz; duration $\geq$0.5 s 8–12 Hz	Central	K complex	Diphasic; large amplitude, duration $\geq$0.5 s	Frontal	
Please note that although all slow waves are in the delta frequency range, not all delta waves are slow waves

The patient may enter stage N1 sleep briefly for one or two epochs and then return to stage W. From stage W, patients typically proceed to stage N1, but infrequently they may enter REM sleep or stage N2 sleep directly, if the pressure to do so is high (reflecting a state of pathological sleep deprivation).

Stage N1 Sleep

Stage N1 sleep is scored if the alpha rhythm is attenuated or replaced by low-amplitude, mixed-frequency activity (4–7 Hz) for more than half of the epoch (Fig. 24.8). Some individuals

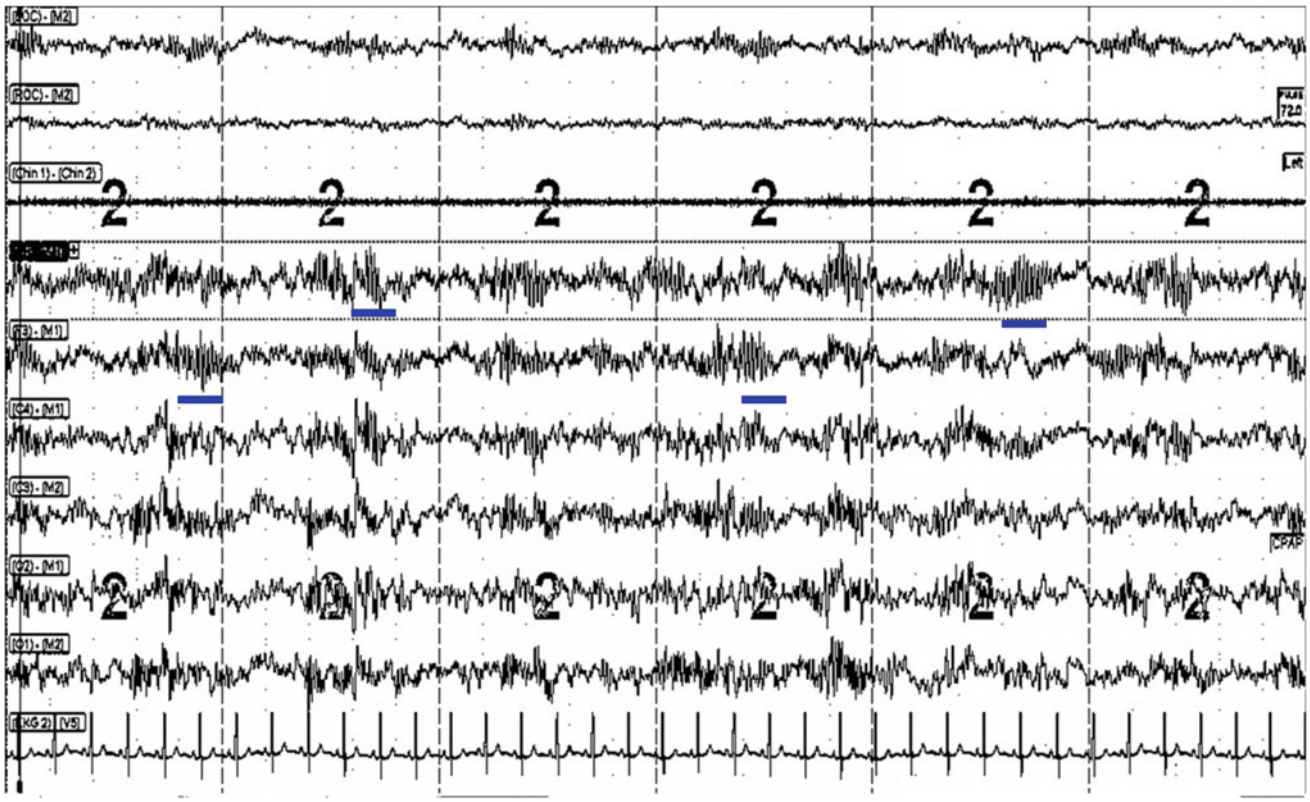

Fig. 24.4 This 30 s PSG epoch in a 45-year-old woman who takes nightly benzodiazepines. "Psuedospindles," or enhanced beta activity (identified by the *blue bars*), are noted during NREM sleep due to use of benzodiazepines

Table-24.3 Major differences between Rechtschafffen and Kales manual (R and K) and the AASM scoring manual from 2007

Differences	R and K manual	AASM scoring manual
EEG Electrodes	Score sleep stages using central (C3 and C4) leads	Score using frontal, central, and occipital leads
Major body movements	Movement time can be scored if more than half the epoch is obscured	No movement time staging exists
Slow wave sleep	Consists of both stage 3 and stage 4 sleep with delta wave amplitude measured using central leads	Only recognizes stage N3 sleep with delta wave amplitude measured using frontal leads
Terminology of stages	Stage 1, stage 2, stage 3, stage 4, and stage REM sleep	Stage N1, stage N2, stage N3, and stage R sleep
Reference electrode	Left and right ear or mastoid termed A1 or A2	Left and right mastoid termed M1 or M2
Scoring stage 2 (or N2) sleep	Three minute rule that states if greater than 3 min pass in between spindles or K complexes, then score stage 1 sleep	No 3 min rule exists

(approximately 10 %) do not generate an alpha rhythm upon eye closure and have similar occipital EEG activity during eye opening or closure. In these individuals, stage N1 is scored if there are vertex waves, slow rolling eye movements, or EEG activity in the range of 4–7 Hz (Fig. 24.9) with slowing of background frequencies by greater than or equal to 1 Hz from stage W. Vertex sharp waves (V waves) are sharply contoured waves lasting less than 500 ms that are maximal over the central regions (Fig. 24.9). Vertex sharp waves may be present but are not required to score stage N1. The EMG shows less activity than in wake, but the transition is gradual and of little assistance in scoring. In patients who have a background rhythm that is theta frequency due to a pathological state (encephalopathy, dementia, etc.), stage N1 sleep can be scored if there is further slowing of the background rhythm by greater than 1 Hz.

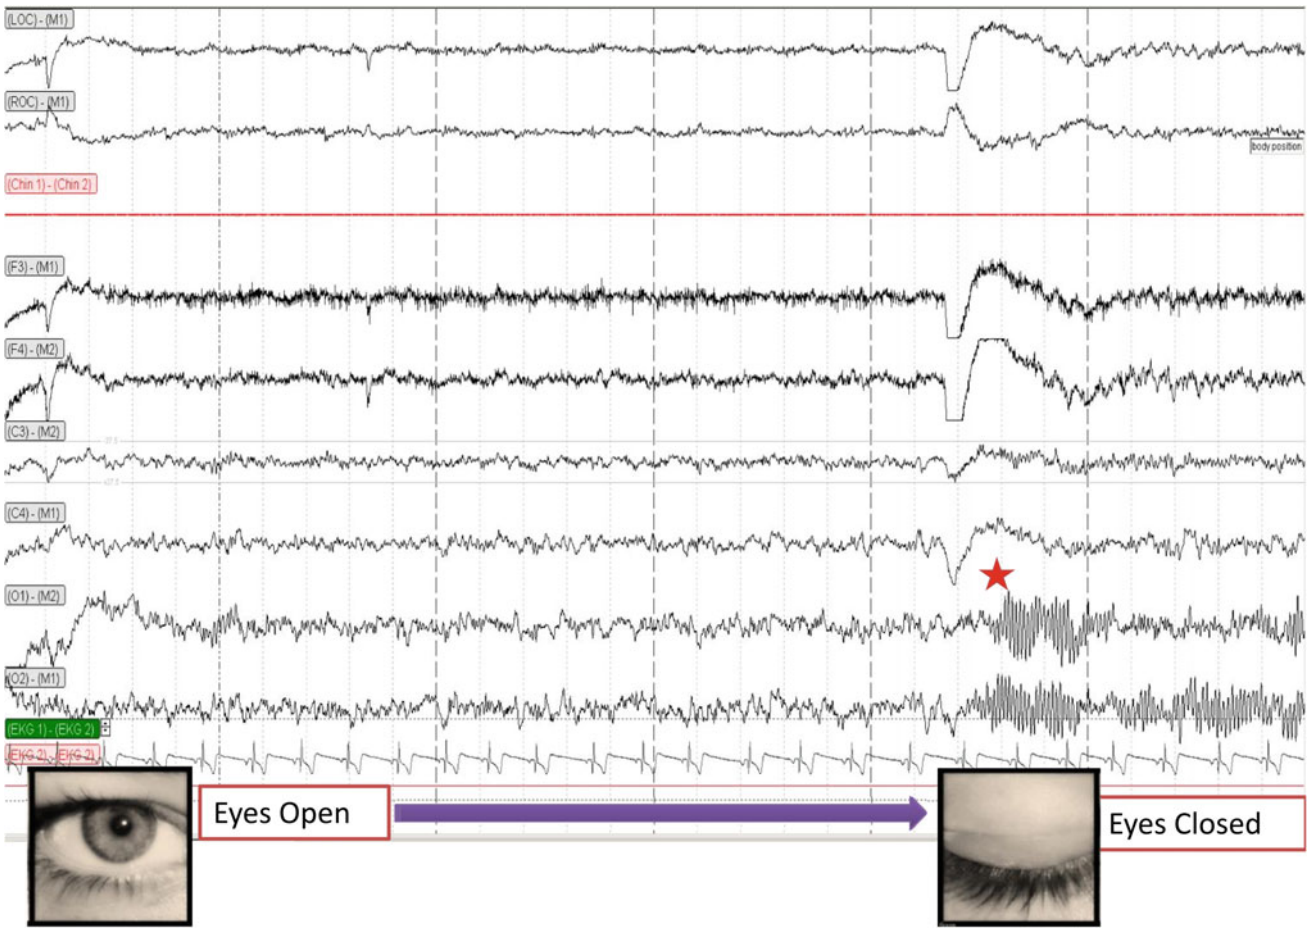

Fig. 24.5 This 30 s polysomnogram epoch showing the appearance of background alpha activity in the occipital leads when the patient is in quiet alertness and closes their eyes (*red star*). This rhythm is not apparent when the subject's eyes are open during the first portion of the epoch. Copyrighted to Raman K. Malhotra, MD

During stage N1 sleep, breathing becomes shallow, heart rate becomes regular, blood pressure falls, and the patient exhibits little or no body movement. The sleeper is still easily awakened and might even deny having slept. Many may have sleep starts during this stage of sleep.

Stage N2 Sleep

Stage N2 NREM sleep (Fig. 24.10) may also be termed *sigma, spindle*, or *intermediate sleep* and is classically demarcated by sleep spindles (red stars) along with K complexes (blue star). Stage N2 is an intermediate stage of sleep, but it also accounts for the bulk of a typical polysomnographic recording. It follows stage N1 sleep and initially lasts about 20 min. Stage N2 can begin to be scored if one or more K complexes (unassociated with arousal) or sleep spindle is noted during the first half of the epoch or the last half of the previous epoch (Fig. 24.11). K complexes are biphasic in morphology consisting of negative (upward deflection) sharp waves followed by a slower positive (downward deflection) component with a total duration of greater than 500 ms (Fig. 24.12). They characteristically stand out from the rest of the background and are seen maximal over the frontal leads, though no minimum amplitude criterion exists for K complexes [4]. K complexes may occur with or without stimuli such as a sudden sound and in this respect may represent a form of cortical evoked potential in a brain still minimally responsive to external stimuli. K complexes may be labeled as spontaneous if they arise from an unknown reason, indicating that their origin is of an endogenous brain activity. They may be labeled as evoked if they are clearly triggered by an external stimulus such as sound or noise. K-alpha complexes may be triggered by other entities such as periodic limb movements in sleep, an apneic event, or in association with an arousal (alpha EEG activity) immediately following the complex.

Sleep spindles are generated in the midline thalamic nuclei (reticular thalamic nucleus) and represent an inhibitory activity. Sleep spindles are characterized by 12–14 Hz

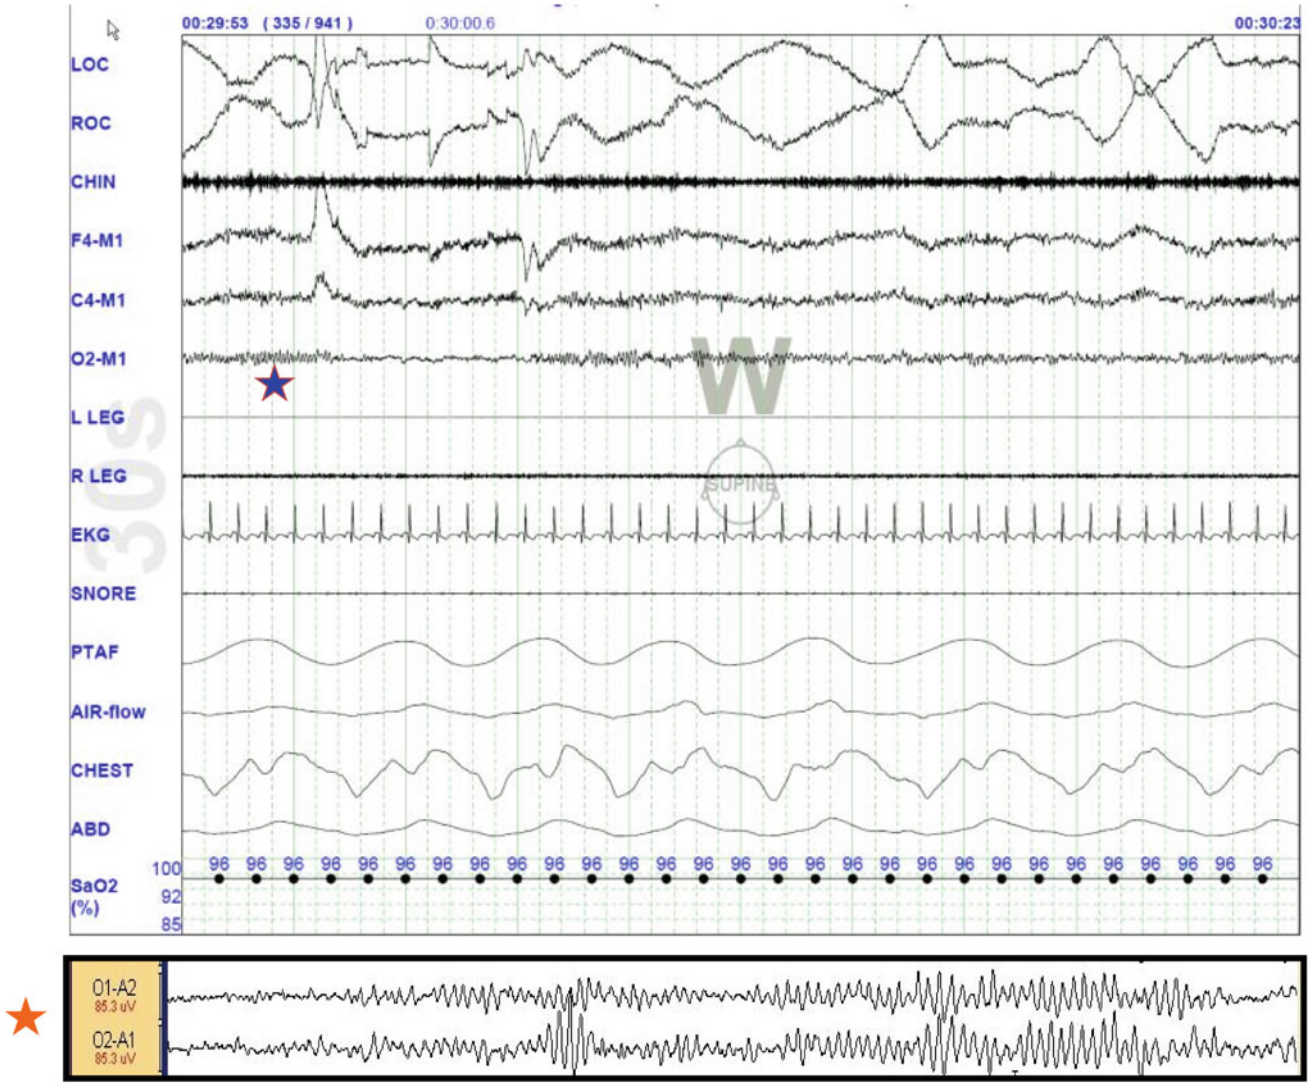

Fig. 24.6 This 30 s polysomnogram epoch demonstrates stage W with alpha rhythm noted in the occipital leads (*blue star*), increased chin EMG tone (CHIN electrode), and rapid eye movements of wakefulness (LOC, ROC). The lower panel demonstrates the prominent alpha activity (*orange star*) primarily seen in the occipital leads. Copyrighted to Alon Y. Avidan, MD, MPH

sinusoidal EEG activity in the central vertex region and must persist for at least 0.5 s (i.e., 6–7 small waves in 0.5 s), but rarely longer than 1 s (Figs. 24.13 and 24.14). Sleep spindles possess a high degree of synchrony and symmetry between the two hemispheres in patients older than one year of age. Although classically described as spindle shaped, they may be polymorphic and may attach as a tail to a K complex. As noted earlier, central nervous system (CNS) depressant drugs (such as benzodiazepines) often increase the frequency of the spindle activity leading to the presence of "pseudo-spindles" as shown in Fig. 24.4.

No specific criteria exist for EOG and EMG in this stage. Submental EMG activity is tonically low. There is typically no eye movement activity, though in some individuals [(i.e., patients on selective serotonin reuptake inhibitors (SSRI's)] slow eye movements may persist in this stage of sleep. Stage N2 is characterized by predominant theta activity (4–7 Hz EEG activity) and occasional quick bursts of faster activity. The EEG may show minimal alpha activity. Delta is only allowed to occur for less than 20 % of the epoch. The threshold triggering stage N3 sleep scoring is reached if 20 % of the epoch is comprised of delta activity.

Once meeting the criteria for N2 sleep, epochs can be continuously scored as stage N2 (even in the absence of K complexes or sleep spindles) assuming that there is not an arousal and the EEG continues to demonstrate low-amplitude, mixed-frequency activity (Fig. 24.15). For example, following an arousal from stage N2 sleep, an epoch would be scored stage N1 until a K complex or sleep spindle occurs again. Stage N2 scoring may end if the epoch meets criteria for wakefulness, stage N3, or stage R, or contains an arousal or a major body movement followed by slow eye movements.

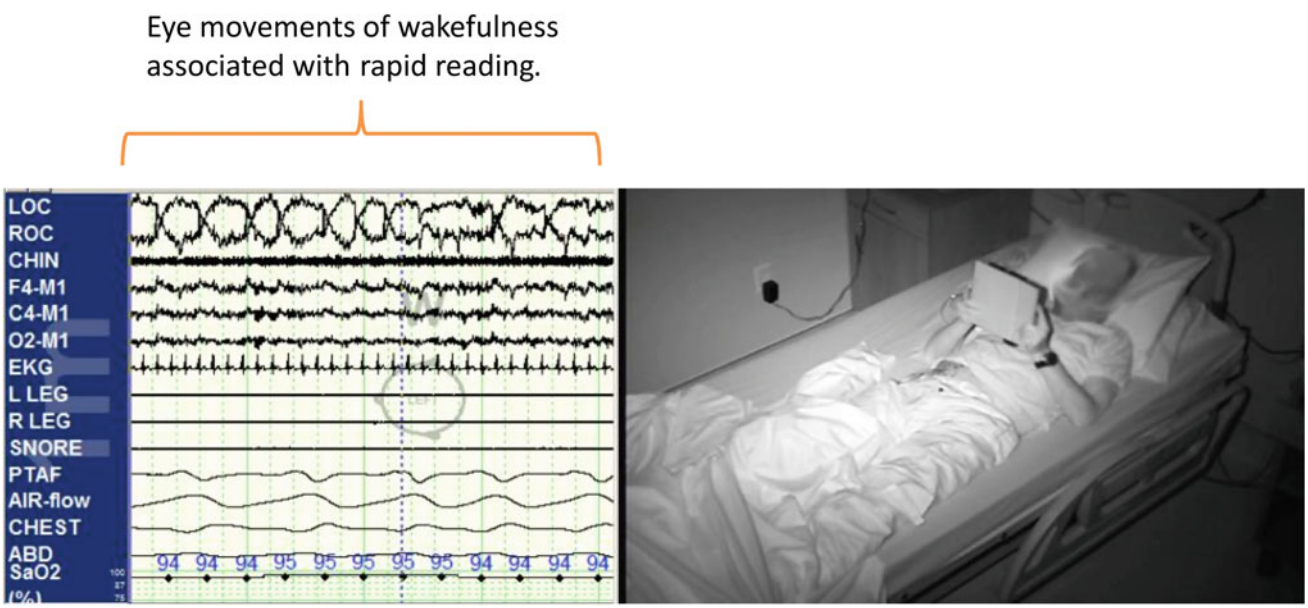

Fig. 24.7 This 60 s polysomnography epoch demonstrates stage W with alpha rhythm noted in the occipital leads, increased chin EMG tone (CHIN electrode), eye movements of wakefulness associated with rapid reading. Copyrighted to Alon Y. Avidan, MD, MPH

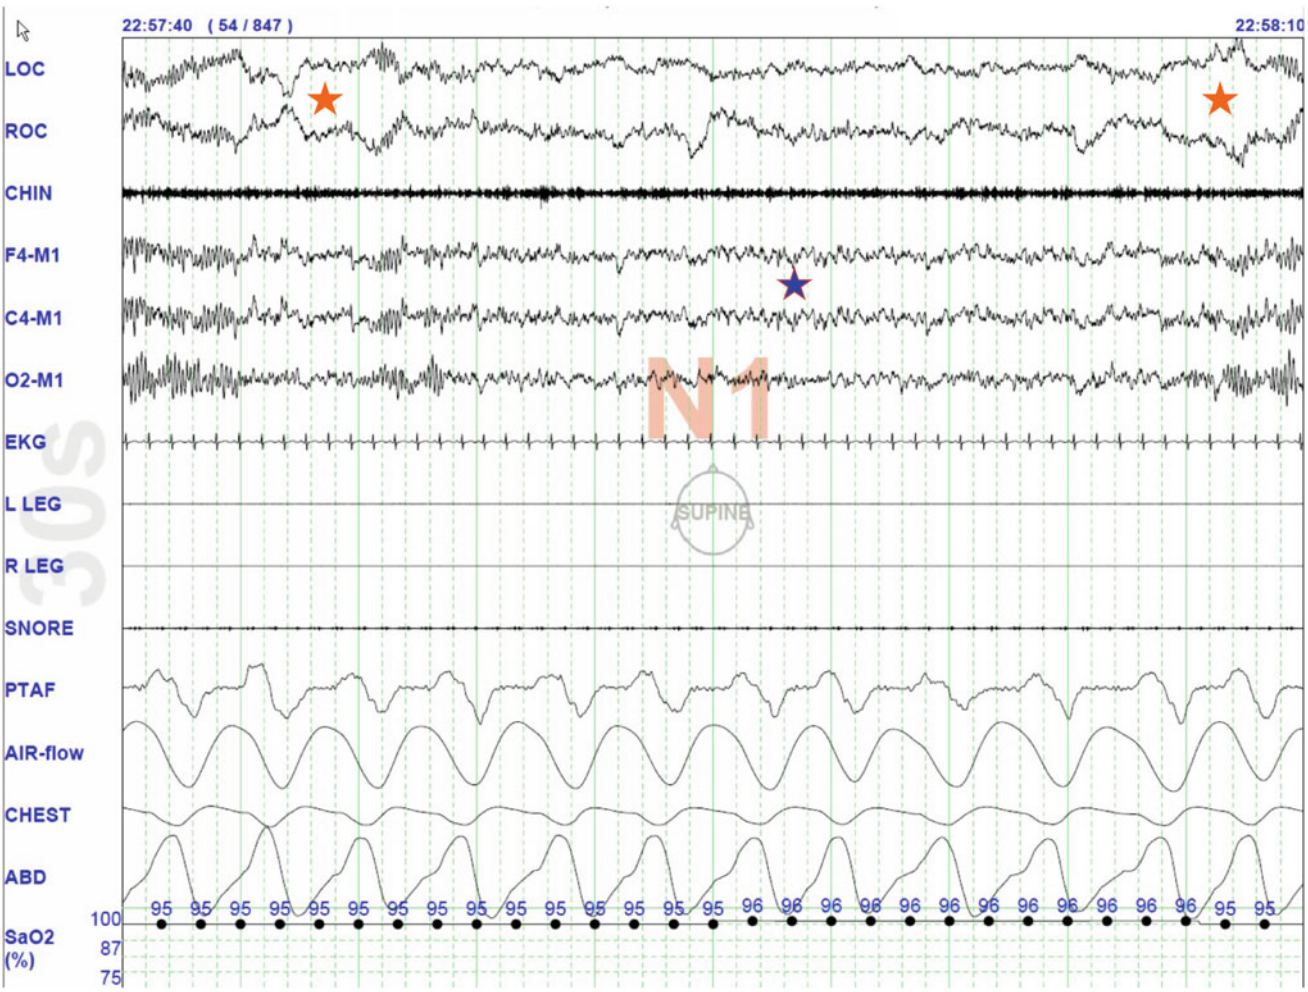

Fig. 24.8 Stage N1 sleep is characterized by the presence of low-voltage, mixed-frequency theta activity demarcated by the *blue star*. Slow rolling eye movements are evident (*orange star*) and so is a more substantial reduction in chin EMG tone (CHIN). Copyrighted to Alon Y. Avidan, MD, MPH

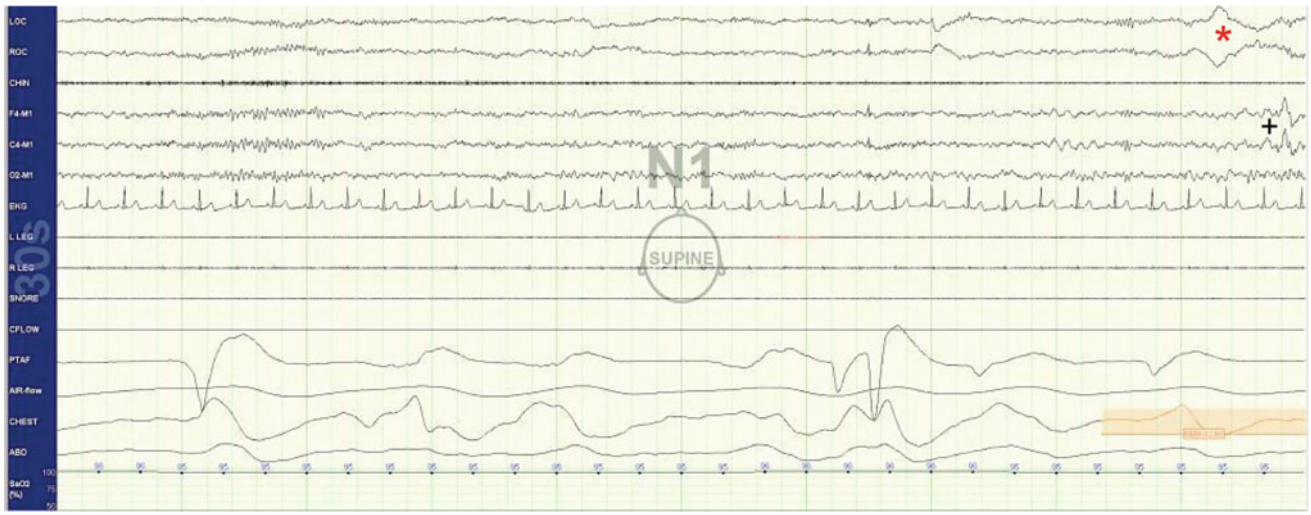

Fig. 24.9 This 30-s epoch is scored as stage N1 sleep as >50 % of the epoch is low-amplitude, mixed-frequency theta activity with some slow eye movements (*asterisk*) and a vertex sharp wave (*plus*) characteristic of stage N1 sleep

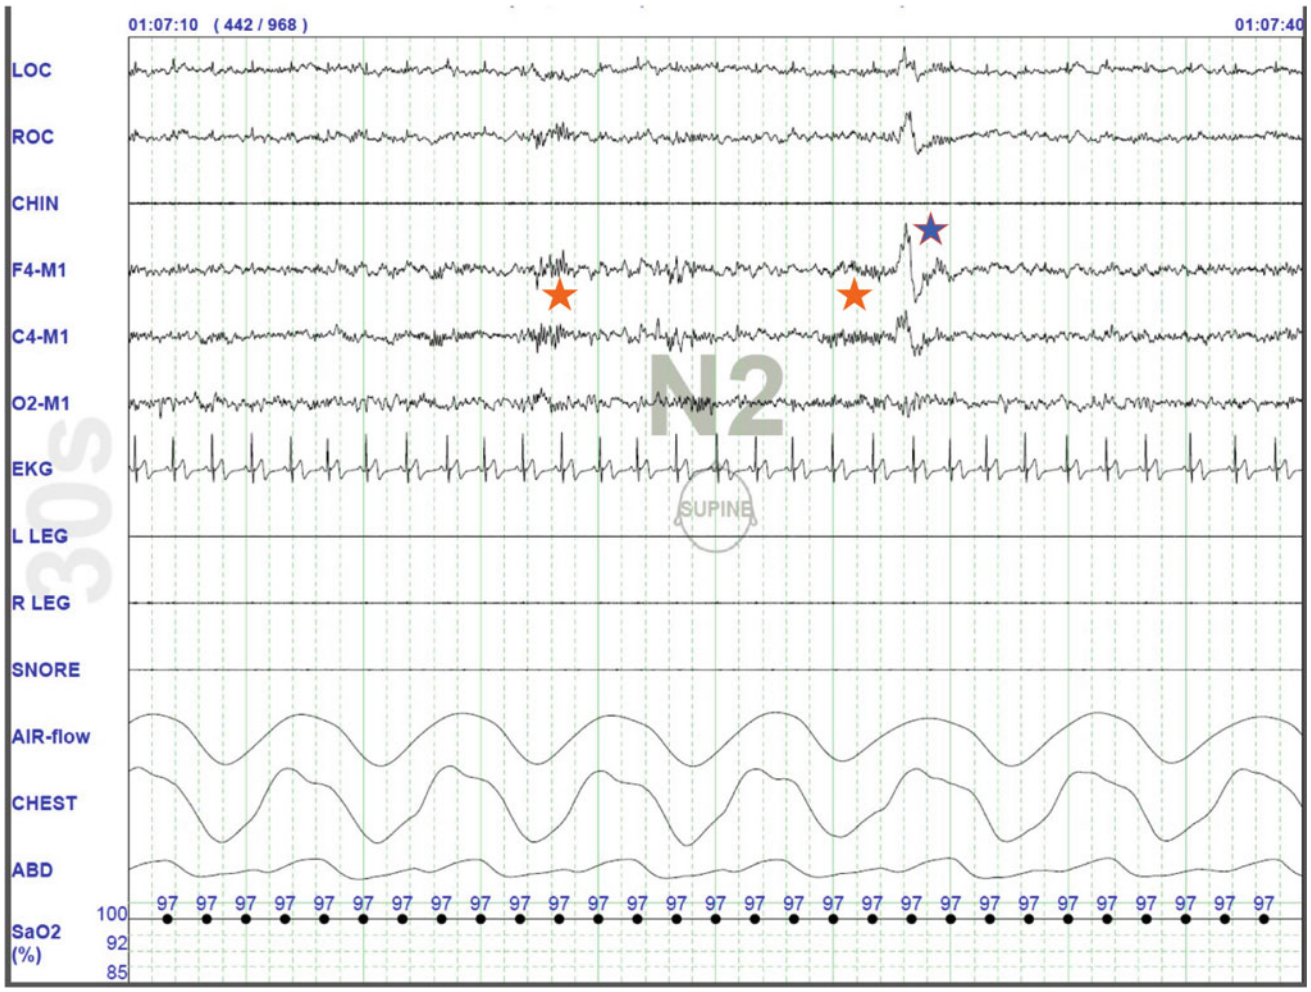

Fig. 24.10 This is a 30-s epoch designed to show the reader the classic characteristics of stage N2 sleep: sleep spindles (*red stars*) along with K complexes (*blue star*). K complexes are characteristic biphasic sharply negative followed by a slower positive deflection. K complexes have a duration criterion and must persist for at least 0.5 s. There is no minimum amplitude criterion for K complexes. Copyrighted to Alon Y. Avidan, MD, MPH

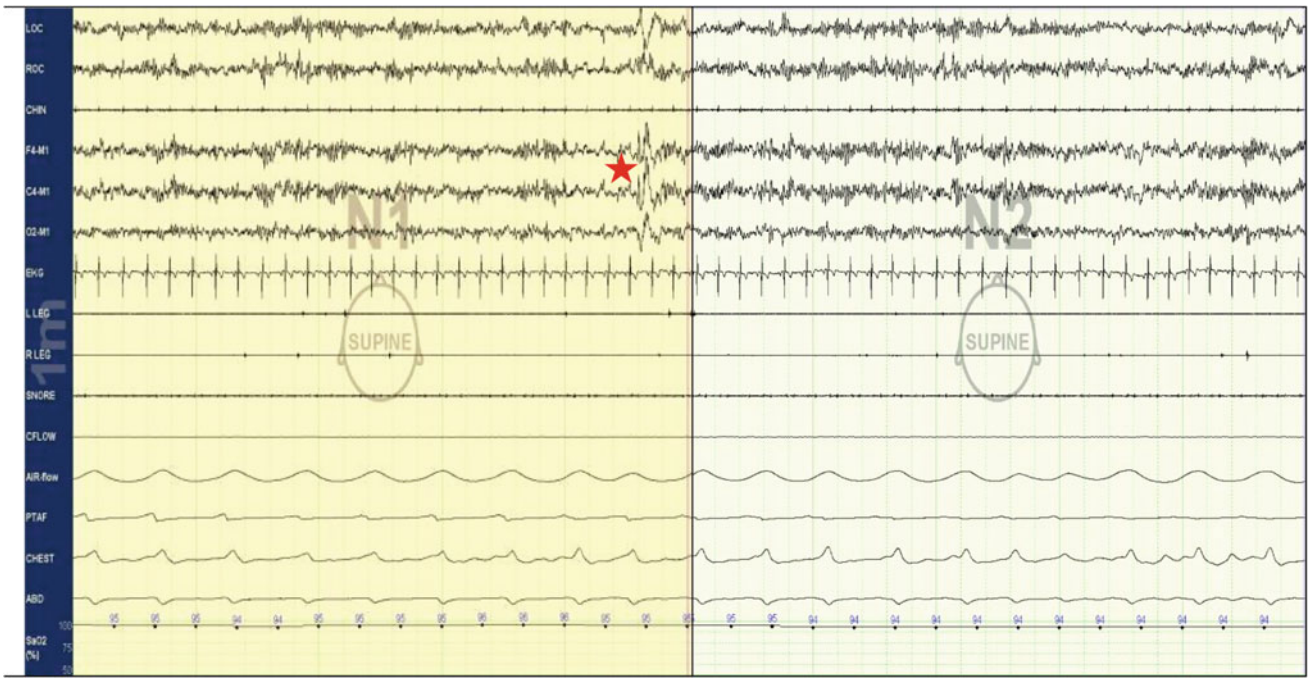

Fig. 24.11 Two consecutive 30 s PSG epochs demonstrating progression from stage N1 to stage N2. The first epoch is scored as stage N1 even with the presence of a K complex (*purple star*) because it occurs during the second half of the epoch. The following epoch is scored as stage N2

Stage N2 sleep is associated with a relative diminution of physiological bodily functions. Blood pressure, brain metabolism, gastrointestinal secretions, and cardiac activity are attenuated at this stage. The patient descends deeper into sleep, becoming more and more detached from the outside world and progressively more difficult to arouse.

Stage N3 Sleep

Stage N3 sleep may also be termed *deep sleep*, *slow-wave sleep (SWS),* or *delta sleep*. The updated AASM stage N3 is comprised of R & K stages 3 and 4 together and does not make a distinction between them as such distinction probably does not appear to serve clear clinical significance. This stage of sleep is marked by high-amplitude slow waves (0.5–2 Hz) with minimum amplitude of 75 microvolts as measured over the frontal regions. Slow-wave activity must be present for greater than or equal to 20 % of the epoch to be scored stage N3 sleep (Fig. 24.16). Both K complexes and sleep spindles may be seen in stage N3 sleep (Fig. 24.17). Pathological wave forms (epileptiform activity, slow waves in encephalopathy) are not counted as slow-wave activity of sleep, and sweat artifact (Fig. 24.18) must not be confused with stage N3. The sweat artifact is identified by high-amplitude slow frequency and may be sometimes confused and erroneously labeled as slow-wave sleep (stage N3). The most common electrodes affected by sweating are the EOG and anterior EEG electrodes [5]. The frequencies seen in sweat artifact are significantly slower, distinguishing them from stage N3 which is a distinguishing factor. Sweat artifact is also known as sway artifact or slow-wave artifact, the latter being a misnomer.

No specific criteria for EOG and EMG exist for stage N3 sleep, but in general, muscle tone is further decreased and there is no eye movement activity. This stage of sleep has the highest threshold for arousal and is associated with many parasomnias such as sleep terrors, sleepwalking, and confusional arousals. If the patient wakes up from stage N3 sleep, they may appear confused or disoriented. The patient may experience *sleep inertia* or *sleep drunkenness*, seeming unable to function normally for several minutes.

Stage REM Sleep

Stage R or rapid eye movement sleep may also be termed *paradoxical sleep* or *active sleep* (Fig. 24.19). REM sleep typically occurs about 90–120 min after sleep onset in adults. REM sleep typically occupies 20–25 % of overnight adult sleep. Stage R is characterized by relatively low-amplitude, mixed-frequency EEG theta waves, intermixed with some alpha waves, usually 1–2 Hz slower than wake. In addition, in order to score stage R, rapid eye movements and low chin EMG tone must be present. Sawtooth waves are frequently seen either during REM sleep or several seconds preceding scorable REM

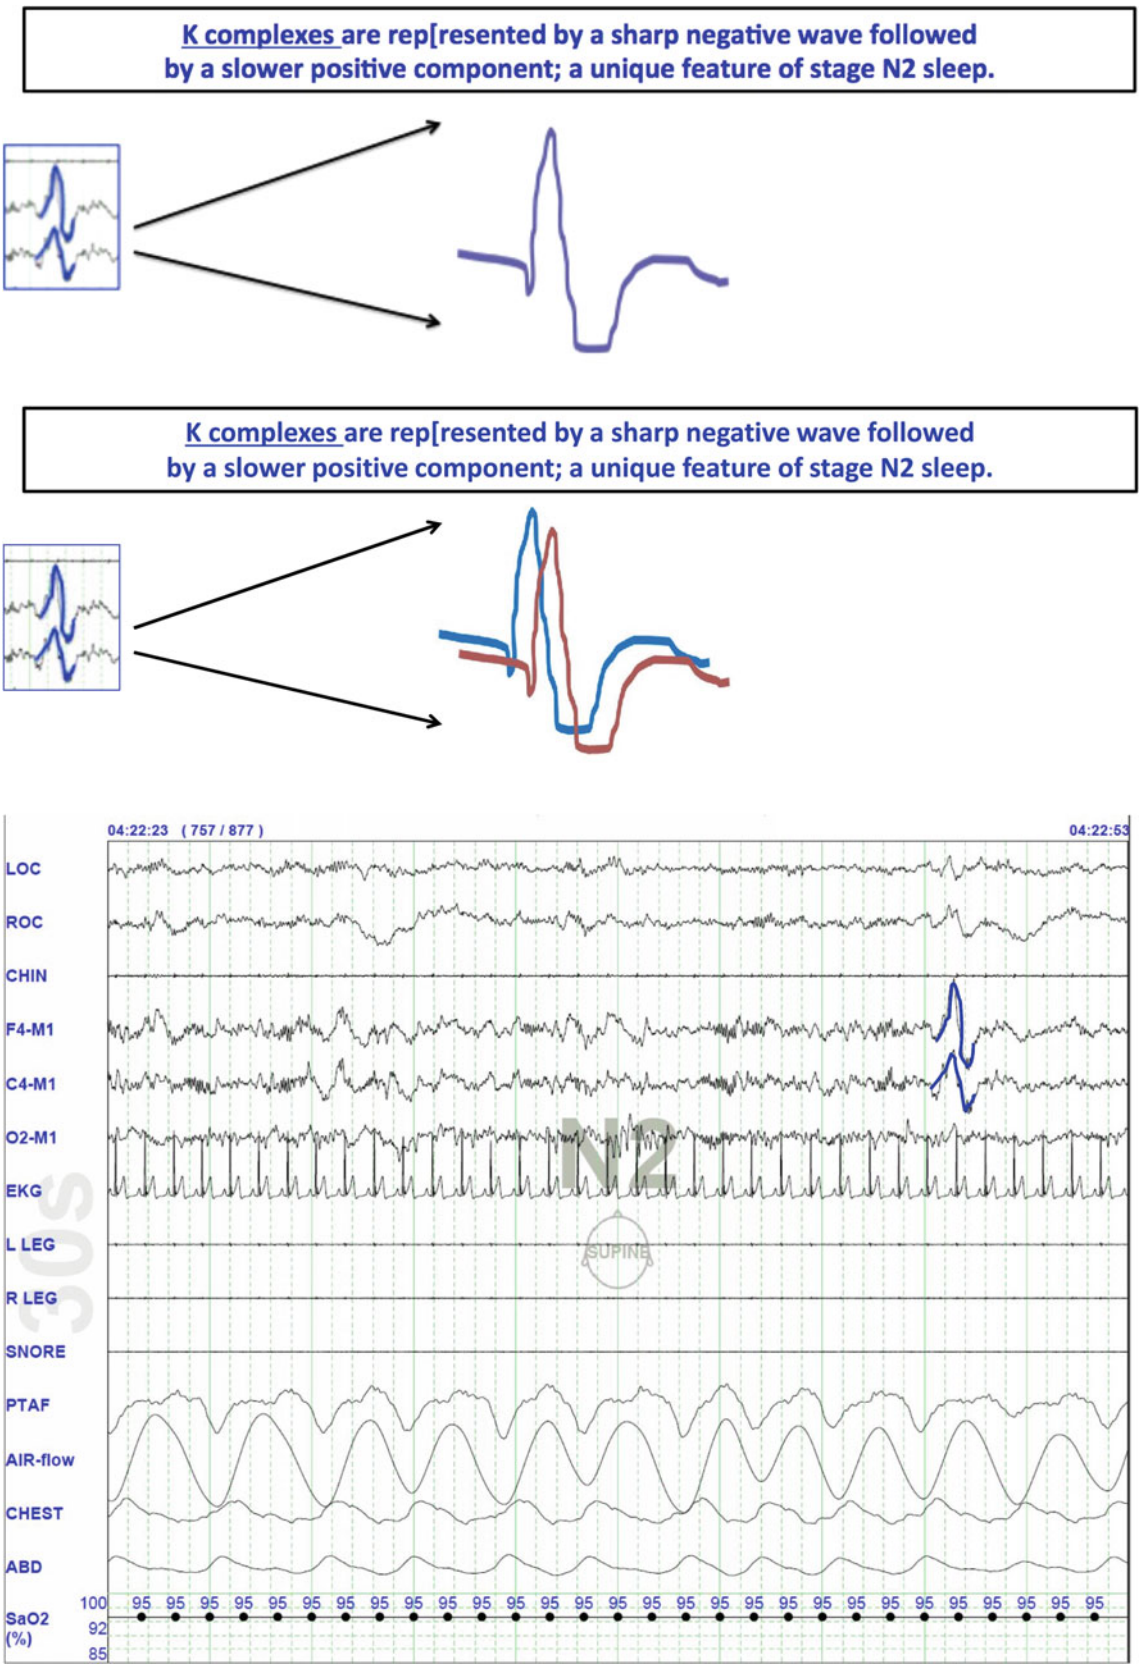

Fig. 24.12 K complexes are retraced in blue on this 30-s epoch with a negative (upward deflection) sharp waves followed by a slower positive (downward deflection) component with a total duration of greater than 500 ms. K complexes lack specific amplitude criteria. Copyrighted to Alon Y. Avidan, MD, MPH

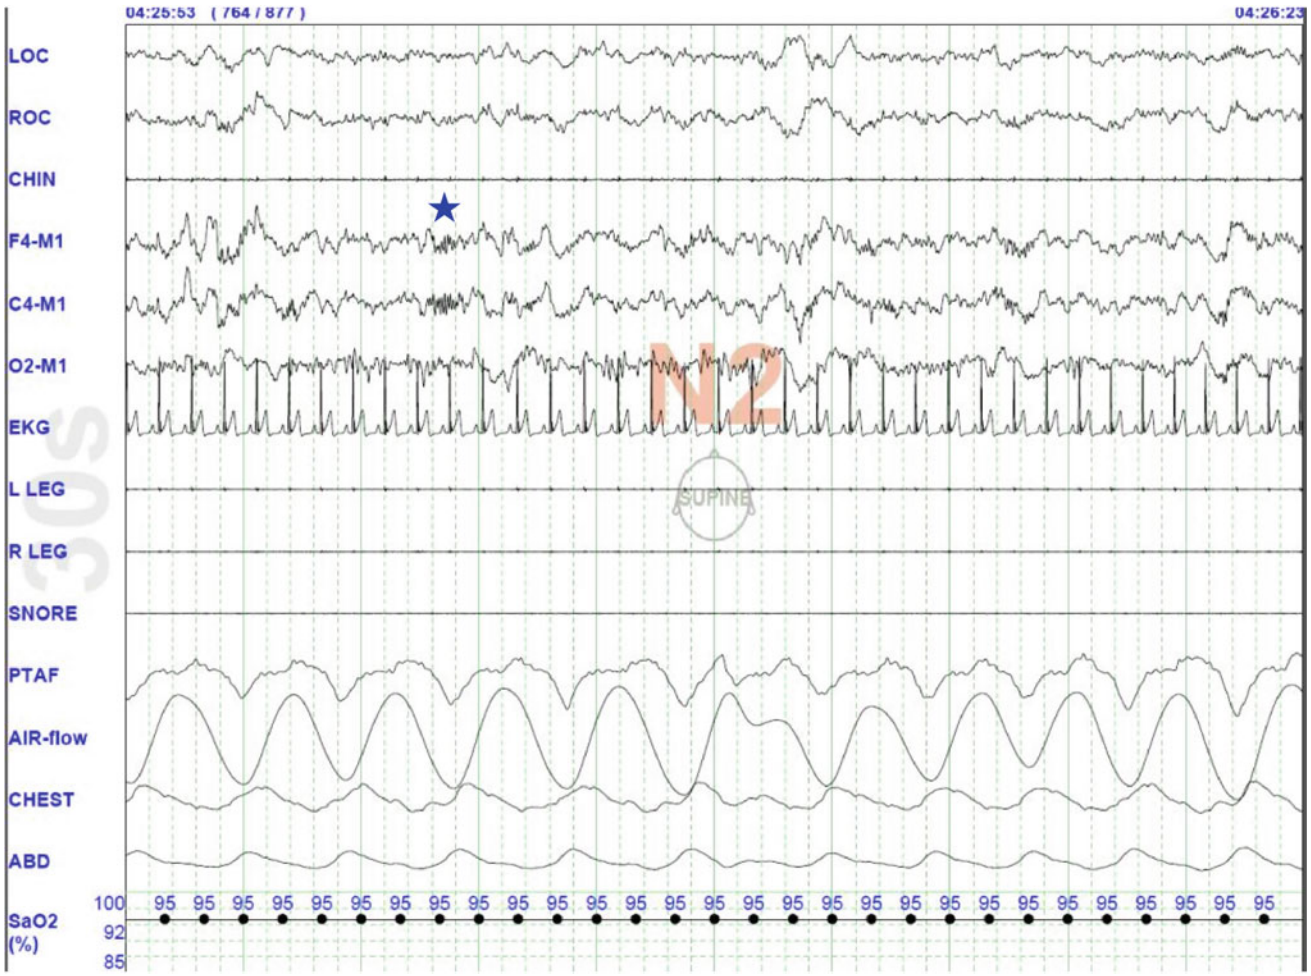

Fig. 24.13 This 30-s PSG epoch demonstrates a sleep spindle, as demarcated by the *blue star*, seen in stage N2 characterized by 12–14 Hz sinusoidal EEG activity in the central vertex region and must persist for at least 0.5 s. Copyrighted to Alon Y. Avidan, MD, MPH

sleep in which time they declare imminent entry into stage R. These are 2–6-Hz, sharply contoured triangular EEG patterns that are jagged-like in morphology and evenly formed, seen maximal in the central leads (Fig. 24.20). Rapid eye movements are conjugate, irregular, and sharply peaked eye movements with an initial deflection usually lasting <500 ms (red star, Fig. 24.21). Chin EMG tone should be at the lowest level of any sleep stage during stage R sleep (green arrows, Fig. 24.21). No specific amplitude criteria currently exist for this determination. Short, irregular bursts of EMG activity (less than 0.25 s), called transient muscle activity, may be seen in the chin, limb, EEG, or EOG leads usually in association with rapid eye movements (Fig. 24.22). Stage R should be continued to be scored for subsequent epochs even without rapid eye movements assuming the EEG shows low-amplitude, mixed-frequency activity without K complexes or sleep spindles, and the chin EMG tone remains low (Fig. 24.23).

REM sleep is sometimes divided into phasic (P) and tonic (T) components. P-REM sleep is characterized by phasic twitching in the EMG channel occurring concurrently with bursts of rapid eye movements. The phasic EMG twitchings in this stage are very short muscle twitches that may occur in the middle ear muscles, genioglossal muscle, and facial muscles and are associated with increased penile & clitoral tumescence. T-REM sleep generally consists of low-voltage activated EEG and is characterized by decreased or absent EMG activity, without obvious EOG activity. Unlike the progressive relaxation noted during the NREM sleep stages N1, N2, and N3, physiological activity during REM sleep is significantly higher. Blood pressure and pulse rate may increase dramatically or may show intermittent fluctuations. Breathing becomes irregular and brain oxygen consumption increases. Men exhibit penile erections, while women experience clitoral engorgement. The body seems to have abandoned its effort to regulate its temperature during the REM phase and resembles a state of poikilothermy, drifting gradually toward the temperature of the environment.

If patients are awakened from stage R sleep, they may often recall dreaming. Pathologically, short REM sleep latency may point to a state of acute or cumulative sleep deprivation, may be

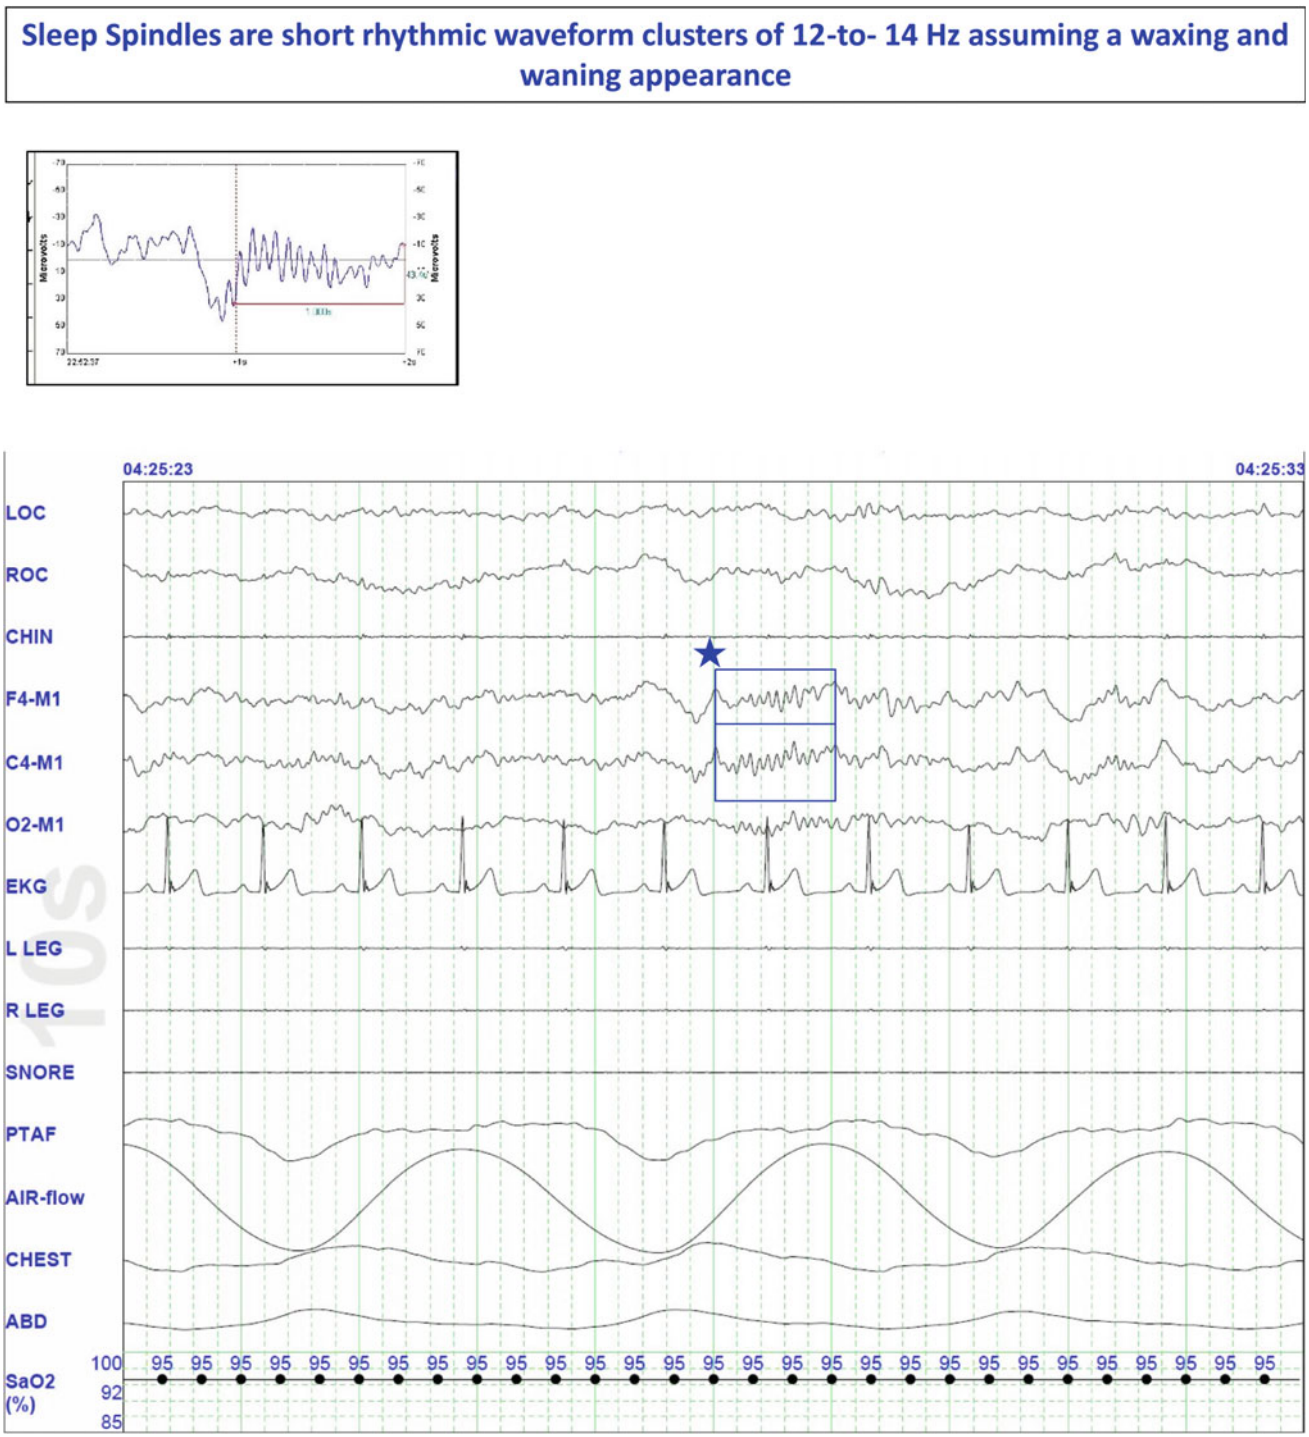

Fig. 24.14 This 10 s PSG epoch taken from the prior epoch demonstrates the sleep spindles within the *blue box* characterized by 12 Hz sinusoidal EEG activity in the central vertex region and must persist for at least 0.5 s. Copyrighted to Alon Y. Avidan, MD, MPH

caused by abrupt discontinuation of REM sleep–suppressing agents (such as antidepressants), narcolepsy-cataplexy syndrome, and may also suggest a major affective disorder. A variety of sleep disorders are strongly associated with REM sleep including a variety of parasomnias [REM sleep behavior disorder (RBD) and REM nightmares] (Fig. 24.24) and obstructive sleep apnea, which may be more pronounced during this sleep period (Fig. 24.25).

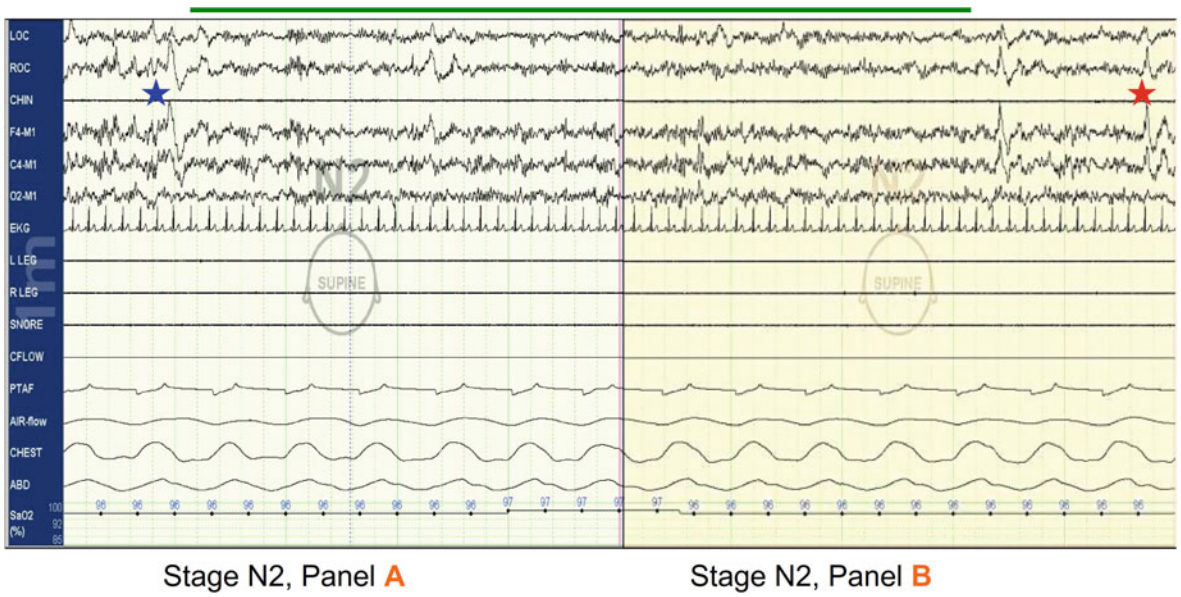

Fig. 24.15 These are two consecutive 30-s PSG fragments. The first epoch (*Panel A*) is scored stage N2 due to the K complex noted (*blue star*) during the first half of the epoch. The second epoch (*Panel B*) is also scored stage N2 sleep even though K complexes are only noted during the second half of the epoch (*red star*) as once an epoch meets criteria for N2 sleep, epochs can be continuously scored as stage N2 (even in the absence of K complexes or sleep spindles) assuming that there is not an arousal pattern and the EEG continues to demonstrate low-amplitude, mixed-frequency activity (the area under the *green bar*)

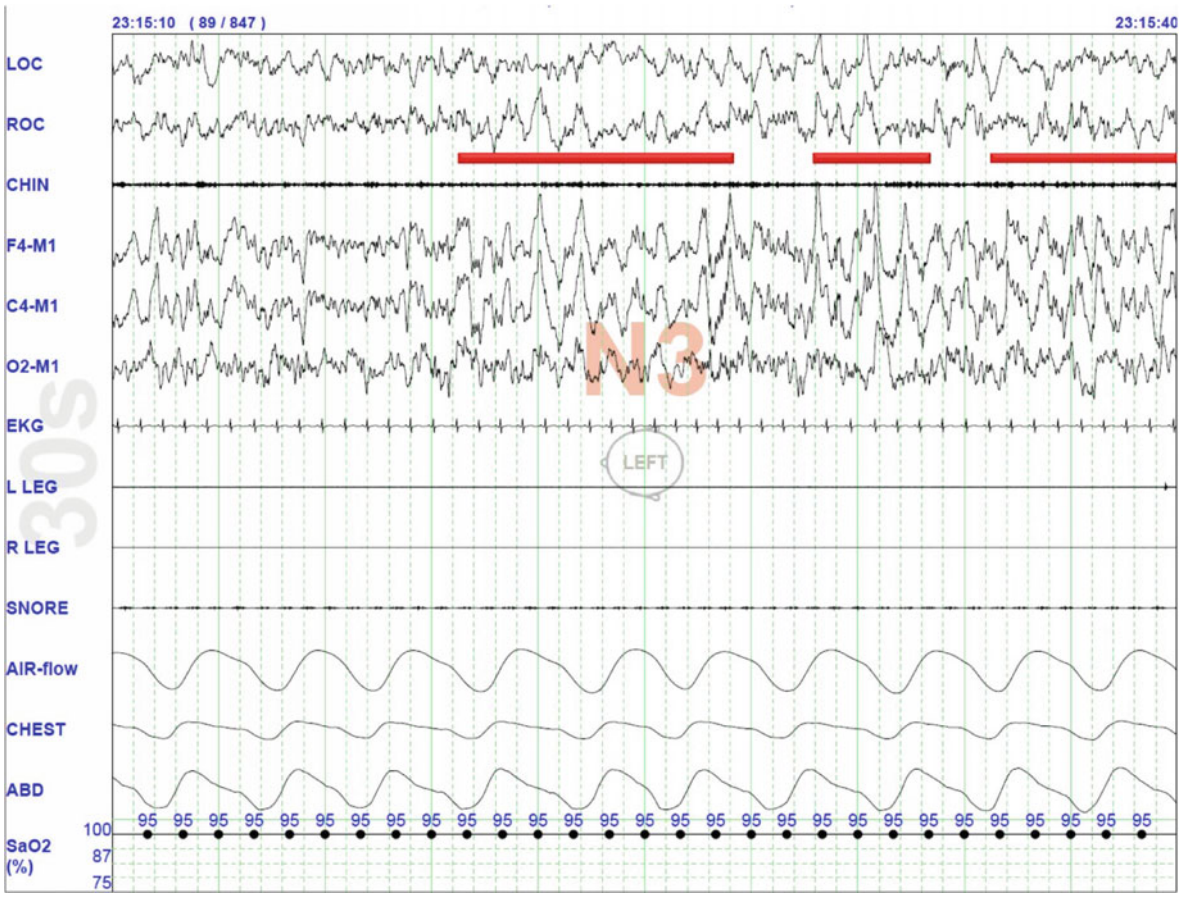

Fig. 24.16 This 30 s PSG epoch is scored as stage N3 sleep due to over 20 % of the epoch consisting of delta waves (0.5–2 Hz, depicted by the *red bars*) with minimum amplitude of 75 μV as measured over the frontal regions. Chin EMG tone is typically low, and there are no slow or rapid eye movements noted during this stage of sleep. Copyrighted to Alon Y. Avidan, MD, MPH

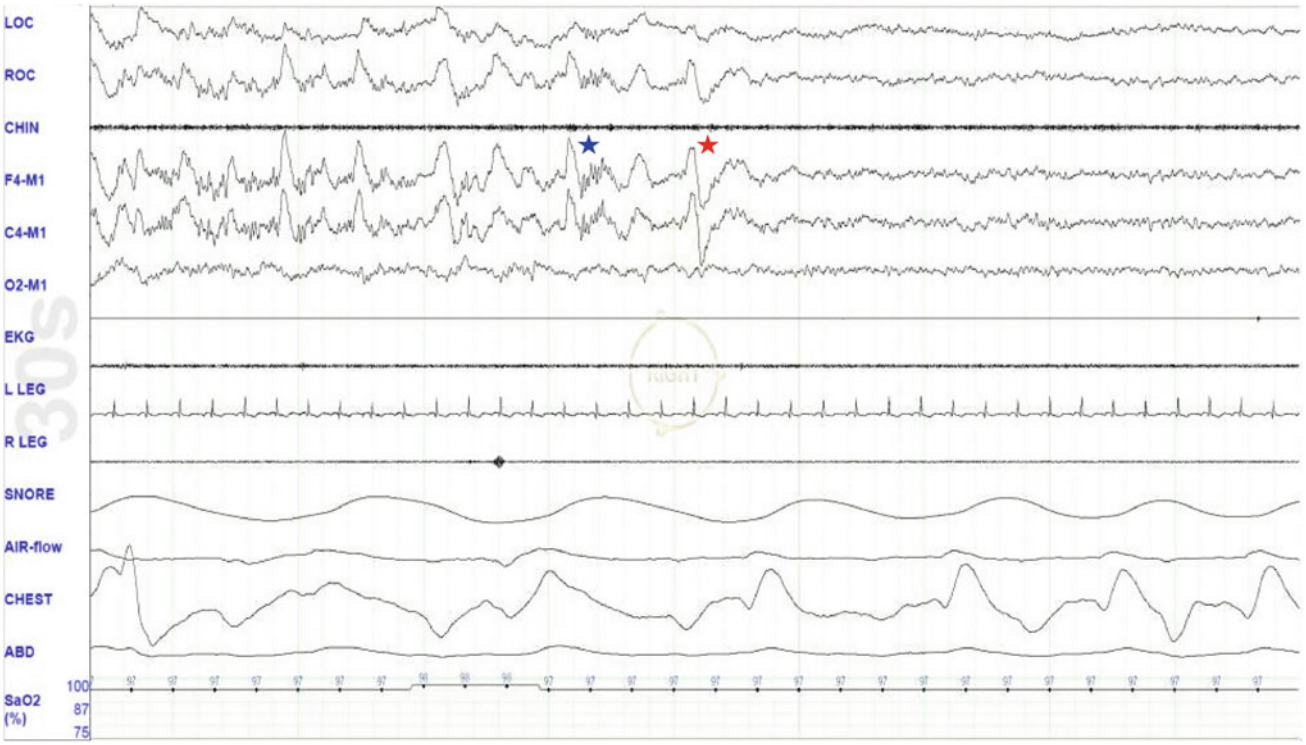

Fig. 24.17 This 30-s epoch is scored as stage N3 sleep due to over 20 % of the epoch containing delta slowing. Sleep spindles (*blue star*) and K complexes (*red star*) may be noted during stage N3 sleep. Copyrighted to Alon Y. Avidan, MD, MPH

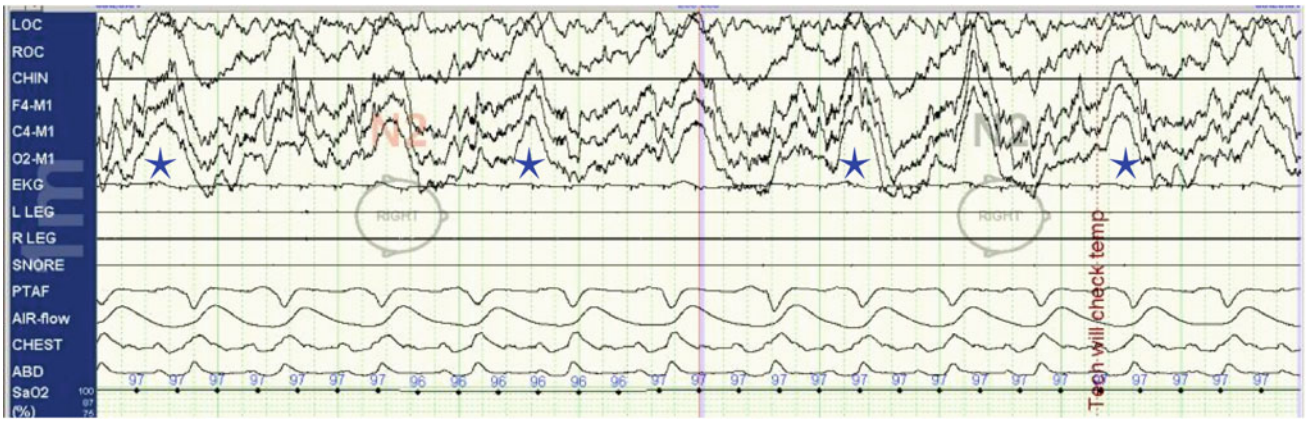

Fig. 24.18 This 60-s PSG epoch is correctly scored as stage N2 although there is evidence of high-amplitude slow-wave activity—sweat artifact—which may be confused as slow-wave sleep. Copyrighted to Alon Y. Avidan, MD, MPH

End Scoring Stage R Sleep

Stage R scoring should continue until there is a clear change to another sleep stage. Stage R ends if an epoch meets criteria for stage W or N3 sleep. In addition, a sustained increase in chin EMG tone with an absence of spindles or K complexes indicates the end of stage R and the beginning of stage N1 if the epoch meets criteria for stage N1 (Fig. 24.26). An arousal or major body movement followed by slow eye movements also indicates the termination of stage R and the beginning of N1. If the chin EMG tone returns to a low level and the epoch demonstrates an absence of slow eye movements, this would characterize the continuation of stage R (Fig. 24.27). If a K complex or sleep spindle appears in the first half of the epoch without any subsequent rapid eye movements, the epoch will be scored as stage N2 even if chin EMG tone remains low. If a sleep spindle or K complex appears in the second half of the

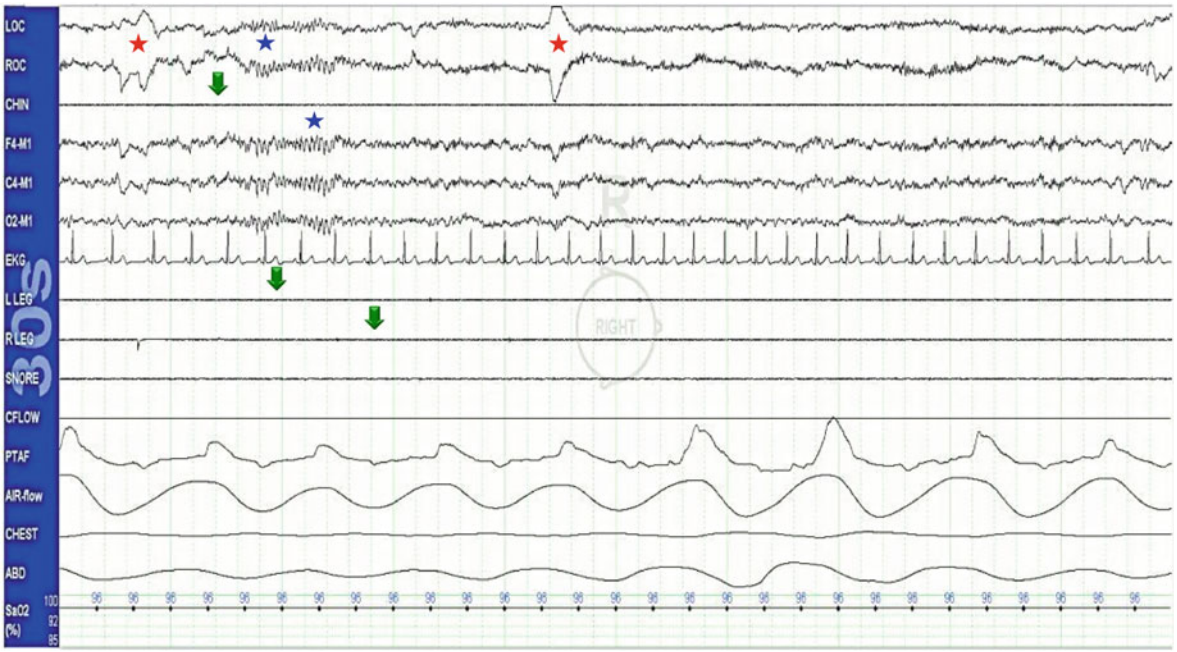

Fig. 24.19 This 30-s epoch demonstrates sawtooth waves (*blue stars*), rapid eye movements (*red stars*), and low chin EMG tone of stage R sleep (*green arrows*). Copyrighted to Alon Y. Avidan, MD, MPH

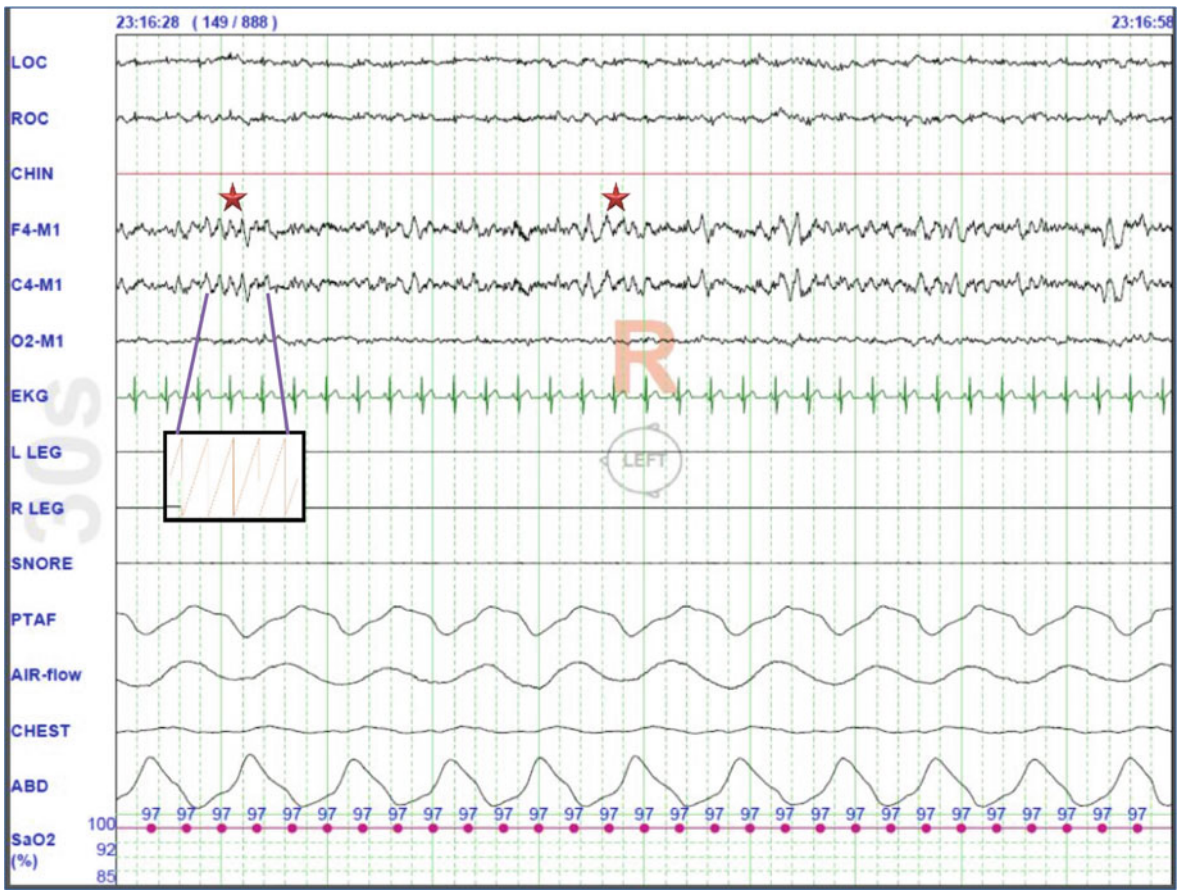

Fig. 24.20 This 30-s epoch demonstrates sawtooth waves (*blue stars*), depicting their characteristic frequency of 2–6 Hz, and sharply contoured triangular EEG jagged-like morphology (*box insert tracings*). Copyrighted to Alon Y. Avidan, MD, MPH

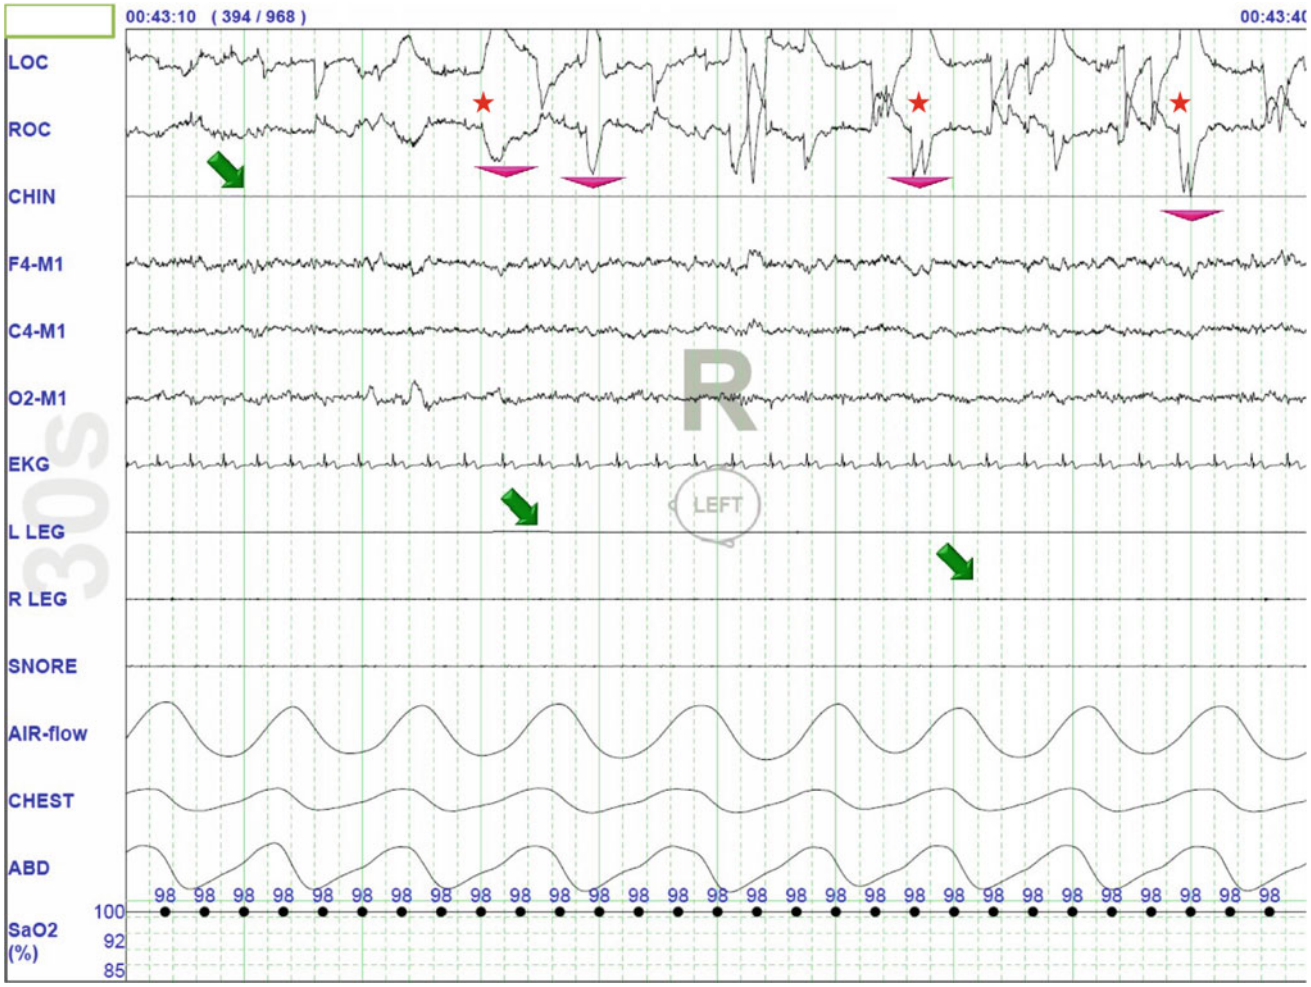

Fig. 24.21 This 30-s epoch demonstrates rapid eye movements (depicted by the *red stars* and highlighted *pink arrow heads*). There is also evidence of low chin EMG tone (*green arrows*). Copyrighted to Alon Y. Avidan, MD, MPH

epoch, then the epoch would still be scored R and the next epoch would be scored N2.

Transitions Between Stage N2 and Stage R

Scoring epochs between stage N2 and stage R can be challenging due to the occasional presence of K complexes and sleep spindles in epochs that otherwise look like stage R sleep. The first epoch after a decrease in chin EMG should be scored as stage R even if there are no rapid eye movements (Fig. 24.28, but K complexes and sleep spindles must be absent. If the record shows sleep spindles or K complexes, in the absence of rapid eye movements, the epoch will be scored as N2 sleep, even following a drop in chin EMG. Furthermore, an epoch with a K complex or spindle will be scored as stage R if either is followed by a rapid eye movement, while chin EMG tone is still low (Fig. 24.29).

Major Body Movements

Major body movement is movement and muscle artifact obscuring the EEG for more than half an epoch making determination of sleep stage difficult. In the updated AASM manual, if an epoch contains a major body movement, it can be scored as stage W if an alpha rhythm is present for any part of the epoch. If no alpha rhythm is noted, but stage W precedes or follows the epoch with a major body movement, it can be scored as stage W. The epoch can be scored the same stage as the epoch that follows it if there is no alpha rhythm present and stage W does not precede or follow the epoch.

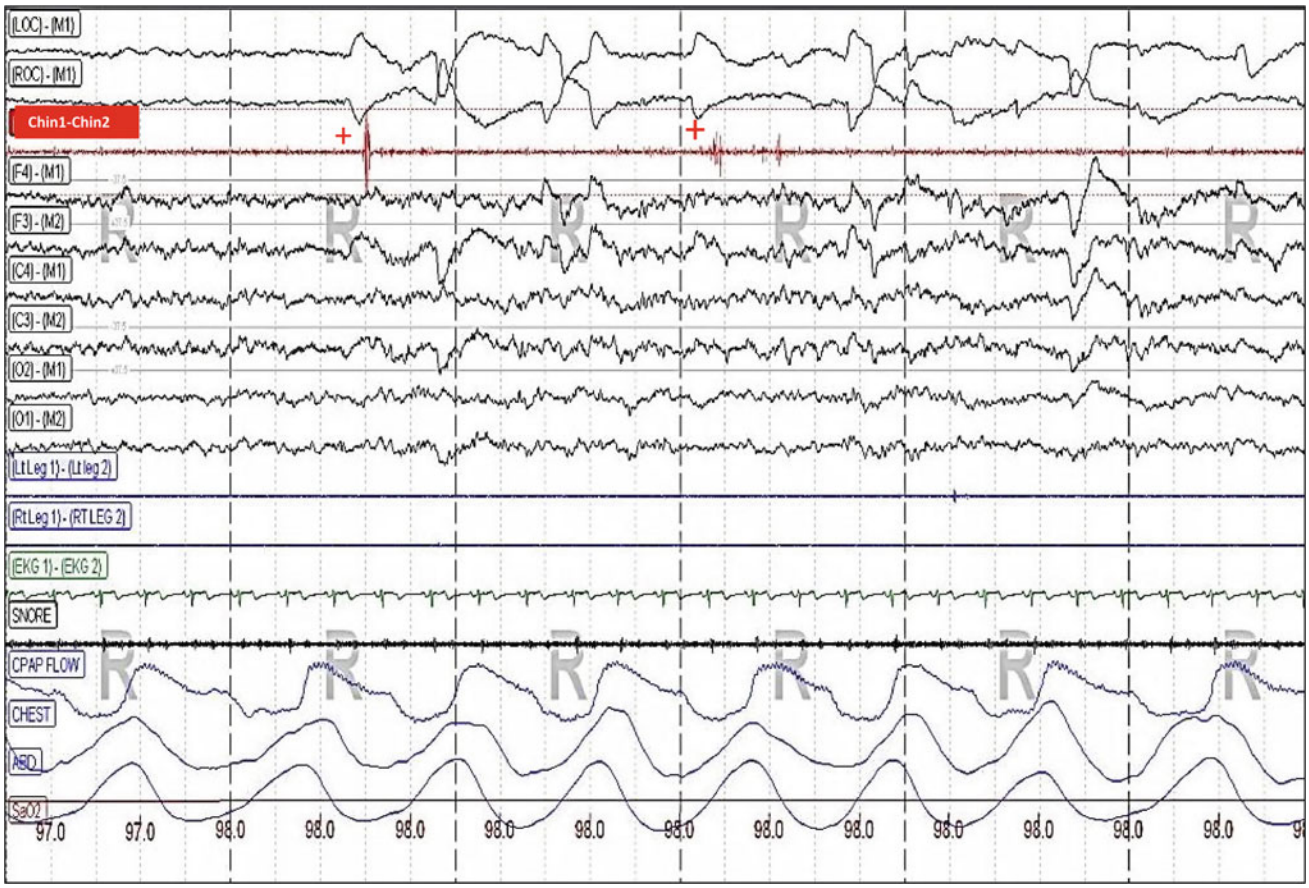

Fig. 24.22 This 30 s PSG epoch demonstrates transient muscle activity (*plus* in the chin EMG lead during REM sleep, short irregular bursts less than 0.25 s in duration, usually in association with rapid eye movements). Copyrighted to Raman K. Malhotra, MD

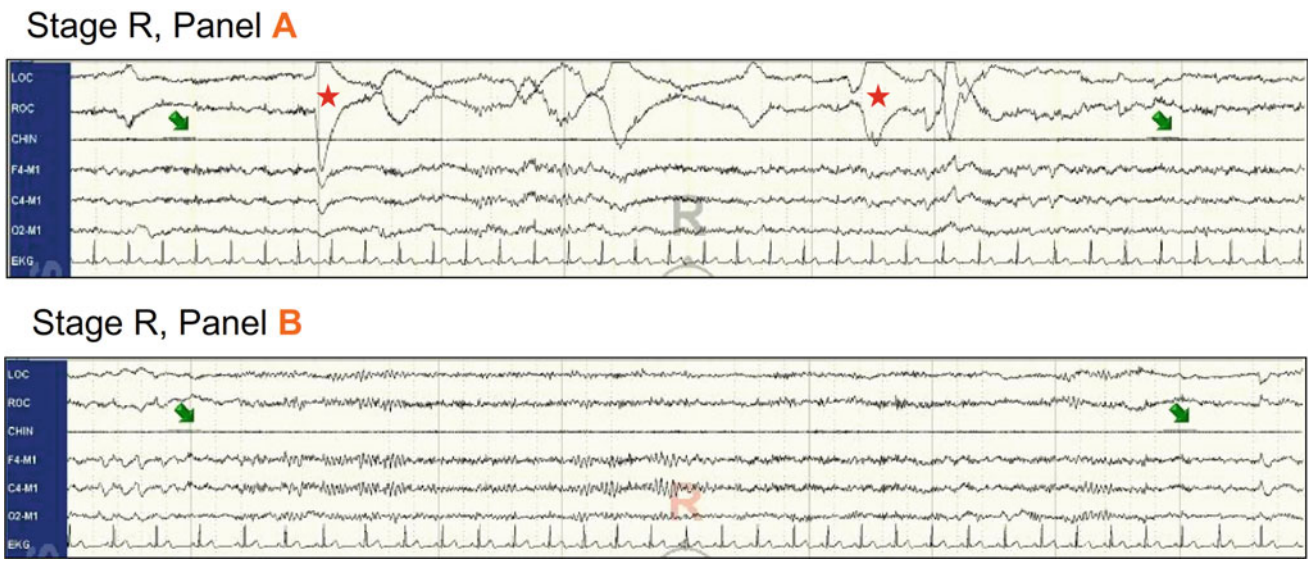

Fig. 24.23 Panel A: The first of two consecutive 30 s PSG epochs is scored as stage R due to low chin EMG tone (*green arrows*), low-amplitude, mixed-frequency EEG, and rapid eye movements (*red arrow*). Panel B: In the second epoch, Stage R should be continued to be even without a rapid eye movement since the EEG shows low-amplitude, mixed-frequency activity without K complexes or sleep spindles, and the chin EMG tone remains low (*green arrows*). Fig. 24.24 A 30-s epoch from the diagnostic polysomnogram of an 75-year-old man who was referred to the sleep disorders clinic for evaluation of recurrent loud snoring and nocturnal awakenings and violent nighttime awakenings. Illustrated in this figure is a typical spell that this patient was experiencing. He was noted to yell, jump from bed, and have complex body movements. The *box* demonstrates the normal REM-associated muscle atonia in the left anterior tibialis muscle. Shown by the two arrows in the figure are abnormal EMG augmentations in the chin (*green arrow*) and limb (*blue arrow*) leads. Copyrighted to Alon Y. Avidan, MD, MPH

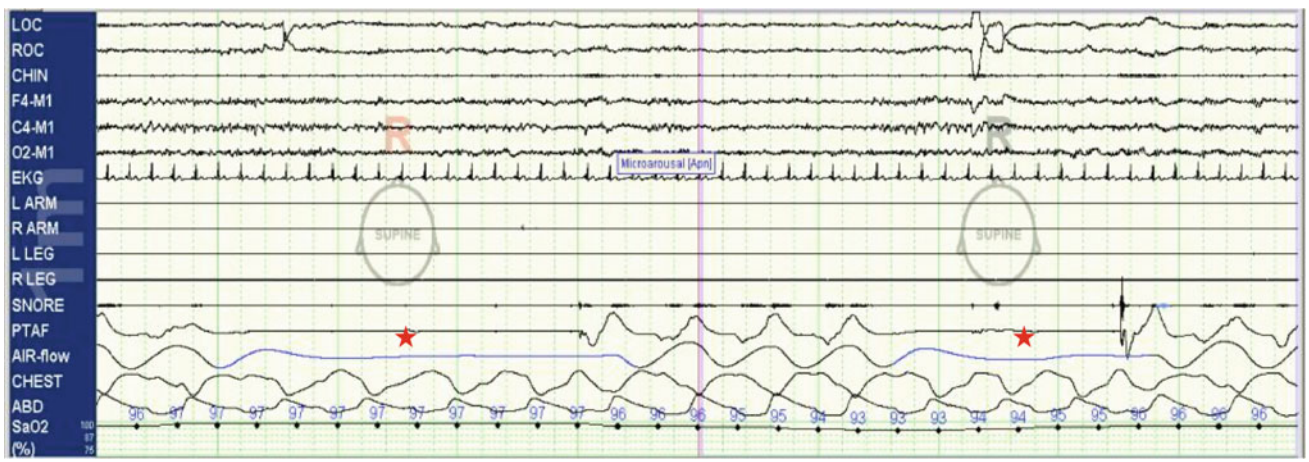

Fig. 24.25 A 60-s epoch from the diagnostic polysomnogram a patient with snoring and daytime sleepiness. Shown by the *red stars* are episodes of REM-related obstructive events, which the patient experienced exclusively during REM sleep. Copyrighted to Alon Y. Avidan, MD, MPH

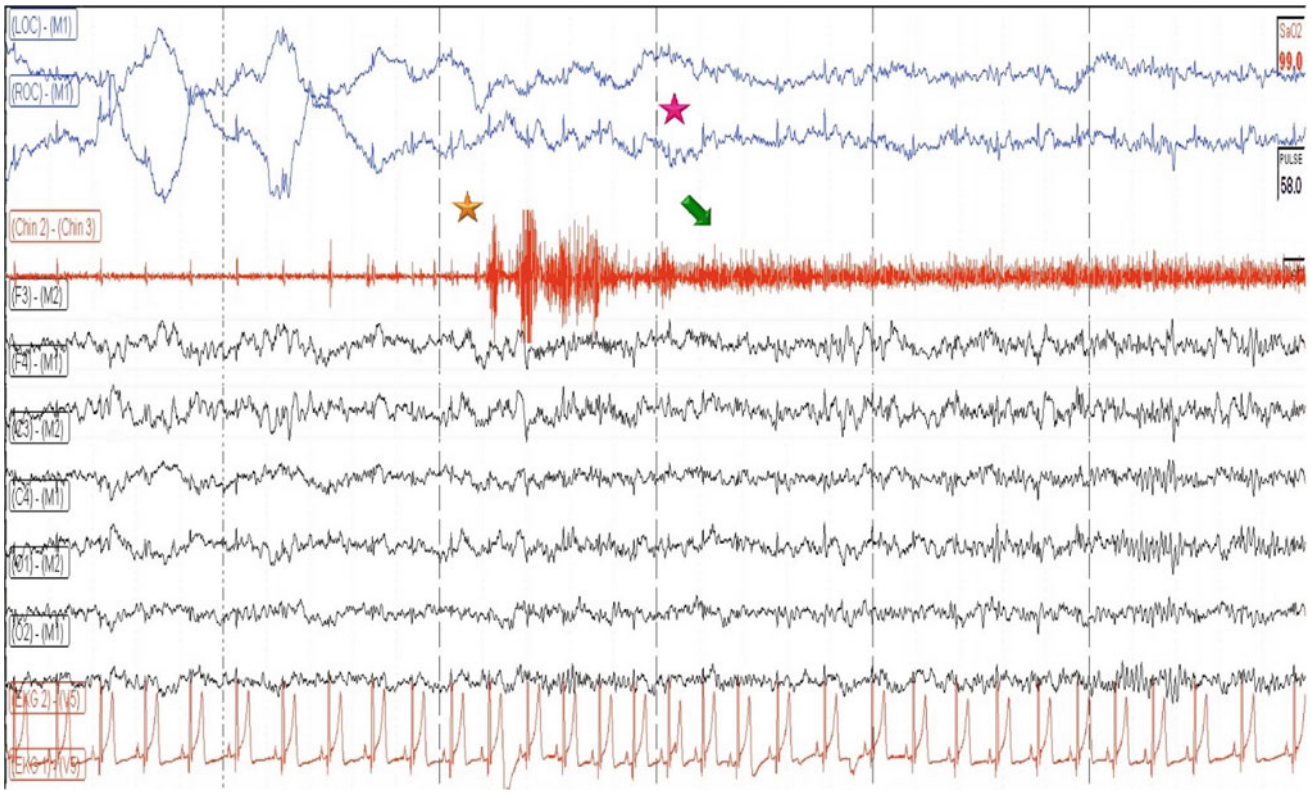

Fig. 24.26 This 30-s PSG epoch demonstrates the termination of stage R with an arousal (*gold star*), subsequent slow eye movement (*pink star*) and increased chin EMG (*green arrow*), with characteristics consistent with stage N1 sleep. This epoch should be scored stage N1 since the majority of the epoch demonstrates stage N1. Copyrighted to Raman K. Malhotra, MD

Arousals

Arousals can be scored during sleep stages if there is an abrupt change in the EEG frequency noted in the occipital or central derivations. This can be alpha, theta, or beta frequency (with the exclusion of spindle-frequency) that last at least 3 s with at least 10 s of stable sleep preceding the change (Fig. 24.30). During stage R, an arousal requires an increase in chin EMG lasting for at least 1 s. The use of other recording channels such as limb EMG, respiratory channels, and EKG may be used to help make the determination of an arousal, but EEG criteria must be met. Arousal can occur for a variety of reasons, some of which may be noted in the study (i.e., respiratory events and limb movements). Other times, the arousal may appear to be spontaneous or occurring due to an event not being monitored during the polysomnography (i.e., back pain and acid reflux).

Pediatric Scoring Rules

The AASM Manual for Scoring has separate scoring rules in children over 2 months of age post-term. Technical specifications for EEG, EOG, and EMG recordings are similar to adult rules with the exception of the distance between the chin EMG electrodes which often needs to be reduced from 2 cm to 1 cm and the distance from the eyes in EOG electrodes often need to be reduced from 1 cm to 0.5 cm in children and infants with small head size. Not all waveforms that are noted in adults are seen in infants even at two months old. Sleep spindles may be seen by age 4–6 weeks post-term and are present in all normal infants by age 2–3 months post-term [6]. At this age, the spindles are asynchronous between the hemispheres but become more synchronous over the first year of life. K complexes are usually present by age 4–6 months post-term. Delta slowing in order to score stage N3 sleep may first appear by 2 months of age

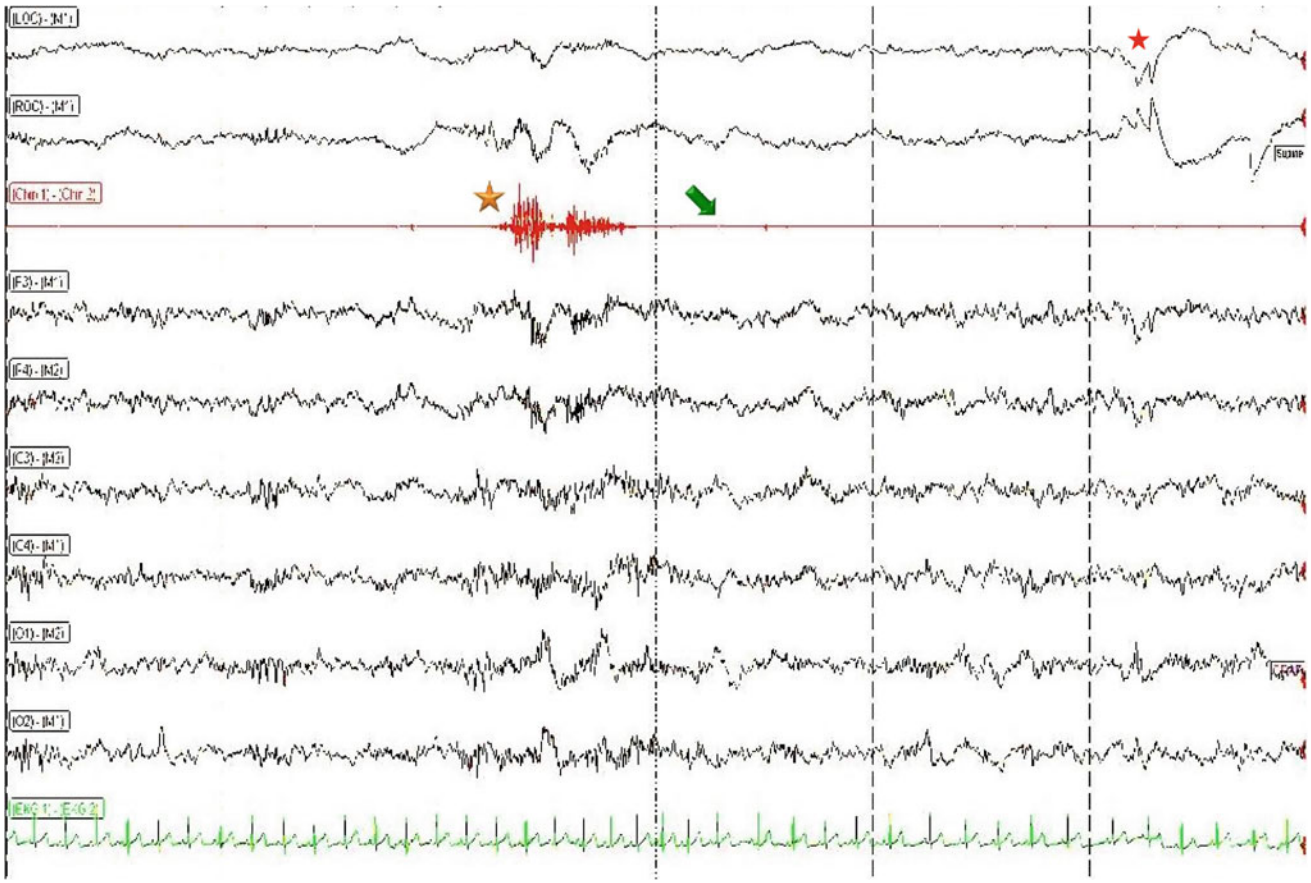

Fig. 24.27 This 30-s epoch is scored as stage R. There is arousal from stage R during the first half of the epoch (*gold star*), but the chin EMG tone returns to a low level (*green arrow*) and a rapid eye movement is noted (*red star*). Copyrighted to Raman K. Malhotra, MD

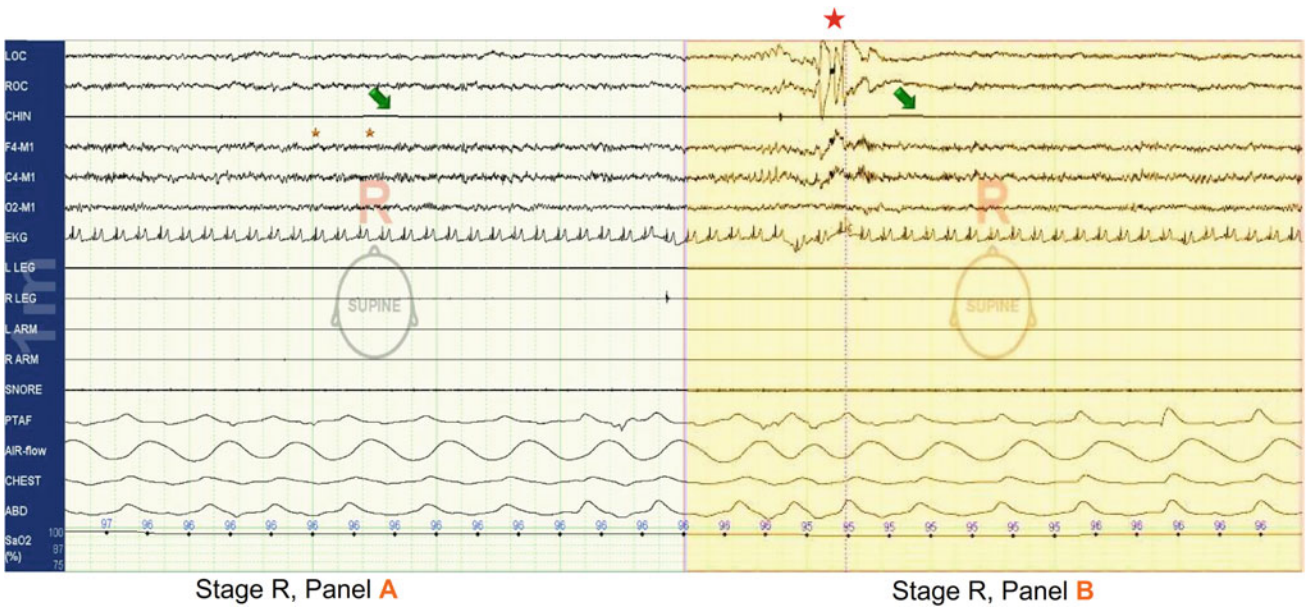

Fig. 24.28 These two consecutive 30-s epochs are both scored as stage R. Even though the rapid eye movements are only noted in the second epoch (*Panel B*), the first epoch (*Panel A*) can also be scored as Stage R because it has low-amplitude and mixed-frequency EEG (*gold stars*), no sleep spindles or K complexes, and low chin EMG tone (*green arrows*). Copyrighted to Alon Y. Avidan, MD, MPH

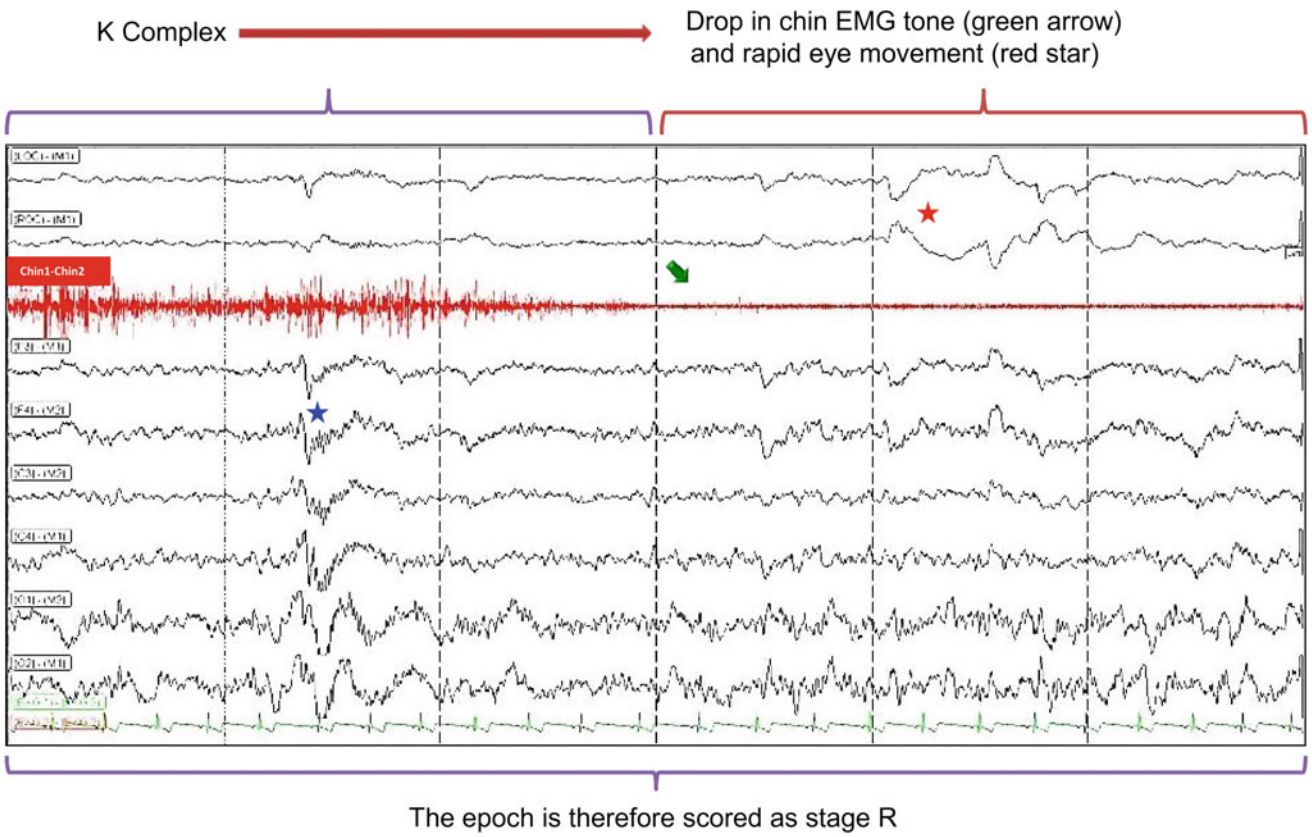

Fig. 24.29 This 30-s PSG epoch is scored stage R. Although there is a K complex (*blue star*) in the first half of the epoch, the entire epoch will be scored as stage R due to the drop in chin EMG tone (*green arrow*) and rapid eye movement noted in the second half of the epoch. Copyrighted to Raman K. Malhotra, MD

and is usually present by age 4–5 months post-term. When EEG markers are not present or clear to help score stages of sleep, it can be helpful to use other information, such as eye movements, chin EMG tone, and respirations to determine NREM versus REM sleep. If sleep spindles, K complexes, or delta slowing are not apparent in NREM sleep due to the age of the child being studied, sleep can be scored as stage N.

In children, the term "posterior dominant rhythm" is used instead of alpha rhythm. The posterior dominant rhythm (PDR) is the dominant reactive EEG rhythm over the occipital regions in relaxed wakefulness with eyes closed which is slower in infants and young children and attenuates with eye opening or attention. Frequency is 3.5–4.5 Hz when first seen in infants 3–4 months post-term, 5–6 Hz by 5–6 months, and 7.5–9.5 Hz by 3 years of age, and amplitude is usually >50 μV.

Stage W is scored in children if over half of the epoch is age appropriate PDR over the occipital region. If no PDR is discernible, score stage W if eye blinks at a frequency of 0.5–2 Hz, reading eye movements, or irregular, conjugate rapid eye movements associated with normal or high chin muscle tone are present. The PDR in infants and children can contain intermixed slower EEG rhythms such as posterior slow waves of youth (PSW). PSW are superimposed or fused with the PDR and bilateral but asymmetric at a frequency of 2.5–4.5 Hz. They block with eye opening and disappear with drowsiness and sleep. PSW are uncommon in children <2 years of age, have a maximal incidence between ages 8 and 14 years, and are uncommon after age 21 years.

Stage N1 is scored if the PDR is attenuated or replaced by low-amplitude, mixed-frequency activity for more than 50 % of the epoch. If children do not generate a posterior dominant rhythm, stage N1 can commence if EEG frequency slows by greater than or equal to 1–2 Hz from those of stage W (Fig. 24.31). It can also be scored if any of the following are present: slow eye movements, vertex sharp waves, rhythmic anterior theta activity, or hypnagogic hypersynchrony. Hypnagogic hypersynchrony (HH) can occur in stage N1 or N2 sleep. It consists of paroxysmal bursts or runs of diffuse, high-amplitude, sinusoidal, 75–350 μV, 3–4.5 Hz waves which begin abruptly, are usually widely distributed but often maximal over the central, frontal, or frontocentral scalp regions (Fig. 24.32). HH is seen in

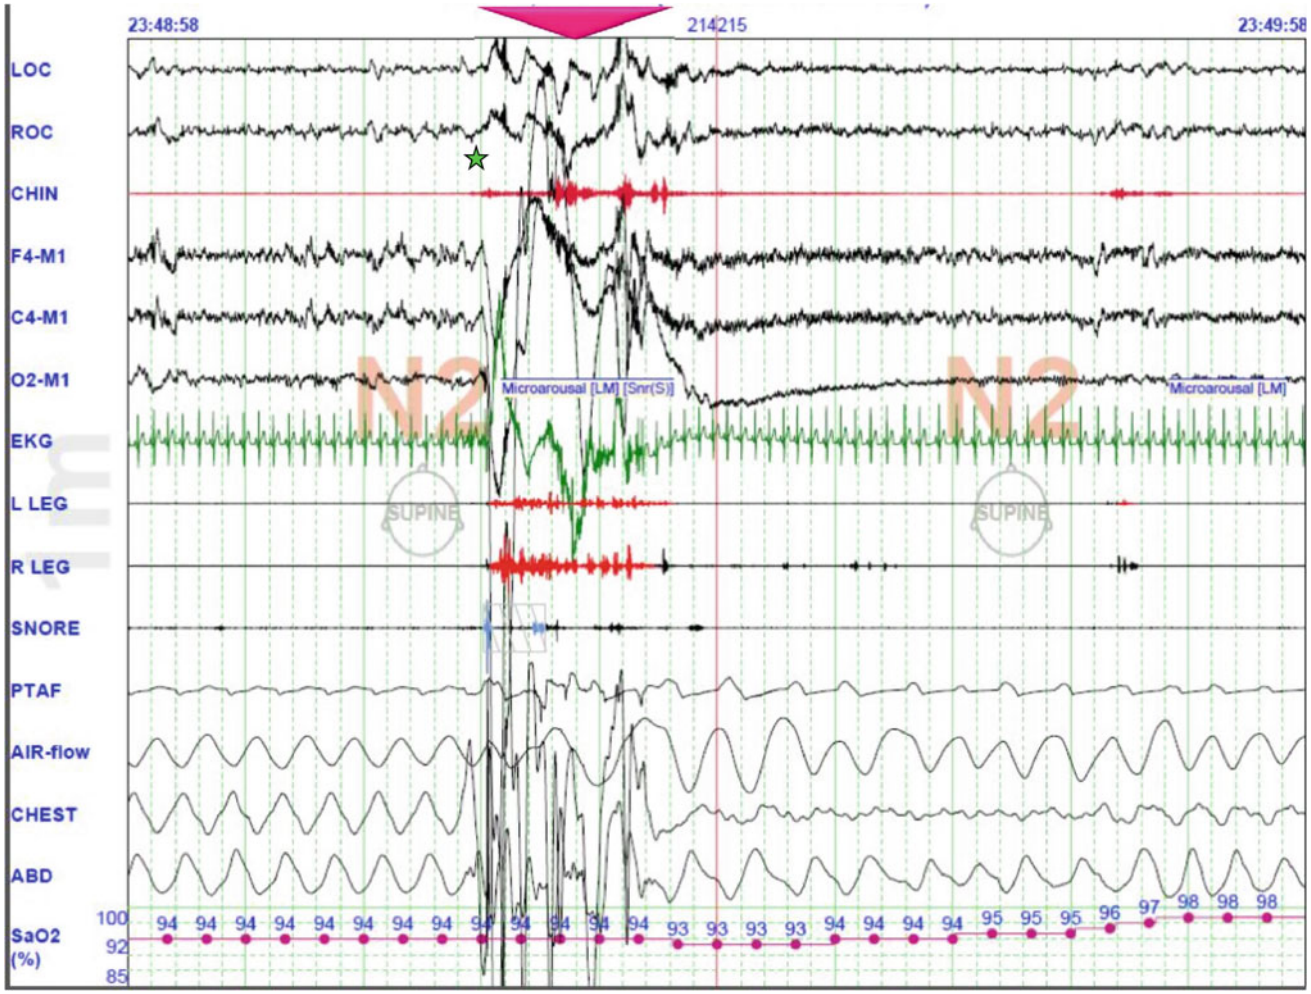

Fig. 24.30 This 60-s PSG epoch represents an arousal pattern. An arousal is scored during sleep stages N1, N2, N3, or R if there is an abrupt shift of EEG frequency including alpha, theta, and/or frequencies greater than 16 Hz (but not spindles) that lasts at least 3 s (*pink bar*), with at least 10 s of stable sleep preceding the change. Scoring of arousal during REM requires a concurrent increase in submental EMG tone. Copyrighted to Alon Y. Avidan, MD, MPH

approximately 30 % of infants at 3 months post-term, 95 % of all normal children ages 6–8 months, and is less prevalent after age 4–5 years; it is seen in only 10 % of healthy children by age 11 and is rarely seen after age 12 years.

Stages N2 and N3 in children are scored with the same rules that are used in adults. Stage R also uses the same rules as in adults. Of note, Stage R in infants and children resembles adults although the dominant frequencies increase with age: approximately 3 Hz activity at 7 weeks post-term, 4–5 Hz activity with bursts of sawtooth waves at 5 months, 4–6 Hz at 9 months, and prolonged runs or bursts of notched 5–7 Hz theta activity at 1–5 years of age. By 5–10 years of age, the low-amplitude, mixed-frequency activity in stage R is similar to that of adults.

Sleep Stage Changes Across the Night

Overall normal sleep stage pattern (sometimes called sleep macroarchitecture) across the night is fairly consistent. A healthy young adult will spend 7–8 h in bed and sleep 85–90 % of that time. It typically takes adult sleepers up to 20 min to fall asleep (possibly longer in a lab setting), and normal entry into sleep for an adult is through stage N1, which quickly evolves into N2. Stage N3 usually follows and persists for some time before giving way to an episode of stage R. Usually the duration of the first stage R episode is brief (5–15 min), and the sleeper then goes back into N2 and possibly N3 for the next hour and a half. Stage R re-occurs at this point and is usually longer in duration than the first

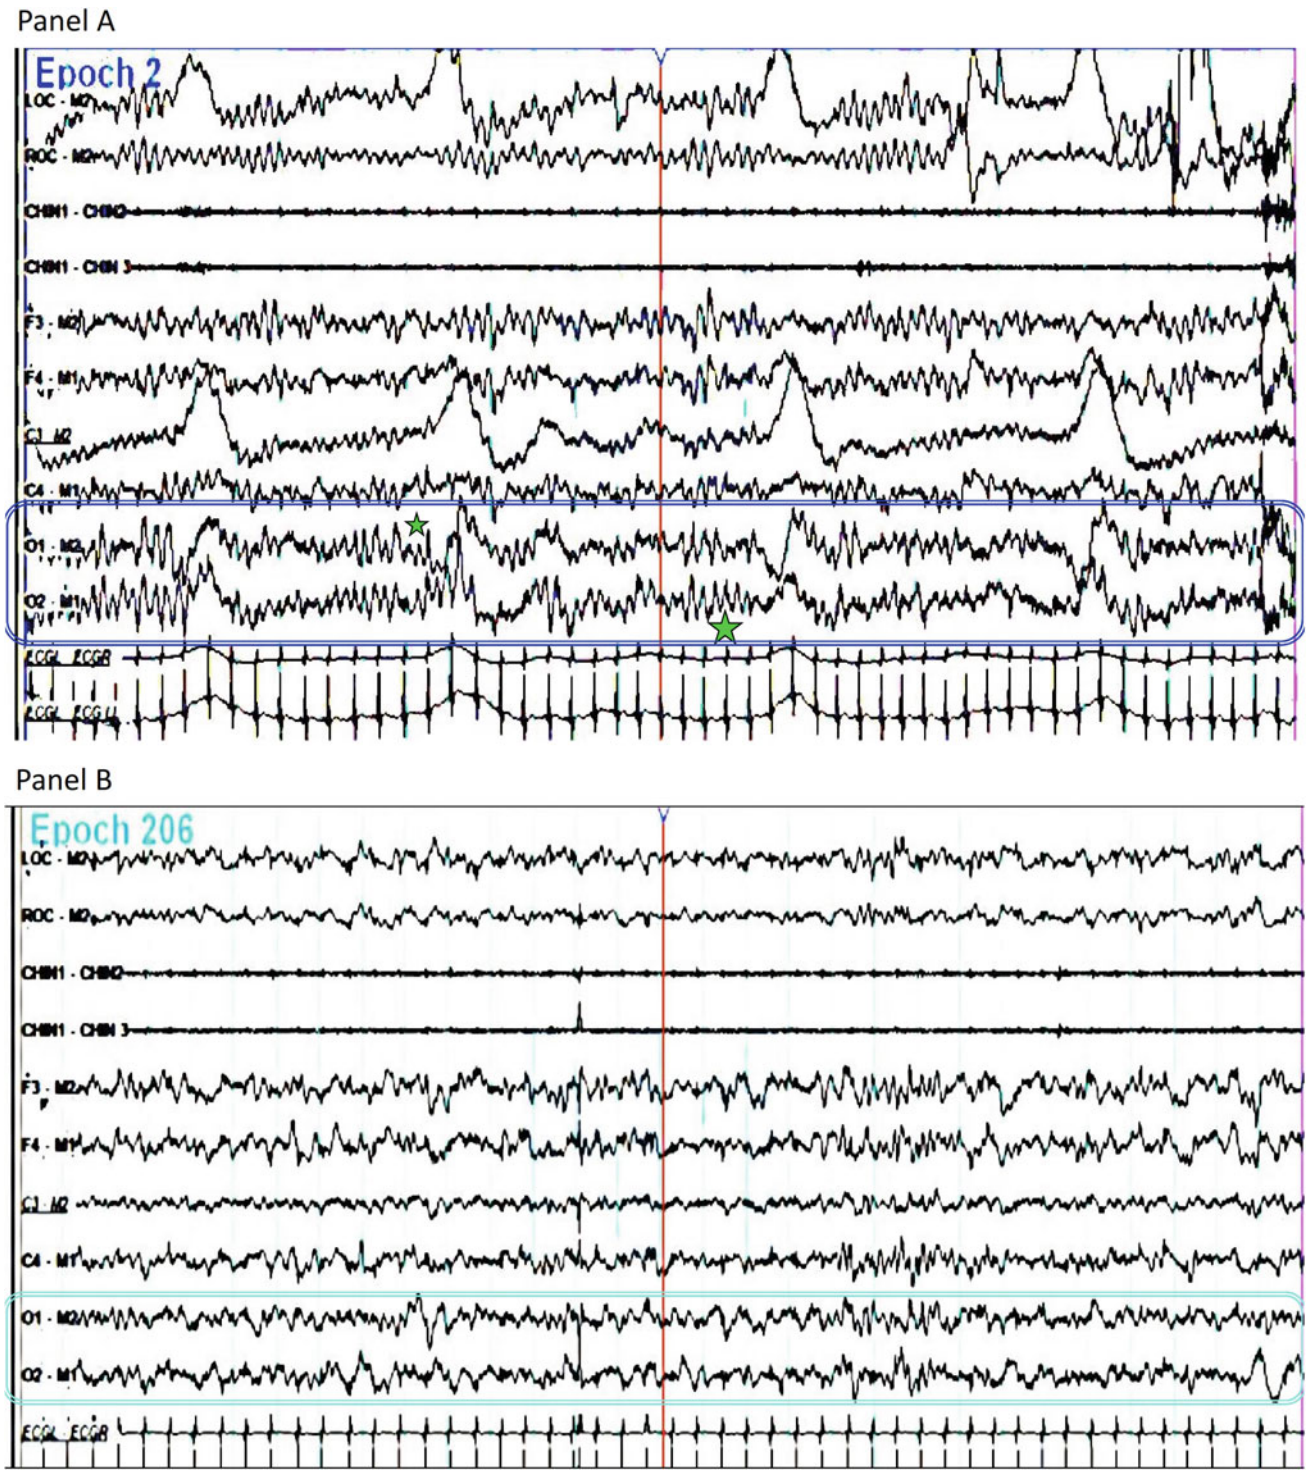

Fig. 24.31 *Panel A* 30-s PSG epoch in a 10 month old who has a posterior dominant rhythm (PDR) of 4–5 Hz as seen in the occipital leads (as noted by the *green stars*). *Panel B* 30 s PSG epoch in same 10 month old showing slowing of the PDR to 3–4 Hz and meeting criteria for scoring stage N1 sleep

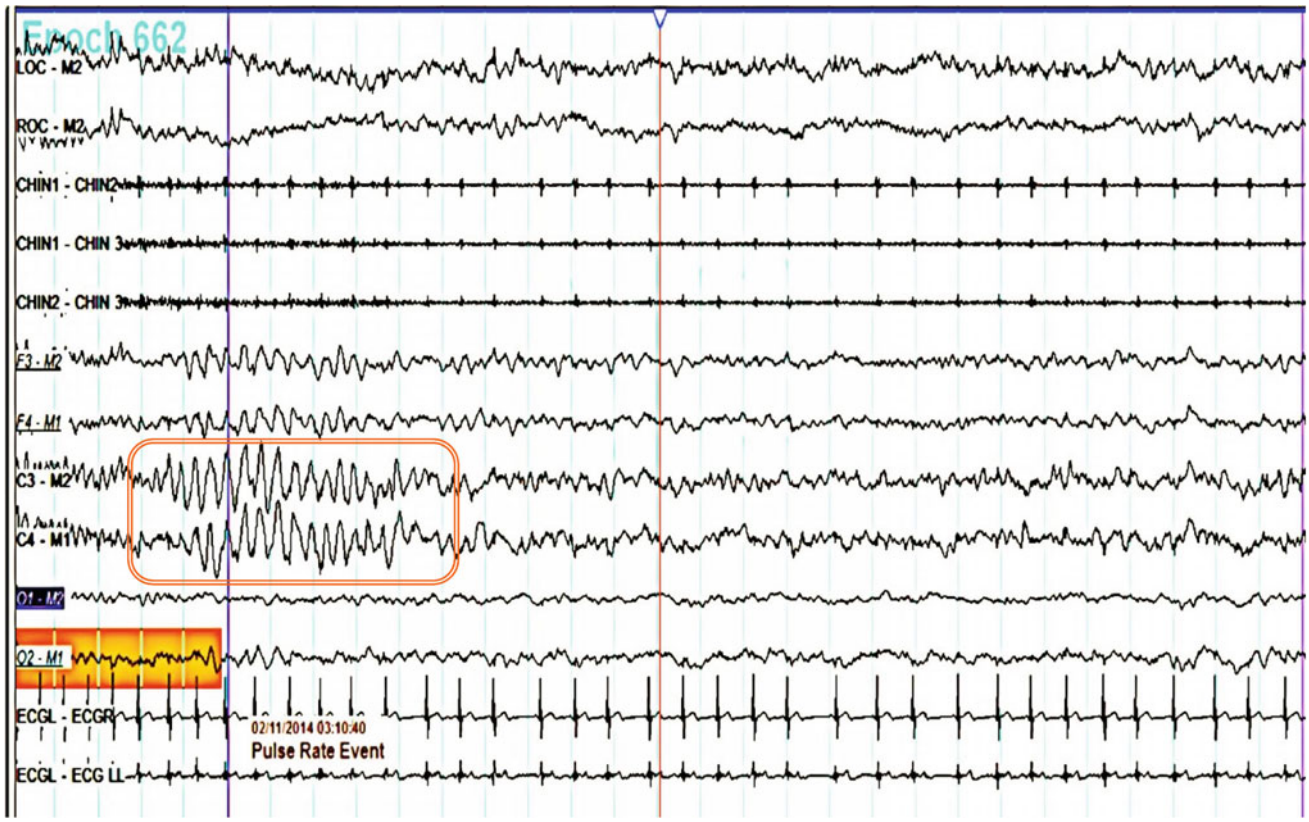

Fig. 24.32 This 30-s PSG epoch in a 2 year old demonstrates hypnagogic hypersynchrony (HH) within the *orange box*, seen most prominently in the central leads. HH is high-amplitude, sinusoidal, 75–350 μV, 3–4.5 Hz waves as noted by the *arrow*

episode [7]. Succeeding NREM-REM cycles usually have less stage N3, more N2, and longer stage R duration as the sleep period progresses. Thus, one could generalize a prototypical night's sleep as having most of the stage N3 in the first third of the night and most of the stage R in the second half of the night. The stage R comes in 4–6 discrete episodes occurring approximately 90–100 min apart. Overall, stage N2 will account for approximately half of the night's sleep and stage R will account for another fifth to quarter. Stage N1 should encompass less than 5 % of total sleep time, distributed mainly at sleep–wake transitions. The remainder of sleep time will consist of stage N3.

Scoring of Sleep-Related Breathing Events

25

Robert Joseph Thomas

Introduction

Scoring respiratory events during sleep is a core requirement for sleep medicine and research. Criteria have evolved over the years, with changes in the primary signal (thermistor vs. nasal pressure), associations (various degrees of oxygen desaturation and arousal), and the montage used (full polysomnogram to cardiopulmonary monitoring). The scoring manual of the American Academy of Sleep Medicine (AASM) accessible through the Internet [1] is a living volume, which undergoes updates, and provides a commonly used standard. This chapter will not duplicate that effort, but will focus on issues critical to the appropriate interpretation of data and can usefully complement the AASM rules. A brief summary of the AASM scoring rules as of 2016 is as follows: (1) Obstructive and central sleep apneas (OSA and CSA), obstructive hypopneas, and Cheyne–Stokes respiration (CSR)/periodic breathing are scored as standards. (2) Obstructive hypopneas require a 30 % signal drop and an associated 3 % oxygen desaturation or an arousal. A 4 % desaturation alone is required for certain medical insurance coverage indications. (3) Central hypopneas and respiratory effort-related arousals are optional. (4) The same rules hold for diagnostic and therapeutic data. (5) Home sleep studies use 3 or 4 % oxygen desaturation to score hypopneas; non-hypoxic, non-apneic events (e.g., hypopneas without desaturation) are not scored. Thus, on ambulatory testing, the current guidelines require an associated oxygen desaturation regardless of the severity of respiratory abnormality unless apneas occur. (6) Central hypopneas require the absence of snoring, flow limitation, and thoracoabdominal paradox. (7) CSR cycle length requirement is ≥ 40 s.

Scoring of respiratory events occurs on the platform of scored sleep. Conventionally, sleep has been scored using 30-s epochs, into wake, rapid eye movement (REM), and non-rapid eye movement (NREM) stages. NREM stages are further characterized into grades, N1 through N3. Alternate methods of characterizing sleep include cyclic alternating pattern (CAP) of NREM sleep [2] and cardiopulmonary coupling (high-, low-, and very low-frequency coupling of autonomic and respiratory drives, modulated by cortical delta power) [3]. NREM stage N3 is usually associated with stable breathing, where discrete respiratory events or arousals are rare. However, such periods frequently occur outside N3, during a stable form of N2, when the EEG usually shows a non-CAP morphology.

Respiratory pathology during sleep overlays the natural physiology of sleep. Thus, wake hypoventilation generally worsens during sleep, especially during REM sleep, and may be exclusively seen during REM sleep. Vulnerable periods for NREM sleep are at sleep onset (at the start of the sleep period, after a REM period, or after major awakenings), during periods of spontaneous lightening, and before REM sleep. Periodic breathing is especially amplified during these transitional periods. Obstructive respiratory events may be seen during NREM or REM sleep, but dominance of obstructive events in NREM sleep raises the possibility of underlying periodic breathing. Body position, time of night, and circadian effects provide further modifiers, and each can increase severity. Scoring strategies that provide a single number for a night loses the dynamics of these complex interactions and is the dominant driver of night-to-night variability. That is, in a given stage or state of sleep, at approximately the same time of the night, and in the same body position, respiratory events are similar across multiple nights, but the proportion of these states will vary. Within a single night, the evolution of respiratory events is also impacted by changes in respiratory chemosensitivity and rostral fluid distribution.

Scoring Centricity

When the usual polysomnogram signals are available (sleep, respiration, oximetry), scoring can be hypoxia centric (AHI 4 % and AHI 3 %), arousal centric (incorporating RERA's), or mixed (2016 AASM recommended criteria). Hypercapnia has never made it into the scoring rules, in part due to lack of measurement capability in the majority of adult-focused sleep centers. There is a biological basis to consider intermittent hypercapnia, if it is present, as a hypopnea qualifier, but the lack of widespread availability of technology makes clinical implications speculative.

Use of associated phenomena can provide important information to increase the confidence of individual events, but does not feature in the standard scoring rules. Examples include autonomic associations (heart rate increases, pulse plethysmographic amplitude reductions), limb movement, chin tone elevation and recovery, blood pressure surges, pulse transit time reductions, brief bursts of slow or rapid eye movements, reversal of paradox on effort channels, and a burst of bruxism activity. In an individual patient, a given signal can be especially informative regarding the quality of sleep state. For example, chin EMG tone elevations during NREM sleep are not part of the conventional arousal definition, but the duration and degree of elevation vary markedly between individuals and stay consistent within individuals. The same concept can be applied to the EEG (arousal duration or return to sleep) and heart rate responses to arousal—inter-individual variability is contrasted with intra-individual stability [4].

The spectrum of arousal phenomena on the EEG

Application of the AASM 3-second arousal rule imposes constraints that are not biologically based [5]. In the specific context of respiratory event termination, shorter degrees of alpha/beta intrusion (<3 s) or K complex and delta bursts are often associated with respiratory event termination and raise the consideration as arousal or event markers [5], even if they reflect protective responses. K complexes are isolated widely distributed cortical downstates [6], which can also be induced by disruptive stimuli. While it may have a sleep-protective function, the complex can draw attention to a potential arousing event. Thus, *arousal scoring* implies classic AASM arousals, while *arousal detection* could imply a broader spectrum of EEG transients to bias differentiation of significant versus non-significant respiratory events. These non-traditional approaches are especially useful when disease (dementia, epilepsy, stroke, trauma, and hydrocephalus) or medication distorts the EEG frequencies—such as benzodiazepines (fast frequencies) and atypical anti-psychotics (slow frequencies). A sleep fragmentation phenotype on PSG can be suggested by prolonged sleep–wake transitional instability (>10 min), low sleep efficiency (<70 %), persistently high N1 stage during positive airway pressure (PAP) titration (>15 %), and poor evolution of slow-wave sleep (<1 Hz) [7].

Sleep State Modulates Respiration

Airflow patterns and arousal thresholds are modulated by sleep macrostructure (REM and NREM sleep, stages of NREM sleep), sleep microstructure (CAP and non-CAP), sleep deprivation, medication, and age. There are data suggesting that NREM sleep is bimodal rather than graded, with stable and unstable regimes (Fig. 25.1), or alternatively conceptualized as effective and ineffective [3]. These periods of stability intrinsic to NREM sleep determine the instantaneous presence or absence of sleep apnea. Cardiopulmonary analysis shows stable breathing periods result in high-frequency coupling of respiration and heart rate variability, simultaneously associated with high EEG delta power. Such periods are not restricted to N3, but make up most of N2 in health. Intermittent periods of stable breathing are well recognized in patients with even severe obstructive sleep apnea, during both N3 and N2 [8]. Flow limitation can be prominent, and both hypoxia and hypoventilation may occur during these obstructed but stable periods. A prolongation of inspiratory time is typical during these periods of partial airway obstruction during stable sleep. These periods do have an impact on the EEG, but visual determination is not possible, and computational methods such as the respiratory cycle-related EEG change are required [9, 10]. The persistence of CAP-type features on the EEG may occur during slow-wave sleep associated with severe persistent flow limitation, suggesting the presence of concomitant disruptive influences.

Is an Arousal Necessary to Enable Airway Opening and Respiratory Recovery?

The standard teaching is that an arousal from sleep was necessary for airway opening. There is new information that only a proportion of respiratory recovery is arousal dependent and that blood gas changes can drive airway opening without an electrocortical arousal [11]. The degree of arousal does amplify associated autonomic features roughly proportional to the degree of alpha/beta intrusion [12]. However, stage and state modulation are almost certainly important. It is conceptually useful to consider NREM as manifesting bimodal stable versus unstable propensities and

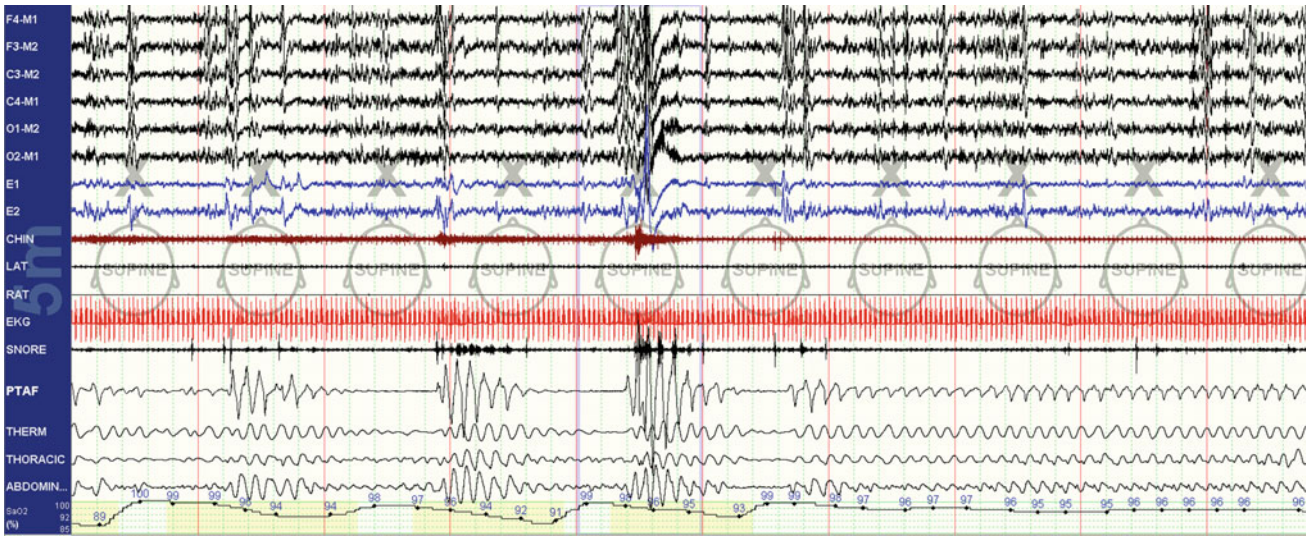

Fig. 25.1 Spontaneous switch from unstable to stable NREM sleep. 5-min polysomnogram snapshot of stage N2, showing the relatively abrupt switch from a state of respiratory event and arousals to a state with stable breathing and the absence of arousals

characteristics. For example, when sleep drive is high, and NREM state is stable, airway opening can likely occur without a classic electrocortical arousal, the high sleep drive masking EEG arousal recognition or simply preventing an arousal, allowing brain stem and chemoreceptor or mechanoreceptor-based respiratory reflexes to open the airway. When NREM sleep is in an unstable as reflected by CAP EEG or low frequency cardiopulmonary coupling, the networked driving of sleep state couples nearly all prevalent physiology and pathology. Thus, tidal volume fluctuations, EEG arousals, heart rate change and hemodynamic/autonomic oscillations, and even periodic motor activation are all coupled and occur nearly simultaneously. During such a condition, it is hard to be sure arousal is *necessary*, but arousals certainly *occur*, in close temporal relationship, to respiratory recovery. K complexes are frequent accompaniments of respiratory recovery and may reflect the interplay and interaction between sleep disruptive and restorative forces. Medications that increase slow wave, such as atypical anti-psychotics, can obscure the faster components of arousals, when clusters of slow waves may be the only visually evident marker of respiratory-related arousal. During REM sleep, respiratory fluctuations occur as part of the REM sleep state and independent of arousals (increase in EMG tone), and it is unknown whether these tidal volume and flow fluctuations when exaggerated but without EMG increases disrupt REM sleep. When REM-without atonia is also present, respiratory-related arousal and REM sleep scoring can be difficult and sometimes impossible.

Event Cycle Characteristics

Event Cycle Length

The cycle length (Figs. 25.2 and 25.3) of a respiratory event reflects the time to arousal, respiratory drivers, and effects of phasic suppression of muscle tone for REM sleep events and intrinsic network properties of the sleeping brain. The time to arousal is dependent on the input traffic to brain stem arousal centers, which may be from within (respiratory effort), somatic afferents from the upper airway, or visceral afferents (including respiratory chemoreflex sensing of O_2 in the carotid body, and CO_2 in the carotid body and retrotrapezoid nucleus neurons).

Respiratory driving may be reactive (response to upper airway obstruction) or active, when the respiratory chemoreflex arc is hyperactive as in congestive heart failure (CHF) [13], at high altitude [14], and after exposure to hypoxia (sensory long-term facilitation) [15]. Phasic effects of REM sleep can cause obstructive, central-looking, or pseudoperiodic patterns, the latter when eye movements occur with similar inter-phasic interval. This latter phenomenon can be incorrectly characterized as periodic breathing, especially if EEG is not available, as in home sleep testing.

The intrinsic network properties of the brain reflect the interactions between multiple components including the cortex, thalamus, various output systems such as respiratory, autonomic, and motor, and the afferent return from the latter systems through baroreflex and chemoreflex arcs. On the

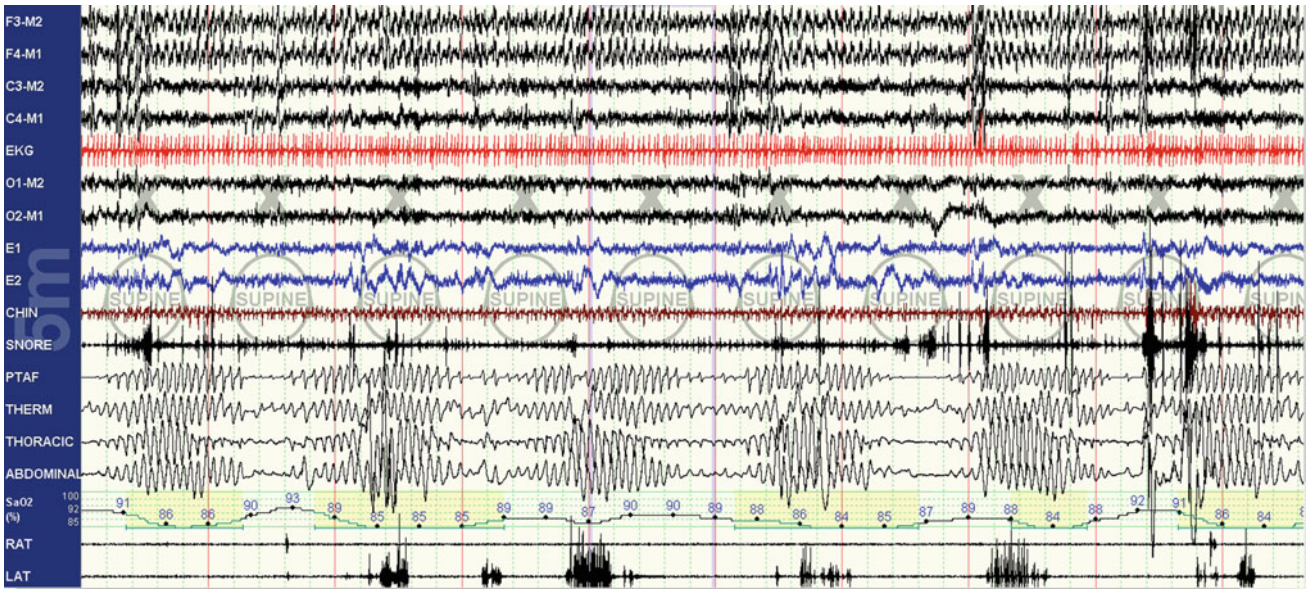

Fig. 25.2 Long-cycle periodic breathing. 5-min polysomnogram snapshot. Cycle times are close to 50 s, in this patient with congestive heart failure

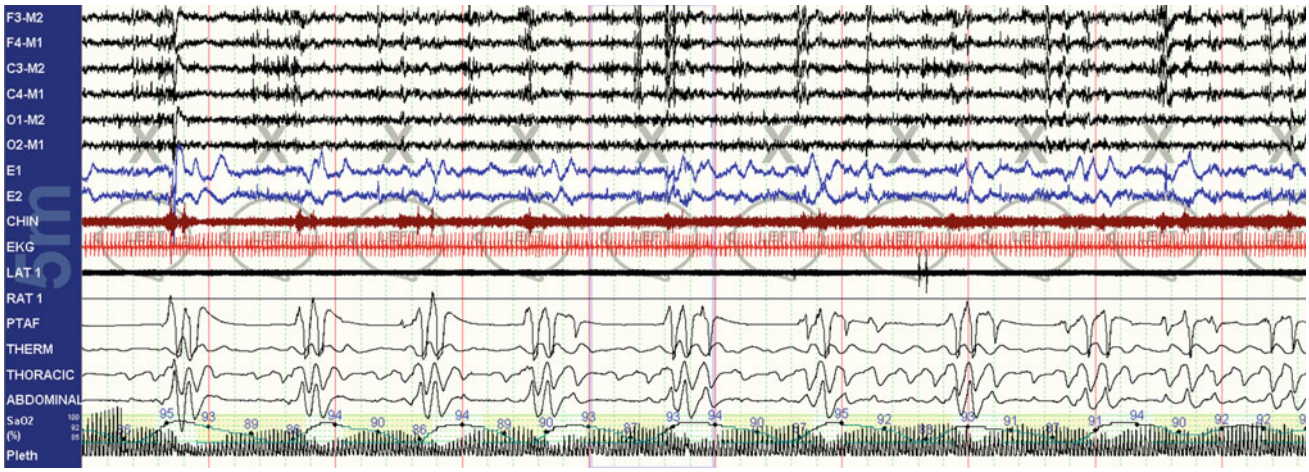

Fig. 25.3 Short-cycle periodic breathing. 5-min polysomnogram snapshot. Cycle times are about 30 s

surface EEG, this network property is represented by CAP. The CAP cycle length imposes an overall structure of the timing of pathological and physiological integrated multi-component repeats.

Event cycle length is entrainable. The best examples are high-altitude (short, less than 30 s, often 15–20 s) and CHF (long, most characteristically 60 s or longer) cycles. Adaptive ventilation can convert a short cycle to a long cycle; I have never seen this therapy convert a long to a short cycle. Respiratory cycle length, the time from one point of an event to a corresponding point, e.g., peak recovery to preak recovery, can also lengthen with supplemental oxygen or use of a non-vented mask to minimize hypocapnia [16], by prolonging the time to arousal. It is plausible that other rhythmic and repetitive arousing stimuli such as experimental auditory arousals can entrain "CAP," but there will be biological constraints on frequencies which can entrain sleep state. These biological constraints in the frequency of coupled multicomponent oscillations are determined by the network properties of the sleeping brain. Too frequent arousing stimuli will wake up the subject, but too infrequent stimuli will likely only transiently arouse the subject without entrainment to the cycle time of the arousing stimulus.

Event Cycle Timing

External driving of sleep respiration can occur with neurostimulators (e.g., vagal, nerve stimulator for epilepsy Fig. 25.4). These stimulation pulses will have a metronomic timing and can cause respiratory suppression with precise repeated timing. Outside experimental settings, metronomic auditory stimulation during sleep does not occur. Strong respiratory chemoreflex modulation, causing periodic breathing/CSR, is the most common cause of metronomic respiratory event timings usually accompanied by equally impressive (consistent timings) oximetry, heart rate, and blood pressure oscillations.

Ultra-Short Respiratory Events

The typical respiratory event evolves over 30–40 s. A commonality of repeat duration is also shared by periodic motor activation and A-phases of CAP. However, when respiratory chemoreflex driving is strong in the setting of normal cardiac function, cycle times shorten and can be as short as 20 s. This pattern strongly resembles that seen at high altitude. Travelers to high altitudes often experience restlessness, frequent brief arousals, and unrefreshing sleep [17], at least in part due to periodic breathing. In contrast to heart failure, the cycle times are 15–25 s, characterized by 2–5 large tidal volume breath clusters followed by apneas of 5–15 s in duration. There is a marked increase in arousals and reduction in slow-wave sleep likely related to hypoxia-induced carotid body sensitization narrowing the $PaCO_2$ reserve and increasing controller gain [18]. A male predominance has been reported [19]. In idiopathic CSA, similar to high altitude, cycles of central apneas are shorter (20–40 s) and not as gradual and smooth as in classical CSR [20, 21]. While 10 s is the standard minimum event length for scoring, shorter events with biological consequences should reasonably be tagged.

Ultra-Long Respiratory Events

Two types of long events are seen. In one pattern, there is prolonged and progressive flow limitation that is terminated by an arousal; this pattern is typical of the pattern called upper airway resistance syndrome. Though this entity has been folded into obstructive sleep apnea, the pattern is distinctive enough. The second pattern is seen in patients with CHF—long-cycle (>60 s) periodic breathing/CSR. One consideration when the event duration is long is that the apnea–hypopnea index/respiratory disturbance index (AHI/RDI) may underestimate severity as there are fewer but longer events.

Assessing Event Significance in Stable NREM Sleep—Periods of Stable Breathing

Respiration is stable during conventional slow-wave sleep. Though described from the early days of recognition of the clinical sleep apnea syndrome, the mechanisms have remained elusive. The state of the cortical sleep network seems important. Increased genioglossus tone and increases in CO_2 occur during the periods of stable breathing [8], with overt hypoventilation and hypoxia if flow limitation is severe. These respiratory features are more likely when obesity or reduced cardiopulmonary reserve is present. In the pediatric age group, obstructive hypoventilation is a common pattern during slow-wave sleep. Spontaneous periods of stable breathing periods do not occur during REM

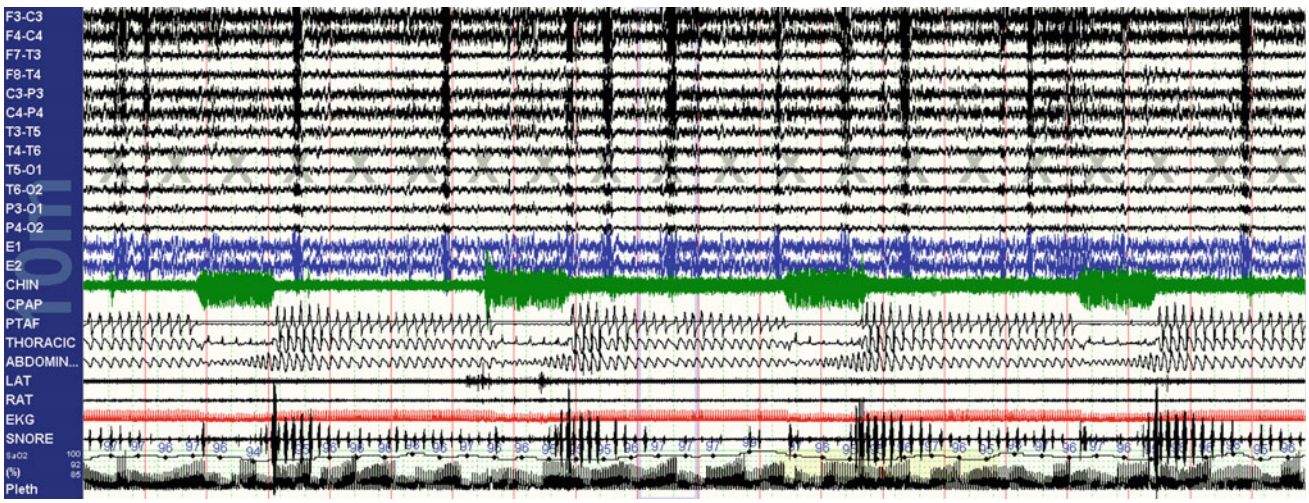

Fig. 25.4 Pseudoperiodic breathing from external driving. 10-min polysomnogram snapshot. Patient using a vagal nerve stimulator for refractory epilepsy. The block-like chin tone increase is a stimulation artifact. During the stimulation phase, there is respiratory suppression

sleep. However, a number of NREM-dominant apnea syndromes, including idiopathic central sleep apnea, periodic breathing, high-altitude sleep apnea, complex apnea/treatment-emergent central sleep apnea, and opiate-induced sleep apnea, show markedly improvements in stability during REM relative to NREM sleep. Metabolic control of respiration and CO_2 dependence on respiratory drive predominates during NREM sleep only.

The clinical problem with associating stable breathing phenomenon exclusively with slow-wave sleep by any definition is that such stable periods occur predominantly in N2, including those with no N3. Figure 25.5a–d demonstrates the impact of these periods in creating stable periods as a component across a dynamic range of pathology. Stable periods dominate the rebound effects of successful PAP titration, and the majority of time is usually N2. Some clues to the nature of this phenomenon can be gained from the concept of NREM sleep bimodality. The first clue came from the description of CAP and non-CAP from Italian researchers in the mid-1980s [22]. CAP and non-CAP periods occur across NREM sleep; non-CAP occurs in N2 or N3 [2]. Subsequently, the autonomic and respiratory associations of CAP/non-CAP were described [13]. Finally, the description of the cardiopulmonary coupling technique showed that NREM sleep has bimodal characteristics in health and disease. High-frequency coupling and low-frequency coupling periods show spontaneous switching and in relation to delta power. That is, high-frequency coupling is associated with high delta power, non-CAP EEG, stable breathing, strong sinus arrhythmia, and blood pressure dipping [3]. Low-frequency coupling is associated with unstable breathing (reaching scorable thresholds of sleep apnea in disease), cyclic variation in heart rate, CAP EEG, and blood pressure non-dipping. Thus, stable breathing periods reflect natural integrated network states of the brain and are amplified and readily recognizable in sleep apnea patients as the two states are markedly different on visual inspection. Benzodiazepines and related drugs increase non-CAP [23, 24] and may be expected to increase stable breathing periods. Zolpidem increases blood pressure dipping [25] and could do so through the induction of stable NREM periods.

The proportion of stable breathing periods will impact the computed apnea–hypopnea index, as these periods do not contribute to the metric. Varying proportions of stable breathing on a night-to-night basis can contribute to night-to-night variability of the apnea–hypopnea index. Successful positive pressure titration markedly increases stable breathing periods on the treatment night and can provide a false sense of success; using the apnea–hypopnea index on a given pressure can be incorrect due to this confound. No current metric captures this pathology, though quantifying the % of flow-limited breaths will provide one measure and is available in some device-related automated analyses. The duty cycle of respiration (% inspiration of the respiratory cycle) will increase during these periods from prolonged inspiration [26]. Audible snoring or recordable upper airway vibrations are frequently noted. The pattern of flow limitation (the shape of the flow-limited breath) may have individual characteristics (similar within the same individual). Analysis of respiratory cycle-related EEG changes during such periods show an impact on electrocortical activity [9].

Assessing Event Significance in REM Sleep

The natural tidal volume fluctuations that occur in REM sleep, especially during phasic REM sleep, can mimic "real" apneas and hypopneas. Of special concern during positive pressure titration, brief events that are not associated with arousals or oxygen desaturation should probably be ignored unless they are actual obstructive apneas.

NREM Versus REM Dominance

For practical purposes, periodic breathing and hypocapnic central apnea do not occur in REM sleep (exception, a patient with CHF who demonstrates periodic breathing during wake state). NREM dominance is well described in idiopathic central sleep apnea [27], periodic breathing associated with heart failure or stroke [28], opiate-induced sleep apnea [29], and high-altitude periodic breathing [30]. NREM dominance is also a feature of complex apnea/treatment-emergent central sleep apnea, regardless of the exact definition used [31].

The simplest method is the NREM versus REM AHI/RDI, but the following are confounds: (1) Body position: Only supine-to-supine comparisons are fair; (2) stage and state of sleep: Periods of stable breathing, which may be associated with N2 or N2 sleep, contribute little to the AHI/RDI, while REM sleep does not have a similar stable equivalent. Determining NREM dominance can be difficult in those with substantial obstruction, where two distinct patterns can coexist—periodic breathing during NREM sleep and obstructive events during REM sleep. The use of PAP usually clarifies the situation—REM disease is readily eliminated, while NREM disease is not.

Ataxic Respiration

When there is continuous variability of rate, volume, and rhythm of breathing during NREM sleep (nearly looking like respiration in REM sleep), often admixed with obstructive or

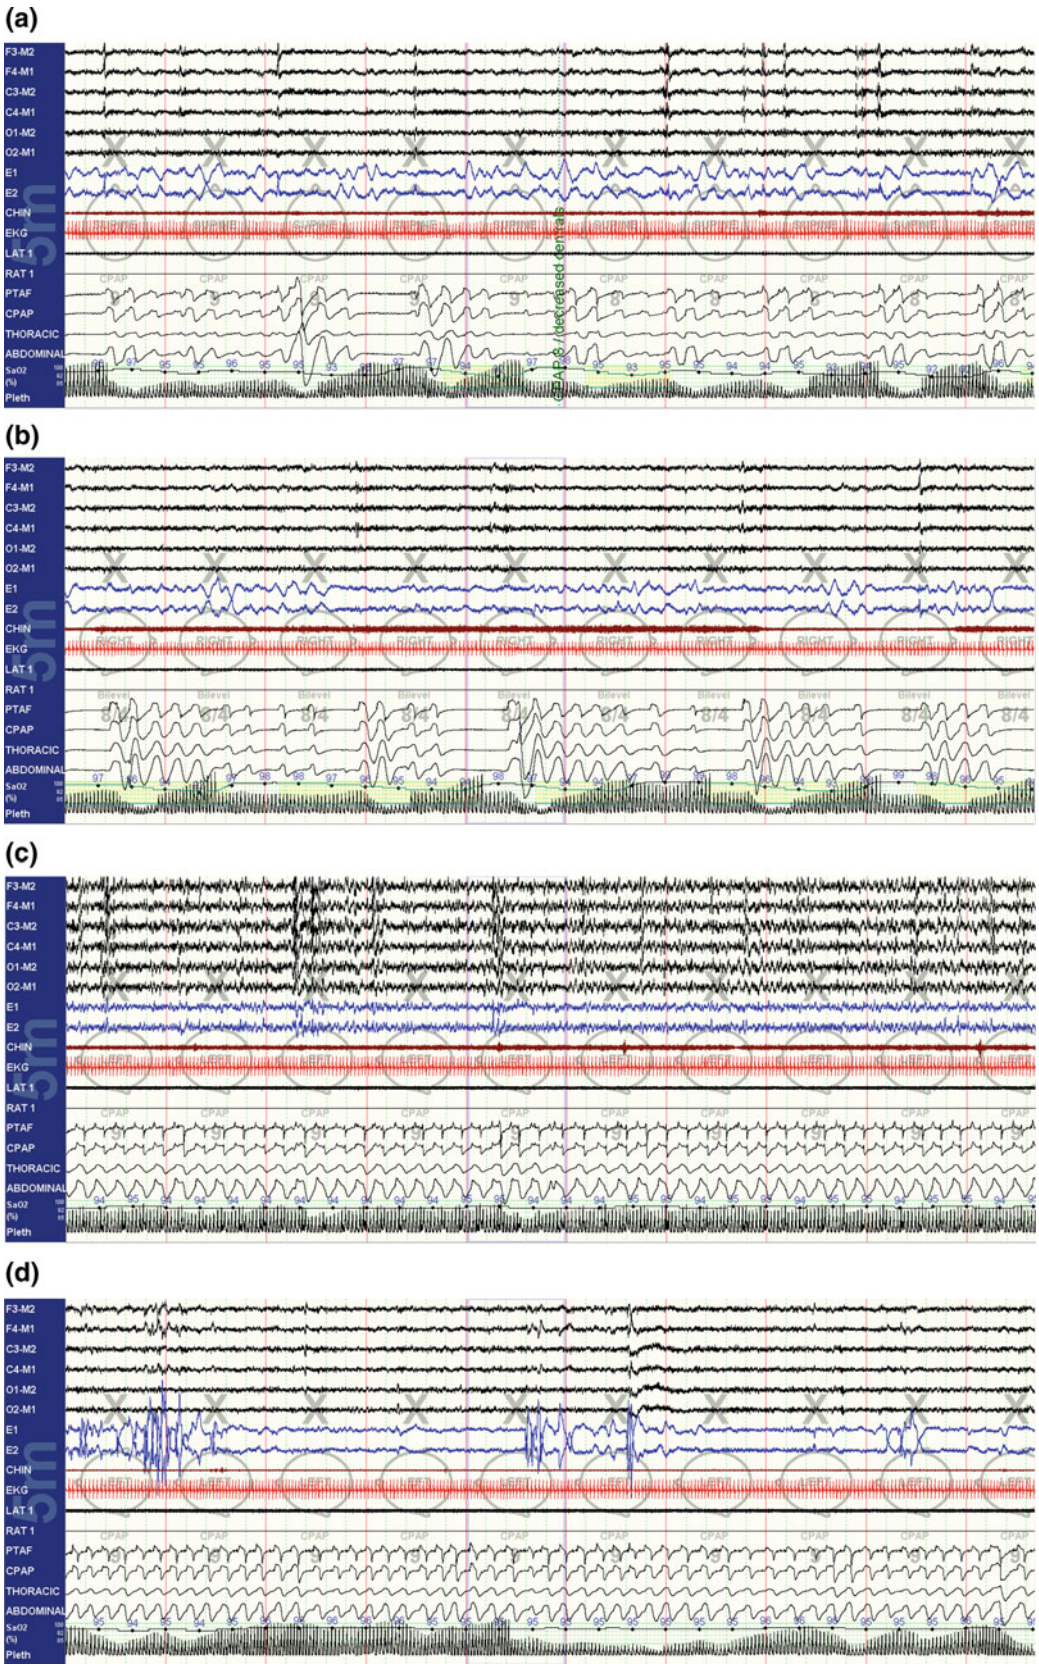

Fig. 25.5 **a** Effect of CPAP on high loop gain sleep apnea. Same subject as in Fig. 5.3. CPAP opens the airway, but the underlying rhythm continues. **b** Effect of non-adaptive bilevel PAP on high loop gain sleep apnea. Same subject as in Fig. 5.3. The cycle times prolong, likely due to worsening of hypocapnia. Events during titration often show minimal oxygen desaturation, or even signal reductions reaching thresholds for hypopnea, and may take atypical long, short, or ataxic patterns. **c** Stabilizing effect of "stable NREM" sleep on sleep apnea. Same subject as in Fig. 5.3. Conventional stage is N3. **d** Stabilizing effect of REM sleep on high loop gain sleep apnea. Same subject as in Fig. 5.3

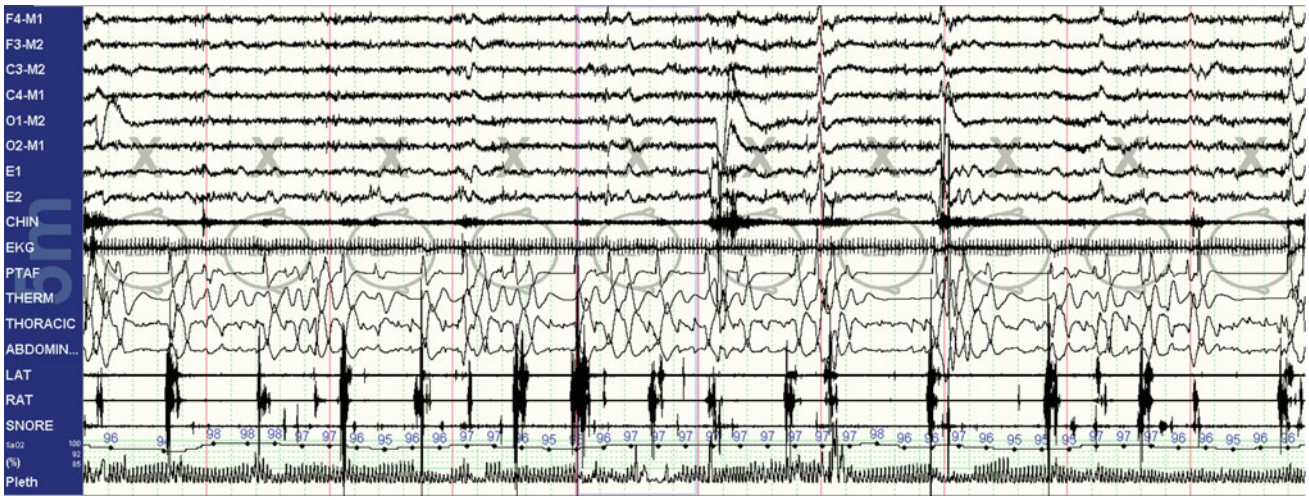

Fig. 25.6 Ataxic respiration from opiate use. 5-min polysomnogram snapshot. *Note* (1) relatively mild oxygen desaturation; (2) short but variable length central apneas; (3) arousals and periodic motor activation

central apneas of variable duration, the term may be used. The events may be so short, and the respiratory abnormality is devoid of predictable fluctuations that the standard rules may over score or underscore events. Opiate use is the most common cause [32, 33], but any brain stem neurological abnormality, such as multiple sclerosis, brain stem stroke, and craniovertebral junctional anomalies, may also exhibit these features. Opiate-associated ataxic breathing (Fig. 25.6) is usually accompanied by mild hypercapnia, and in general, ataxic breathing is sensitive to reductions in CO_2 by increasing ventilation such as by applying continuous PAP (CPAP).

Loop Gain—A Concept Relevant to Understanding Scoring Approaches and Limitations

Breathing during NREM sleep is under metabolic/automatic control and can be understood through interaction between its components: *controller*, *plant*, and *mixer*. The "controller" converts the signal from the chemoreceptors into a ventilatory drive for the plant (an anticipated ventilation for a given $PaCO_2$). The "plant" refers to the lungs, blood, and the tissues where CO_2 is stored. It is the effector of the controller that produces the change in $PaCO_2$ for a given change in ventilation stimulus. Its performance depends on mechanical and biochemical properties of its components (e.g., lung compliance, ventilation–perfusion matching, hemoglobin concentration). For most of the awake individuals, eupneic $PaCO_2$ ~40 mmHg and for sleeping individuals, it is ~45 mmHg. The "mixer" represents the time it takes for the capillary blood from the lungs to reach the chemoreceptors and is primarily a function of cardiac output.

Sensitivity (chemosensitivity) of each of the system's components to a change in input dictates how responsive the entire system is. This responsiveness has been termed "gain" or (▲ output/▲ input), an engineering term used to describe how stable or unstable a system is. The higher the gain, the less stable the system is. The controller gain is the (▲ Ve/▲ $PaCO_2$), and plant gain (▲ PaCO2/▲ Ve), and the mixing gain determines the speed with which changes in $PaCO_2$ and PaO_2 from plant are detected by the controller [34]. The overall gain of the system (loop gain, Ve disturbance/Ve production) determines the stability of the system and is the product of controller, plant, and mixing gains. Loop gain varies between individuals and with disease states [35]. High loop gain is found in systems with large swings in blood gases and ventilation, while low loop gain indicates a stable system but also one that may also not respond adequately to a change in ventilation.

The metabolic respiration control system is exquisitely sensitive and designed to maintain $PaCO_2$ homeostasis rather than oxygenation. Two levels of $PaCO_2$, the apneic and eupneic thresholds, are critical to its operation. As elegantly demonstrated by Bulow in the 1960s [36–38], *apneic threshold* represents a level of $PaCO_2$ below which breathing stops. *Eupneic threshold* is defined above. Below eupneic threshold, ventilatory drive is reduced, while above it is increased [39]. During sleep, the apneic threshold is usually 2–6 mm Hg below the eupneic sleeping $PaCO_2$ level, but only 1–2 mmHg below the wakefulness eupneic $PaCO_2$ level [40, 41]. This small difference between awake eupneic and sleep apneic $PaCO_2$ is one reason behind instability of the respiratory system during sleep. When loop gain is too high, periodic breathing, hypocapnic central apneas, and NREM dominance of sleep apnea emerge. When loop gain is too low, hypoventilation results. High loop gain protects

Table 25.1 Recognition of strong chemoreflex modulation of sleep breathing [7]

Polysomnographic feature	Relatively pure OSA	Chemoreflex-modulated SA
Periodic breathing, Cheyne–Stokes	Rare	Typical (often short cycle, <30 s in the absence of CHF)
Respiratory event timing	Variable (each event tends to have different durations)	Self-similar/metronomic
Severity during sleep state	Greater severity in REM	Minimal severity in REM
Effort signal morphology	Well maintained during obstructed breath	Complete or partial loss between recovery breaths
Flow–effort relationship	Discordant: Flow is reduced disproportionately to reduction in effort	Concordant: Flow and effort follow each other in amplitude
Arousal timing	Early part of event termination	Crests event, often in the center of the sequence of recovery breaths
Oxygen desaturation	Irregular, progressive drops, V-shaped contour	Smooth, symmetric, progressive drops rare
Response to continuous positive airway pressure	Normalization of flow, sleep, oxygenation, and ventilation	Persistence or "emergence" of central apneas or periodic breathing

respiration during REM sleep and may explain why NREM-mixed periodic breathing with obstruction improves or "disappears" during REM sleep.

Quantitative polysomnogram analysis has also been used to differentiate cardiac-related periodic breathing from non-cardiac causes and may help predict effectiveness of CPAP for CSA-CSB. In brief, loop gain can be determined from the ratio of ventilation length (VL) divided by the apnea length (AL) or (VL/AL). VL/AL > 1 [42] and cycle duration/length (CL = VL + AL) of > 45 s [43] are suggestive of CSA of cardiac cause. Loop gain (LG) can also be derived by the means of a duty ratio (DR = VL/CL) of periodic breathing, $LG = 2\pi/(2\pi DR - \sin 2\pi DR)$ [44]. In a pilot study of 14 CHF-CSB patients, LG was significantly higher among the non-responders and value of >1.2 predicted lack of response to CPAP in 7/7 patients [44]. Although simple to determine and encouraging from pilot data, such findings are limited to patients with already clear periodic breathing and should be validated in a larger, prospective manner. Table 25.1 summarizes some of the differentiating features of obstructive and chemoreflex driving of respiratory events.

Assessing Pathological Respiratory Chemoreflex Activation: Cheyne–Stokes Respiration and Central Hypopneas

The AASM scoring manual requires the following for scoring a CSR event: cycle length of 40 s or greater, a typical concordant waxing–waning of flow and effort, a minimum of 3 cycles with these characteristics for any single CSR event, and an overall CSR index of $\geq$5/h of sleep. The ICSD-3 specifies that these should make up $\geq$50 % of all scored events. Central hypopnea scoring is "optional" in the scoring standards, yet recognition of CSR is recommended.

The events that make up CSR are essentially strings of central apneas and hypopneas. However, events at both sea level (often) and high altitude (always), and in patients with positive pressure induced or amplified respiratory instability, have short cycles that are less than 30 s. If 40 s is a requirement, then these short-cycle events will be falsely characterized as obstructive.

Flow limitation excludes a "central hypopnea" in the scoring manual, yet this idea has been conclusively shown to be false from the following data: (a) At high altitude, a pure chemoreflex form of sleep apnea, flow limitation occurs frequently; (b) heart failure patients with otherwise classic CSR can demonstrate flow limitation; (c) the airway can close during polysomnographic central apnea [45, 46]; and (d) central hypopneas demonstrate flow limitation [47]. In clinical practice, snoring can be seen in association with CSR—but usually occurs associated with the arousal, while in more purely obstructive event, the snoring occurs during the event and transiently resolves during the arousal.

Recognition of CSA syndromes generally requires a full-night recording of standard polysomongraphy with special attention to inspiratory effort. Cardiopulmonary recordings may also be sufficient, with the limitation of inability to differentiate REM from NREM-dominant disease, which has diagnostic and therapeutic implications. The current gold standard to determine whether apnea is central (no inspiratory effort throughout the event) is the use of esophageal balloon catheter [48, 49]. Contrary to current

clinician perceptions and practice, a survey of 799 patients who underwent esophageal balloon placement during their sleep study revealed that 85 % felt minimal, if any, discomfort and only 3 % of patients refused the catheter on second occasion [50]. Attempts at using "less invasive" techniques such as respiratory inductive plethysmography or strain gauges, as well as pulse wave artifacts in the oronasal flow signal, produce unreliable results [51, 48]. Pulse transit time measurements can provide supportive information regarding central genesis. The lack of esophageal balloon data complicates the detection of *central hypopneas* even further. The exact threshold of when effort is adequate versus not is also somewhat arbitrary. Alternative strategies, using PSG-based algorithms, have been developed, but show only marginal accuracy (68 % in one study) [52].

A consistent feature of hypocapnic, heightened chemoreflex-mediated central apnea is predominance of events during NREM sleep, especially during non-slow-wave stages [7, 28, 53–55, 56, 57]. A metronomic self-similar appearance (identical event length and morphology in a consecutive series of events; consecutive hypopneas appear like clones of the preceding and following ones), even if individual events fulfill obstruction criteria, is typical, except in opiate-induced CSA, where variability of expiratory phase is characteristic. In contrast to hypocapnic CSA, in OSA and in many cases of hypercapnic CSA, the disease worsens markedly during REM sleep, especially if the motor neurons of the diaphragm are involved [34, 54]. Notable exceptions are congenital central hypoventilation syndrome (CCHS) and opioid-induced CSA, where the disease is worse in NREM sleep.

Treatment-Emergent Central Sleep Apnea (TE-CSA) and Complex Sleep Apnea

The $PaCO_2$ reserve is labile during NREM sleep [58] and arousals due to maladaption to PAP can occur and drive instability [31]. The compliance or pressure at which passive critical closing of the upper airway occurs (P_{crit}) shows overlap between patients with OSA and controls [59]. Variations in P_{crit} alone account for only a portion of variations in the AHI [60] or differences in phenotype [61].

In some patients with OSA, central apneas and periodic breathing emerge during the initiation of CPAP. This phenomenon is called treatment-emergent CSA in the ICSD 3rd edition and defined when there are 5 or greater central apneas and hypopneas per hour of sleep making up greater than 50 % of all respiratory events during titration of CPAP in those fulfilling obstructive apnea criteria during diagnostic polysomnography. The ICSD tries to clear some of the controversies over "complex sleep apnea" [62]. The existence of TE-CSA apnea as a unique entity has been controversial in the sleep world. The original description [58] noted a set of relatively unique features on *diagnostic* polysomnography and an incomplete treatment response that included induction of central apneas or persistent periodic breathing when CPAP was applied. The key feature is NREM-dominant central hypopneas or periodic breathing with obstruction, resolving spontaneously during REM sleep. That is, induction of central apneas was not required. A subsequent publication "defined" complex apnea proposing the currently deployed ICSD criteria [62], which also became the criteria used by medical insurance to qualify patients for the more expensive adaptive ventilators.

The ICSD allows the coexistence of periodic breathing and obstructive sleep apnea (a "splitting" approach). The term "complex apnea" (a "lumping approach") may have clinical utility in that a single term captures a number of ICSD categories with a common pathogenesis and identical responses to therapy. Central hypopneas are rarely scored in clinical practice, and thus, reports of complex/treatment-emergent sleep apnea, especially if using the ICSD treatment-emergent category and criteria, likely include only patients on one end of the spectrum of chemoreflex-driven instability than the middle of the obstruction-central continuum where a substantial minority of patients could belong. In these patients, short-cycle (≤ 30 s) periodic breathing, with features of admixed obstruction, highly reminiscent of high-altitude periodic breathing, can occur and was part of the original description [58]. It is possible that long cycles, ≥ 60 s, may be caused by subclinical cardiac diastolic dysfunction (proven by echocardiography), but data are lacking on cardiac function differences between patients demonstrating purely long- versus short-cycle events.

A consistent feature of patients with treatment-emergent/complex sleep apnea, documented in most publications, is disproportionate sleep fragmentation, which often persists despite reasonable respiration-targeted therapy. As arousals amplify hypocapnic instability, inadequate cohesion of the NREM sleep-related network activity seems to be the core pathology in some of these patients. This phenomenon is reminiscent of the reports of CHF patients, showing persistent sleep fragmentation beyond that attributable to respiratory events [63].

Titration Versus Diagnostic Data

The AASM recommends the same criteria for scoring respiratory events on both the diagnostic and therapeutic polysomnograms. However, eliminating apneas and significant hypoxia is more readily achieved, and much of positive pressure titration is focused on normalizing flow (eliminating RERA's). Thus, normalizing the RDI rather than the AHI is necessary. An even better target may be enabling stable

breathing. Scoring titration polysomnograms using the "recommended" criteria (3 % desaturation or arousal, 30 % signal change) will miss RERA's.

Oximetry Analysis

Three distinct oxygenation abnormalities have specific pathophysiological significance. Periodic breathing and central sleep apnea are associated with a "band-like" desaturation profile, as the individual dips are highly similar due to the self-similar event duration and severity typical of respiratory chemoreflex driving. A "V"-shaped desaturation is seen only during REM sleep and is a good reflection of the biological drive of REM sleep, as saturations begin to improve even before the termination of polysomnographic "surface" REM sleep. Finally, a "sagging" oxygen desaturation profile, where the return to baseline is progressively impaired, is often seen in hypoventilation. If CO_2 is monitored, an envelope of elevation that mirrors this sag may be seen. Figure 25.7 shows some of these patterns.

Capnometry Analysis and Hypoventilation

Measurement of CO_2 in the adult sleep laboratory has been neglected because of technical inadequacy (the development of cheap, rapidly responsive, and accurate monitor, similar to an oximeter) in clinical diagnostic application (not measured in the vast majority of sleep laboratories dealing with adults patients), tracking of home treatment responses in the ventilation community, and research exploring the basic science of hypercapnia at local and systemic levels [64]. Obesity hypoventilation syndrome requires daytime hypercapnia regardless of the severity of sleep hypercapnia—do we really need to wait until wake CO_2 regulation fails before recognizing an important sleep state dysfunction? The 10-min threshold for elevated CO_2 is fairly arbitrary—even if a reasonable minimum severity grading is necessary. Pediatric norms (>25 % of the total sleep time as measured by either the arterial PCO_2 or surrogate is spent with a PCO_2 >50 mmHg) are better defined from polysomnography, but the correlation of the degree of hypercapnia to cognitive and cardiovascular outcomes, if any, remains to be established.

What about high values of PCO_2 during brief periods of REM sleep in a patient with neuromuscular disease that cause arousals (and thus a transient reduction in CO_2) without quite hitting a duration (% total sleep time or a certain number of minutes above threshold) mark? There are instances when hypercapnia emerges once CPAP stabilizes respiration and sleep is no longer fragmented—prior to treatment, the repetitive arousals protected the patient from severe hypercapnia. Is hypercapnia on treatment as acceptable as hypercapnia before treatment? Do we call this treatment-emergent hypercapnia? The majority of sleep

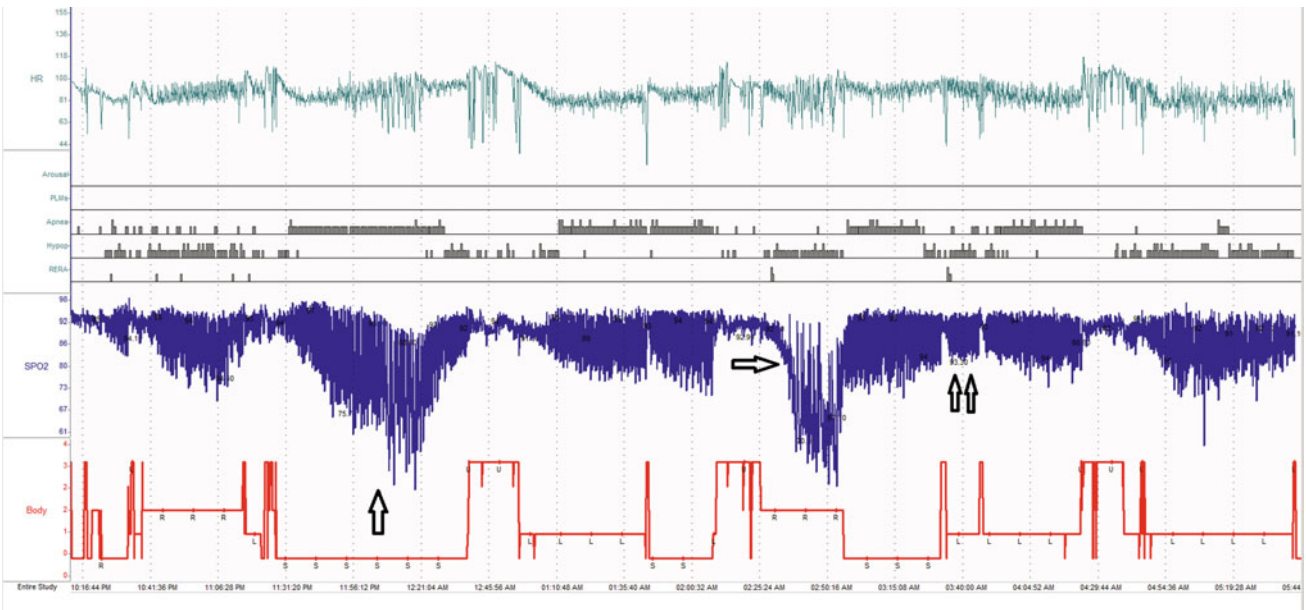

Fig. 25.7 Oximetry analysis. Home sleep study. Besides the obviously abnormal oxygenation, *note* **a** V-shaped desaturation virtually pathognomonic of REM sleep-related sleep apnea (*vertical single arrow*); **b** possible REM sleep hypoventilation (*right pointing arrow*): V-shaped desaturation and failure of return to baseline of oximetry; **c** band-like oxygen desaturation typical of periodic breathing. In this instance, the concomitant obstructive features resulted in greater desaturations that is typically seen with periodic breathing

laboratories do not have the technology (and thus not even the technical expertise) to manipulate CO_2.

There is unfortunately no polysomnographic feature equivalent to CSR to suggest hypoventilation, other than disproportionate oxygen desaturation, which can have other causes, such as ventilation–perfusion mismatch. Respiratory rate may be low (contributing to hypoventilation) or high (a response to hypercapnia) and thus not be diagnostically useful in adults, though in children tachypnea during sleep can suggest disease. Patients on opiates have a relatively unique phenotype of ataxic respiration, central apnea propensity, and mild hypercapnia. I have seen rare patients with classic CSR who are hypercapnic, especially when CHF develops in a previously obese hypercapnic patient, or when advanced chronic obstructive lung disease and heart failure coexist.

Adaptive Ventilation

Adaptive servo ventilation (and ventilators, ASVs) provides expiratory support, inspiratory pressure support (PS), and backup supportive responses guided by measures of ventilation or flow averaged over several minutes [65, 66]. Treatment with ASV is better tolerated than CPAP and is effective in suppressing central apneas and improving oxygenation. Positive effects on sleep architecture are less impressive. The ASVs distort the polysomnogram respiratory signals; scoring respiratory events and using scoring to guide titration and determine treatment efficacy require understanding this distortion and the algorithms of the individual devices.

The ResMed adaptive ventilator (VPAP^{TM} Adapt SV) [67–71] provides a baseline degree of ventilatory support and an auto-EPAP in the Auto mode. The subject's ventilation is servo controlled with a high-gain integral controller (0.3 cm H_2O per L/min per second, clipped to 4–10 cm H_2O) to equal a moving target ventilation of about 90 % of the long-term average ventilation (time constant 3 min). If the subject suddenly ceases all central respiratory effort, machine support (i.e., pressure swing amplitude) will increase from the minimum of 5 cm H_2O up to whatever is required to maintain ventilation at 90 % of the long-term average (up to a maximum of 10 cm H_2O, reached in approximately 12 s). Algorithm changes will likely continue, to improve patient–ventilator synchrony, such as dealing with slow breathing rates (current backup default is 15/min) and slow rates (maximum rate at which target ventilation can rise, currently 0.01389 L/min/sec) [66].

The Philips Respironics Bilevel positive airway pressure (BiPAP) autoSV Advanced (flow-targeted dynamic bilevel positive pressure ventilator) provides PAP support to sustain upper airway patency [72–74]. The expiratory pressure automatically adjusts within the available (or prescribed) range (4–25 cm H_2O). Expiratory pressures can also be set at fixed levels if desired. The algorithm's automatic backup rate is based on calculations performed on a moving window of the last 12 spontaneous breaths. The flow-targeted dynamic BPAP device modulates the maximum and minimum PS above the expiratory positive airway pressure (EPAP) as required to maintain a target peak inspiratory airflow: When the device detects normal breathing, flow-targeted dynamic BPAP operates like conventional CPAP by providing the minimal PS; when the patient does not maintain the target peak inspiratory airflow, the device increases the PS up to a maximum inspiratory positive airway pressure (IPAP), which can be set by the user. Peak flow is captured on a breath-by-breath basis and is monitored over a moving 4-min window; as one breath is added, the initial breath falls off. At every point within this 4-min period, an average peak flow is calculated, and the peak flow target is established around that average and is based on the patient's needs.

The Weinmann SOMNOvent CR is available in Europe and combines auto and adaptive pressure [75]. The pressure is measured using a pressure sensor, snoring is calculated based on the high-frequency variations of the pressure signal, and the flow is determined based on pressure and blower parameters. The minute ventilation is compared with the average minute ventilation in a moving window and is focused by 50 % on the last 2 min and by 50 % on the previous time. The treatment mode is called *anticyclic modulated ventilation*. The device applies three pressure levels: the IPAP, which represents the pressure level during inspiration; the EPAP, which represents the pressure level in the early expiration; and the end-expiratory positive airway pressure (EEPAP). The EEPAP regulation is based on the cumulative sum of obstructions within a 2-min epoch, not on single events. During periodic hypopneas, the algorithm increases the difference between IPAP and EPAP continuously to raise the tidal volume. During hyperventilation, the difference between IPAP and EPAP is reduced and can reach CPAP level (zero difference between IPAP and EPAP). During apneas, mandatory breaths are applied automatically.

Recognition and Scoring of Respiratory Abnormality During Adaptive Ventilation

Scoring respiratory events during adaptive ventilation needs to use both the conventional flow signal and the pressure output signal from the ventilator. The flow signal reflects the new output of patient + ventilator, and the pressure signal the output to achieve ventilation. This is roughly equal and opposite the patient's abnormality. The flow and effort signals combine patient and ventilator contributions and give a

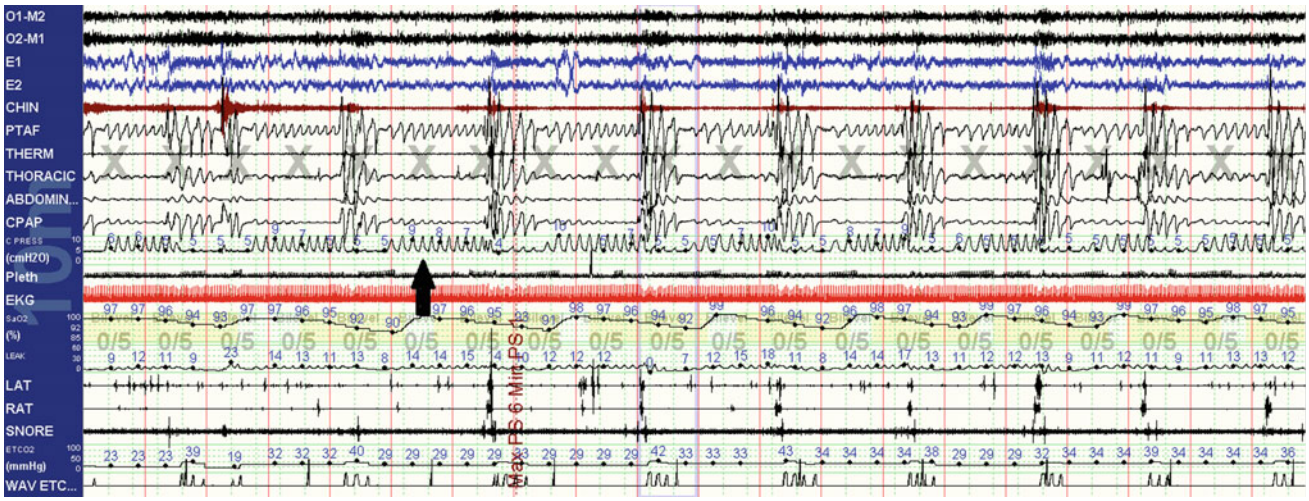

Fig. 25.8 Pressure cycling with adaptive ventilation. 5-min snapshot. The *arrow points* to typical pressure cycling of failing adaptive ventilation (CPRESS trace)

false sense of success. See Fig. 25.8 for excessive "pressure cycling," which is the response of an adaptive ventilator to ongoing periodic breathing. When pressure cycling persists, sleep fragmentation can be severe even if respiration is "improved." Speeding or slowing of the native respiration rate, hypocapnia, breath stacking (rapid ventilator delivered breath on top of the spontaneous breath), variability of expiratory duration mimicking an opiate effect are all patterns of patient–ventilator asynchrony. When the ventilator enables stable respiration, cycling between the minimum and maximum PS zone is minimal. These patterns can be see both on laboratory polysomnograms and from analysis of raw data from devices during use. Although adaptive ventilators can markedly reduce central apneas as conventionally scored, the recent results of the "Treatment of Predominant Central Sleep Apnoea by Adaptive Servo Ventilation in Patients With Heart Failure (Serve-HF)" study, where no clinical or biomarker improvements and increased mortality were noted in the ASV arm, suggest that this specific mode and machine have undesirable biological effects in chronic heart failure patients with reduced ejection fraction (≤ 45 %) and predominantly central sleep apnea [76].

Home Sleep Testing—Cardiopulmonary Recordings or Autonomic Activation-Based Approaches

The approach to score cardiopulmonary sleep measurements can be identical to conventional polysomnography, with the following differences: sleep or wake, REM, or NREM are not known, and EEG or EMG arousal phenomena are absent. Nevertheless, respiratory signal amplitude reduction, oxygen desaturation associations, event cycle time, periodic breathing, and stable breathing periods are readily identifiable, allowing generating metrics very close to conventional polysomnography. However, relatively mild respiratory disease can have substantial sleep quality impacts, and this is the obvious limitation of home sleep testing. Cardio-acceleration and finger plethysmographic amplitude reduction can be useful event tags (arousal equivalents) along with abrupt flow recovery of previously flow-limited breaths. The AASM guidelines restrict scoring to apneas and hypopneas with associated 3 or 4 % oxygen desaturation under the reasoning that arousals are not available to determine the presence or impact of arousals. However, there is ample useable surrogate information of high-probability respiratory events on home sleep testing—respiratory recovery with abrupt large amplitude breaths and associated cardioacceleration and plethysmographic amplitude reductions. There is further information in flow patterns such as plateau-like or downward sloping flow limitation and increases in duty cycles across a sequence of breaths associated with snoring and abrupt return to baseline of both features.

Autonomic tone-based devices incorporating pulse transit time into the analysis and the peripheral arterial tonometry (PAT)-based device [77–80] use the invariant sympathetic burst occurring with arousals—causing a blood pressure surge, cardio-acceleration, stiffening of the vascular tree, and reducing the amplitude of arterioles in the finger tip. The PAT device applies cuff pressure and complex algorithms that improve the precision of the pulse wave amplitude detection and integrates heart rate change, sympathovagal tone, and oximetry information to provide both

sleep quality and sleep apnea information. The analysis is automated and not readily accessible for direct visualization and manual correction if needed. Utility in phenotyping sleep apnea remains to be established (obstructive vs. central disease including periodic breathing detection). Phenotyping is more readily done currently during conventional scoring of flow and effort signals, and by spectral dispersion of low-frequency cardiopulmonary coupling [81].

Scoring Approaches to Positive Pressure Therapy Data

Flow-based and derivatives of flow data are readily available from positive pressure therapy devices [82].

Therapy Waveform Analysis—Continuous and Non-adaptive Positive Pressure Therapy

Direct visualization of data from CPAP machines (Fig. 25.9) can readily identify periods of stable and unstable breathing. It is more challenging to differentiate normal REM-related tidal volume fluctuations from obstructive hypopneas, but the absence of abrupt flow reversals and variability of rate and rhythm are suggestive of REM state effects. Periodic breathing is readily recognized, as are overt obstructive events. Differentiation of obstructive from central sleep apnea can be aided by device determination of open and closed airway apnea using forced oscillation. Individual manufacturers use different thresholds for the detection of individual events and periodic breathing, so discordance between automated detection and visual analysis is to be expected.

Waveform Analysis—Adaptive Bilevel Ventilation

The fundamental question is—what is the primary scoring channel? Adaptive ventilators by their very nature distort the respiratory signals. Thus, a maintained tidal volume can be any instantaneous proportion of patient and machine inputs, and a maintained tidal volume does not reflect biological stability of the respiratory system. However, by computing and displaying the pressure output from the adaptive ventilator, the "work" performed by the ventilator, which is targeted to be equal and opposite to the patients' respiratory output, provides the critical information required to assess efficacy. Pressure cycling reflects the need to respond to periodic breathing, and, if associated with arousals, oxygen desaturation or patient–ventilator desynchrony is marker of failure. Thus, the automatic tagging of current adaptive ventilators, which use percentage reductions in tidal volume, can overestimate success (low AHI flow in the presence of potentially disruptive pressure cycling). Scoring, manual or automated, should be based on both the tidal volume and the pressure output channels, and either one being abnormal can be used as event thresholds (similar to thermistor and nasal pressure for diagnostic polysomnography). Stable respiration in this context requires minimal pressure cycling and stable tidal volumes.

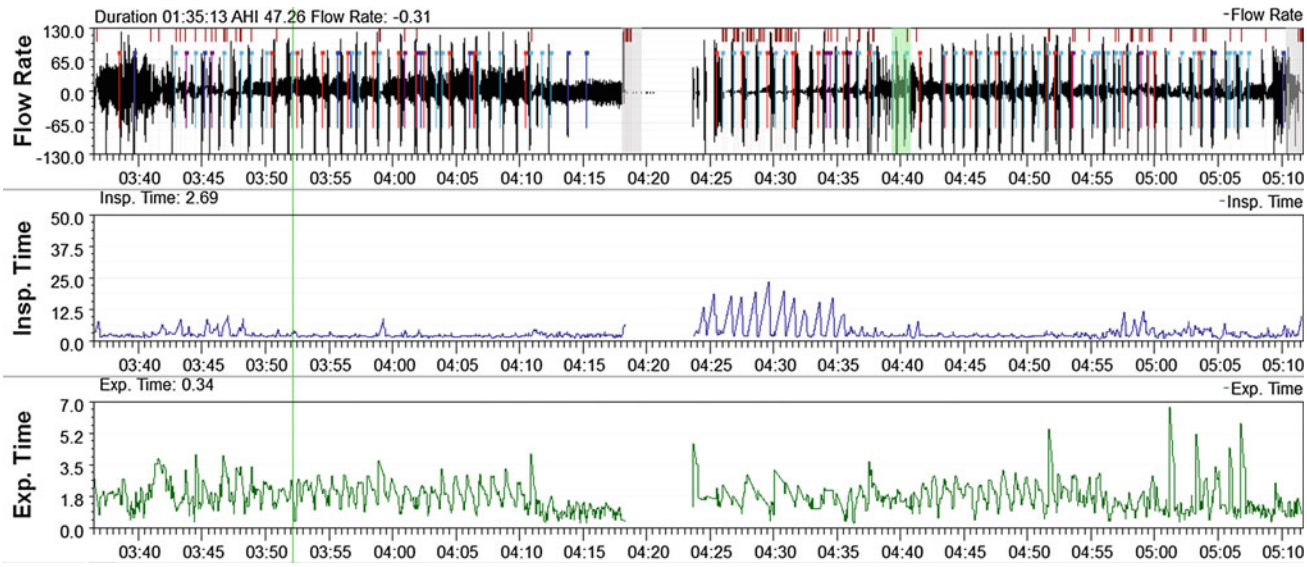

Fig. 25.9 Periodic breathing on CPAP, home therapy data. About 145 min of data. From *top* airflow, inspiratory time, and expiratory time. *Note* Repeated flow oscillations with a self-similar timing and marked variability of expiratory time across the entire period

Waveform Analysis—Ventilators

As sleep medicine specialists are increasingly drawn into the management of complex sleep ventilation problems, understanding the nature of pathology, ventilator–patient interactions, and the impact these have on device-generated and conventionally recorded signals will be needed. The SomnoNIV group has proposed criteria for the assessment of respiratory polygraphy in ventilator-dependent patients [83, 84]. Leak effects are critical in volume and adaptive ventilation more than standard continuous or bilevel ventilation. Abnormal triggering, patient–ventilator desynchrony, over-ventilation, induction of central sleep apnea, and atypical patterns of muscle activation (accessory muscle use) are only some of the challenges in this population.

Other Evidence of Suboptimal Therapy of Sleep Respiration

Several respiratory measures are likely stable in a given individual across nights. These include respiratory rate, inter-breath interval, inspiratory and expiratory time, duty cycle, and, in the case of modes with a backup rate, percentage machine- or patient-triggered breaths. Certainly, these measures "appear" stable across a night and multiple nights when viewing waveform/machine flow-based data. The commercial vendors do not provide the ability to compute such metrics, an area of development that may provide tools for improved therapeutic precision. Variability in the above-noted measures could be a sign of patient–ventilator asynchrony, instability of disease and ventilatory control, leak effects, and impact of sleep stage or state. Tracking such metrics over time may also provide early warning signals of deterioration.

Summary

Scoring of respiratory events using rigid criteria is often practical and pragmatic, but does not sufficiently capture the dynamic range of pathology in sleep-disordered breathing diagnosis and therapy. The AASM guidelines should be considered a minimum expectation, but is insufficient for research and identifying all valuable phenotypes. Scoring RERA's and periodic breathing should not be considered optional. Testing the usefulness of some of the ideas discussed in the chapter may move the field to more precise and biologically meaningful qualitative and qualitative metrics, including that driven by computational analysis. If treatment outcomes can be improved, new and old approaches can usefully coexist and inform each other in moving the art and science of sleep respiratory scoring forward.
