OP 1
Pathogenesis of NIDDM

1

PATHWAYS OF WHOLE BODY GLUCOSE DISPOSAL AFTER FASTING

F. Féry, L. Plat and E.O. Balasse, University of Brussels, Brussels, Belgium.

In order to identify the effects of prior fasting on the pathways of insulin-stimulated glucose disposal, 6 normal volunteers underwent in random order and at 3 weeks interval two 4-h euglycemic hyperinsulinemic (100 μU/ml) clamps, one after an overnight fast, the other after 4d of fast. Each test included the measurments of (1) total glucose turnover (3-^{3}H-glucose infusion); (2) glycolytic rate (^3H_2O production); (3) circulating glucose oxidation (U-^{14}C-glucose infusion with measurement of $^{14}CO_2$ output); (4) total carbohydrate oxidation and net carbohydrate balance (indirect calorimetry). Fasting was associated with a significant reduction in glucose disposal rate (- 48 ± 6 %; P < 0.001), glycolytic flux (- 49 ± 2 %; P < 0.001), glycogen synthesis via the direct pathway (- 44 ± 13 %; P < 0.02), glucose oxidation (- 57 ± 3 %; P < 0.001), nonoxidative glycolysis (- 36 ± 4 %; P < 0.001) and total carbohydrate oxidation (- 87 ± 4 %; P < 0.001). Net carbohydrate balance was maintained (- 13 ± 14 %; NS), and fat oxidation was increased 6-fold. In 5 additional subjects, the experimental protocol was modified (identical rates of glucose infusion for both tests + pancreatic clamp) so that fasted subjects had the same glucose disposal rate as the nonfasted through the intervention of hyperglycemia. Under these conditions, prior fasting stimulated glycogen synthesis (+ 30 ± 4 %; P < 0.005) and inhibited glycolysis (- 27 ± 5 %; P < 0.01) in relation to a decrease in oxidation (- 40 ± 4 %; P < 0.001) with no change in nonoxidative glycolysis (- 1 ± 14 %; NS). Results of these two series of experiments suggest that in normoglycemia, the main effect of fasting is to inhibit insulin-mediated glucose transport-phosphorylation. When a normal glucose disposal is restored through hyperglycemia, fasting stimulates glycogen synthesis and inhibits glycolysis mainly in its oxidative component. These effects tend to optimize glucose carbon retention.

2

NORMALIZATION OF SKELETAL MUSCLE BLOOD FLOW DOES NOT IMPROVE GLUCOSE UPTAKE IN OBESITY

H. Laine, H. Yki-Järvinen, M. Raitakari, J. Knuuti, P. Nuutila. Universities of Turku and Helsinki, Finland

Defects in insulin stimulation of blood flow have been suggested to contribute to insulin resistance of glucose uptake. To directly examine whether amelioration of a blood flow defect in obesity reverses insulin resistance in obesity, we studied 7 obese (age 26±1 years, BMI 36±1 kg/m^2) and 7 nonobese males (age 25±2, BMI 22±1). Muscle blood flow was increased in one leg by an intrafemoral artery infusion of bradykinin (48 μg to obese, 27 μg to normal subjects over 100 min) during normoglycemic hyperinsulinemic (insulin infusion rate 1 mU·kg^{-1}·min^{-1}) conditions. Blood flow was measured in both legs before and during hyperinsulinemia using [^{15}O]-labelled water and positron emission tomography (PET). Glucose uptake was measured immediately thereafter using [^{18}F]-fluoro-deoxy-glucose and PET. Basal muscle blood flow was lower in the obese (1.5±0.1 ml·kg^{-1}muscle·min^{-1}) than in the nonobese (2.1±0.3, ml·kg^{-1}muscle·min^{-1}, p<0.05). During hyperinsulinemia, glucose uptake in the control leg was 63 % lower in the obese (21±5 μmol·kg^{-1}muscle·min^{-1}) than in the nonobese (56±10 μmol·kg^{-1}muscle·min^{-1}, p<0.01). Bradykinin increased blood flow in the obese to a level (3.0±0.4 ml·kg^{-1}muscle·min^{-1}) which exceeded flow in the control leg in the nonobese (2.4±0.5 ml·kg^{-1}muscle·min^{-1}). Despite this, glucose uptake was unaltered in the bradykinin infused leg (19.4±4.6 μmol·kg^{-1}muscle·min^{-1}) compared to the control leg (20.9±5.0 μmol·kg muscle^{-1}·min^{-1}) in the obese. In the nonobese subjects, bradykinin increased flow by 58 % (3.8±0.9 vs 2.4±0.5 ml·kg^{-1}muscle·min^{-1}, p<0.005) but had no effect on muscle glucose uptake (58±11 vs 56±10 μmol·kg^{-1}muscle·min^{-1}). These data demonstrate that normalization of blood flow in skeletal muscle of obese subjects has no effect on insulin stimulated glucose uptake.

3

MYOCARDIUM IS NOT RESISTANT TO THE EFFECT OF INSULIN TO INCREASE GLUCOSE UPTAKE IN NIDDM

***T. Utriainen, P. Nuutila, T. Takala, T. Rönnemaa, M. Luotolahti, and H. Yki-Järvinen.* Universities of Turku and Helsinki, Finland**

Insulin resistance of skeletal muscle glucose uptake characterizes patients with non-insulin-dependent diabetes mellitus (NIDDM). It is, however, unclear whether the myocardium also is affected by insulin resistance. We used [^{18}F]-2-deoxy-glucose combined with positron emission tomography to quantitate skeletal muscle and myocardial glucose uptake, and the euglycemic insulin clamp technique (5 mU/kg·min insulin infusion) to measure whole body glucose uptake in patients with NIDDM (n = 10, HbA_{1c} 8.1 ± 0.5%, age 43 ± 2 yrs, BMI 27 ± 1 kg/m^2) and in normal subjects (CTRL, n = 7, age 47 ± 2 yrs, BMI 26 ± 1 kg/m^2). All patients had a normal exercise test and resting ECG. In patients with NIDDM, rates of whole body (35 ± 3 *vs* 44 ± 3 μmol/kg body weight·min, NIDDM *vs* CTRL, p < 0.05) and skeletal muscle (71 ± 6 *vs* 96 ± 7 μmol/kg muscle·min, respectively, p < 0.02) glucose uptake were significantly decreased. However, no significant difference was found in myocardial glucose uptake (761 ± 82 *vs* 672 ± 63 μmol/kg muscle·min, respectively, p = 0.4). Myocardial glucose uptake was positively correlated with the left ventricular wall stress (r = 0.47, p < 0.05) and inversely with the ejection fraction (r = -0.61, p < 0.01) and stroke volume (r = -0.54, p < 0.05). There was no correlation between myocardial, and skeletal muscle (r = 0.05) or whole body (r = 0.00) glucose uptake. Serum FFA concentrations were comparable during the insulin infusion (205 ± 23 *vs* 168 ± 23, NS). We conclude that skeletal muscle and heart insulin resistance do not coexist in patients with NIDDM.

4

ANALOG EFFECTS OF FDG IN HUMAN SKELETAL MUSCLE: PHYSIOLOGIC IMPLICATIONS OF INSULIN INDUCED REDUCTIONS OF "LC"

D. Kelley, J. Price, J. Beattie, B. Lopresti, B. Goodpaster, S. Andreko and F. Jedali. University of Pittsburgh, Pittsburgh, Pennsylvania, US

Though positron emission tomography (PET) imaging of 18-fluoro-deoxy glucose (FDG) metabolism in skeletal muscle offers the potential to examine *in vivo* regulation of transport and phosphorylation, delineation of analog effects of FDG *vis a vis* glucose for human skeletal muscle has not been examined across a range of insulin doses. In general, FDGis transported more avidly but phosphorylated less efficiently than glucose; the lump constant (LC) expresses the net effect, each step weighted by its relative role in controlling glucose metabolism. To examine whether the LC in human skeletal muscle is altered by insulin, 16 lean healthy volunteers underwent simultaneous measurements of leg glucose uptake (A-V * blood flow) and 90 min dynamic PET imaging of FDG uptake at euglycemic insulin infusions rates of 0, 20, 40, and 120 mU/m2-min; (n=4 per dose). Insulin induced a highly significant (p<0.001) 4-fold step-wise decrement in LC. Net glucose influx (K) determined by PET was correlated with LGU (r=0.78, p<0.01) and K was identical whether calculated by Patlak analysis or derived from 3-compartmental modeling of dynamic tissue activity (r=0.99,p<0.01). Insulin stimulated an increase in the volume of distribution of FDG in muscle (K1/k2 ratio), and dose-dependent increases of the phosphorylation fraction (PF=k3/ (k2+k3);p<0.001). In step-wise multiple regression, K1/k2 and k3 accounted for 90% of individual variance in LGU. In summary, insulin stimulates a decrement in the LC for FDG; a physiologic implication being that insulin progressively induces re-alignment in the locus of control of glucose metabolism in skeletal muscle toward glucose phosphorylation, an interpretation further supported by the incremental insulin stimulation of PF.

5

EFFECTS OF PRIOR PROTEIN MALNUTRITION ON GLUCOSE INTOLERANCE AFTER HIGH-ENERGY/HIGH-FAT FEEDING

M.J. Holness, Department of Biochemistry, Basic Medical Sciences, Queen Mary & Westfield College, London University, London, UK

Impaired pancreatic development during early life may predispose individuals to the development of glucose intolerance and non-insulin-dependent diabetes in later life, particularly if nutrition is inappropriate. The present study investigated whether impaired pancreatic development induced by exposure to suboptimal protein nutrition during early life exacerbated the development of glucose intolerance in response to the provision of a high-energy/high-fat (HEF) diet of normal protein content. Rats were exposed to either a standard (20% protein) diet (control, C) or a low (8%) protein diet (LP) during fetal life, early development and after weaning. At 20 weeks of age, both C and LP groups were transferred to HEF diet. After 8 weeks HEF feeding, glucose tolerance was assessed after an i.v. glucose load (0.5 mg/kg body wt.) in conscious, unstressed rats. HEF feeding elicited 24% (n.s.) and 53% ($P<0.05$) increases in incremental areas under the curve (IAUC values) for glucose in the C and LP groups respectively. The rate of glucose disappearance (K value, calculated from data obtained between 2 and 15 min after the intravenous glucose load) was unaffected by HEF feeding in the C group, but there was a 40% ($P<0.05$) decline in the K value for LP rats. The study therefore demonstrates that exposure to a high-fat/high-energy diet for a prolonged (8 week) period leads to greater loss of glucose tolerance in rats exposed to suboptimal protein nutrition in early life.

6

ANALYSIS OF PPARγ, C/EBPα, GLUT4, LPL AND *OB* mRNA LEVELS IN ADIPOSE TISSUE OF RHESUS MONKEYS.

K. Hotta, T. A. Gustafson, S. Yoshioka, H. K. Ortmeyer, N. L. Bodkin, B. C. Hansen. University of Maryland, Baltimore, MD, USA

Many, but not all, rhesus monkeys (*Macaca mulatta*) become obese after sexual maturation. Obesity is usually associated with insulin resistance and hyperinsulinemia, and NIDDM often develops at a later stage. Peroxisome proliferator-activated receptor γ (PPARγ) and CCAAT/enhancer-binding protein α (C/EBPα) coordinate the expression of genes involved in creating and maintaining the adipocyte phenotype such as GLUT4 glucose transporter. We measured the mRNA levels of PPARγ, C/EBPα, lipoprotein lipase (LPL), GLUT4 and *ob* in adipose tissue to examine whether these genes were differentially expressed in normal, obese hyperinsulinemic and NIDDM monkeys. The levels of mRNAs were quantitated by slot blot hybridization analysis. For probes, the cDNA fragments were amplified from monkey adipose tissue RNA and cloned. The mRNA levels of PPARγ, LPL and GLUT4 were approximately 2-fold higher in normal monkeys compared with obese hyperinsulinemic and NIDDM monkeys ($p's<0.05$). We observed no differences between hyperinsulinemic and NIDDM monkeys. In contrast, the level of *ob* mRNA was highest in hyperinsulinemic monkeys ($p<0.05$). In addition, LPL, GLUT4 and C/EBPα mRNA levels were significantly correlated to PPARγ mRNA levels (C/EBPα; $r=0.775$, LPL; $r=0.888$, GLUT4; $r=0.945$, $p's<0.001$). In contrast, *ob* mRNA levels were not related to PPARγ mRNA. Our data suggested that continued high-level expression of mRNAs of PPARγ, C/EBPα, LPL and GLUT4, levels may not be required for the maintenance of the obese or NIDDM states and that expression levels of PPARγ, C/EBPα, LPL and GLUT4, but not the *ob* gene, are highly coordinated.

7

IMPAIRED EFFECT OF INSULIN ON BOTH GLUCOSE TURNOVER AND LIPOLYSIS IN NIDDM RELATIVES

JW Eriksson[1], M Elam[2], U Smith[3], P Lönnroth[3] and P-A Jansson[3]. [1]Dept of Medicine, Umeå University, [2]Dept of Clinical Neurophysiology and [3]the Lundberg Laboratory for Diabetes Research, Göteborg University, Sweden.

To elucidate early mechanisms in the pathogenesis of NIDDM we studied 10 young healthy individuals with two first-degree relatives with NIDDM (**R**) and 10 control subjects (**C**) pairwise matched for sex (M/F 4/6) age (35±1 vs 35±1) and BMI (23.6±0.6 vs 23.2±0.4). During a euglycemic clamp at two insulin levels (**L**ow~20 and **H**igh~90 mU/L) glucose turnover was assessed and abdominal subcutaneous adipose tissue (SAT) lipolysis and blood flow were studied with microdialysis and ^{133}Xe-clearance. Fasting glucose, insulin and C-peptide levels were similar in **R** and **C**. During the clamp, insulin sensitivity index for glucose disposal was lower ($P<0.03$) in **R** than **C** (**L** 12.0±1.6 vs 18.1±1.4, **H** 9.4±0.8 vs 12.9±0.6 (100*mg*L/mU/min)) and this was partly attributed to slightly higher insulin concentrations in **R** ($P<0.05$) indicating an impaired insulin clearance. SAT lipolysis measured as local glycerol release did not differ under basal conditions (2.0±0.2 vs 2.1±0.2 μmol/kg/min), but the inhibition during insulin infusion was attenuated in **R** compared to **C** (glycerol release: **L** 0.92±0.09 vs 0.68±0.16, **H** 0.71±0.10 vs 0.34±0.10 $P<0.03$). Plasma FFA also tended to be higher in **R** than **C** (basal 498±27 vs 483±41 μmol/L, **L** 145±37 vs 94±19, **H** 77±24 vs 55±18, NS). In contrast, isolated subcutaneous adipocytes obtained through needle biopsies displayed no differences between **R** and **C** with respect to in vitro effects of insulin on ^{14}C-glucose uptake or lipolysis. Moreover, muscle sympathetic nerve activity (MSA) was assessed with microneurography of the peroneal nerve. Under resting conditions no difference was found (**R** 27±4 and **C** 31±4 bursts/min) whereas the increase in activity during a standardized stress test (immersion of one hand in ice-cold water) was clearly higher in **R** than in **C** (364±152 vs 150±15 %, $P<0.05$). **Conclusion:** Resistance to insulin action in vivo on both glucose turnover and lipolysis is an early feature in the development of NIDDM. This may in part be caused by neural or humoral factors. An enhanced sympathoadrenal activity, which impairs insulin action, may play a role.

8

METABOLIC IMPACT OF FAMILY HISTORY OF NIDDM

A. Vaag, L. Groop, P. Thye-Rönn and M. Lehtovirta, for the European Group for the Study of Insulin Resistance (EGIR). University of Lund, Malmö and Lund, Sweden.

Some previous studies found evidence of insulin resistance in non-diabetic relatives of NIDDM patients, while others did not. However, the numbers of subjects in previous studies were relatively small, and different techniques were used to measure insulin action. The euglycaemic hyperinsulinaemic clamp represent the "golden standard" technique for measuring insulin action. EGIR data base contain measurements of insulin action using the insulin clamp technique (1mU/kg/min) in normal glucose tolerant subjects from 20 European centers. The aim of this study was to determine the impact of family history of NIDDM on insulin action, and on glucose and lipid oxidation, based on the EGIR data base. Family history of NIDDM was positive in 235 (FH+) and negative in 564 individuals (FH-) respectively. BMI was slightly higher in FH+ compared with FH- (26.7±0.3 vs 25.8±0.2 kg/m^2, $p<0.02$). Age, waist-to-hip ratio, lean body mass, weight and height were similar in FH+ and FH-. After correction for covariates according to differences between investigators and subject characteristics including BMI (ANOVA), insulin stimulated glucose disposal was lower in FH+ vs FH- (30.3±0.6 vs 34.3±0.4 μmol/kg/min, $p<0.00001$). Despite this, insulin stimulated glucose oxidation (as determined using indirect calorimetry in some individuals) was elevated in FH+ vs FH- (16.3±0.5 vs 14.9±0.3 μmol/kg/min, $p<0.05$, N=76 vs 213). Consequently, insulin stimulated non-oxidative glucose metabolsim (= disposal - oxidation) was markedly reduced in FH+ vs FH- (15.2±0.9 vs 20.0±0.5 μmol/kg/min, $p<0.0005$, N=76 vs 213). After adjusting for BMI, basal lipid oxidation was lower in FH+ vs FH- (3.1±0.1 vs 3.5±0.1 μmol/kg/min, $p=0.05$, N=76 vs 181). Basal glucose oxidation and insulin stimulated lipid oxidation rates were similar in FH+ and FH-. In conclusion, insulin resistance is present in European non-diabetic relatives of NIDDM patients. The insulin resistance is restricted to the pathway of non-oxidative glucose metabolism, whereas insulin stimulated glucose oxidation is compensatorily increased in some NIDDM relatives. The tendency to obesity in NIDDM relatives may be increased by a lower oxidation of fat.

Insulin Secretion in Vitro: Ion Channels and Oscillation

9

REGULATION OF FREE Ca^{2+} IN NON-MITOCHONDRIAL STORES OF INDIVIDUAL PANCREATIC ß-CELLS.

A. Tengholm, E. Gylfe and B. Hellman. Department of Medical Cell Biology, University of Uppsala, Sweden.

To study the regulation of intracellular Ca^{2+} stores, single mouse pancreatic ß-cells were loaded with the low-affinity Ca^{2+}-indicator furaptra and permeabilized with digitonin to release cytoplasmic dye. After permeabilization, the 340/380 nm fluorescence excitation ratio was stable, corresponding to a free Ca^{2+} concentration ($[Ca^{2+}]$) of 249±10 µmol/l (n=84) in the presence of 3 mmol/l ATP and 200 nmol/l Ca^{2+}. The ratio was insensitive to ruthenium red and changes in the Mg^{2+} concentration in the 0.1-1 mmol/l range. Moreover, removal of ATP or Ca^{2+} resulted in a marked and sustained decrease, indicating that the signal reflects changes of $[Ca^{2+}]$ in non-mitochondrial ATP-dependent stores. More than 90% of the stored Ca^{2+} was released by the intracellular Ca^{2+}-ATPase inhibitor thapsigargin, the rest being mobilized by omission of ATP or addition of Br-A23187. Inositol-1,4,5-trisphosphate (IP_3) mobilized Ca^{2+} in a dose-dependent manner, releasing 52± 4% of the thapsigargin-sensitive Ca^{2+} at a maximally stimulating concentration (10 µmol/l). It was possible to differentiate between various Ca^{2+} stores on the basis of their resistance to digitonin treatment. After plasma membrane permeabilization, prolonged exposure to the detergent resulted in a further release of furaptra. In 5 of 9 cells this release resulted in a decrease of both IP_3-sensitivity and $[Ca^{2+}]$. In the remaining cells the IP_3 sensitivity persisted while $[Ca^{2+}]$ increased, probably reflecting loss of furaptra from a store with low $[Ca^{2+}]$. It is concluded that the pancreatic ß-cell exhibits at least two non-mitochondrial ATP-dependent Ca^{2+} stores differing with regard to their sensitivity to IP_3.

10

HUMAN α ENDOSULFINE, ENDOGENOUS LIGAND FOR THE SULFONYLUREA RECEPTOR: CLONING AND EXPRESSION.

L. HERON, K. PEYROLLIER, A. VIRSOLVY, A. LE CAM, D. BATAILLE. INSERM U376, Montpellier, France.

Endosulfine, the endogenous ligand for the sulfonylurea receptor, exists under two molecular forms, α and ß. We have isolated from porcine brain the 13KDa α form which presents strong structural similarities with a bovine 12-13KDa cyclic AMP-regulated phosphoprotein, called ARPP-19. Based on the sequence of a partial cDNA clone coding for bovine α endosulfine, we have shown recently that α endosulfine and ARPP-19 are distinct molecular entities. In the present studies, we used primers derived from the known structures in heterologous species to amplify by PCR a 233 bp human cDNA fragment. This fragment was then used as a probe for cloning the full length cDNA from a human brain λGT11 library. We confirm that α endosulfine and ARPP-19 are distinct proteins, encoded by different genes, with a 71% degree of identity in their aminoacid sequences. We have expressed α endosulfine in a bacterial system and compared its properties to those of the protein isolated from porcine brain. The recombinant and the extracted proteins display the same qualitative and quantitative features in inhibiting the binding of [^{3}H]-glibenclamide to both rat cortex and ß cell membranes. Mutational studies and enzymatic fragmentation of the recombinant protein are now being carried out to determine the molecular moiety required for interaction with the sulfonylurea receptor. Considering the importance of the sulfonylurea receptor/K-ATP channel complex in regulating insulin secretion and action, our results open up a new avenue of research on the biological role of the now complete endosulfine-receptor-channel regulatory system. It will also be of interest to look for mutations in the human α endosulfine coding sequence in various pathological states, particularly in non-insulin dependent diabetes.

11

INTERACTIONS BETWEEN TOLBUTAMIDE AND NUCLEOTIDES ON CLONED K-ATP CHANNELS.

FM Gribble, SJ Tucker and FM Ashcroft. University Laboratory of Physiology, Oxford, UK

Sulphonylureas stimulate insulin secretion by blocking ATP-sensitive K-channels (K-ATP channels). It has previously been shown that intracellular MgADP enhances the sensitivity of K-ATP currents to tolbutamide (Schwanstecher et al., 1994 Br. J. Pharmacol. 111,302). The aim of this study was to investigate the molecular basis of this effect. The K-ATP channel comprises 2 types of subunit: Kir6.2 and the sulphonylurea receptor (SUR1). Mutations in the nucleotide binding domains of SUR1 (K719A/K1385M) abolish the activation of K-ATP currents by MgADP but do not alter the inhibitory effects of nucleotides (ATP or ADP). We therefore examined the effect of these mutations on the modulation of tolbutamide sensitivity by MgADP. We expressed Kir6.2 with wild-type SUR1 or mutant SUR1 (K719A/K1385M) in *Xenopus* oocytes, and measured K-ATP currents in giant inside-out patches. In the absence of nucleotides, tolbutamide dose-inhibition curves for wild-type and mutant currents suggested the presence of 2 binding sites, with K_i of 1.6 µM (0.6-4.5) and 1.8 mM (1.3-2.5) (n=8; geometric mean (SD range)). High-affinity binding reduced the current by ~50%. In the absence of tolbutamide, 100µM MgADP enhanced wild-type K-ATP currents by 55 ± 13% (n=5; mean ± SEM). Tolbutamide inhibited MgADP-activated currents and at >20 µM tolbutamide, K-ATP currents were smaller than in the absence of MgADP. MgADP did not significantly alter the K_i for tolbutamide at either binding site. 100µM MgADP reduced mutant currents (by 68 ± 3%, n=5), without otherwise affecting the tolbutamide dose-response curve. We conclude that, in oocytes, tolbutamide inhibits K-ATP currents by interacting with 2 separate binding sites. Further, the enhancement of tolbutamide block by MgADP is apparent rather than real: it results from tolbutamide, acting at the high-affinity site, producing a dose-dependent inhibition of MgADP-induced activation. At high tolbutamide concentrations this is sufficient to unmask the inhibitory action of MgADP.

12

FREQUENCY OF SUR1 AND KIR6.2 MUTATIONS ASSOCIATED WITH FAMILIAL HYPERINSULINISM (HI)

A.Nestorowicz, P.Behn, B.Glaser. B.A.Wilson, K.P.Schoor, H.Landau, C.A. Stanley, P.S.Thornton, M.A.Permutt. Washington University, St. Louis, USA.

The islet β-cell ATP regulated K^+ channel is composed of 2 subunits, the sulfonylurea receptor (SUR1) and the small inward rectifier K^+ channel (Kir6.2). HI is an autosomal recessive disease associated with function-altering mutations in either of these two genes. To define the spectrum of genetic defects in a large heterogeneous group of HI patients, 78 probands were screened for SUR1 (39 exons) and Kir6.2 (1 exon in 6 fragments) mutations by single strand conformation polymorphism analysis (SSCP). Variants were confirmed by direct sequencing and by PCR-RFLP analysis of genomic DNA. Nineteen mutations were found in SUR1, including 4 frameshift, 1 nonsense, 9 missense and 5 intronic mutations. The missense mutations were at highly conserved regions, and some were found to produce functional disruptions. One nonsense mutation was found in Kir6.2. A total of 103 HI probands were then screened by PCR-RFLP assays developed for each mutation. Two of the SUR1 variants, accounting for ~90% of HI, were found in the 36 Ashkenazi Jewish probands, with 15 homozygotes, 8 compound heterozygotes, and 11 simple heterozygotes. Of 9 Arab probands 2 were homozygous and 1 was heterozygous for different SUR1 mutations, and 1 was homozygous for a Kir6.2 mutation. In 29 Northern European Caucasian HI probands, 2 compound heterozygotes and 6 simple heterozygotes were found. Combined results of 36 other probands from other ethnic backgrounds yielded 3 homozygotes, 2 complex heterozygotes, and 4 simple heterozygotes. Except for the 2 mutations found commonly in the Ashkenazi Jewish patients, all others were private mutations which were found in the homozygous state only in consanguineous families. In summary, mutations were found in SUR1 in 34/36 (95%) Ashkenazi HI patients, while they were found in SUR1/Bir6.2 in 21/74 (28%) patients from other populations. Functional analysis of the missense mutations will provide important new information on the structure/function relationships of the islet KATP channel.

13

POTASSIUM CURRENTS IN NORMAL AND DEFECTIVE HUMAN B-CELLS.

C. Ämmälä, K. Cosgrove, R.F.L. James, A. Aynsley-Green, K.J. Lindley and M.J. Dunne. Department of Biomedical Science, University of Sheffield, Sheffield, UK, Department of Surgery, Leicester Royal Infirmary, Leicester, UK and Institute of Child Health & Great Ormond Street Hospital for Children, London University, London, UK.

K_{ATP} channels have a key role to play in depolarization-response coupling of insulin release. In β-cells these channels are composed of the subunits, SUR1 and $K_{IR}6.2$. Mutations in the genes encoding these proteins cause altered β-cell function in humans leading to persistent hyperinsulinaemic hypoglycaemia of infancy (PHHI); a disorder associated with hypersecretion of insulin in infancy. In this study we have examined for the first time recordings of patch-clamp whole-cell K^+ currents in β-cells isolated from two patients with PHHI and compared these with the properties of normal human insulin-secreting cells *in vitro*. Control tissue was obtained from cadaveric organ donors, and PHHI β-cells isolated from the pancreas following surgery to alleviate hypoglycaemia. Three series of experiments were performed under standard whole-cell electrophysiological conditions. First, when cells were dialysed with an 'ATP-free' solution, this led to a marked increase in K_{ATP} channel currents in normal tissue due to wash-out of endogenous ATP(n=8), but the procedure was without significant effect in PHHI β-cell experiments (n=16). This alludes to an alteration in the function of K_{ATP} channels. Secondly, when 'ATP-containing' solutions were used in parallel experiments, no increase in K_{ATP} currents was obtained upon dialysis of normal β-cells (due to the presence of ATP) and K_{ATP} channels were by activated by diazoxide (0.5mM) and inhibited by the tolbutamide (0.5mM) (n=4). By contrast, diazoxide, tolbutamide and somatostatin (0.1mM) were all without effect in PHHI β-cell experiments (n=9). Finally, outward K^+ current recordings were used to assess the function of two K^+ channels in PHHI β-cells - the large conductance K_{Ca} channel and the delayed-rectifier K^+ channel. These channels were activated by a depolarisation, and their pharmacological properties assessed by TEA^+ (20mM) and quinine (0.01mM). There were no significant alterations in the properties of these channels in PHHI β-cells (n=11). We conclude that loss of function in β-cells of PHHI patients is specific to a defect in K_{ATP} channel activity.

14

'KNOCK-OUT' OF K_{ATP} CHANNEL ACTIVITY IN HUMAN β-CELLS: IMPLICATIONS FOR STIMULUS-SECRETION COUPLING.

M.J. Dunne, C. Kane, R.M. Shepherd, C. Ämmälä, R. James, L. Aguilar-Bryan, A. Pallet, N. Morgan, A. Aynsley-Green and K. Lindley. Biomedical Science, Sheffield University, UK, Surgery Department, Leicester University, UK, Baylor College, Houston, USA, Biological Sciences, Keele University, UK, Institute of Child Health, London University, UK.

Depolarization-response coupling mechanisms in β-cells are dependent upon the function of K_{ATP} channels, which are composed of two subunits $K_{IR}6.2$ and SUR1. Here, we have isolated intact islets from two neonates with persistent hyperinsulinaemic hypoglycaemia of infancy (PHHI) and studied the functional properties of β-cells *in vitro*. Both children were from families with a previous history of PHHI and both were unresponsive to medical therapy, necessitating a near-total pancreatectomy to alleviate hypoglycaemia. Post-operatively islets were isolated from the tissue. Analysis of genomic DNA from both patients revealed a mutation in exon 35 (G1398A) of the SUR1 gene, which is predicted to truncate the second nucleotide binding fold of SUR1. Patch-clamp studies of isolated β-cells revealed an absence of K_{ATP} channels in both children and the appearance of Ca^{2+}-dependent action potentials at rest (n=34). Diazoxide (200-500μM) had no effect on either K^+ currents (n=8), or changes in cytosolic Ca^{2+} (n=10) when measured by microfluorimetry with fura-2 loaded cells. The loss of K_{ATP} channel activity was confirmed in reconstitution studies using an engineered mutation in SUR1, which when expressed with $K_{IR}6.2$ in COS cells, failed to reconstitute functional K_{ATP} channels as assayed by $^{86}Rb^+$ efflux (n=4). By measurements of membrane capacitance from isolated PHHI β-cells, we found that exocytosis of secretory granules was augmented by a rise in intracellular Ca^{2+} (n=8) and that this was *inhibited,* and not stimulated as in normal β-cells by the sulphonylurea tolbutamide (5-100μM) (n=11). Finally, by directly measuring insulin secretion from intact islets using radioimmunoassay, we found that glucose (20mM) promoted insulin release: a response that occurs despite the absence of functional K_{ATP} channels, and the inability of glucose to elevate $[Ca^{2+}]_i$ (n=10). In summary, our data show how β-cells are severely compromised by a gene mutation in SUR1 and that glucose-induced secretion of insulin can also occur via non-Ca^{2+}-dependent mechanisms.

GLUCOSE- AND SULPHONYLUREA-EVOKED PULSATILE INSULIN RELEASE FROM SINGLE ISLETS AS DETECTED BY 5-HT MICROAMPEROMETRY

L.M. Rosário[1,2], A.M. Silva[1,3], C.M. Antunes[1], A.R Tomé[1,2], R.M. Santos[1,2] and R.M. Barbosa[1,4]. [1]Centre for Neurociences of Coimbra; [2]Dept. Biochemistry, Fac. of Sciences and Technology, University of Coimbra; [3] UTAD, Vila Real; [4]Fac. of Pharmacy, University of Coimbra, Portugal.

Pancreatic islets secrete insulin in a pulsatile fashion in response to a rise in glucose concentration. However, previous insulin measurements have had minimal temporal resolution and consequently little is currently known about the true dynamics and metabolic requirements of the oscillatory signalling pathway encoding for bursts of exocytotic secretion. Using simultaneous real time measurements of cytosolic free calcium ($[Ca^{2+}]_i$) and pre-loaded 5-hydroxytryptamine (5-HT) release as an electrochemical marker of insulin secretion from single mouse islets, we show that glucose (11-20 mM)-stimulated islets secrete 5-HT/insulin in a pulsatile fashion under physiologic conditions, and that this activity is, for the most part, encoded by regular high-frequency (1-6 min-1) $[Ca^{2+}]_i$ oscillations. The amount of 5-HT/insulin secreted per cycle bears a linear relationship with the duration of the underlying $[Ca^{2+}]_i$ oscillation regardless of the glucose concentration in the range 11-20 mM. In addition, we demonstrate the occurrence of low-frequency variations in global 5-HT/insulin release (0.2-0.5 min^{-1}), supported by intermittent high-frequency oscillations. Tolbutamide (100 μM) evokes pulsatile 5-HT/insulin release transiently in the absence of glucose, in spite of the fact that it triggers sustained (but brief) $[Ca^{2+}]_i$ oscillations. Pulsatile 5-HT/insulin release can, however, be reactivated following reintroduction of glucose, which enhances the duration of the $[Ca^{2+}]_i$ oscillations. We conclude that pulsatile insulin release is stringently dependent upon the dynamics of the $[Ca^{2+}]_i$ oscillations. In the case of sulphonylureas, the effectiveness of the latter requires minimum metabolic input (presumably through metabolic activation of voltage-sensitive Ca^{2+} channels).

16

IN HUMANS AT LEAST SEVENTY-FIVE PERCENT OF OVERALL INSULIN SECRETION ARISES FROM PUNCTUATED HIGH-FREQUENCY INSULIN SECRETORY BURSTS

N. Pørksen, B. Nyholm, K.Y. Hove, J.D. Veldhuis, P.C. Butler and O. Schmitz. Medical Department M, Aarhus University Hospital, Aarhus, Denmark, Department of Medicine, Charlottesville, VA, and Department of Medicine, The University of Edinburgh, Edinburgh, Scotland.

Insulin is secreted in a pulsatile manner, resulting in small oscillations in its circulating concentrations. Detection of insulin secretory bursts in the peripheral blood is hampered by hepatic insulin extraction, dilution and a time-delayed damping of the amplitude. To examine human pulsatile insulin release we used a high-sensitivity, specificity and precision insulin ELISA, and optimized an established deconvolution methodology to quantify the frequency, mass and amplitude of insulin secretory bursts, as well as estimate the relative contribution of pulsatile insulin release. Four protocols were performed. 1) Insulin kinetics were determined following intravenous insulin bolus injection. 2) Criteria for detecting insulin secretory pulses were refined through analysis of insulin concentrations resulting from repetitive assay of pooled plasma, and from sampling during ablated insulin secretion and a constant insulin infusion. 3) Optimal sampling intensity was examined by sampling every 30 seconds and performing pulse analysis using the uncensored series, and every second, fourth or sixth sample. 4) The above defined optimal parameters were applied to 20 healthy humans to examine pulsatile insulin secretion during glucose stimulation (4.5 mg/kg/min). Using minutely sampled insulin concentrations measured by highly sensitive insulin ELISA, and insulin kinetics of 2.8 minutes (first half life), 5.0 minutes (second half life) and a fractional slow component of 0.28, the deconvolved insulin secretion rates could be resolved into a series of high frequency (4.7 ±0.1 minute/pulse) approximately symmetric insulin secretory bursts with a mean mass of 87 ±12 pmol/L/pulse and a mean amplitude of 35 ±4.7 pmol/L/minute. The relative contribution of pulsatile to overall insulin secretion was 75 ±1.6% (range 59 to 85%). We conclude that human insulin secretion during glucose stimulation consists of a series of insulin secretory bursts accounting for at least 75% of total insulin secretion.

IDENTIFICATION OF MUTATIONS IN THE HNF-1α GENE (MODY3) IN GERMAN SUBJECTS WITH EARLY-ONSET NIDDM

T. Lindner, J. Schulze, H.-E. Schröder, C. Petzold, G. Meincke and H. Schmechel. Howard Hughes Medical Institute, The University of Chicago, Chicago, IL, USA; Department of Internal Medicine III, University Clinic Carl Gustav Carus, Technical University Dresden, Dresden, Germany; Diabetes Outpatient Clinic Kiel, Germany; and the Hufeland Clinics, Weimar, Germany.

Recent studies have shown that mutations in the gene encoding the transcription factor HNF-1α are the cause of one form of maturity-onset diabetes of the Young (MODY3). We have screened the HNF-1α gene for mutations in a group of 12 subjects of German ancestry who were diagnosed with NIDDM before 35 years of age (mean age = 24.1 ± 10.4 years) and had another first degree relative with NIDDM. Although not meeting the strict diagnostic criteria for MODY, it is likely that several of these subjects had this form of diabetes. PCR amplification and direct sequencing of the promoter region and 10 exons revealed three mutations: Dresden-1, P291fsinsC; Dresden-2, R131Q; Dresden-3, R229Q. The age at diagnosis of NIDDM in these three subjects was 17, 18 and 21 years of age, respectively. Moreover, the subjects were not obese.
This result suggests that it may be worthwhile to screen subjects with early-onset NIDDM for mutations in the HNF-1α gene even in the absence of a strict diagnosis of MODY.

18

A MUTATIONAL HOTSPOT IN THE POLY-C TRACT OF EXON 4 OF THE HEPATIC NUCLEAR FACTOR 1ALPHA GENE; SCREENING IN MATURITY ONSET DIABETES OF THE YOUNG.

T.Frayling[1], M.Bulman[1], S.Ellard[1], M.Appleton[1], M.J.Dronsfield[2], S.C.Bain[2], G.I.Bell[3] and A.T.Hattersley[1]. [1]Institute of Clinical Science, University of Exeter, Exeter, UK. [2]Department of Medicine, University of Birmingham, UK. [3] Howard Hughes Medical Institute, The University of Chicago, USA.

Mutations in the HNF-1α gene have recently been shown to cause Maturity Onset Diabetes of the Young (MODY). A common mutation has not been found. Patients are defined as having MODY if diagnosed as having non-insulin-dependent-diabetes before the age of 25 with an autosomal dominant mode of inheritance. We performed mutation detection on 15 probands from MODY families by PCR amplification and semi-automated sequencing of the 10 exons and adjacent splice sites of HNF-1α. A common mutation, P291fsinsC, occurring in the poly-C-tract of exon 4, was identified in 4 of 15 probands. Specific screening of exon 4 in a further 32 less strictly defined probands, aged <40 years, identified this mutation in 2 further pedigrees, giving an overall frequency of 13% (6/47). The mutation was found to cosegregate with 20 additional diabetic family members and was also found in 2 non-diabetic subjects, aged 22 and 26; these may develop diabetes later in life. Analysis of intragenic polymorphisms showed this mutation had occurred on at least three different haplotypes. This suggests the high frequency of this mutation is not due to a founder effect resulting from a single common ancestor, but that this region represents a mutational hotspot. Our results therefore suggest that this mutation is the most common single mutation causing MODY in UK families. Rapid screening for this mutation should now be carried out in MODY pedigrees before commencing mutation screening in other exons.

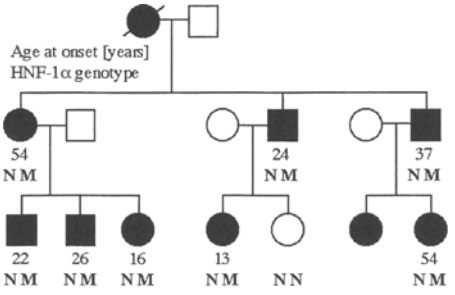
19

DISRUPTION OF THE HNF-4α BINDING SITE IN THE HNF-1α PROMOTER IN AN ITALIAN FAMILY WITH MODY

C. Gragnoli, T. Lindner, G. Marozzi and D. Andreani. Howard Hughes Medical Institute, The University of Chicago, Chicago, IL, USA; Hospital S. Spirito Rome, Rome, Italy; and University of Rome La Sapienza, Rome, Italy.

Mutation screening of the promoter and 10 exons of the HNF-1α gene in an Italian MODY family revealed an A→C substitution in the proximal promoter region. This mutation which is located in a putative HNF-4α binding site, cosegregates with MODY/NIDDM in this family.

normal allele: GGCTGAAGTCCAAAGTTCAGTCCCTTCGCT
mt. HNF-4α binding site: GGCTGAAGTCCCAAGTTCAGTCCCTTCGCT



We propose that this mutation affects transcriptional regulation. This mutation is associated with a progressive form of NIDDM characterized by increasing severity with age and the appearance of diabetes complications around 50 years of age.

20

MITOCHONDRIAL DNA MUTATIONS ARE HIGHLY ASSOCIATED WITH TYPE 2 DIABETES MELLITUS IN JAPANESE PATIENTS

M. Tawata, Y. Ikegishi, E. Iwase, K. Aida and T. Onaya. Third Department of Internal Medicine, Yamanashi Medical University, Tamaho, Yamanashi , Japan.

Since inheritance of mitochondrial DNA (mtDNA) is exclusively maternal, mtDNA mutations have been implicated in this maternal inheritance of diabetes mellitus. The prevalence studies in a large population of diabetic patients revealed about 1 to 1.5% of mtDNA mutation at 3243 in different countries including Japan. However, it is possible that we are underestimating the precise prevalence of mtDNA mutation(s) associated with type 2 diabetic patients, because we have data on only 3243 mutation. Recently, we found at least 56 mtDNA mutations in Japanese by polymerase chain reaction-restriction fragment-single strand conformation polymorphism (PCR-RF-SSCP) analysis compared with the Cambridge Sequence. We investigated the prevalences of these mtDNA mutations in randomly selected 99 patients with type 2 diabetes mellitus and in 115 healthy control subjects by PCR-SSCP or PCR-RFLP analyses. We found that 8.1% (8/99) of Japanese patients with type 2 diabetes mellitus were associated with A to C mtDNA mutation at 1382, which was significantly higher than 1.7% (2/115) of control subjects. In addition, 14.1% (14/99) of diabetic patients were associated with mutations either at 1382 or A to G at 12026. Since none of the 14 patients with mutations either at 1382 or 12026 had mutation at 3243, we think that these two sites are new mtDNA mutations highly associated with type 2 diabetes mellitus in Japanese. The mutations were all homoplasmic. The mutation at 1382 is located in 12S rRNA and mutation at 12026 is expected to cause amino acid replacement from isoleucine to valine in NADH dehydrogenase 4. In conclusion, our investigation demonstrates that mtDNA mutations are much more frequently associated wih type 2 diabetic patients in Japanese than it has previously been reported. The prevalences of these mtDNA mutations needs to be examined in other countries or in other ethnic groups.

21

GENETIC POLYMORPHISM OF LIPOPROTEIN LIPASE IS ASSOCIATED WITH NIDDM

S.Colagiuri, H.Cai, R.Borger, XL.Wang, D.Wilcken. Prince of Wales Hospital, Randwick, Australia.

NIDDM is a polygenic disease commonly associated with lipid abnormalities, particularly elevated triglyceride levels. Lipoprotein lipase (LpL) is a key enzyme for triglyceride metabolism. This study explored the possible association between NIDDM and lipoprotein lipase (LpL) gene polymorphism in people with NIDDM. 597 Australian Caucasians were studied [mean (SE) age 58 (0.3)]. 214 had confirmed NIDDM. All were genotyped for LpLPvuII using PCR technique. Polymorphism of LpLPvuII is caused by the presence (+) or absence (-) of a PvuII recognition site in intron 6. The frequency distribution of PvuII +/+, PvuII +/- and PvuII -/- was 0.304, 0.502 and 0.194 respectively, and was in Hardy-Weinberg equilibrium. Using logistic regression analysis, there was a significant association between the PvuII polymorphism and the presence of NIDDM (r=0.137, p=0.0055) independent of age, gender and other circulating lipid variables. Whilst PvuII +/+ was associated with higher circulating triglyceride levels, the association between NIDDM and the Pvu II polymorphism was not affected by triglyceride levels. The odds ratio (OR) for patients homozygous for PvuII +/+ to have NIDDM was 2.51 (95% CI: 1.36-4.62) compared with PvuII -/- homozygotes. Among heterozygotes (PvuII +/-) there was also a trend towards increased NIDDM risk (OR:1.44, 95% CI: 0.82-2.54) compared with PvuII -/-. Furthermore in NIDDM patients with the Pvu II +/+ genotype there was an independent association with the presence of coronary artery disease in logistic regression analysis (p=0.0155). The frequency of PvuII +/+ in NIDDM patients with coronary heart disease was significantly higher than in those without (51.7% v 30.5%, $\chi^2 = 8.52$, p=0.014). LpLPvuII polymorphism and the occurrence of NIDDM are significantly associated and NIDDM with PvuII +/+ are more likely to have coronary artery disease.

22

GENOMIC SCAN FOR GENETIC MARKERS LINKED TO DIABETES IN PIMA INDIANS.

WC Knowler, RL Hanson and the Pima Diabetes Genes Group. National Institutes of Health, Phoenix, USA

Genetic factors are likely to play a role in the etiology of non-insulin-dependent diabetes mellitus (NIDDM), but susceptibility loci for the most common forms of NIDDM have not been identified. A genome-wide scan was conducted to identify genetic markers linked to NIDDM in Pima Indians. Among 264 nuclear families containing 1862 sibling pairs, 517 anonymous genetic markers were genotyped from all 22 autosomal chromosomes. In 563 of these pairs, both siblings had NIDDM with age of onset < 45 yrs and analyses of the mean proportion of marker alleles identical by descent (IBD), which is expected to be 0.5 under the null hypothesis of no linkage, were conducted. The Haseman-Elston test of linkage, which regresses the proportion of marker alleles IBD against the squared difference in the sibs' trait values, was also conducted among all sib-pairs, using a cumulative incidence method to account for age of onset. Two chromosomal regions showed "suggestive" linkage to diabetes ($p < 0.0007$). Chromosome 7, in the vicinity of D7S1799 was linked in the affecteds-only analysis ($p = 0.0004$) and chromosome 11, in the vicinity of D11S4464, was linked by the cumulative incidence method ($p = 0.0003$). Seven other regions also had tentative evidence for linkage ($p < 0.01$). These results suggest that diabetes-susceptibility genes may be located at 7q21-22 and 11q23-25. Several other genetic loci may also contribute to NIDDM. These findings need to be extended in other studies of Pima Indians and, if possible, replicated in other populations. Additional fine mapping of these areas is needed to localize further the genetic elements involved.

23

PPARγ AND HUMAN ADIPOCYTE DIFFERENTIATION: EVIDENCE FOR SITE-SPECIFIC EFFECTS OF THIAZOLIDINEDIONES AND PG$\Delta^{12,14}$J2

J.B. Prins[1,2], C. Montague[1,2], M. Adams[1], J.C. Holder[3], S.A. Smith[3], M. Lazar[4], L. Sanders[1,2], V.K.K Chatterjee[1] and S .O'Rahilly[1,2]. Depts of Medicine[1], and Clinical Biochemistry[2], University of Cambridge, UK; SmithKline Beecham[3], Welwyn, UK; Univ. Penn.[4], Philadelphia, PA, USA.

The gamma isoform of peroxisome proliferator activated receptor (PPARγ) is highly expressed in adipocytes and promotes the differentiation of murine preadipocyte cell lines. Thiazolidinediones, a novel class of antidiabetic agent, enhance insulin action and bind to PPARγ with high affinity. The prostanoid 15-deoxy-D12,14 prostagandin J2 ($\Delta^{12,14}$ PGJ2) may represent the natural ligand for PPARγ. We have examined the effects of these agents on the differentiation of human Omental (Om) or Subcutaneous (Sc) preadipocytes from non diabetic subjects. Under control conditions, Om or Sc preadipocytes exhibited negligible differentiation, as assessed by lipid accumulation, glycerol-3-phosphate dehydrogenase (G3PDH) enzyme activity and G3PDH gene expression. Following BRL 49653 or troglitazone exposure, G3PDH activity and gene expression in Sc preadipocytes were markedly increased and differentiation was also evident morphologically. At 1mM, BRL 49653 was 100-fold more potent than troglitazone, stimulating G3PDH activity 16-fold ($p<0.001$) vs 6-fold for troglitazone ($p<0.05$). Furthermore, the rank order of potency of these agents to induce differentiation correlated with their ability to stimulate reporter gene activity via human PPARγ. In contrast, Om preadipocytes were refractory to differentiation by thiazolidinediones. Western blotting showed abundant PPARγ expression in both Om and Sc preadipocytes and adipocytes, and nuclear PPARγ expression, as assessed by immunofluorescence confocal microscopy, was equally enhanced by thiazolidinediones in Om and Sc preadipocytes. The mechanism of the divergent cellular responsiveness to these compounds remains to be elucidated. Given the close link between central fat distribution and insulin resistance, a site-specific effect of the thiazolidinediones may have clinical relevance.

24

THIAZOLIDINEDIONES INCREASE EXPRESSION OF UNCOUPLING PROTEIN, TYPE II IODOTHYRONINE 5'-DEIODINASE AND MITOCHONDRIA IN C3H10T1/2 CELLS.

M.A. Paulik, J.E. Weiel and J.M. Lenhard. GlaxoWellcome, Research Triangle Park, North Carolina, USA.

The thiazolidinediones (TZDs) are a new class of oral antidiabetic agents whose mechanism of action is not fully understood. Recently, the TZDs (*e.g.,* troglitazone) were identified as high affinity ligands for the peroxisome proliferator-activated receptor γ (PPARγ), a ligand-activated transcription factor in adipocytes. This suggests that the antidiabetic action of these compounds may involve PPARγ-mediated transcription of adipose genes involved in lipid and carbohydrate metabolism. To further understand the action of TZDs, we explored the effects of these agents on differentiation of C3H10T1/2 cells, a pluripotent stem cell-line of mesodermal origin. Histochemical and biochemical analysis revealed that when these cells were treated with TZDs and insulin, they accumulated lipid and expressed the adipocyte marker aP2, indicating they differentiated into adipocytes. Treatment during the growth phase with TZDs resulted in maximal lipogenesis, indicating a need for clonal expansion for efficient adipogenic differentiation. Further analysis revealed that addition of TZDs to the cells increased i) the lipolytic response of the cells to $ß_3$-agonists, ii) mitochondrial-staining, iii) expression of uncoupling protein (UCP) and, iv) expression of mRNA for type II iodothyronine 5'- deiodinase (5'D-II). The presence of UCP and 5'D-II are hallmarks of brown adipose tissue (BAT). Thus, this represents the first direct evidence indicating that brown adipocytes may arise from pluripotent stem cells of mesenchymal origin. Furthermore, these results suggest the antidiabetic effects of TZDs may involve BAT differentiation. This, in turn, may lead to increased $ß_3$- and UCP-mediated thermogenesis resulting in increased fuel metabolism.

OP 4

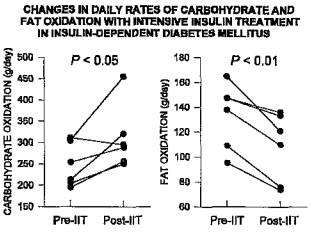
Insulin Therapy in IDDM

25

INTENSIVE INSULIN THERAPY ALTERS DAILY SUBSTRATE OXIDATION IN INSULIN-DEPENDENT DIABETES MELLITUS.

M.G. Carlson, M. Sun, and A. Hayes. Vanderbilt University, Nashville, USA

Weight gain and increased adiposity often accompany the improved glycemic control with intensive insulin therapy (IIT) in IDDM due to reductions in glycosuria, daily energy expenditure (EE), and basal fat oxidation. To investigate the role of changes in energy metabolism and metabolic efficiency during exercise in the propensity for weight gain with IIT, we studied 6 adult IDDM patients (gender 2M/4F, age 33±4 yrs, weight 75±7 kg, body mass index [BMI] 24±1 kg/m^2, diabetes duration 14±4 yrs) before and after 4 wks of insulin pump therapy. Daily EE, sleeping metabolic rate (SMR), basal metabolic rate (BMR), and EE and mechanical work (MW) during a standardized exercise protocol were measured during 24h stays in a respiratory chamber equipped with a novel force platform floor system, allowing simultaneous measurement of the amount and energy cost of physical activity. Metabolic efficiency during exercise was calculated as MW/EEex, where EEex is the increment in EE with exercise. After 4 wks of IIT, HbA1c improved (10.4±0.7 to 8.7±0.6%, $P < 0.05$) and glycosuria decreased (217±89 to 89±28 mmol/d, $P < 0.05$). Daily EE (9.58±0.78 vs 9.73±0.82 MJ/d), SMR (5.87±0.54 vs 6.00±0.45 MJ/d), BMR (6.32±0.61 vs 6.46±0.59 MJ/d), EEex (1.89±0.15 vs 1.89±0.19 MJ/d), and metabolic efficiency during exercise (23.1±3.2 vs 23.1±2.8%) were similar before and after IIT. However, daily rates of carbohydrate oxidation increased (246±21 vs 311±31 g/d, $P < 0.05$) and fat oxidation decreased (133±11 vs 108±11 g/d, $P < 0.01$). Thus, IIT alters substrate oxidation but does not appear to alter metabolic efficiency or EE during exercise in patients with IDDM. These results suggest that the reductions in fat oxidation and glycosuria with IIT are the major factors that contribute to the propensity for weight gain and increased adiposity in intensively treated patients with IDDM.



26

SUBCUTANEOUS GLUCOSE MONITORING DURING 8 DAYS IN IDDM PATIENTS: WHAT HAVE WE LEARNT?

F. Sternberg[1], M. Salgado[1], U. Henkel[1], U. Hoss[1], H. Rinne[2] and E.F. Pfeiffer[1]. [1]Institut für Diabetes-Technologie an der Universität Ulm, Ulm, Germany. [2]Boehringer-Mannheim, Mannheim, Germany.

Introduction: The hypothesis that hypoglycemia as well as hyperglycemia occur in IDDM patients much more frequently than what patients themselves may recognise whether by symptoms or by measuring their capillary glucose is one of many questions we may answer with the help of continuous tissue glucose (TG) monitoring. We designed a protocol to observe the glucose changes in IDDM patients during 48h under daily life conditions. Methods: We developed a glucosensor based on the enzymatic-amperometric method in combination with a microdialsyis probe (Ulmer Zuckeruhr-System) to monitor on-line the TG changes on a continuous basis. We performed 4 series of TG monitoring in 2 IDDM patients (sex: 1:1, age: 39.5±10.6 years; BMI: 23.7±3.0 kg/m^2, HBA1$_c$: 7.2±0.3) under intensified insulin therapy (injection therapy), each monitoring lasting 48 hours. Patients stayed during the first 24h within the facilities of our institute. During this time blood glucose was hourly measured with a reflectometric glucometer. In the following 24h the patients were allowed to go to their work or just to carry their normal life and were asked to control at least 5 times their capillary glucose. Results: Blood glucose values fluctuated between 35 mg/dl and 350 mg/dl. The sensor signal correlated well with the glucose reference values. Hypoglycemia, i.e. glucose values <54 mg/dl occurred 21 times, but it was recognised only 12 times by the patients. Most of the episodes occurred during day time (n=18). Additionally, hyperglycemic values >250 mg/dl occurred 12 times (9 episodes during day time) while patients detected only 7 episodes. Conclusions: Our patients detected just above half of their blood glucose extreme variations, which mostly occurred during the day. On the other hand, our glucosensor showed to be reliable to monitor the TG for 48h in all the cases.

27

IMPACT OF RECENT CHANGES IN THE MANAGEMENT OF IMPLAN TABLE PUMPS. REDUCTION OF DYSFUNCTIONING

N. Jeandidier, S. Boivin, S. Boullu, and M. Pinget.
Service d'Endocrinologie,
Hôpitaux Universitaires - Strasbourg, France

Recent changes in insulin stability have led to an increase in catheter (KT) and/or pump related problems from 1993 to 1994. Simultaneously, physicians and manufacturers have introduced several improvements in the management of implantable pumps including changes in the refill frequency, in refill and rince procedures and development of a new KT (MiniMed 4027) with direct access (side-port : SP).

The aim of the study was to evaluate the impact of these changes on the functionnality of pump (from 01/93) and KT (from 11/94) together with the consequences on the patients including rate of surgical reintervention. Therefore, data from our group have been analysed within 3 periods : period I as a reference (before insulin stability decrease) : from 1991 to 1992, period II : from 1993 to 1994 (decrease in insulin stability), period III : from 1995 to 1996 (effects of technical improvements). All the patients were treated with MIP 2001 pumps, using U400 Hoechst 21 PH insulin. Results are summerized in the following table :

	Period I	Period II	Period III
Nb of pumps	43	51	55
Study duration (PxY)	50.04	57.96	56.02
Nb of KT flush/PxY	NA	NA	0.54
Nb of NaOH rince/PxY	NA	0.66	1.32
Nb of Kt exchanges/PxY	0.16	0.17	0.05
Discontinuation (%pumps)	0	37	0

PxY : patient x year

These data clearly demonstrate that the changes developed have fully restaured the safety and the feasability of intraperitoneal insulin infusion by means of implantable pumps.

28

INADEQUATE USE OF INSULIN AS A CAUSE OF POOR GLYCAEMIC CONTROL AND KETOACIDOSIS

Morris AD, Greene SA, Boyle DIR, MacDonald TM, and Newton RW·
University of Dundee, Scotland.

A variety of manipulations of insulin treatment are perceived as a cause of poor glycaemic control and ketoacidosis. There are no direct data confirming poor compliance in IDDM. We present data (April 1993 to September 1994) comparing the known prescribed insulin dose (units) with insulin supplied using the Diabetes Audit and Research in Tayside Study (DARTS) database. DARTS contains complete data on all prescribed drugs encashed at all Tayside pharmacies. The cumulative volume of insulin prescriptions supplied was used to calculate the days of total insulin coverage, expressed as the compliance index. Relationships between compliance index, glycaemic control (HbA1c) and episodes of ketoacidosis were investigated in all patients attending our young adult and paediatric diabetes clinics. Eighty-nine patients aged 16±7 (mean ± S.D.) years, diabetes duration 8±4 years, HbA1c 8.4±1.9% were studied. Taken as a whole, mean insulin dosage prescribed was 48±19 units/day; mean insulin encashed was 58±25 units/day. Twenty-five patients (28%) encashed less insulin than their prescribed dose (mean deficit 115±68 insulin-free days per annum; range 9-246 days). A strong negative relationship existed between the compliance index and HbA1c (R^2 0.39; $p<0.001$) which remained when adjusted for all other covariates (e.g. age, weight, diabetes duration; $p<0.001$, multiple linear regression). In the top quartile (HbA1c>10%), 14 (64%) of subjects had insulin encashment records suggestive of poor compliance (mean deficit 55 insulin free days per annum) compared with only 2 (9%) in the lowest quartile (HbA1c<7%; mean excess 296 insulin days p.a.). Of all 10 ketoacidosis episodes, 9 occurred in subjects with a poor compliance index ($p<0.001$; mean deficit 108 insulin free days per annum). These data represent the first direct evidence of insulin under-utilisation in young patients with IDDM. They suggest poor compliance is a major factor contributing to long-term poor glycaemic control and ketoacidosis.

29

VARIABILITY OF THE METABOLIC EFFECT OF S.C. INJECTED REGULAR INSULIN AND THE RAPID ACTING INSULIN-ANALOGUE B28ASP

L. Heinemann, C. Weyer, M. Rauhaus, S. Heinrichs and T. Heise. Dept. of Metabolic Diseases and Nutrition, Heinrich-Heine-University of Düsseldorf, Germany

We studied the intra- and interindividual variability of the metabolic activity of regular insulin (R) and of the rapid acting insulin analogue B28Asp. Nine healthy male volunteers (age 25±1 years, BMI 22.6±2.1 kg/m²) recieved s.c. injections of R (Actrapid HM, NOVO NORDISK; U100; 0.2 U/kg, 14.4±1.6 U) during euglycaemic glucose clamps on 4 study days (blood glucose 5 mmol/l, basal i.v. insulin infusion 0.15 mU/kg/min). Ten other volunteers (age 26±2 years, BMI 22.9±1.9 kg/m²; N.S.) received on the 4 days injections of B28Asp (NOVO NORDISK). In the 600 min after the injections glucose infusion rates (GIR) and serum insulin concentrations were determined. In comparison to R s.c. injection of B28Asp resulted in a more rapid onset of action and a shorter duration of action. We investigated the variation in action of these insulin by calculating coefficents of variation (CV). Even under the strictly controlled experimental conditions of this study, the s.c. injection of R resulted in a intra-individual variability of the metabolic activity of 10-25 % in healthy volunteers (see table). Injection of B28Asp resulted in a lower variability in the time needed until maximal serum insulin concentrations were reached than with R. The inter-individual variability was approximately 10 % higher than the intra-individual with both insulin preparations.

	intra-indivi. CV (%)			inter-indivi. CV (%)

REDUCED NOCTURNAL HYPOGLYCAEMIA WITH INSULIN ANALOGUE LISPRO IN TYPE 1 DIABETIC PATIENTS

A. M. E. Ahmed and P. D. Home. University of Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom.

Unmodified insulin has a long absorption tail, unlike short-acting insulin analogues, and may contribute to hypoglycaemia in the early part of the night. A randomized, crossover, double-blind study was therefore performed to compare blood glucose concentrations in the early part of the night in Type 1 diabetic patients, receiving lispro or unmodified insulin, in random order, on two separate study days. Twenty three C-peptide negative patients, 12 using a basal-bolus insulin regimen, and 11 using twice-daily insulin, were studied. The patients were admitted to the investigation unit at 1700 h, and received a single dose of lispro or unmodified human insulin before the evening meal. In both groups the NPH insulin doses remained unchanged. Identical meals and snacks were eaten at the same time during both study days. Average postprandial (1800 - 2400 h) blood glucose concentrations were significantly lower after lispro therapy compared to unmodified insulin therapy (8.0 ± 0.3 (SE) vs 9.0 ± 0.3 mmol l^{-1}, p = 0.003). Night-time (2400 - 0400 h) blood glucose concentrations were significantly higher after lispro compared to unmodified insulin therapy (10.3 ± 0.4 vs 9.1 ± 0.4 mmol l^{-1}, p = 0.02). This difference was greater in patients on the basal-bolus insulin regimen (11.6 ± 0.5 vs 8.7 ± 0.4 mmol l^{-1}, p = 0.000). The incidence of nocturnal hypoglycaemia (2400 - 0400 h, blood glucose < 3.5 mmol l^{-1}) was less with lispro compared to unmodified insulin (1 vs 6 patients, p = 0.04). Thus on a basal bolus insulin regimen, evening lispro gives less hypoglycaemia in the early part of the night at the expense of average blood glucose control.

31

IMPROVEMENT OF HBA1C WITHOUT INCREASING HYPOGLYCEMIA RISK IN DIABETIC PATIENTS TREATED WITH INSULIN LISPRO IN EXTERNAL PUMPS.

H. Hanaire[1], J. Bringer[2], V. Lassmann-Vague[3], N. Jeandidier[4], L. Meyer[5], P. Blin[6], J.P. Tauber[1] and B. Augendre[7], CHU Rangueil, Toulouse[1], Hôpital Lapeyronie, Montpellier[2], C.H.U. La Timone, Marseille[3], Hôpital Civil, Strasbourg[4], Hôpital Jeanne d'Arc, Toul[5], Eval, Paris[6], Lilly France, Saint-Cloud, France[7].

The aim of this 6-month randomized, open, crossover, multicenter trial was to compare the effects of insulin lispro (LP) to Actrapid HM 100 pump formulation (Actr.) on glycemic control in Type I diabetics. These diabetic patients have been using a continuous subcutaneous insulin infusion (CSII) for at least 1 year. Thirty-nine patients (mean age ± SD: 38.9 ± 9.9 yr; BMI: 24.5 ± 2.4 kg/m²; mean disease duration: 22.2 ± 9.6 yr; mean duration of pump treatment: 5.1 ± 3.0 yr; mean HbA1c= 7.84% ± 0.76) were treated on CSII using an external pump (Minimed 506). The patients were randomized to LP or Actr. for 3 months then switched to the other insulin for 3 months. Boluses were given 0 to 5 min. before 3 meals for LP and 15-30 min. before for Actr. Six blood glucose (BG) measurements were taken daily (3 pre- and postprandial) and stored in a memory meter. At the end of the 3-month period, HbA1c had a larger decrease with LP (0.62% ± 0.58 [7.74% ± 0.90 to 7.11% ± 0.69]) compared to Actr. (0.09% ± 0.63 [7.97% ± 0.53 to 7.88 % ± 0.65]) (p=0.01). The standard deviation (SD) of BG values, an index of glycemic fluctuation and the main criteria of the study, is 3.46 ± 0.55 mmol/l with LP compared to 3.79 ± 0.66 mmol/l with Actr. (p=0.0001). Mean postprandial BG decreased significantly with LP (8.19 ± 1.04 mmol/l compared to 9.79 ± 1.26 mmol/l) (p=0.0001), as well as the SD of the postprandial BG : 3.55 ± 0.55 mmol/l (LP) compared to 3.88 ± 0.66 mmol/l (Actr.) (p=0.0002). The mean and SD of preprandial BG were similar in the 2 groups. The incidence of hypoglycemia per 30 days (BG<3.3 mmol/l) was lower but not significantly decreased in the LP group (10.89 ± 7.16 compared with 12.90 ± 6.07) (p= 0.36). At the end of the crossover study, all but one patient chose insulin lispro for the extension phase. In conclusion, insulin lispro optimized the metabolic control of Type I diabetics treated by CSII, reducing significantly the HbA1C levels, without increasing the risk of hypoglycemia. These results could be related to the pharmacokinetic profile of LP used in CSII as basal and bolus insulin therapy.

32

DOSE RESPONSE WITH LONG-ACTING INSULIN ANALOG NN304 FOLLOWS ANALOG DYNAMICS IN HINDLIMB LYMPH IN DOGS.

M. Hamilton-Wessler, M. Ader, M. Dea, D. Moore, J. Markussen*, and R. Bergman. U. of Southern California-School of Medicine, Los Angeles, CA, USA and *Insulin Research, Novo Nordisk A/S, DK-2880 Bagsvaerd, Denmark.

The new long-acting insulin analog, Lys^{B29}-tetradecanoyl, des(B30) human insulin (NN304) has shown a protracted action profile with I.V. injection and infusion. This protraction is assumed to be due to albumin binding in plasma and interstitial fluid. However, the temporal profile for dose-dependent activation and deactivation of glucose turnover by NN304 has not been examined. This study examined glucose utilization (Rd) and glucose production (HGO) in response to NN304 infusion at three doses. Euglycemic clamps (Hot GINF), with arterial and hindlimb lymph (HL) sampling, were performed in normal dogs during somatostatin infusion (0.8 µg/min/kg) plus basal insulin replacement (1.2 pmol/min/kg) for 660 min. NN304 was infused at 3.6 (N=4), 10 (N=4), or 18 (N=1) pmol/min/kg for 0-320 min (activation), then suspended from 320-660 min (deactivation). Tracer (3-^{3}H-glucose) was infused throughout starting at -120 min.

	3.6 pmol/min/kg	**10** pmol/min/kg	**18** pmol/min/kg
NN304, plasma (pM)	2412 ± 522	4958 ± 456	14397
HL (pM)	176 ± 27	430 ± 26	1687
Rd (mg/min/kg)	7.2 ± 1.2	14.2 ± 0.6	15.6
HGO (mg/min/kg)	1.2 ± 0.3	1.5 ± 0.6	0.2

During activation, steady state (SS) plasma and HL NN304, Rd and HGO differed by dose (P<0.02). Activation/deactivation times to 50% of SS ($t_{1/2}$) were similar within each dose with a tendency toward delayed deactivation (P≥0.10, limited power of detection). Activation of Rd and suppression of HGO were similar to NN304 $t_{1/2}$ in hindlimb lymph, but not plasma (P<0.01). These data 1) indicate that transendothelial transport is rate-limiting for NN304 as with native insulin, and 2) are consistent with protracted action of the analog due to albumin binding.

METFORMIN ASSOCIATED TO INSULIN THERAPY FOR TREATMENT OF OBESE NIDDM.

G. Perriello, G. Di Matteo, S. Pampanelli, G. Santamaria, E. Picchio, G. B. Bolli. DiMISEM and C.A., Perugia, Italy.

Albeit its widespread use, the advantages of combined sulfonylurea-insulin (SU) treatment in NIDDM are questionable. On the other hand, metformin-insulin (MI) combination would be potentially beneficial for NIDDM patients, because of peripheral action of metformin. To assess the effects of MI as compared to SI on fasting plasma glucose (FPG), Hba_{1c}, body weight and insulin dose, we studied 100 patients with NIDDM (35M, 65F), treated with MI (N=27 obese, BMI=34.5±0.7, and N=23 nonobese, BMI=26.9±0.6) or SI (N=22 obese, BMI=34.8±0.9, and N=28 nonobese, BMI=26.8±0.4) for 6 months. Both treatments decreased to a similar extent FPG (MI, 11.4±0.6 and SI, 10.9 ±0.6 mmol/L, p=NS) and Hba_{1c} (MI, 8.1±0.2 and SI, 7.7±0.3 %, p=NS) in nonobese NIDDM patients, but weight gain (MI, 0.4±0.1 vs SI, 3±0.1 kg, $p<0.05$) resulted lower after MI. In obese NIDDM patients, FPG (MI, 9.1±0.4 vs SI, 9.9±0.8 mmol/L) and Hba_{1c} (MI, 7.4±0.2 vs SI, 8.2±0.3 %, $p<0.05$) and body weight (MI, -2.3±1.5 vs SI, -1±0.8 kg, $p<0.05$) decreased to a greater extent after MI (all, $p<0.05$). Interestingly, daily insulin dose decreased after MI but not after SI, in nonobese (MI, -8±2.9 vs SI, 6±2.2 Units) and obese (MI, -12±1.7 vs SI, 3±2.1 Units) NIDDM patients (both, $p<0.05$). In conclusion, in nonobese NIDDM, MI prevents weight gain and increase in insulin dose; in obese NIDDM, MI determines a better glycemic control and weight loss. Therefore, MI appears to be more effective than SI in the treatment of obese NIDDM.

34

METFORMIN-ASSOCIATED LACTIC ACIDOSIS

R Misbin, L Green, B Stadel, J Gueriguain, A Gubbi, and A Fleming, Food and Drug Administration, Rockville, Maryland USA (The views expressed here are those of the authors and not necessarily those of the FDA).

Metformin was introduced in the USA in May 1995. Through June 30, 1996, the FDA received reports of 66 cases of lactic acidosis attributed to metformin. In 47 patients, the diagnosis was confirmed by a lactate level of 5.0 mM or greater. Characteristics of these patients are shown in the table. In the remaining 21 patients, 2 were found to have not been taking metformin, 3 had no lactate reported, 7 had normal lactate levels (under 2.7 mM), and 7 had mild hyperlactatemia with levels between 2.7 to 4.9 mM. All patients with mild hyperlactatemia recovered.

	DIED	RECOVERED
number (male/female)	20 (9/11)	27 (9/18)
age, mean ± SEM	70.5 ± 2.7	67.3 ± 2.1
lactate, mM	15.9 ± 1.9 *	11.2 ± 1.3 *
pH	7.085 ± 0.01 *	7.29 ± 0.01 *
dose, mg/day	1259 ± 145	1349 ± 115
time to onset, days	64.6 ± 26.1	56.3 ± 18.1
creatinine> 1.4	16 **	7 **
creatinine< 1.5	1 **	8 **

* $p<0.05$ by t test ** $P<0.05$ by exact permutation test

Based on an estimate of about 1 million patients who have been treated through June 30, 1996, the reporting rate of confirmed lactic acidosis was about 5 per 100,000. Mortality was 43%.

35

DO SULFONYLUREAS INCREASE GROWTH HORMONE SECRETION IN MAN?

A. Alzaid*, A. Basu, and R.A. Rizza. *Riyadh Armed Forces Hospital, Riyadh, Saudi Arabia, Mayo Clinic, Rochester, USA.

It has been recently demonstrated that glipizide stimulates growth hormone (GH) release and antagonizes somatostatin (SRIF) action in cultured somatotrophic cells. To determine the relevance of this observation to humans, we measured GH secretion in 12 healthy subjects following ingestion of glipizide (5mg) or placebo at time 0 min. On each occasion, GHRH (i.v.bolus 0.1μg/kg) was given at 60 and 210 min, with SRIF being infused from 180-330 min. Glucose was clamped (glipizide day) at 5mM. The order of the studies was random. As expected, glipizide induced a profound increase in insulin that was completely suppressed by SRIF. In the presence of normal plasma glucose concentrations, glipizide (vs. placebo) produced 20% increase in GH secretion over entire study duration (AUC 2961±456 vs. 2469±334ng/ml/6hrs, $p<0.05$) and nearly doubled GH secretion during SRIF suppression period (AUC 1105±260 vs. 656±90 ng/ml/2.5hr, $p<0.05$). Our data therefore indicated a stimulatory effect of sulfonylureas on GH secretion *in vivo*. Since excess GH secretion may accelerate diabetic complications, the present findings if confirmed in diabetic patients, may have significant clinical implications to patients treated with sulfonylureas.

36

EFFECT OF SULPHONYLUREA DRUGS ON ARRHYTHMIAS AND DEATH RATE INDUCED BY ISCHAEMIA AND REPERFUSION.

E. Kocsis, I. Pósa, M.Z. Koltai and G. Pogátsa. National Institute of Cardiology, Budapest, Hungary

Influence of glimepiride (GM), glibenclamide (GB), gliclazide (GC) and tolbutamide (TB) was analyzed on incidence of ventricular ectopic beats (VEB), on duration of ventricular fibrillation (VF) and on death rate (DR; vs. solvent:23±1%) induced by coronary clamping (CC;30 min) or reperfusion (CR ; 50 min following 10 min CC) in healthy (H) and streptozotocin-diabetic (D) rats. Drugs (0.1-1000 μmol/kg) were administered i.p. 30 min before CC. Data were compared using Student's t-tests and regression analysis, $p<0.05$ was considered significant. During CC only GB decreased these parameters (VEB: y= -400logx+635; VF:y=-45logx+97; DR:28±6%) in H rats, whereas GC (VEB:y=732logx +1350; VF:y=174logx+179; DR:65±5%), GM (VEB:y=573logx+739; VF:y=24logx+82; DR:74±7%) and TB (VEB:y=626logx+1635; VF:y=285logx+260; DR:66±5%) increased them. During CR only GM decreased these variables (VEB:y=-61ogx+13; VF:y= -5logx+13; DR:21±6%), while GB (VEB:y=20logx+32; VF:y=3logx+22; DR:60±6%), GC (VEB:y=9logx+46; VF:y=3logx+22; DR:53±5%) and TB (VEB:y=19logx+46; VF:y=8logx +42; DR:60±8%) enhanced them. In D condition the effects of GM and GB changed. Namely, GM decreased these parameters (VEB:y=-269logx+425; VF:y=-146logx+251; DR:13±6%) during CC and GB (VEB:y=-141ogx+31; VF:y=-17logx+29; DR:10±6%) during CR. Suggesting that only GB and GM should be preferred in oral antidiabetic treatment of type-2 diabetic patients suffering from ischaemic and reperfusion events.

37

WHITE COAT EFFECT IN DIABETES: AMBULATORY BLOOD PRESSURE MEASUREMENT IN RELATION TO CLINIC BASED MEASUREMENT.

E. Ebbehøj, P.L.Poulsen, K.W. Hansen and C.E. Mogensen. Medical Department M, Diabetes & Endocrinology, Aarhus Kommunehospital, DK-8000 Aarhus C, DK.

Aim: To quantify differences between clinic and ambulatory blood pressure (AMBP) recordings in diabetic patients with suspected hypertension, and to relate the white coat effect to renal function, gender, age, and antihypertensive treatment. **Methods and Patients:** Within 3½ years (1.1.93 - 5.31.96) 119 diabetic patients were referred to AMBP monitoring from our out-patients' clinic. 103 fulfilled WHO's criterion of hypertension (Systolic BP > 140 mmHg and/or diastolic BP > 90 mmHg) at two blood pressure measurements obtained in the usual out-patient clinical setting. AMBP was measured using Spacelab apparatus (model 90202). Sixty-one had IDDM, 42 NIDDM, 64 males, 39 females. The mean age for the whole population was 48.7 years (16.6 - 80.2 years), 44 patients received antihypertensive treatment. Forty-eight patients were normoalbuminuric (albumin/creatinine ratio <2.5 mg/mmol for males and <3.5 for females), 55 patients had microalbuminuria or nephropathy. Among the 48 normoalbuminuric patients 17 received antihypertensiva prior to the AMBP recording. **Results:** BP measurements recorded in the clinic was significantly higher compared with day-time AMBP: for the systolic BP in average 15.6 mmHg (5 and 95% percentiles: -13.1 and 51.3 mmHg, $p < 0.0001$) and for the diastolic BP in average 10.1 mmHg (5 and 95% percentiles: -7.5 and 29.7 mmHg, $p < 0.0001$). The differences between the BP measurements were not related to gender, age, diabetes duration, type of diabetes, UAE, or to antihypertensive treatment. In consequence of the AMBP measurement only 5 patients among 31 normoalbuminuric patients started antihypertensive treatment, in another 7 normoalbuminuric patients ongoing treatment was intensified. **In conclusion:** 1) The white coat effect in diabetic patients are in accordance with other studies of non-diabetics. 2) The white coat effect varies considerably among patients and is not predictable. 3) AMBP recording may be relevant especially in normoalbuminuric diabetic patients with high clinic BP recordings, since unnecessary treatment may be avoided in a large fraction of patients - in this material 83%.

38

TREATMENT OF NIDDM: FAIR GLYCAEMIC CONTROL DURING 5 YEARS PREVENTS PROGRESSION OF ALBUMINURIA

P. Thorsby, KF Hanssen, B Kilhovd, U Rishaug, S Vaaler and KI Birkeland. Department of Endocrinology and Hormone Laboratory, Aker Diabetes Research Centre, Aker University Hospital, Oslo, Norway.

Aim: To compare the effect of insulin and sulphonylurea therapy in patients with NIDDM and study the effect of good glycaemic control on progression of albuminuria. **Material and methods:** Thirty-one men and 24 women aged 59.3 ± 6.2 (mean, SD) years, with a duration of NIDDM for 7.3 ± 3.1 years and BMI 26.7 ± 3.7 kg/m^2 were randomised to continue sulphonylurea therapy (SU, n=26) or start insulin (I, n=29) and followed for a median of 5 (3-6) years. Levels of HbA_{1c} and albuminuria was measured 3-6 monthly. Progression of albuminuria was defined as an increase in the overnight albumin excretion rate from normoalbuminuria (<20µg/min) to microalbuminuria (MA 20-200 µg/min), or from MA to proteinuria (>200 µg/min). **Results:** 1) In the I group HbA_{1c} was reduced from 8.7 ± 1.6 to 7.8 ± 1.1 % ($p=0.001$) after one year and remained unchanged thereafter. In the SU group, HbA_{1c} increased continuously, and 21 of 26 patients had to be given insulin after a mean of 2.1 years due to hyperglycaemic symptoms or HbA_{1c} >10 %. When changed to insulin therapy, these patients achieved similar glycaemic control as those originally randomised to insulin 2) Due to the change of therapy in the SU group, we analysed the data according to the glycaemic control achieved, and found that 23 subjects had fair glycaemic control (average HbA_{1c} from year 1-5 < 8.0%). None of these patients had progression of albuminuria during the study, while 6 of the patients with average $HbA_{1c} \geq 8.0\%$ had such a progression. 3) The insulin dose at the end of the study was 0.82 ±0.4 U/kg. There was a significant negative correlation between the insulin dose and the insulin sensitivity index (GDRI) measured with the euglycaemic clamp technique at baseline ($p<0.01$). However, variations in GDRI predicted only 22% of the variations in insulin dose among patients. **Conclusion:** Insulin, but not SU therapy is able to achieve and maintain good glycaemic control during long term and good glycaemic control may prevent progression of albuminuria in patients with NIDDM.

39

A RANDOMIZED TRIAL OF COUNSELING FOR FAT RESTRICTION VERSUS USUAL DIETARY ADVICES IN THE TREATMENT OF NIDDM

C.Holler, E.Schrattenholzer, S.Pusarnig, M.Seifert, H.Abrahamian, and K.Irsigler. L.Boltzmann Research Institute for Nutrition and 3rd.Med.Dept. Lainz, Vienna, Austria

Dietary fats play a major role in the development of obesity and insulin resistance leading to NIDDM. In this study we tested the assumption that promoting a high carbohydrate- low fat diet consumed ad libitum may be a more effective dietary treatment of newly diagnosed NIDDM patients, than is a caloric restriction with a defined amount of carbohydrates. Fourty NIDDM patients were randomized to one of the two treatment groups and so far received intensive dietary counseling over a period of 6 months (a 5 year follow up is planned). One group (FAT-group) was instructed in reducing dietary fat with the possibility to eat carbohydrates and protein ad libitum. The other group (CAL-group) underwent the usual dietary advices, as caloric restriction with a defined daily amount of carbohydrates. Dietary intake, body weight, body composition, diabetes control (HbA1c) and dietary compliance (difference between resting energy expenditure and energy intake in %) were measured.

In contrast to the CAL-group energy derived from fat decreased significantly in the FAT-group (43% to 28% vs. 43% to 36%). The carbohydrate component increased in the FAT-group but remained constant in the CAL-group (43% to 51% vs. 42% to 44%). The resulting weight reduction after 6 months was significantly higher in the FAT-group (-3,5kg vs. -1,7kg in the CAL-group; $p<0,05$). The FAT-group reduced mainly body fat mass (80%), the CAL-group mainly lean body mass (75%). Diabetes control improved in both groups (HbA1c: FAT-group 10,6% to 7,1%; $p<0,01$ vs. CAL-group 10,0% to 7,6%, $p<0,01$). Dietary compliance ranged from 20 to 98% and was positively correlated to the loss of body fat mass and negatively to the loss of lean body mass. It was significantly better in the FAT-group (mean 72% vs. 45% in the CAL-group; $p<0,01$).

In conclusion, a 6 month counseling for fat restriction with ad libitum carbohydrate and protein intake in the dietary therapy of NIDDM decreases HbA1c in the same amount as an usual dietary advice. Nevertheless the compliance to the dietary advices was significantly higher in the FAT-group, resulting in a significantly higher weight reduction, mainly of fat mass.

40

CARBOHYDRATE MALABSOPTION FOLLOWING ACARBOSE ADMINISTRATION.

M. Mori, H. Sobajima, T. Niwa, S. Naruse, T. Kondo and T. Hayakawa Ogaki Municipal Hospital, Ogaki and Nagoya University, Nagoya, Japan.

Carbohydrate absorption during Acarbose administration was determined to investigate the action and side effects of this drug. In seven healthy volunteers, the breath hydrogen concentration was obtained at 15-min. intervals after administration of 6 g of lactulose, and the area under the concentration-time curve for four hours from the time that breath hydrogen exceeded the pretreatment level by ≥10 ppm was determined as the standard. Then the amount of undigested carbohydrate following administration of various doses of Acarbose and Ensure Liquid was calculated. In addition, breath hydrogen data were obtained before and after two and four months of Acarbose therapy in eight patients with non-insulin-dependent diabetes.There was a mean of 5.3 g, 7.7 g, and 10.8 g of carbohydrate unabsorbed after administration of 50 mg of Acarbose with 250 ml or 500 ml of Ensure and 100 mg of Acarbose with 500 ml of Ensure, respectively. Gastrointestinal symptoms (flatulence and loose stools) occurred when the amount of unabsorbed carbohydrate was 10 g or more.In the eight diabetic patients, breath hydrogen excretion decreased to 31.6% of the initial value following two months of Acarbose administration. Improvement of the hemoglobin A1C level was maintained after five months of administration.These results show that the increase of unabsorbed carbohydrate depends on the Acarbose dose and the carbohydrate load, as do the gastrointestinal symptoms experienced. Although the amount of unabsorbed carbohydrate decreases with continued Acarbose administration and gastrointestinal symptoms subside accordingly, improved glycemic control is maintained.

LONG TERM BENEFITS OF IMMEDIATE, INTENSIVE EDUCATION AT DIAGNOSIS OF NIDDM

J Everett, E Jenkins, P Miles, D Cavan and D Kerr. Metabolism unit, Royal Bournemouth Hospital, Bournemouth, UK.

In Bournemouth, all patients with new onset NIDDM are seen **within one week** of diagnosis in a group education programme. For the first 3 months, their sole care is given by the diabetes nurse specialist and dietitian according to pre-determined protocols. At 3 months, patients are screened for diabetic complications and the majority transferred to primary care for follow up as part of an integrated service. We have prospectively followed up a cohort of 156 patients referred between January and July 1994. 97% patients completed the programme and 92% were transferred to primary care within 12 months from diagnosis (of whom 8% have been referred back to secondary care).

Results	n	156	151	151	151	147
Outcomes(median)		Time from diagnosis(months)				
		0	3	6	12	24
HbAIc(%)		10.1	8.2	7.8	7.4	7.3
Weight(Kg)		80	79	76.9	77	77
Treatment(%)						
Diet only		100	49	51	46	46
Tablets		0	49	46	51	50
Insulin		0	2	3	3	4
Home monitoring(%)		Blood			42	38
		Urine			56	60
		None			2	2

	Nephropathy		10			12
	Neuropathy		11			13
	Macrovascular		17			17

Nurse led immediate patient management at diagnosis of NIDDM produces sustained, acceptable clinical outcomes.

42

EFFECTIVENESS OF EDUCATIONAL COURSES FOR INSULIN-TREATED WORKING-AGED PERSONS WITH DIABETES

J. Marttila, UKK-institute, Tampere, Finland, S. A. Salo, E. Haapa, L. Heinonen, M. Puomio, Diabetes Center, Tampere, Finland, L. Koskinen, The University Hospital of Tampere, Finland.

The aim of the study was to evaluate the effectiveness of six day educational courses for insulin-treated working-aged persons with diabetes. The main focus in the study was on subjective evaluations of the outcomes of treatment, selfcare practices, attitudes towards diabetes and its selfcare, and quality of life. The measures used were based on the Health Belief Model and perceived control of selfcare. HbA_{1C}-values were used as measures of blood glucose levels. Four measurements were done at different time points: the first one month prior to the course, the second (HbA_{1C} not included) in the beginning of the course, the third three months after and the fourth 12 months after the course. The same measurements were performed on the intervention group (N = 110) attending the courses and the reference group (N = 80) not attending the courses. The HbA_{1C}-values of the intervention group were significantly ($p < .01$) lower three months after the course (M = 8.54, SD = 1.39) compared to the values before the course (M = 9.17, SD = 1.55). The course attendees also considered some aspects of selfcare, especially nutrition, more effective and less demanding and had more trust in their ability to practice selfcare in these areas. The reference group did not show similar changes. One year after the course there was not much left of the positive effects observed in the three month follow-up. The courses did have some significant positive effects, but they were not very lasting. The potential key to more lasting results could be closer and more frequent cooperation between the course attendee and his or her local health care unit even after the course. The aim would be to reinforce the altered attitudes and selfcare practices.

43

LONGITUDINAL STUDY ON GLYCEMIC CONTROL AND QUALITY OF LIFE IN REFERRED NIDDM PATIENTS

P.P.M. Goddijn, H.J.G. Bilo, E.J.M. Feskens, K.H. Groenier, K I. VanderZee and B Meyboom-de Jong. Hospital De Weezenlanden, Zwolle, the Netherlands

Aim of the study was to describe the impact of improved glycemic control on Quality of Life (QoL) in NIDDM patients referred for insulin therapy to an outpatient department (OPD). The study population consisted of 94 NIDDM patients referred to and treated by an OPD diabetes team aiming at achieving acceptable glycemic control by means of maximizing oral therapy, if necessary switching over to insulin therapy, information and education provided by a diabetes nurse and dietician. QoL was measured by using a disease-specific (Diabetes Health Profile - DHP) and a generic questionnaire (RAND-36). After one year the medical examination and QoL measurement were repeated. Changes in QoL during one year were compared between subgroups according to hyperglycemic complaints at baseline, switching over to insulin therapy, and achieving good metabolic control. Regression analysis included presence of hyperglycemic complaints at baseline, switching over to insulin therapy and change in glycosylated hemoglobin (GHb) as independent variables and changes in QoL-outcome as dependent variables. After one year, both GHb and QoL improved in the total group. Patients with hyperglycemic complaints (n=46) improved more in QoL than those without, especially on physical functioning, social functioning, vitality, and health change of the RAND-36, but at the final examination still scored lower on most of the DHP and RAND-36 dimensions. Patients switched over to insulin (n=61) improved in a similar manner as the others, but at the final examination they had more problems with social functioning and pain. Patients who achieved good glycemic control (GHb $\leq$ 8%, n=57) after one year improved in a similar manner as the others. At an OPD, the efforts of a diabetes team to achieve acceptable glycemic control in referred NIDDM patients resulted in improved glycemic control and increased QoL outcome. Reduction of hyperglycemic complaints seemed to be a determinant of improvement in QoL-outcome, whereas achieving good metabolic control was not. Changing to insulin therapy did seem to have a negative impact on the dimensions social functioning and pain, but not in other dimensions.

44

DOCTOR-PATIENT COMMUNICATION DURING OUTPATIENT CONSULTATIONS IN NIDDM

A.M.van Dulmen and P.F.M.Verhaak, NIVEL (Netherlands institute of primary health care), Utrecht, the Netherlands

The treatment of NIDDM largely depends on self-management. Therefore, patients' needs need special consideration during medical consultations by means of effective communication. This will lead to higher levels of patient compliance and satisfaction, necessary in preventing complications and improving metabolic control. Patients' needs are likely to change through time. Ideally, doctor's communication patterns change accordingly. Our aim was to examine how communication behaviors actually change during a series of consecutive outpatient consultations in NIDDM. Therefore, the first 3 consultations between 18 newly referred patients with poorly controlled NIDDM and their internist were videotaped. Communication was measured by means of the Roter Interaction Analysis System. Changes in communication behaviors during these 54 consultations were analyzed using one-way analysis of variance and t-test. Results indicate that the doctor spoke longer than the patients during the repeat visits ($p<.05$). Accordingly, the amount of time the doctor looked at the patient declined gradually from initial to third consultation (58, 48 and 39% of the consultation time, resp., $p<.05$). In addition, during the first outpatient consultation the doctor was more attentive (e.g. he paraphrased more and requested more clarifications). Apparently, communication patterns do indeed change; during the initial consultation the doctor-patient interaction is more equal and reciprocal. To examine the impact of these communication patterns we are now investigating its relation with patients' attitude towards and intention to use insulin as well as on metabolic control by observing 120 consultations with 8 internists.

45

INTERACTION STRATEGIES IN DIETARY COUNSELLING OF DIABETIC CHILDREN

E. Pyörälä. University of Helsinki, Helsinki, Finland.

The purpose of this study was to analyse interaction strategies in naturally occurring dietary counselling encounters between a dietician, a diabetic child and his or her parent. The diabetics were either school starters (7 to 9 year-old) or teen-agers (13 to 15 year-old) who had had diabetes for at least half a year, and had had previous dietary counselling encounters. The research data consisted of 57 tape-recorded dietary counselling encounters at pediatric out-patient clinics of five hospitals in different regions of Finland. The recordings were transcribed according to the rules used in conversation analysis. The transcripts were then analysed in detail to trace the stable organized interaction formats in dietary encounters. The following formats were identified: opening sequence; definition of problems; dietary recall; picturing everyday-life of the diabetic and his or her family; information delivery; negotiating dietary change; and closing sequence. In most encounters several problems were raised and discussed, not only in the beginning but also in the course of the encounter. The following aspects were found to be important in order to make a dietary counselling encounter effective and interactive: 1) The dietician was flexible in switching from one format to another and in using formats within other formats according to the turns of speech of the other participants of the encounter. 2) The problems raised by a parent and especially those raised by the diabetic himself or herself were inmediately discussed. 3) The dietary changes were thoroughly negotiated and the opinion of the diabetic himself or herself was taken into account in a new dietary plan.

46

DIABETIC FOOT: PATIENTS' PERCEPTIONS OF RISKS, AND BARRIERS TO FOOTCARE MAY BE FINAL DETERMINANTS OF ULCERATION

L Vileikyte, JE Shaw and AJM Boulton, Department of Medicine, Manchester Royal Infirmary, Manchester, UK.

Neuropathic foot ulceration remains common despite the use of screening and educational programs. Patients' attitudes and beliefs may be important in determining footcare behaviour. We therefore investigated patients' beliefs about risks (severity and personal vulnerability) of foot complications, and barriers to and benefits of footcare, using Likert response scales, based on the Health Belief Model. 129 patients without evidence of peripheral vascular disease (PVD) were included - 39 diabetic controls (C), 47 patients with diabetic neuropathy (DN), 29 patients with previous neuropathic foot ulceration (DNU) and 14 patients with Charcot neuro-arthropathy (CH). Scores for severity showed foot complications (ulceration and gangrene) rated as highly as cardiac, renal and retinal disease. Vulnerability scores (range 0-5) were also similar for the major complications (cardiac 3.2, blindness 3.0, renal 3.0, foot ulcer 2.6, PVD 3.1), but in the DN group, vulnerability to foot ulceration scored lower than to PVD (2.3 ± 1.5 vs 3.03 ± 1.33, $p<0.05$). Subjects from DN, DNU and CH scored personal vulnerability to foot ulceration no higher than that for the "average diabetic patient" (2.7 ± 1.7 vs 2.8 ± 1.6). Benefits of footcare were rated universally highly in all 4 groups. Scores for barriers (range 0-6) to wearing appropriate shoes were reported as significantly higher than barriers to performing other aspects of footcare (3.6 ± 2.1 vs 2.5 ± 2.2, $p<0.001$). In conclusion, patients recognise the severity of foot complications, but even those at "high risk" do not accept their personal vulnerability. Also, barriers to appropriate footwear may explain the high rate of shoe induced ulcers.

47

GLUCAGEN® ADMINISTRATION - UNDEREVALUATED AND UNDERTAUGHT

G.Harris, A.Diment, M. Sulway and M. Wilkinson. Diabetes Education, Royal North Shore Hospital, Sydney, Australia.

Glucagen® treatment requires a manually dextrous 'operator' who is composed, confident and competent in the whole procedure. Anecdotal reports of difficulty from parents in this emergency led us to investigate the 'techniques' of 136 parents (106 parents of teenagers (T) mean age 14.7yrs, duration of DM 4.7yrs, and 30 parents of young children (C) mean age 5.8 yrs, duration of DM 2.4 yrs). A simulated administration by parents using Glucagen® Kits was timed, rated and compared with a group of diabetes health professionals. Parent's 'real life' experiences of education and administration were obtained with a standard questionnaire. Glucagon residues in syringes and vials were assayed in a laboratory.

GLUCAGEN® ADMINISTRATION	% UNUSED
Parents of teenagers (T)	21.3
Parents of children (C) > 25Kg	30.3
Parents of children (C) < 25Kg.	20.7

ADMINISTRATION TIME IN MINUTES -(MEANS)

Duration of Diabetes >2yrs(T)	<2yrs(T)	>2yrs(C) *	<2yrs(C)
Fathers (n=28) 3.32	(n=16) 2.90	(n=4) 1.62	(n=7) 2.22
Mothers (n=41) 3.03	(n=15) 2.68	(n=10) 1.83	(n=9) 2.35
Professionals (n=10) Mean = 1.28 ± 0.20 (sig. faster for all groups except *)			

We found the following problems: no home Glucagen® - 8.7%, handling difficulties - opening pack , sheath removal, mixing, needle bending - 70%, total syringe separation 4.4%, injecting water only - freeze dried powder left in vial- 3.7%.

Conclusion The simulated administration and survey have identified some difficulties which could seriously alter the effectiveness of this treatment. These findings indicate families need hands on demonstration at diagnosis plus regular re-education to minimise the risks of severe hypoglycaemia.

48

DRUG MISUSE IN TYPE 1 DIABETES

J.D. Quin and C. Prajapati. Department of Medicine, Royal Sussex County Hospital, Brighton, Sussex , U.K.

Exposure to illicit drugs in the young has increased dramatically over the past five years. Case reports illustrate the risks to patients with IDDM who indulge in drug misuse. We tried to determine the prevalence of drug misuse amongst our population with Type 1 diabetes. A survey was sent to 245 patients with IDDM in our district as identified by computer records with anonymity preserved for reply. A total of 111 (45.3%) replied, age range 16-45, mean 29 years, sex ratio 1.04 male/female. The number of patients with a history of being offered drugs was 49 (44%). The number who have used illegal drugs was 37 (33.3%) with 20 (18%) admitting to current use. The number with experience of cannabis was 36 (32.4%), amphetamine 10 (9%), cocaine 6 (5.4%), LSD 6 (5.4 %) and MDMA (ecstasy) 4 (3.6%). Two admitted to abuse of temazepam with one each for heroin and solvents. In conclusion drug misuse is not uncommon in our group. Given the mean age of reply we strongly suspect under-reporting of misuse in those under 20 years. These drugs may impair control and complicate ketoacidosis, as recently reported with MDMA.We would recommend that all young patients with IDDM should be questioned about drug misuse and given advice accordingly. This is particularly appropriate where illicit drugs are easily available.

CYTOKINES INDUCE DNA STRAND BREAKS AND APOPTOSIS IN HUMAN PANCREATIC ISLET CELLS C.A. Delaney[1], D. Pavlovic[2], A. Hoorens[2], D.G. Pipeleers[2] and D.L. Eizirik[1,2]. [1]Dept of Medical Cell Biology, Uppsala University, Uppsala, Sweden, [2]Dept of Metabolism and Endocrinology, Vrije Universiteit Brussel, Belgium.

We have previously shown that 6 days exposure of human pancreatic islets to a combination of cytokines (interleukin-1β 50 U/ml + tumour necrosis factor-α 1000 U/ml + interferon-γ 1000 U/ml), severely impairs β-cell function. In the present study we examined whether this condition affects the DNA integrity and viability of human islet cells. Cells were studied after 3, 6 and 9 days of cytokine treatment by both single cell gel electrophoresis (the "comet assay", a sensitive method for detection of DNA strand breaks) and by a cytotoxicity assay using the DNA binding dyes Hoechst 33342 and propidium iodide as indices for counting the number of viable, necrotic or apoptotic cells. Cytokine treatment for 6 and 9 days resulted in significant DNA strand breaks (n = 5; $P<0.05$ vs controls), and in the appearance of apoptotic cells (day 6, 46 ± 6% vs 13 ± 3% in controls, $P<0.001$; day 9, 56 ± 3% versus 20 ± 5% in controls, $P<0.001$). Treatment with cytokines did not increase the percentage of necrotic cells. Inhibitors of nitric oxide formation failed to prevent cytokine-induced DNA strand breaks and apoptosis.The present data suggest that prolonged (6-9 days) exposure of human pancreatic islets to a mixture of cytokines induces DNA strand breaks and cell death by apoptosis. These deleterious effects of cytokines appear to be independent of nitric oxide generation.

50

ROLE OF FAS LIGAND IN THE DEVELOPMENT OF INSULITIS IN THE NON-OBESE DIABETIC MICE

S. Sainio-Pöllänen[1,2], S. Erkkilä[1,2], S. Alanko[1,2], A. Hänninen[3], P. Pöllänen[1] and O. Simell.[2,1]Department of Anatomy, [2]Department of Pediatrics, University of Turku, and [3]National Public Health Institute, Turku, Finland

The aim of the present study was to study the role of Fas ligand-induced lymphocyte apoptosis in the development of insulitis in the non-obese diabetic (NOD) mice. Fas Ligand with a M_r of 45 kD appeared in the pancreas of NOD mice during onset of insulitis as demonstrated by western blot analysis. In situ DNA end-labelling (ISEL) of the pancreases of NOD mice demonstrated positive cells in the islets of Langerhans with an age-dependent increase in density and the frequency of animals with islets containing ISEL-positive cells. In the pancreatic islets of BALB/c mice, no ISEL-positive cells were observed in any of the studied age groups. In ultrastructural analysis degenerating cells with condensed or fragmented nuclei and plasma membrane detached from neighbouring cells were observed both in and around the islets. In some cases, these cells were being phagocytosed by the neighbouring islet cells. Degenerating cells with characteristics of lymphocytes were seen in contact with healthy lymphocytes around the islets. Neutralizing Fas-ligand antibodies affected ^{3}H-TdR incorporation of CD3+CD28+ pancreatic lymphocytes from 12-30-week-old NOD mice in one of three cultures. There was no difference in the effect of neutralizing Fas Ligand antibodies between the pancreatic and blood lymphocytes. The present results on the increase in density of apoptotic cells in the pancreatic islets of NOD mice simultaneously with the onset of insulitis and appearance of Fas Ligand suggest that the pancreas infiltrating lymphocytes may be destroyed by Fas-ligand-induced apoptosis.

OP 8

Epidemiology and Prevention of NIDDM

51

COLORECTAL CANCER (CRC): ANOTHER COMPLICATION OF DIABETES MELLITUS (DM)?

JCWill, DA Galuska, F Vinicor and E Calle. Centers for Disease Control and Prevention and the American Cancer Society, Atlanta, USA.

Delayed stool transit time and other gastrointestinal abnormalities are commonly observed in DM and are also known to be associated with CRC. Previous studies have generally included too few subjects with both DM and CRC to adequately assess the contribution of DM to CRC incidence after adjustment for important covariates. The 1959-1972 Cancer Prevention Study I, with more than one million respondents, provided a unique opportunity to explore whether the 15,500 eligible persons with DM were more likely to develop CRC during a 13 year follow-up period than were the 850,946 eligible persons without DM (CRC cases detected, DM=158, without DM=7069). Using proportional hazards analysis, we found that the age-adjusted incidence density ratio (IDR) for the association of DM with CRC among men was 1.27 (95% confidence interval [CI]=1.02,1.58) and 1.06 (CI=.84-1.34) for women. After adjustment for CRC risk factors such as race, educational level, body mass index, smoking, alcohol use, dietary intake, aspirin use, physical activity, and family history of CRC, the IDR was 1.30 (CI=1.03-1.65) for men and 1.16 (CI=0.87-1.53) for women. Restricting the analysis to persons aged 60 years and older (to eliminate persons who died early from heart disease, thus allowing a more equal comparison between persons with and without DM) resulted in a multivariable-adjusted IDR stronger for men (1.45,CI=1.07,1.97), but not for women (.99, CI=.66,1.49). In summary, a moderately increased risk for CRC among men with DM was observed. Future studies should clarify the intriguing possibility of a cancer-promoting gastrointestinal mileau, including delayed stool transit and elevated fecal bile acid concentrations, associated with hyperglycemia and neuropathy.

52

SERUM ANTIOXIDANTS AND RISK OF NON-INSULIN DEPENDENT DIABETES

A. Reunanen, P. Knekt, R-K. Aaran and A. Aromaa
National Public Health Institute, Helsinki, Finland

Antioxidants are shown to be protective factors for many chronic diseases but the knowledge of their role in the etiology of non-insulin dependent diabetes mellitus (NIDDM) is very scarce. We studied the association of serum levels of alpha-tocopherol, beta-carotene and retinol with the incidence of NIDDM in a nested case-control study within a prospective population study. Serum levels of the antioxidants were determined in 106 patients with NIDDM and 201 controls matched for sex and age. High levels of serum beta-carotene and alpha-tocopherol were associated with a decreased risk of NIDDM. The relative risk of diabetes between the highest and lowest tertiles of the beta-carotene and alpha-tocopherol distributions were 0.45 (95 % confidence interval 0.22 - 0.92) and 0.61 (95 % confidence interval 0.32 - 1.15), respectively. The trend in the decrease of the risk was statistically significant ($p < 0.05$) with the serum level of alpha-tocopherol. The trend remained significant after adjustment for the strongest risk factors for NIDDM, body mass index and fasting blood glucose at baseline. No association was observed with the serum levels of retinol and the risk of NIDDM. Our results support the hypothesis that high levels of antioxidants may decrease the risk of NIDDM.

53

NON INSULIN DEPENDENT DIABETES MELLITUS AND OBESITY IN MEXICAN PIMA INDIANS.

ME Valencia, J Esparza, E Ravussin, PH Bennett, C Fox, and L Schulz. Centro de Investigacion en Alimentacion y Desarrollo, Sonora, Mexico, NIDDK, NIH, Phoenix, AZ, USA, and University of Wisconsin, Milwaukee, WI, USA.

The development of NIDDM and obesity depends on both genetic and environmental factors. To investigate the impact of the environment we compared the prevalence of NIDDM and the mean body mass index (BMI) in Mexican Pimas living in Maycoba in the Sierra Madre mountains of Mexico to those in the Pima Indians of Arizona. These two groups of Pima Indians are thought to have separated 700-1000 years ago. The Mexican Pimas of Maycoba still live a traditional lifestyle with non-mechanized agriculture and lumber milling activities. We also compared the Mexican Pimas with non-Pimas living in the same environment. The entire population of Maycoba and surrounding community, aged 20 and over, were invited to undergo a 75g oral glucose tolerance test and anthropometric measures (weight, height). NIDDM and IGT were classified using WHO criteria. 141 Pimas (70F/71M) and 194 non-Pima Mexicans (101F/93M) from Maycoba were compared to 1004 Arizona Pima Indians (593F/411M) from the Gila River Indian Community. The prevalence rates are age-standardized to the Mexican Pima population and presented with 95% confidence intervals.

	Mex Pimas	NonPima Mex	AZ Pimas
NIDDM %	6.4 (2.2,10.6)	3.4 (3.3,6.4)	38.2 (33.8,42.6)
IGT %	6.4 (2.2,10.6)	8.2 (3.8,12.5)	10.5 (8.4,12.6)

The mean BMI in the Mexican Pimas was 24.9±3.9 (SD). This was similar to the non-Pima Mexicans (25.7±4.6), and lower than in the Arizona Pimas (34.2±8.2). The prevalence of NIDDM in the Mexican Pimas was only one-sixth of that in the Arizona Pimas, whereas the rate in the Mexican Pimas was higher, but not significantly so, than in non-Pimas. These results indicate the importance of environmental factors in preventing the development of both NIDDM and obesity in populations who presumably carry a genetic susceptibility to these conditions.

54

DECREASED TESTOSTERONE IS A PREDICTOR OF INCREASED INTRA-ABDOMINAL FAT IN SECOND-GENERATION JAPANESE-AMERICAN MEN

E.C. Tsai, E.J. Boyko, L. Newell-Morris, D.L. Leonetti and W.Y. Fujimoto. University of Washington, Seattle, USA.

Visceral adiposity is a risk factor for development of non-insulin dependent diabetes (NIDD) and coronary heart diseases (CHD). Because sex hormones also have been implicated in NIDD and CHD, we examined the association between baseline serum testosterone (T) levels and changes in visceral adiposity in a cohort of second-generation Japanese American (Nisei) men over 7.5 years (yr) of follow-up. At baseline, these men were assessed for glucose tolerance with a 75 g oral glucose tolerance test (WHO criteria); body mass index (BMI; weight in kg/height in cm^2); visceral adiposity measured as intra-abdominal fat area (IAF) at the level of umbilicus using computed tomography; and serum total T levels. IAF was re-measured at 7.5 yr follow-up. The outcome was defined as Δ IAF (7.5 yr IAF - baseline IAF). The final analysis included a total of 112 Nisei men with the following baseline characteristics (in mean±SD): age, 64±6 yr; BMI, 25.3±2.8; IAF, 120.9±49.2 cm^2; T, 16.8± 4.5 nmol/L. Also at baseline, impaired glucose tolerance (IGT) was diagnosed in 37 (33.0%) men and NIDD, 13 (11.6%). At the 7.5 yr follow-up, overall visceral obesity was increased by a mean ΔIAF of 6.0 (range 163 to -112). ΔIAF was significantly correlated only with: baseline T (r= -0.249, p=.004) and NIDD status (-0.247, .004), but not with age, baseline IAF, or BMI. In a multiple linear regression model with ΔIAF as the dependent variable, adjusting for baseline NIDD status, IAF, BMI, and age, baseline T was significantly related to ΔIAF (coefficient [β] = -8.60; 95% confidence limits [CL] -14.37 to -2.97; p=0.003). Therefore, in this Japanese-American male cohort, lower total testosterone is strongly predictive of an increase in visceral adiposity, independent of age, IAF, BMI, or NIDD status at baseline. This would suggest that visceral adiposity is one of the physiological manifestations through which testosterone could exert its influence on the development of NIDD and CHD, consistent with the role of this sex hormone in modulating body fat distributions.

55

FASTING PROINSULIN LEVELS PREDICT THE DEVELOPMENT OF NIDDM IN KOREAN SUBJECTS

H.K.Lee, C.S.Shin, J.H.Ahn, S.K.Kim, K.S.Park, C-S. Koh, Y.S.Park, H.Y.Paik, Y.I.Kim, Y.S.Shin and B.K.Yang, Seoul National University College of Medicine, Yonchon Health Center, Seoul, Korea

To investigate whether baseline insulin and proinsulin levels can predict the development of NIDDM in Korean people, we conducted a prospective study on the non-diabetic cohort for 2 years in Yonchon County of Korea. Among the initial 1197 non-diabetic subjects, a total of 67 subjects became diabetic in two years. We compared the baseline fasting insulin and proinsulin concentrations of these 67 subjects(New-DM) with those of age, sex, BMI and WHR-matched subjects(Non-DM, n=66) who remain non-diabetic. The baseline insulin concentrations of the New-DM group were not different from those of the Non-DM group(8.0 ± 2.9 vs. 7.3 ± 1.8 uIU/ml, $p>0.05$). However, the baseline fasting proinsulin levels of the New-DM group were significantly higher compared to Non-DM group(15.3 ± 14.5 vs. 8.7 ± 5.7 pmol/L, $p<0.05$). When we observed the natural history of the initial IGT subjects(n=153), 13% became diabetic and 53% remain IGT and 34% reverted to normal glucose tolerance status. The initial fasting proinsulin levels in these 3 groups were 20.6 ± 19.0, 13.0 ± 9.5, and 11.9 ± 7.7 pmol/L respectively ($p<0.05$, ANOVA). These results suggest that beta-cell dysfunction (as reflected by higher proinsulin levels) rather than insulin resistance (reflected by fasting hyperinsulinemia) plays the most important role in the future development of diabetes in Korean population.

56

HYPERINSULINAEMIA AND THE RISK OF STROKE: 22-YEAR FOLLOW-UP RESULTS OF THE HELSINKI POLICEMEN STUDY

M.Pyörälä, M.Laakso and K.Pyörälä, University of Kuopio, Kuopio, Finland

Several studies have shown that hyperinsulinaemia is associated with the risk of coronary heart disease, but little information is available on the association of hyperinsulinaemia with the risk of cerebrovascular disease. We have studied this association in a cohort of 1124 Helsinki policemen aged 34-64 years without previous stroke and diabetes at baseline examination in 1971-72 which included an oral glucose tolerance test (OGTT) with blood glucose and plasma insulin measurements at 0, 1 and 2 hours as well as measurements of other cardiovascular risk factors. The area under the plasma insulin response curve (AUCins) during OGTT was used as a composite variable reflecting plasma insulin levels. During 22-year follow-up 90 men had a fatal or non-fatal stroke. Age-adjusted and multiple-adjusted hazard ratios for stroke were calculated using the Cox proportional hazards model for men in the highest AUCins quintile vs those in the combined four lower quintiles. The age-adjusted hazard ratio for stroke risk was 1.68 (1.06-2.65;p=0.026). Adjustment, in addition to age, for the area under the blood glucose curve reduced the hazard ratio to 1.47 (0.90-2.42;NS), for body mass index to 1.23 (0.74-2.03;NS), for subscapular skinfold thickness to 1.27 (0.78-2.05;NS), and for systolic blood pressure to 1.55 (0.98-2.46;p=0.059). Similar adjustment for other factors potentially related to the risk of stroke (plasma cholesterol and triglycerides, smoking, degree of physical activity, and history of previous myocardial infarction) did not substantially reduce the hazard ratio. In a multiple adjustment including all the risk factors mentioned above the hazard ratio was reduced to 1.24 (0.74-2.09;NS). In conclusion, the association of hyperinsulinaemia with the risk of stroke was not independent of other risk factors. In particular, this association was closely linked with indices of obesity.

57

METABOLIC CHARACTERISTICS OF INSULIN RESISTANT SUBJECTS WITH S_I=0: THE INSULIN RESISTANCE ATHEROSCLEROSIS STUDY

S Haffner, G Howard, R Bergman, M Saad, A Karter and L Mykkänen, University of Texas Health Science Center, San Antonio, TX, USA.

We have previously shown in subjects from the Insulin Resistance Atherosclerosis Study (IRAS) that relatively few subjects with non-insulin dependent diabetes mellitus (NIDDM) are insulin sensitive (8% or 37/479) as judged by the median level of insulin sensitivity (S_I>1.67 10^{-4}•min•μU^{-1}•ml^{-1}) in non-diabetic subjects. One potential problem with the use of insulin modified frequently sampled intravenous glucose tolerance test (FSIGT) in diabetic subjects is that a relatively large number of NIDDM subjects have a S_I= 0. Characteristics of subjects with S_I=0 have not well characterized and could reflect either extreme insulin resistance or modeling problems. The distribution of insulin sensitivity in subjects with NIDDM was: insulin sensitive (S_I>1.67) 8%, n=37; insulin resistant (0<S_I≤1.67) 57%, n=270; and insulin resistant (S_I=0) 35%, n=172. Little is known about what characterizes these insulin resistant subjects with S_I>0 (n=270) vs. other insulin resistant subjects with S_I=0 (n=172). Results (by analyses of variance) are shown below:

	BMI	WHR	FI	TG	PAI-1
S_I=0	32.7	0.92	29.7	210	38.5
0<S_I≤1.67	31.0	0.91	21.0	178	29.8
p-value	<0.05	NS	<0.001	<0.001	<0.001

Abbreviations: *BMI=body mass index (kg/m²); WHR=waist/hip ratio; FI=fasting insulin (μU/ml); TG=triglycerides (mg/dl); PAI-1=plasminogen activator inhibitor-1 (ng/ml)*

Therefore, subjects with S_I=0 tended to be more obese, having higher FI and increased cardiovascular risk factors as suggested by high TG and PAI. These results suggest that NIDDM subjects with S_I=0 have metabolic characteristics associated with severe insulin resistance.

58

EARLY DIABETES INTERVENTION TRIAL

R.R.Holman, B.V.North and F.K.E.Tunbridge on behalf of the EDIT study group, UK.

The Early Diabetes Intervention Trial (EDIT) is a nine-centre three-year trial which aims to determine whether progression to diabetes can be prevented or delayed in subjects, thought to be at risk of diabetes, with two successive increased fasting plasma glucose (fpg) levels (5.5 - 7.7 mmol l^{-1}). 668 self-referred subjects (50% male) have been randomised, in a factorial design, to double-blind treatment with acarbose or placebo and metformin or placebo. Their mean (SD) age was 52 (10) y, body mass index 28.6 (4.6) kg m^{-2}, fpg 5.9 (0.7) mmol l^{-1} and glycosylated haemoglobin (HbA_{1c}) 5.9 (0.6) % (normal ≤6.2%). WHO categorisation of mean glucose levels from two post-randomisation 75g oral glucose tolerance tests (OGTT), two weeks apart, showed 46% to have normal glucose tolerance (NGT), 37% impaired glucose tolerance (IGT) and 17% diabetes (NIDDM). Mean HbA_{1c} levels increased by OGTT category (NGT 5.7%, IGT 5.9%, NIDDM 6.4%, p=0.0001) with 11%, 19% and 59% respectively having a raised HbA_{1c} (>6.2%). Regression analysis showed a two-hour glucose of 11.1 mmol l^{-1} was equivalent to an fpg of 6.2 mmol l^{-1}. 53% of subjects with an fpg above this value had a raised HbA_{1c}. Conclusion: 54% of the subjects studied, with increased but not diabetic fpg values, have IGT or NIDDM on OGTT. Follow up will determine whether classification of dysglycaemia by fpg, HbA_{1c} or OGTT best predicts those will progress to diabetes and whether early acarbose or metformin therapy can reverse, prevent or delay this progression.

RETINAL NEOVASCULARIZATION FROM EXPERIMENTAL ISCHEMIA IS INHIBITED BY A PKCβ INHIBITOR, LY333531.

R.P. Danis, D.P. Bingaman, M. Jirousek, L. Vignati, D.K. Ways. Department of Ophthalmology, IndianaUniversity School of Medicine, Indianapolis, Indiana, USA.

We tested the inhibition of preretinal and optic nerve head neovascularization from an ischemic stimulus by PKCβ inhibition to determine the therapeutic potential of this strategy. Orally-administered LY333531 was employed in a porcine model of neovascularization from branch retinal vein occlusion. Branch retinal vein occlusion was produced in 20 eyes of 10 pigs using Rose Bengal photodynamic therapy and argon laser treatment. Five animals with branch retinal vein occlusion were untreated as controls and five were fed LY333531 1 mg/kg twice daily. The eyes were followed clinically for 12 weeks by fundus photography and fluorescein angiography. The neovascularization was graded from fundus photographs and histopathology in a masked manner. Untreated eyes had a mean neovascularization grade of 1.9, and LY333531-treated eyes had a mean grade of 3.1. Treatment resulted in significant inhibition of neovascularization (p=0.04 by t-test). The drug was well tolerated. PKCβ inhibition with LY333531 effectively inhibited preretinal and optic nerve head neovascularization in the pig model of branch retinal vein occlusion, consistent with known signal transduction pathways by angiogenic growth factors, including VEGF. PKCβ inhibition may be effective in the therapy of diabetic neovascular eye disease, which is also ischemia-mediated.

60

EVALUATING RISK OF PROGRESSION TO PHOTOCOAGULATION BY RETINAL PHOTOGRAPHY OR DIRECT OPHTHALMOSCOPY.

I.M. Stratton[1], D.R. Matthews[1], E.M. Kohner[2], S. Aldington[2], R.R. Holman[1], and R.C.Turner[1]. University of Oxford[1] and Hammersmith Hospital, London[2], U.K.

The UK Prospective Diabetes Study is a randomised controlled trial of therapies of Non Insulin Dependent Diabetes. Four field 30° stereo photographs of each eye are graded centrally using the modified Wisconsin '191' scheme. This analysis is restricted to 788 subjects who had both eyes photographed and graded at each of the diagnosis, three, and nine year visits and direct ophthalmoscopy at diagnosis.

		Progression to photocoagulation	
Retinopathy level	n	3 years	9 years
No retinopathy	478	0.4%	2.5%
Microaneurysms only	190	1.0%	6.3%
Haemorrhages or hard exudates	58	12.1%	32.8%
Cotton wool spots or IRMA	62	41.9%	71.0%

		Progression to photocoagulation	
Ophthalmoscopy report	n	3 years	9 years
No retinopathy	701	1.0%	5.1%
Microaneurysms	32	15.6%	33.0%
Haemorrhages	10	30.0%	40.0%
Hard exudates	21	42.9%	61.9%
Cotton wool spots or new vessels	24	66.7%	83.0%

The sensitivity of increasing retinopathy levels from retinal photographs for progression to photocoagulation at 9 years is 0.86, 0.72 and 0.51 respectively and for ophthalmoscopy severity 0.59, 0.43, 0.38 and 0.23 respectively. We conclude that: progression to photocoagulation can occur within 3 years in newly diagnosed NIDDM subjects even when there is none at baseline; that baseline retinopathy level is a strong predictor of progression; that graded photography is a more sensitive method of identifying those who will progress than routine ophthalmoscopy.

61

EFFECT OF MODIFIED LOW DENSITY LIPOPROTEIN CHOLESTEROL AND α-TOCOPHEROL ON MESANGIAL CELL VIABILITY.

T.J. Lyons, T. Dean, W. Li, D. Gates, A. Jaffa, J-x. Ma, M. Willingham, S.R. Thorpe, J.W. Baynes and A.J. Jenkins. Medical Univ. of South Carolina, Charleston, U.S.A.

Background: Low Density Lipoprotein (LDL) cholesterol has been implicated in the development of glomerulosclerosis. LDL modified by glycation and/or oxidation, may contribute to diabetic nephropathy. α-tocopherol may ameliorate vascular damage. Previously we have shown that modified LDL toxicity to cultured retinal microvascular cells is abolished by α-tocopherol enrichment of LDL.

Aims: To determine the effects of modified LDL on mesangial cell viability, and if cell death is observed to determine if it is by apoptosis or necrosis.

Methods: Mesangial cells were cultured from non-diabetic Sprague-Dawley rats. Pooled LDL from non-diabetic humans was enriched *in vitro* with α-tocopherol, and subsequently modified by glycation, and/or minimal oxidation, and/or marked (Cu^{++} catalyzed) oxidation. Non-enriched modified LDL was also studied. Passage 3-6 cells were studied in growth phase and in quiescence, in triplicate. After 3 days exposure to LDL (protein 200 μg/ml) cell counts were determined by hemocytometer. Differences between cell counts (day 3/day 0) were assessed by 1 way ANOVA, with post-hoc analysis by Tukey's test. Video microscopy, flow cytometry and DNA fragmentation were used to evaluate cell death mechanism.

Results: Relative to unmodified LDL, that modified by glycation, minimal oxidation, and by the combination (glycoxidation) did not affect cell viability of quiescent cells (n = 3) or of cells in growth phase (n = 2) $p>0.05$. Relative to these LDL conditions markedly oxidized LDL and oxidized-glycated LDL was highly toxic $p<0.001$. Supplementation with α-tocopherol had no effect. Preliminary results suggest that growing cells die by apoptosis, and quiescent cells by necrosis.

Conclusions: Mesangial cell viability is not reduced by glycated, minimally oxidized and/or glycoxidized LDL. Markedly oxidized and oxidized glycated LDL is highly toxic. α-tocopherol supplementation of LDL has no effect. Death of growth phase cells is by apoptosis, while that of quiescent cells is necrosis.

62

THE EFFECT OF BLOOD PRESSURE RHYTHM ON THE PROGRESSION OF DIABETIC NEPHROPATHY.

C Farmer, J Cox, P Dallyn, P Sharpstone, J Kingswood, J Quin and D Goldsmith. Trafford Department of Renal Medicine, Brighton, England.

The aim of this study was to assess the contribution of an abnormal blood pressure diurnal rhythm on the progression of diabetic nephropathy. We retrospectively studied 26 patients with diabetic nephropathy between 1990 and 1996. Patients underwent ambulatory blood pressure monitoring and were classified as either 'dippers' or 'non-dippers' according to their blood pressure diurnal rhythm. Dippers were those patients whose mean sleeping blood pressure (systolic and diastolic) was 10% less than blood pressure whilst awake. Weight, glycated haemoglobin, serum creatinine,blood pressure and antihypertensive regime was recorded on a three monthly basis, with annual creatinine clearance and 24 hour urine protein excretion. The rate of decline of creatinine clearance was derived from serum creatinine estimation. Creatinine clearance was calculated using the Cockcroft-Gault formula. The two groups were compared using the Mann-Whitney U test,$p<0.05$. There were 13 patients in each group. There was no statistical difference between the the ages in each group (dippers:55, non-dippers:52), mean glycated haemoglobin (dippers: 7.4%, non-dippers: 8.5%), body mass index (dippers: 27kg/m^2, non-dippers: 29kg/m^2), 24 hour protein excretion (dippers: 2.7g/24hrs, non-dippers 3.5g/24hrs), starting serum creatinine (dippers: 105μmol/l, non-dippers: 95μmol/l) and numbers with Type 1 diabetes (Dippers:3, non-dippers:4). Mean clinic blood pressure and mean daytime ambulatory blood pressure were not statistically dirrerent in each group. Night time blood pressure was significantly higher in the non-dipper group as expected. The rate of decline of creatinine clearance (dipper: 2.9ml/min/yr, non-dipper 7.9 ml/min/yr, $p<0.05$) and the serum creatinine at the end of the study were significantly higher in the non-dipper group. In conclusion we found that there was a profound effect of non-dipping upon the rate of decline of creatinine clearance in patients with diabetic nephropathy.

63

A NEW HUMAN ATRIAL NATRIURETIC PEPTIDE GENE C/T POLYMORPHISM CORRELATES WITH MICROALBUMINURIA IN IDDM PATIENTS.

M. Nannipieri, G. Penno, L. Pucci, A. Bertacca, G. Cammarota, L. Rizzo, S. Bandinelli, L. De Giorgio, R. Navalesi. Pisa University; *La Spezia Hospital.*

Diabetic nephropathy develops in 30% of type 1 (IDDM) diabetic patients and carries an increased risk of early mortality from renal failure and cardiovascular disease. Microalbuminuria predicts clinical nephropathy and increases the long-term risk of cardiovascular disease. Based on the physiological actions on the kidney and in searching for a candidate gene for susceptibility to diabetic nephropathy, we studied the gene encoding for the human Atrial Natriuretic Peptide (hANP) in IDDM patients and in healthy controls. A fragment of 640 bp (from exon I to exon II) of the hANP gene was amplified by Polymerase Chain Reaction (primers: sense 5'-AGAC-AGAGCAGCAA-GCAGTG-3', antisense 5'-CATTTCCATCCCCAGTTCC-3'). To detect for point mutations, non-isotopic Single-Strand Conformation Polymorphism and direct sequencing have been used. We detected a new point mutation (708 C/T) in the hANP gene, introducing a new restriction site for *Bst*XI. Alleles' and genotypes' frequencies of this polymorphism were studied by RFLP analysis in 442 IDDM unrelated patients (216 M, 226 F) and 58 healthy controls (C) (28 M, 30 F). 313 IDDM subjects were normoalbuminuric (NA, AER <20 μg/min), 79 persistently microalbuminuric (mA, AER 20-200 μg/min), 50 macroalbuminuric (MA, AER >200 μg/min). The four groups were well matched for sex, age and BMI. Diabetes duration (years) was: 16±9, 18±7, 24±6; SBP (mmHg): 120±14, 121±16, 155±15, 120±12; DBP: 77±9, 78±12, 95±9, 75±8; serum creatinine (mg/dl): 0.86±0.2, 0.86±0.1, 1.82±1.5, 0.88±0.1; HbA1c (%): 7.6±1.9, 7.8±2.3, 8.9±1.4, 5.2±0.8, in NA, mA, MA and C, respectively. Alleles' frequencies were: NA: allele wild (W) 95.3%; allele mutant (M) 4.7%, mA: W 89.3%, M 10.7%; MA: W 96%, M 4%; C: W 96.5%, M 3.5%, p=0.001. Genotypes' distribution was: NA: W/W 90.4%, W/M 9.6%, M/M 0; mA: W/W 77.2%, W/M 21.5%, M/M 1.3%; MA: W/W 92%, W/M 8%, M/M 0; C W/W 93.1%, W/M 6.9%, M/M 0; p=0.001. The significant difference of the polymorphism distribution between microalbuminuric subjects and the other groups (NA, mA and C) persisted also when within NA patients were included only patients with a diabetes duration above 20 years (low risk of diabetic nephropathy). No difference was observed in the C/T polymorphism distribution in IDDM with or without hypertension and in IDDM with different degree of diabetic retinopathy. In conclusion, the new polymorphism in the hANP gene is not associated with overt nephropathy, but results associated with microalbuminuria.

64

METABOLIC AND GENETIC PREDICTORS OF PROGRESSION OF DIABETIC KIDNEY DISEASE.

A. Alaveras, S Thomas, M Margaglione[1], S de Cosmo[1], D Burt and G.C. Viberti. Unit for Metabolic Medicine, UMDS, UK,[1]Division of Endocrinology IRCC 'Casa del Sollievo della Sofferenza' San Giovanni Rotondo, Italy.

Hyperglycaemia, raised blood pressure and an insertion/deletion (I/D) polymorphism in the ACE gene, have all been implicated as risk factors for the development of diabetic kidney disease(DKD) but their relative role as promoters of progression remains unresolved. **Aim:** To assess in a cohort of IDDM patients with DKD the relative importance of blood glucose, blood pressure (BP) and the ACE genotype on disease progression. **Methods:** All IDDM patients with persistent albuminuria (> 300mg/24 hours) attending the diabetic clinic at Guy's Hospital between 1977 and 1993 were recruited. Measurements of BP, HbA_1 and GFR were performed six monthly until end - stage renal disease or death. The mean follow up period was 8 years (range 1.5 - 15.5 years). 58 patients were followed and ACE genotype was determined by PCR in the 34 surviving subjects still resident in the UK. Baseline and time dependent variables were related to the rate of change of GFR using weighted linear regression and stepwise multiple regression analysis. Analysis of co-variance was used to adjust for the effect of confounders. **Results:** Patients had well controlled BP throughout the observation period (mean arterial pressure 97 ± 8 mmHg) and the mean rate of fall of GFR was 4.32 ± 4.08 mls/min/year. Patients with a higher HbA_1 lost GFR at a faster rate. In stepwise multiple regression analysis both mean HbA_1 and mean diastolic BP were significantly and independently related with a faster rate of progression ($p< 0.0001$ and $p=0.019$ respectively). The I I genotype was independently associated with a slower rate of GFR fall ($p< 0.05$) **Conclusions:** In IDDM subjects who develop DKD, those with the I I genotype have a slower rate of progression, a process modifiable by blood glucose and BP control.

65

INCREASED ALBUMIN EXCRETION RATE IN NON-DIABETIC OFFSPRING OF NIDDM PATIENTS WITH DIABETIC NEPHROPATHY.

C. Forsblom, C. Saloranta, S. Karanko, and L. Groop, The Botnia Study Group. Helsinki University, Helsinki, Finland, and Lund University, Malmö, Sweden.

Diabetic nephropathy (DNP) clusters in families with both IDDM and NIDDM. Offspring of NIDDM patients have an increased risk of developing diabetes and have also been shown to have an increased albumin excretion rate (AER). It is not known whether this is a general feature of NIDDM or a consequence of increased AER in the diabetic parent. To address this question we studied non-diabetic offspring of 16 (10M/6F) NIDDM patients with (DNP+), and 49 (22/27) NIDDM patients without any sign of diabetic nephropathy (DNP-). Both groups of NIDDM patients had similar age (73±1 vs 70±1 yrs), BMI (28.2±1.1 vs 27.5±0.5 kg/m^2), and diabetes duration (9.1±1.3 vs 10.7±0.6 yrs). Data presented are mean±SEM. Offspring of DNP+ were more obese (p=0.0002) and had increased AER vs offspring of DNP- even after adjustment for BMI (p=0.01).

	OffspringDNP+	OffspringDNP-	p-value (adj.BMI)
n (M/F)	26 (8/18)	90 (30/60)	
Age (yrs)	42.0±1.2	41.4±0.8	
BMI (kg/m^2)	28.4±0.9	24.4±0.3	0.0002
Waist/hip	0.924±0.016	0.882±0.009	0.025 (0.3)
SBP / DBP (mmHg)	124±3 / 78±2	124±1 / 79±1	
FBG (mM)	5.1±0.1	5.0±0.1	
AUCgluc	165±30	144±13	
FSI (pM)	52±7	43±2	
AUCins	29040±2760	28020±1800	
lnAER (µg/min)	1.94±0.19	1.23±0.08	0.002 (0.01)

In conclusion, a genetic predisposition to both DNP and NIDDM, is associated with increased AER and obesity, particularly abdominal obesity, in the offspring.

66

PROGRESSION OF DIABETIC NEPHROPATHY DURING LONGSTANDING ANGIOTENSIN CONVERTING ENZYME INHIBITION - THE IMPACT OF POLYMORPHISMS IN THE RENIN ANGIOTENSIN SYSTEM

L.Tarnow, P.Rossing, F.S.Nielsen, F.Cambien* and H.-H. Parving. Steno Diabetes Center, Copenhagen, Denmark; *INSERM SC7, Paris, France.

We tested the concept, that polymorphisms in the genes coding for angiotensin converting enzyme (ACE) (ACE/ID), angiotensinogen (Ang235 and Ang174) and the angiotensin-II-Type 1 receptor (AGT1R^{1166}) predicts the therapeutic efficacy of ACE inhibition on progression of diabetic nephropathy. Sixty six IDDM patients with diabetic nephropathy were investigated before and during ACE inhibition for a median of 8 (range 3-12) years. No difference in glomerular filtration rate (GFR), albuminuria, blood pressure and haemoglobin A_{1c} was observed between patients with DD-genotype (n=20) and patients with ID or II genotype (n=46) at baseline. In 80% of patients a loop-diuretic was added to captopril (mg/day)(DD: mean 59 (SD 26) and ID +II: 48 (30), NS). Captopril induced nearly the same reduction in mean arterial blood pressure (mm Hg) to mean 102 (SD 8) vs 100 (10) in DD vs ID+II,respectively. Geometric mean albumin excretion (µg/min) remained unchanged in the DD group 567 (antilog SE 1.2), while it decreased from 820 (1.1) before to 419 (1.1) during ACE inhibition in the ID+II group, (p=0.04, comparing changes between groups). The sustained rate of decline in GFR (linear regression of all GFR measurements during ACE inhibition, ml/min/yr) was significantly steeper in DD than in ID+II patients, 4.1 (13.0 to -1.0) vs 2.7 (19.3 to -1.0), respectively (p= 0.03). Patients with the AA genotype of the AGT1R gene polymorphism (n=34) tended to progress at a faster rate than AC+CC patients(n=32), 3.9 (19.3 to -1.0) vs 2.5 (13.0 to -0.7) ml/min/yr, respectively (p= 0.05), while no difference in decline in GFR was observed between the different genotypes of the Ang235 or the Ang174 polymorphisms. The lowest rate of progression was found in patients with ID+II and AC+CC genotype, 2.0 (7.6 to -0.7), (analysis for trend, p= 0.02). Our study suggests that the deletion polymorphism in the ACE gene reduces the longterm beneficial effect of ACE inhibition on albuminuria and the progression of diabetic nephropathy in IDDM patients. The impact on deterioration of kidney function from the Ang235, Ang174 and AGT1R polymorphisms are less important.

OP 10

Coagulation and Lipids

67

HYPERGLYCEMIA ACTIVATES BLOOD COAGULATION IN NORMAL SUBJECTS INDEPENDENT OF HYPERINSULINEMIA

G. Boden, X. Chen, V. Chouhan and A.K Rao. Temple University Hospital, Philadelphia, PA, USA

Patients with NIDDM have increased blood coagulability. It was the purpose of this study to investigate in healthy males whether hyperglycemia or hyperinsulinemia may contribute to this defect. Hyperglycemic clamps (glucose ~ 11 mM, insulin ~ 1000 pM) were performed for 48 h in 4 subjects. Hyperinsulinemic-euglycemic clamps (insulin ~ 1000 pM) were performed for 48 h in 5 subjects and served as controls. Plasma factor VIIa (FVIIa, measured with soluble tissue factor), FVIIC and FVIIIC (measured by one stage clotting assays), tissue factor pathway inhibitor antigen (TFPI) and prothrombin fragment F1.2 (reflecting thrombin generation) all rose during hyperglycemic/hyperinsulinemic clamps but remained unchanged during hyperinsulinemic/euglycemic clamps.

	Hyperglycemia		Hyperinsulinemia	
	Baseline	48 hrs	Baseline	48 hrs
FVIIa (mU/ml)	14.3±1.14	80.3±17.7*	33.7±3.21	33.6±3.33
FVIIC(U/ml)	09.0±0.05	1.64±0.16*	0.81±0.08	0.81±0.08
FVIIAg (%)	68.3±2.8	62.1±0.74	72.2±5.02	69.1±3.61
TFPI (ng/ml)	68.0±7.02	105.0±15.95*	74.6±6.85	74.8±4.58
FVIIIC(U/ml	1.11±0.05	1.37±0.02*	1.10±0.07	1.10±0.07
F1.2 (nM)	0.81±0.09	1.25±0.14*	1.22±0.16	1.64±0.46

Comparison of baseline vs 48 hrs: *p<0.05

We conclude that hyperglycemia per se can activate blood coagulation in healthy subjects and may be a factor predisposing chronically hyperglycemic patients for cardiovascular complications.

68

SUPPRESSION OF FIBRINOLYSIS AND INCREASED FACTOR VII CONCENTRATIONS WITH DYSGLYCAEMIA.

P.J.Grant*, S.Karunakaran† and R.R.Holman† on behalf of the EDIT study group. Leeds General Infirmary* and the University of Oxford†, UK

Subjects with non-insulin dependent diabetes (NIDDM) or impaired glucose tolerance (IGT) are at increased vascular risk. Tissue plasminogen activator (tPA) Ag, plasminogen activator inhibitor-1 (PAI-1) Ag and factor VII Ag are haemostatic risk factors that cluster with insulin resistance in relation to dysglycaemia. Plasma concentrations were assayed in 248 subjects with increased fasting plasma glucose (fpg) levels (5.5 - 7.7 mmol l^{-1}) recruited into the Early Diabetes Intervention Trial (EDIT). The mean of two oral glucose tolerance tests (OGTT) showed 19% to have NIDDM, 36% IGT and 45% normal glucose tolerance (NGT). tPA Ag levels (mean) correlated with OGTT status (NIDDM 11.2, IGT 10.7, NGT 9.2 ng ml^{-1}, p=0.0014) and were higher than in 164 non-diabetic (fpg <5.5 mmol l^{-1}) controls (7.6 ng ml^{-1}). PAI-1Ag levels were higher than controls (7.7 ng ml^{-1}) and showed a similar OGTT trend (NIDDM 40.1, IGT 38.9, NGT 32.8 ng ml^{-1}, n.s.) as did factor VII Ag (NIDDM 132.8, IGT 126.9, NGT 124.8 ng ml^{-1}, n.s.). Ln PAI-1 Ag, tPA Ag and factor VII Ag were significantly correlated with insulin resistance features including body mass index, triglyceride and Ln fasting RIA insulin. Factor VII Ag levels were higher in females (132.4 *vs* 122.3 ng ml^{-1}, p=0.006) and tPA Ag levels higher in males (10.9 *vs* 9.2 ng ml^{-1}, p=0.0002). PAI-1 Ag levels did not differ with gender. These results indicate that haemostatic risk factors are increased in early dysglycaemic states and may contribute to IGT associated atherothrombotic risk.

69

GENETIC AND ENVIRONMENTAL DETERMINANTS OF FACTOR VII ACTIVITY IN HONG KONG CHINESE DIABETIC PATIENTS

KSL Lam, ED Janus, OCK Ma and C Bourke. Dept. of Medicine, Clinical Biochemistry and Pathology, University of Hong Kong, Hong Kong.

We studied the effects of genetic and environmental influences on factor VII coagulant activity (VIIc) in Chinese diabetic patients (264 NIDDM and 78 IDDM) and 143 normal controls. VIIc was measured by one-stage biological assay. The Arg→Glu mutation at residue 353 of the factor VII gene, which leads to loss of an MspI restriction site (M2 allele) and lower VIIc levels, was detected after MspI digestion of polymerase chain reaction-amplified genomic DNA. In both diabetic and control Chinese subjects the allele frequencies for M1 and M2 were 0.96 and 0.4 respectively, the corresponding reported frequencies in Caucasians being 0.89 and 0.11 respectively. As in Caucasians, VIIc levels were 22% lower in Chinese controls with M1M2 versus M1M1 genotype ($p<0.01$). The corresponding difference was 4% for NIDDM and 24% for IDDM patients respectively ($p=NS$). Despite similar genotypic distributions, NIDDM patients had higher mean VIIc levels than controls and IDDM patients ($p<0.01$); they were also older, and had higher serum creatinine, triglyceride, apo B (all $p<0.01$) and HbA1c ($p<0.01$ and <0.05 respectively), and lower HDL-cholesterol and apo A1 (both $p<0.01$). VIIc levels were similar between IDDM and controls. On multivariate regression analysis, serum triglyceride was the most significant independent determinant of VIIc ($p<0.0001$), contributing to over 25% of the variability in controls and diabetic patients. The contribution of the Arg_{353}→Glu genptype, although significant ($p<0.001$) was only 2.1 % for all subjects and 1% for diabetic patients. Other significant environmental determinants included age, female sex, total cholesterol, serum creatinine, mean albumin excretion rate and HbA1c. VIIc was higher in diabetic patients with macroangiopathy ($p<0.005$) and retinopathy ($p<0.0001$). In conclusion, the M2 allele is apparently less common in Chinese than in Caucasians. Plasma VIIc is determined by both genetic and environmental influences such that in NIDDM patients, the effect of environmental factors, particularly that of hypertriglyceridaemia predominates, almost negating the genetic influence. High VIIc may contribute to the development of macroangiopathic complications and perhaps also retinopathy in patients with NIDDM.

70

HYPERTRIGLYCERIDEMIA IS AN INDEPENDENT PREDICTOR OF ELEVATED ENDOTHELIN-1 AND BLOOD PRESSURE LEVELS IN SUBJECTS WITH PLURIMETABOLIC SYNDROME.

P.M. Piatti, L.D. Monti, C.V. Phan, G. Valsecchi, B. Guazzini, L. Baruffaldi, B. Dallagrassa, E. Fochesato, A. Pizzini, A.E. Pontiroli, G. Pozza. Istituto Scientifico H. San Raffaele, Milano, Italy.

Subjects with plurimetabolic syndrome or syndrome X (sX) show higher risks to develop cardiovascular disease and increased endothelin-1(ET-1) levels than normal subjects. Since sX is a composite of metabolic alterations (hyperinsulinemia, insulin resistance, hypertriglyceridemia, low HDL cholesterol, visceral obesity), it is not completely elucidated the contribution of each component to increase ET-1 levels. To answer this question we studied one hundred forty subjects divided in three groups. Group 1 included patients with impaired glucose tolerance (IGT: n=10) or non-insulin dependent diabetes mellitus (NIDDM: n= 30) with sX and group 2 included patients with IGT (n=8) or NIDDM (n=32) without sX. Groups 1 and 2 were matched for age, sex, fasting and 120 min post OGTT blood glucose (BG) levels, HbA1c, physical activity, duration of diabetes and diabetic complications. Group 3 included 60 normal subjects as control. Triglycerides, insulin levels, insulin resistance index (HOMA), waist/hip ratio and mean blood pressure were significantly higher ($p<0.05$) in group 1 than in groups 2 and 3. In contrast, only BG, HbA1c, insulin levels and HOMA were significantly different between group 2 and 3. ET-1 levels were higher in group 1 than in groups 2 and 3 (9.8±06 vs 8.0±0.5 and 7.0±0.4 pg/ml, $p<0.01$; NS between group 1 and group 2). At single regression analysis, ET-1 levels significantly correlated with triglyceride ($r= 0.35$; $p<0.0001$), insulin levels ($r=0.26$; $p<0.002$), body weight ($r=0.18$; $p<0.003$), HOMA ($r=0.22$; $p<0.009$) and mean blood pressure ($r=0.23$; $p<0.005$). On the contrary, at multiple regression analysis, only triglyceride levels remained independently correlated with ET-1 ($p<0.001$) and mean blood pressure ($p<0.001$). In conclusion, our data seem to suggest a strong role of chronic hypertriglyceridemia as an independent predictor of increased ET-1 levels and hypertension in subjects with syndrome X.

71

IMPROVED METABOLIC CONTROL MAKES LDL MORE RESISTANT TO OXIDATION IN SUBJECTS WITH NIDDM.

WA Oranje, GJWM Rondas, GNM Swennen and BHR Wolffenbuttel. Dep of Endocrinology, University Hospital Maastricht, The Netherlands.

Oxidised LDL may play an important role in the development of atherosclerosis because it can induce foam cell formation and exerts cytotoxic and immunogenic effects. Studies on LDL oxidation in NIDDM have yielded controversial results. We studied whether improvement of metabolic control, achieved by insulin therapy, reduced LDL oxidation, assessed by two parameters (Thiobarbituric Acid Reactive Substances (TBARS) and production of Conjugated Dienes after Cu^{2+}-induced oxidation). Twenty subjects with NIDDM and secondary failure to oral antihyperglycaemic agents (age (mean±SD) 58±12 yrs; median time from diagnosis of diabetes 9 (range 1-38) yrs, body mass index 30.2±7.1 kg/m^2; HbA1c 10.5 ±1.0 %) participated. Serum total cholesterol was 6.6±0.9 , HDL 0.9±0.3, LDL 3.8±0.7 and TG (median,range) 3.07 (0.95-7.09) mmol/l. While HbA1c level decreased to 8.0±0.6 % ($p<0.001$) after on average 4 months, lag phase, as a measure of the resistance to oxidation, was prolonged from 60.7±6.2 to 67.5±8.0 min ($p<0.003$). Dienes production rate decreased from 16.9±2.3 to 14.8±1.9 umol/g protein ($p=0.001$). T max (time at which maximum production of dienes is reached) was prolonged from 108±9 to 121±11 min ($p<0.001$). The change in lag phase did not correlate with the decrease in HbA1c, fasting glucose, triglycerides, total cholesterol or LDL cholesterol. Serum TBARS levels did not show any change. We conclude that resistance of LDL to oxidation is improved in subjects with NIDDM when better metabolic control is achieved. This is not reflected by lowering of TBARS levels, which can be explained by the fact that TBARS is an overall index of oxidation and does not measure solely lipid peroxidation.

72

LDL SIZE, INSULIN RESISTANCE, AND CORONARY HEART DISEASE IN AMERICAN INDIANS: THE STRONG HEART STUDY

R. Stuart Gray, David C. Robbins, Wenyu Wang, Jeunliang L. Yeh, Richard R. Fabsitz, Linda D. Cowan, Thomas K. Welty, Elisa T. Lee, Ronald M. Krauss, Barbara V. Howard; Medlantic Research Institute, Washington, DC

Small, dense LDL has been associated with the insulin resistance syndrome and coronary heart disease (CHD). The aim of the study was to examine the distribution of LDL size and phenotype within a population-based sample of American Indians to determine relationships with prevalent CHD and to examine associations with hyperinsulinemia and other components of the insulin resistance syndrome. Data are available for 4505 men and women 45-74 years of age who are members of 13 American Indian communities in three geographic areas. Diabetes, CHD, and CHD risk factors were assessed by standardized techniques; LDL size was measured by gradient gel electrophoresis. LDL size was smaller in men compared to women, and in diabetics compared to nondiabetics. In multivariate analysis, LDL size was significantly related to several components of the insulin resistance syndrome, including triglycerides (inversely) and HDL cholesterol (positively). Although univariate relations were positive, LDL size was not significantly related to fasting insulin concentrations or body mass index in the multivariate model. LDL size also showed no relationship to apoE phenotype. When LDL size was compared in those with and without CHD, no significant differences were observed in nondiabetic or diabetic individuals. We conclude that LDL size is most strongly related to lipoprotein components of the insulin resistance syndrome, especially plasma triglycerides. However, in this population with low LDL, it is not related to cardiovascular disease.

73

CHOLESTERYL ESTER TRANSFER PROTEIN GENE POLYMORPHISMS IN CHINESE PATIENTS WITH NON-INSULIN-DEPENDENT DIABETES MELLITUS

KCB Tan, SWM Shiu and KSL Lam. Department of Medicine, University of Hong Kong, Hong Kong.

We determined the effect of variation at the cholesteryl ester transfer protein (CETP) gene locus on plasma lipid levels in 129 healthy volunteers and 191 Chinese patients with non-insulin-dependent diabetes mellitus (NIDDM). The TaqIA restriction fragment length polymorphism (RFLP) generates two alternative fragments of 7.5kb (A1) and 9.0kb (A2) whereas the TaqIB RFLP produces fragments of 4.4kb (B1) and 5.3kb (B2). There were no significant differences in the allele distribution at these polymorphic loci between the controls (A1=0.86, A2=0.14; B1=0.56, B2=0.44) and the diabetic patients (A1=0.91, A2=0.09; B1=0.65, B2=0.35) and the allele frequencies were similar to those described in Caucasian populations. Diabetic patients with the genotype 1-1 of the TaqIA polymorphism had significantly lower HDL cholesterol (HDL-C) than those with the genotype 1-2 (male: 1.05 ± 0.31 mmol/l vs 1.29 ± 0.45, $p<0.05$; female: 1.14 ± 0.30 vs 1.32 ± 0.42, $p<0.05$). No significant differences were observed in age, body mass index, total cholesterol, triglyceride, LDL cholesterol or HbA1c levels between the two genotypes. A similar association between TaqIA polymorphism and HDL-C was not seen in the controls. Fasting lipid levels between subjects with different genotypes of the TaqIB polymorphism were not significantly different in either the diabetic patients or the controls. In summary our data indicate that there is an association between TaqIA polymorphism of the CETP gene and plasma HDL-C concentration in Chinese patients with NIDDM.

74

EFFECTS OF POSTMENOPAUSAL HORMONE REPLACEMENT THERAPY ON SERUM LIPIDS AND LIPOPROTEINS IN NIDDM WOMEN

S. Lahdenperä, J. Saltevo, J. Puolakka and M.-R. Taskinen, University of Helsinki and Jyväskylä Central Hospital, Finland

Postmenopausal hormone replacement therapy (HRT) is associated with a decrease in coronary disease risk in nondiabetic women. However, the effects of postmenopausal hormone replacement therapy on the common CAD risk factors in women with NIDDM are still unknown. Therefore, the aim of the present study was to evaluate the effects of HRT with transdermal or oral estrogen/progestin on serum lipoproteins in postmenopausal women with NIDDM. Twelve postmenopausal NIDDM women (age 54.4±4.0 years, BMI 31.3±5.3 kg/m^2) receiving oral hypoglycemic medication participated into this cross-over study. All the study subjects received oral HRT (estradiol 2 mg/day plus norethisterone acetate 1 mg/day) for 3 months and transdermal HRT (patches delivering estradiol 50 μg/day) for 3 months. Active treatment phases were separated by a placebo period of 3 months. Blood samples for serum lipoprotein measurements were obtained at the end of each treatment period.

	Baseline	Transdermal HRT	Placebo	Oral HRT
HbA1c,%	7.7±1.4	8.1±1.3	8.2±1.4	7.6±1.0
Cholesterol,mM	6.0±1.0	6.1±1.2	5.8±1.1	5.4±1.0*
Triglycerides,mM	1.8±0.7	1.7±0.7	1.7±0.7	1.8±0.7
HDL-Chol,mM	1.06±0.25	1.06±0.18	1.03±0.21	1.02±0.22
LDL-Chol,mM	4.1±1.0	4.2±1.0	4.0±1.1	3.4±0.8*
ApoB,mg%	110±21	109±16	110±14	109±25
Lp(a), mg%	260±287	203±230	264±269	231±234*

*p<0.05 vs Baseline, Transdermal HRT, and Placebo

We conclude that 1. The route of HRT administration determines the effects on lipoproteins, and 2. postmenopausal HRT with continuous oral administration of estradiol and progestin induces antiatherogenic changes in serum lipoproteins without any deterioration in glycemic control.

THE SARDINIAN SCHOOL CHILDREN - IDDM (SSI) STUDY. GEOGRAPHICAL DISTRIBUTION OF ISLET-RELATED AUTOANTIBODIES IN 7574 HEALTHY SCHOOL CHILDREN.

V Sepe, A Loviselli*, F Velluzzi*, MA Cambosu*, S Mariotti*, G Fanciulli**, G Delitala**, M Shattock, R Foxon, M Songini***, GF Bottazzo & the SSI Study Group. *Dept of Immunology, St Bartholomew's & The Royal London School of Medicine & Dentistry, UK; * Dept of Internal Medicine, Cagliari University & **Dept of Endocrinology, Sassari University & *** Centre for Metabolic Diseases and Atherosclerosis, Cagliari, Italy.*

In order to identify high and low risk areas of pre-IDDM in Sardinia, 7574 school children (sc) have been recruited in 27 towns (t) of the 4 Sardinian provinces, Cagliari (CA, t=7, sc=2628), Oristano (OR, t=5, sc=1727), Nuoro (NU, t=12, sc=1908) and Sassari (SS, t=3, sc=1311). The sera collected were tested for ICA (7574), GADA (5408) and IA-2icA (5411) respectively. CA showed the highest prevalence of ICA$^+$ for titres $\geq$5 JDFu (5.7%; p<0.01 vs OR=2.8% and NU=3.5%), whereas CA (1.4%) and OR (1.2%) had the highest prevalence of ICA$^+$ for titres >20 JDFu (p<0.05 vs NU=0.5%). OR also had the highest prevalence of GADA$^+$ (2.1%; p<0.05 vs CA=1.1%, NU=0.7% and SS 0.7%) and IA-2icA$^+$ (1.5%; p<0.05 vs SS=0.3%). Combination of autoantibody specificities was always higher in OR than in the 3 other provinces. The prevalence of ICA$^+$ & IA-2icA$^+$ in OR was 0.9% (p<0.01 vs SS=0.1%), GADA+ & IA-2icA$^+$ was 1.0% (p<0.05 vs CA=0.2%, NU=0.0% and SS=0.1%) and ICA$^+$ & GADA$^+$ & IA-2icA$^+$ was 0.7% (p<0.05 vs CA=0.2%, NU=0.0% and SS=0.1%). The identification of OR as an area with the highest prevalence of islet-related autoantibodies is consistent with the EURODIAB data, also showing the highest incidence of IDDM in OR (45 new cases /100,000 inhabitants /0-14 yrs) when compared with CA (38), NU (35) and SS (30). NU and SS, with the lowest incidence of IDDM, had the lowest prevalence of islet-related autoantibodies, either when analysed as individual or combined specificities. Our data showed that, within the island of Sardinia, the geographical pattern of potential pre-IDDM individuals, identified thought islet-related autoantibody determination in a large sc cohort, seems to follow that of the incidence of the disease.

76

IA-2 ANTIBODIES IN GENETICALLY HIGH AND LOW RISK SIBLINGS OF CHILDREN WITH IDDM

P. Kulmala, K. Savola, H. Reijonen, E. Tuomilehto-Wolf, J. Ilonen, H.K. Åkerblom, M. Knip and the DiMe Study Group. Department of Pediatrics, University of Oulu, Oulu, Finland, Department of Virology, University of Turku, Turku, Finland, National Public Health Institute, Helsinki, Finland, and the Children's Hospital, University of Helsinki, Helsinki, Finland

To explore the relation between IA-2 antibodies (IA-2A) and genetic risk markers of IDDM, 703 siblings (323 boys) of children with newly diagnosed IDDM were examined. The mean age of the siblings was 9.9 years (range 0.8-19.7 years). IA-2A were tested with a radioligand assay. All siblings with available samples were typed for HLA A, B, C, DR and DQB1 alleles. Data on HLA DQB1 alleles were available for 447 siblings. Thirty-six siblings (5.1%) tested positive for IA-2A in their first sample (cut-off level 1.46 relative units based on the outer fence of 374 healthy control children). 11% of HLA identical siblings had IA-2A compared to 3.1% of haploidentical and 3.5% of non-identical siblings (p=0.0005). 15% of HLA DR3/DR4 heterozygous individuals had IA-2A, compared to 6.6% of DR4/x positive (x=other than DR3), 1.1% of DR3/y positive (y=other than DR4) and 2.3% of siblings negative for DR3 and DR4 (p=0.0002). HLA DR3/DR4 heterozygous siblings had higher IA-2A levels compared to the others (p=0.029). Only one (0.8%) of of those 118 siblings with the protective HLA DR2 allele tested positive for IA-2Acompared to 6% of the other siblings (p=0.021). 21% of siblings with the DQB1*0201/0302 genotype tested positive for IA-2A, compared to 10% of those positive for DQB1*0302/x (x=other than 0201), 4.8% of those positive for DQB1*0201/y (y=other than 0302), and only 1.4% of the remaining siblings (p=0.00002). Siblings heterozygous for DQB1*0201/0302 tended to have higher antibody levels than the other siblings (p=0.069). Two (1.6%) out of 126 siblings positive for the protective DQB1*0602 or 0603 alleles were IA-2A positive compared to 8.1% of the remaining siblings (p=0.011). These results indicate that IA-2A are more frequent in siblings HLA identical with the diabetic proband than in haplo- and non-identical siblings. IA-2A positivity is associated with HLA DR and HLA DQB1 risk alleles, and the frequency of these antibodies increases as a function of enhanced genetic risk for IDDM. Subjects with the strongest genetic risk seem to have higher IA-2A levels than the other siblings. The protective HLA DR and DQB1 alleles are inversely associated with IA-2A, but do not provide a complete protection against these antibodies.

77

COMPARISON OF PROTEIN TYROSINE PHOSPHATASES: EXPRESSION, PROCESSING AND ANTIGENIC DETERMINANTS

A.L. Notkins, J. Lu, H. Xie, B. Zhang, Q. Li, and M.S. Lan. National Institutes of Health, Bethesda, Maryland U.S.A.

To identify protein tyrosine phosphatases (PTPs) present in pancreatic islets, transcripts isolated from αTC-1 (glucagon-secreting) and βTC-1 (insulin-secreting) cell lines were used as templates. A pair of degenerative primers, based on the conserved regions of known PTPs, was used to amplify the transcripts by polymerase chain reaction. A total of 1,620 clones was examined by restriction enzyme analysis and cDNA sequencing. Twenty-one different PTPs were found to be expressed in islet cells: 18 known PTPs and 3 previously unknown PTPs. Some of these PTPs were expressed predominantly in β cells and others in α cells. The degree of relatedness of these PTPs to each other and their differential expression in tissue will be discussed in relationship to their reactivity with autoantibodies in IDDM sera. To analyze in more detail the molecular processing of PTPs, one of them IA-2, was expressed in baculovirus-infected Sf9 insect cells. A 120 kDa IA-2 protein was detected during the early, but not late, phase of the infection. Tunicamycin treatment revealed that the 120 kDa protein was glycosylated, and pulse-chase experiments showed that the it was processed into a 64 kDa doublet and then into several smaller fragments in the 20 to 40 kDa range. Sera from IDDM patients reacted with several of these fragments. The location of the antigenic determinants on these various fragments was analyzed by expressing different portions of IA-2/IA-2β in a reticulocyte transcription/translation system. Immunoprecipitation with IDDM sera revealed that the major antigenic determinants reside in the C-terminus and minor antigenic determinants in the N-terminus of the intracellular domain. It is concluded that many PTPs are expressed in pancreatic islets and that IA-2/IA-2β are the precursors of islet cell antigenic fragments to which autoantibodies in IDDM sera react.

78

IDENTIFICATION OF ISLET-RELATED MIMOTOPES BY SCREENING RANDOM PEPTIDE LIBRARIES ON PHAGE WITH TYPE 1 DIABETIC SERA

A. Fierabracci , P.A. Biro, Y. Yiangou, D.R. Hurst and G.F. Bottazzo. Dept of Immunology, St Bartholomew's and the Royal London School of Medicine and Dentistry, London, UK

Random peptide libraries on phage (RPL) represent a powerful tool for the identification of disease-specific mimotopes reacting with antibodies in human sera. Type 1 diabetes-specific mimotopes could provide a set of novel reagents for diabetes prediction and could also lead to the identification of novel autoantigens or antigens related to possible environmental agents involved in the pathogenesis of the disease. With this aim we screened random nonapeptide libraries of epitopes fused to the major coat protein pVIII of the filamentous bacteriophage F1. Affinity selection with a newly diagnosed Type 1 diabetic serum, immunological screening with 2 other diabetic sera and ELISA re-screening using different human sera (58 newly diagnosed, 23 long-term, 21 polyendocrine, 15 autoimmune organ-specific, 9 autoimmune non-organ specific and 50 normal controls) lead to the selection of 5 phage clones bearing mimotopes (phagotopes) that show a significant difference in the frequency of reactivities between diabetic and normal individuals. Comparing their amino acid sequences with protein bank databases did not show any significant homology with known autoantigens. Among the 5 clones selected, we have characterized phagotope CH1p which we showed to be a mimotope of osteopontin, an islet-related autoantigen expressed by somatostatin cells. In continuing the characterisation of the others, phagotope 195Dyn was represented in 20% of newly diagnosed IDDM sera, but completely negative in normal controls. A rabbit antibody raised against the its encoded synthetic peptide: 1) stained human islets with a classical ICA pattern; and 2) recognized a specific band of approximately 70kD in Western Blot analysis of human pancreatic islet preparations. Absorption studies of ICA positive sera with known IDDM-related autoantigens have indicated that their staining is not completely abolished, thus 195Dyn phagotope may mimic the epitope of a still uncharacterized islet-related autoantigen.

79

CHARACTERISTICS OF GAD-REACTIVE T-CELLS IN IDDM AND IN AUTOIMMUNE POLYENDOCRINE DISEASE TYPE 1 (APECED)

O.Vaarala, P.Klemetti, J.Paronen, J.Kantele, E.Savilahti, J.Perheentupa and H.K.Åkerblom. National Public Health Institute, Children's Hospital, University of Helsinki, Helsinki, Finland.

Cellular immunity to GAD is found in IDDM but also in patients with APECED, many of whom do not have IDDM. Characteristics of GAD65-reactive T-cells, such as T-cell proliferation response to GAD65 and IFN-γ secretion of GAD65 stimulated T-cells by EIA were studied. Expression of gut-specific homing receptor α4β7-integrin on GAD65-reactive T-cells was analysed by immunomagnetic depletion of T-cells with high expression of α4β7. T-cell proliferation to GAD (SI>3) was more common in children with newly diagnosed IDDM than in healthy children (15/28 vs 7/27; p=0.05), as well as in patients with APECED than in healthy adults (15/44 vs 3/28; p=0.03). IFN-γ secretion by GAD stimulated T-cells was found in 50% (5/10) of children with IDDM and in 57% (16/28) of patients APECED. T-cell proliferation or IFN-γ response to GAD did not associate with IDDM in APECED (8 of 44 patients had IDDM). Depletion of $\alpha4\beta7^{high}$ T-cells resulted into a significant decrease (mean 70%) in reactivity to GAD in 4 of 7 children with IDDM. In three APECED patients, a decrease of 37% in reactivity to GAD was found only in the patient with IDDM. In contrast, reactivity to tetanus toxoid increased in the majority of the patients studied. Our results indicate that occurrence of GAD-reactive T-cells is a common finding in IDDM but also in patients with APECED without IDDM. Thus, occurrence of IFN-γ secreting GAD-reactive T-cells did not imply clinical IDDM in APECED. Association of α4β7-integrin expression on GAD-reactive T-cells with IDDM suggests that gut-specific homing properties of β-cell reactive T-cells may be important determinant in development of IDDM.

80

ALTERED IMMUNE RESPONSE TO INSULIN IN NEWLY DIAGNOSED VERSUS INSULIN TREATED PATIENTS AND CONTROL SUBJECTS

N.Schloot, B.Roep, D.Wegmann, L.Yu, H.Chase, T.Wang and G.Eisenbarth Barbara Davis Center for Childhood Diabetes, Denver, Colorado, USA; University Hospital Leiden, Dept.of Immunohematolgy & Bloodbank, NL

Insulin dependent diabetes mellitus is the result of a T-cell mediated autoimmune ß-cell destruction,which is accompanied by autoantibodies. We analyzed the cellular and humoral immune response to insulin and insulin peptides in recent onset IDDM patients, IDDM patients treated with insulin, non-diabetic first degree relatives and unrelated control subjects. There were no differences in T-cell reactivity to whole insulin or insulin peptides in general between age matched groups of IDDM patients, relatives or healthy control subjects. In contrast to investigations in NOD mice, no imunodominant or disease specific insulin peptide could be identified. Surprisingly, a positive correlation of T-cell responses to insulin with age was noted ($p<0.005$). This resulted in an inverse relation of IAA and insulin reactive T-cells ($p<0.001$) together with the well described negative correlation of IAA with age. Interestingly, insulin treated patients differed from age matched recent onset IDDM: First, simultaneous immune recognition of insulin with T-cells and IAA was only seen in patients treated for 6 months with insulin, second, insulin treated patients rarely responded to whole insulin; third, they displayed less determinant spreading, and finally, recognition of multiple insulin peptides was not accompanied by crossreactivity to whole insulin. These distinct observations in insulin treated IDDM patients, together with the inverse correlation between humoral and cellular responses to insulin, may result from activation or modulation of different T-cell subsets, and may be of relevance to insulin therapy trials, in which selective activation of non-destructive T-cell subsets may be a key to successful intervention.

81

MOLECULAR DISSECTION OF THE INSULIN-LIKE GROWTH FACTOR AXIS IN THE HUMAN THYMUS

V. Geenen, O. Kecha*, I. Achour, B. Goxe, R. Winkler* and P.J. Lefèbvre
Department of Medicine, Laboratories of Neuroendocrine-Immunology and Molecular Oncology*, University of Liège, B-4000 Sart Tilman, Belgium.

Our previous studies identified immunoreactive (ir) insulin-like growth factor-II (IGF-II) as the dominant polypeptide of the insulin hormone family expressed in the thymic epithelial environment. Preliminary data have revealed a defect of ir IGF-II expression in the thymus of diabetes-prone BB rats. The objective of the present work was to characterize at the molecular level the components of the thymic IGF system, *i.e.* IGF-II gene transcripts, IGF receptors and IGF-binding proteins (IGFBPs). Specific binding of radiolabelled IGF-II was observed on a murine pre-T cell line (RL12-NP), as well as on thymocytes extracted from 4 month-old mice. Only IGF-II, but neither IGF-I nor insulin, could compete with [^{125}I]-IGF-II, with an ED50 around 10 nM. The human Jurkat T-cell line also exhibits a specific binding of IGF-II with an ED50 of 1.5 nM. By affinity cross-linking, the IGF-II receptor protein detected in murine T cells and Jurkat T cells was found to have a molecular weight around 260 KDa. By ribonuclease protection assays, IGF-II gene transcripts were detected in the human thymus, as well as in cultures of human thymic epithelial cells (TEC). Using reverse-transcriptase polymerase chain reaction and specific primers, the promoters of IGF-II expression in the thymus were found to be the same as in other fetal and adult extrahepatic tissues. IGFBP3 to 6 mRNAs were detected by Northern blotting in human TEC with a marked dominance of IGFBP4. With the exception of IGFBP1 and 2, an analogous pattern of expression was observed in the human liver used as a positive control tissue. Interestingly, the human Jurkat T-cell line did not express any IGFBP mRNAs. Altogether, these data confirm that IGF-II is the dominant member of the insulin family synthetized by human TEC, and that there exists a parallel dominance of IGF-II and IGFBP4 in this cell type. Similar investigations are currently performed on the thymus of diabetes-prone and diabetes-resistant BB rats. These observations further support our hypothesis that the thymic IGF axis (in particular IGF-II) is intimately involved in the central T-cell self education to the insulin family.

DEFECTIVE MONOCYTE-DERIVED DENDRITIC CELLS FROM HIGH-RISK IDDM RELATIVES

K. Takahashi, M. C. Honeyman and L. C. Harrison, The Walter and Eliza Hall Institute, Melbourne, Australia

Dendritic cells (DC) play a key role in antigen presentation. Defective DC function in the autologous mixed lymphocyte reaction (MLR) in human insulin-dependent diabetes mellitus (IDDM) has been postulated as a cause of defective regulatory T cell maturation. Therefore, we investigated functional and phenotypic characteristics of monocyte-derived DC generated in the presence of GM-CSF and interleukin-4, from high-risk IDDM relatives and HLA-, sex- and age- matched controls (n=12). Adherent cells were obtained from peripheral blood mononuclear cells (PBMC) by 2-hour adhesion, and cultured for 7 days in medium containing 600 U/ml rhGM-CSF + 400 U/ml rhIL-4. The yield of DC was significantly lower in IDDM relatives ($8.0 \pm 3.3 \times 10^6$ DC from 10^7 PBMC) ($p<0.001$, U test) than in controls ($15.4 \pm 4.8 \times 10^6$ DC from 10^7 PBMC). 90 ± 8.8 % of culture adherent cells from the relatives and 95 ± 3.6 % from controls exhibited the DR+CD14- phenotype. CD1a expression on these cells was significantly lower in IDDM relatives ($72 \pm 20\%$) ($p<0.01$, U test) then in controls ($90 \pm 11\%$). B7-1 and B7-2 expression was also significantly lower in the relatives ($36 \pm 26\%$ and $34 \pm 24\%$) ($p<0.01$, U test) than in the controls ($67 \pm 21\%$ and $62 \pm 22\%$). DC from IDDM relatives displayed significantly lower stimulatory capacity to autologous CD4 cells (27596.2 ± 14691.4 cpm) ($p<0.04$, U test) than DC from controls (42308.6 ± 10893.3 cpm), but not to allogeneic responder cells. In conclusion, DC from high-risk IDDM relatives are generated less efficiently and display defective expression of phenotypic markers and antigen presenting capacity.

OP 12

Endogenous Glucose Production

83

BASAL HEPATIC GLUCOSE PRODUCTION IS REGULATED BY THE PORTAL VEIN INSULIN CONCENTRATION

D. K. Sindelar, C. A. Chu, D. S. Edgerton, D.W. Neal, A. D. Cherrington, Vanderbilt University School of Medicine, Nashville, TN, USA

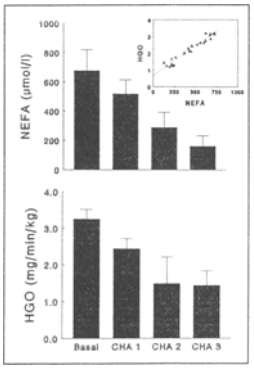
The ability of portal insulin to regulate hepatic glucose production (HGP) is greatly debated. The aim of our study was to determine if the liver responds to a selective decrease in portal vein insulin. Isotopic (^{3}H-Glucose) and A-V difference methods were used to measure HGP in conscious overnight fasted dogs. A pancreatic clamp (SRIF, basal portal insulin and glucagon) was used to control the endocrine pancreas. A 40 min control period was followed by a 180 min test period. During the latter, portal vein insulin was selectively decreased and while arterial insulin was maintained by turning off the portal insulin infusion and giving insulin peripherally at half the basal portal rate (↓PI, n=5). In ↓PI, a selective decrease of 138 pmol/l in portal vein insulin was achieved while arterial insulin levels did not change (42±7 pmol/l). Portal glucagon remained unchanged (63±8 ng/l) and glucose SA was clamped. In response to the selective decrease in portal vein insulin, net hepatic glucose output (NHGO) increased significantly from 8.1±0.5 (cont) to 30±5.5 by 15 min and eventually reached 14.2±2.3 µmol/kg-min (last 30 min, $p \leq 0.05$). Tracer data confirmed NHGO. Since NHGO increased, arterial plasma glucose increased from 5.9±0.2 to 10.5±0.4 mmol/l. Non-esterified fatty acids (NEFA) dropped from 804±122 (cont) to 420±92 µmol/l (last 30 min, $p \leq 0.05$). Since NEFA levels fell, another group (↓PI+FAT n=5) had intralipid infused during the test period to maintain NEFA levels. In ↓PI+FAT, a selective decrease of 93 pmol/l in portal insulin resulted, while arterial insulin (42±6 pmol/l) and portal glucagon (49±4 ng/l) did not change. NEFA level rose slightly [(470±77 (cont) to 864± 87 µmol/l (last 30 min)]. NHGO again increased quickly from [10.8±2.5 (cont) to 30.2± 6.0 by 15 min and eventually reached 13.4±2.6 µmol/kg-min (last 30 min, $p \leq 0.05$) and arterial plasma glucose increased from 6.0±0.2 to 14.4±0.7 mmol/l. Thus, the liver responds quickly to decreases in portal insulin and NEFA levels play no role in this response. These studies indicate that HGP is acutely regulated by the portal insulin level.

84

CAUSAL LINK BETWEEN SUPPRESSION OF LIPOLYSIS VERSUS HEPATIC GLUCOSE OUTPUT SUGGESTS INDIRECT INSULIN ACTION

S. Mittelman, Y. Fu, and R Bergman. University of Southern California, USA.

We have previously shown that insulin suppression of hepatic glucose output (HGO) is prevented by the concomitant infusion of Liposyn, supporting the hypothesis that HGO suppression is not a direct effect of insulin on the liver, but rather an indirect effect mediated by suppression of lipolysis in the adipocyte. To examine whether acute suppression of lipolysis independent of insulin increase will suppress HGO, we infused the adenosine analogue N6-cyclohexyladenosine (CHA) into 4 conscious dogs. Following a 2 hour basal period (1.0 mg/min/kg somatostatin, 0.2 mU/min/kg portal insulin, and 1.0 ng/min/kg portal glucagon), CHA was infused in three sequential doses (0.167, 0.500, and 1.667 µg/kg/min) lasting 1 hour each. CHA suppressed NEFA levels in a dose dependent manner (see figure, $p < 05$ ANOVA), causing HGO to fall ($p<.05$ ANOVA) in a nearly identical manner. The correlation between NEFA and HGO was linear with an R value of 0.97



To control for additional effects of CHA, Liposyn (20%, 0.5 ml/min) and heparin (250 U + 25 U/min) were infused with CHA in 2 experiments to maintain NEFA levels above basal. Indeed, Liposyn infusion yielded NEFA levels over basal (891±49 vs. 537±287 µM average of steady-state values vs basal) and prevented the fall in HGO caused by CHA alone (2.2±0.3 basal vs. 1.9±0.1, 2 1±0.1, and 2.1±0.1 at each successive dose, p=n s.). Thus, CHA suppresses lipolysis and HGO similarly, and the suppression of HGO depends on the fall in NEFA levels. However, a decline in glycerol cannot yet be ruled out as contributing to this HGO suppression.

85

INSULIN INHIBITS GLUCONEOGENESIS PREDOMINANTLY THROUGH SUPPRESSION OF PHOSPHOENOLPYRUVATE CARBOXYKINASE

R.A.Dickins, G.Rosella, J.Zajac and J.Proietto. The University of Melbourne, Department of Medicine, Royal Melbourne Hospital, Parkville, Australia 3050.

Insulin is known to inhibit endogenous glucose production but the exact mechanism by which it achieves this is not known. It may act at several sites within both the gluconeogenic and glycolytic pathways, or alternatively it has been suggested that the prime mechanism is via the peripheral actions of insulin to inhibit substrate availability. A rat overexpressing an insulin insensitive phosphoenolpyruvate carboxykinase (PEPCK) gene was recently developed (1). This animal model provides a tool for investigating the role of PEPCK in insulin suppression of endogenous glucose production (EGP). After 3 days recovery from surgery, overnight fasted, chronically catheterised, conscious 16 week old rats were studied using the hyperinsulinaemic euglycaemic clamp technique combined with tracer methodology to quantitate glucose turnover. Basal plasma glucose was the same in both groups (5.1±0.2 vs 5.1±0.2 mM in control and transgenic rats respectively), however transgenic rats were hyperinsulinaemic (8.3±0.5 vs 12.6±1.6 μU/ml, $p<0.02$, $n=13$). During the clamp, plasma glucose was not different between the two groups of rats (7.0±0.4 vs 6.1±0.3 mM, p=ns). Insulin levels were significantly increased during insulin infusion but were the same in both groups (30.8±5.7 vs 43.9±6.9 μU/ml, p=ns). As expected, hyperinsulinaemia resulted in significant suppression of EGP by insulin in control rats (44±4 to 24±6 μmol/kg/min, $p<0.05$, $n=10$). However, EGP was not decreased by insulin in transgenic rats (43±5 to 45±6μmol/kg/min). It is concluded that insulin suppresses gluconeogenesis predominantly by inhibition of PEPCK.

86

INSULIN REGULATION OF RENAL GLUCOSE METABOLISM IN HUMANS.

E. Cersosimo, P. Garlick and J. Ferretti. State University of New York, Stony Brook, NY, USA.

We investigated whether simultaneous renal glucose production (RGP) and utilization (RGU) occur in humans, and whether these processes are responsive to physiologic hyperinsulinemia, using arteriovenous balance measurements combined with tracer technique. After approval by the Institutional Review Board and informed consent, six healthy subjects (3F/3M), mean age 36 yrs, mean BMI 26 kg/m2, were admitted to the Clinical Research Center following an overnight fast for arterialized hand vein and renal vein catheterization under fluoroscopy. Systemic and renal glucose and glycerol kinetics were measured with peripheral infusions of [6-2H2]glucose and [2-13C]glycerol before and after a 2-h period of peripheral insulin (0.125 mU/kg.min) and variable dextrose infusions to maintain arterial glucose concentration and plasma enrichment constant. Renal plasma flow was determined by PAH clearance. Plasma insulin concentration increased from 29±5 to 43±12 pmol/l ($p<0.05$) during the experiment, but there was no change in either arterialized (4.8±0.6 vs 4.7±0.7 mM/l, p=NS) or renal vein (4.7±0.7 vs 4.6±0.7 mM/l, p=NS) plasma glucose concentration. Following insulin infusion endogenous glucose production decreased from 9.9±1.5 to 6.9±1.0 umol/kg.min ($p<0.01$); RGP decreased from 2.4±0.5 to 1.5±0.2 umol/kg.min ($p<0.05$); RGU decreased from 2.6±0.5 to 1.4±0.2 umol/kg.min ($p<0.05$); and renal gluconeogenesis from glycerol decreased from 0.26±0.04 to 0.16±0.06 umol/kg.min ($p<0.05$).

These results indicate that renal glucose production and utilization account for 25% of glucose turnover in postabsorptive humans. Mild physiologic hyperinsulinemia suppresses renal glucose production and utilization by 40%. We conclude that the kidney makes a major contribution to systemic glucose metabolism which is in part regulated by insulin.

87

HUMAN KIDNEY SUBSTRATE UTILIZATION AND GLUCONEOGENESIS

C. Meyer, M. Stumvoll, S. Welle, M. Kreider, S. Nair and J. Gerich, University of Rochester, Rochester, NY, USA

Recent studies indicate that the human kidney may be as important for gluconeogenesis (GN) as the liver. We therefore investigated renal net balance (NB), fractional extraction (Fx), uptake, release and incorporation into glucose of various GN precursors, lactate (N = 17), glutamine (N = 16), glycerol (N = 9) and alanine (N = 9), in relation to their systemic turnover (ST) and systemic GN (SGN) in 43 normal postabsorptive subjects using a combination of isotopic (6-3H glucose, U-14C glutamine, U-14C glycerol, 3-13C lactate and 3-13C alanine) and organ balance (renal vein catheterization) techniques. Our results are shown in Table 1.

Table 1.

	Glucose	Lactate	Glutamine	Glycerol	Alanine
ST (μmol/kg/min)	11.4±0.3	11.8±0.4	5.2±0.3	2.1±0.1	4.6±0.3
SGN (μmol/kg/min)		1.88±0.15	0.46±0.02	0.53±0.09	0.68±0.07
RGN (μmol/kg/min)	2.57±0.19	0.89±0.09	0.33±0.02	0.16±0.02	0.02±0.01
% of SGN		52.9±8.1	72.2±3.1	33.6±4.1	3.3±1.1
% of renal uptake		61.7±6.0	62.6±6	54.6±6.9	10.7±3.5
NB (μmol/min)	-43 ± 8.0	191 ± 23	39±5	37 ± 6	13 ± 10
Fx (%)	2.2 ± 0.2	27.4 ± 1.9	9.7±0.8	53.5 ± 2.7	8.8 ± 1.0
Uptake (μmol/min)	145±11	256 ± 25	55±6	40±6	44±9
% of ST	17.3±1.3	30.4 ± 3.1	14.7±1.1	31.7±4.5	12.7±2.3
Release (μmol/min)	185±12	65±9	16±2	3±1	31±10
% of ST	22.3±1.4	8.1±4.1	4.3±0.6	2.9±1.1	10.2±3.4

Our data indicate that lactate is the major renal GN precursor followed by glutamine and glycerol; renal alanine GN is negligible. The fact that the proportion of lactate, glutamine and glycerol uptake used for GN was comparable (~ 60 %) suggests that substrate availability is rate limiting for renal GN. The kidney uses and produces lactate, glutamine and alanine but only uses glycerol. Since renal uptake accounts for ~ 30 % of systemic lactate and glycerol disposal, the kidney is a major organ for utilization of these substrates.

88

CONTROL OF GLUCOSE-6 PHOSPHATASE mRNA AND ACTIVITY IN SMALL INTESTINE OF FASTED AND DIABETIC RATS.

G. Mithieux, N. Bruni, S. Tarpin and C. Zitoun. Institut National de la Santé et de la Recherche Médicale (U.449), Lyon, France.

Glucose-6 phosphatase is the last enzyme of gluconeogenesis and glycogenolysis. In agreement with the concept that only liver and kidney express glucose-6 phosphatase (Glc6Pase), it has been recently reported, using a RT-PCR approach, that Glc6Pase mRNA was not detectable in 9 other tissues. Using the same approach, we demonstrated the presence of Glc6Pase mRNA in duodenum (DUO) and jejunum (JEJ) of normal fed rats, whilst Glc6Pase mRNA was not detected in stomach, ileon, colon, brown adipose tissue, adrenals and bladder. Glc6Pase mRNA and activity were also evidenced in human small intestine. We studied the effect of diabetes and fasting on Glc6Pase mRNA (by Northern blot) and activity (using a highly specific Glc6Pase assay) in small intestine in rats. The Glc6Pase mRNA abundance was increased by 8 times and 6 times ($p<0.01$) in DUO and JEJ in streptozotocin diabetic rats. It was normalized in both tissues upon insulin treatment for 10h. Glc6Pase activity was increased by 300 % in DUO (2.6±0.8 vs 0.83±0.09 U/g wet tissue, mean±S.E.M., n=4, $p<0.05$) and JEJ (1.9±0.3 vs 0.63±0.03 U/g, $p<0.01$) in diabetic rats as compared to normal rats. The Glc6Pase mRNA abundance was increased by 8 and 7 times in DUO and JEJ of 48h-fasted rats. It was normalized in both tissues upon refeeding for 7 hours. Glc6Pase activity was significantly increased in fasted rats (2.5±0.6 and 1.3±0.2 U/g in DUO and JEJ, means±S.E.M., n=5, $p<0.05$ vs normal fed rats). In addition, Glc6Pase mRNA and activity were also expressed in ileon during fasting (1.3±0.4 U/g). These data show that small intestine might possess the capacity to produce endogenous glucose in portal blood. This should have important implications in various metabolic situations.

89

ASPECTS OF SYNDROME X DEVELOPING IN RATS WITH GENETICALLY ENGINEERED HEPATIC INSULIN RESISTANCE.

M. Baldwin, A. Thorburn, D. Myers, G.Rosella, J Zajac and J.Proietto.
University of Melbourne Department of Medicine, Royal Melbourne Hospital, Parkville Australia 3050

Central obesity, glucose intolerance, hyperlipidaemia and hypertension form a cluster of disorders (Syndrome X) affecting a large number of individuals. It has been hypothesised that these various abnormalities are all caused by insulin resistance, but definitive proof is lacking. One approach to investigate this hypothesis is to study the development of Syndrome X in animals in which insulin resistance has been produced by genetic engineering. We have made transgenic rats overexpressing an insulin unresponsive PEPCK gene, the rate-limiting enzyme in gluconeogenesis, and shown that they are hyperinsulinaemic (1). The aim of this study is to investigate which aspects of Syndrome X develop in these animals and how a cafeteria (high fat) diet interacts with this genetic defect. Male and female transgenic and control rats aged 26 weeks were studied. Rats were fed either a standard rat chow, or rat chow plus a selection of palatable foods such as potato chips, biscuits and chocolate. Total percent fat measured using DEXA scanning was higher in chow fed (12.0 ± 0.9 vs 17.1 ± 0.9 % $p < 0.05$) and cafeteria fed (34.1 ± 1.4 vs 42.6 ± 1.6% $p < 0.05$) female transgenic rats while in male transgenic animals % body fat was not different in chow fed rats (15.2 ± 0.5 vs 14.4 ± 1.4 % but was higher in cafeteria fed transgenic rats (24.5 ± 1.9 vs 35.3 ± 2.7 % $p < 0.05$). At this age, transgenic rats were not hyperglycaemic but had fasting hyperinsulinaemia (7.6 ± 0.7 vs 11.6 ± 1.4 mU/L $p = 0.017$ $n = 10$). Chow fed transgenic rats had elevated triglyceride (0.6 ± 0.06 vs 1.0 ± 0.1 mmol/l $p = 0.014$) and cholesterol (2.9 ± 0.1 vs 3.7 ± 0.2 $p = 0.006$ $n = 11$) levels. Cafeteria feeding increased insulin and triglycerides but not cholesterol levels in both control and transgenic animals. Blood pressure was not different in chow or cafeteria fed rats. It is concluded that rats with genetically engineered insulin resistance develop several aspects of Syndrome X, strongly supporting the hypothesis that insulin resistance is the initiating defect in this cluster of disorders.

90

MECHANISM BY WHICH INSULIN INHIBITS NET HEPATIC GLYCOGENOLYSIS IN MAN K. Falk Petersen, D. Laurent, D. L. Rothman, G. W. Cline and G. I. Shulman, Department of Internal Medicine, Yale University School of Medicine, New Haven, CT

^{13}C NMR spectroscopy was used to assess rates of hepatic glycogen synthesis and glycogenolysis under different plasma concentrations of glucose and insulin. Subjects were infused for 6 hrs with insulin (4mU/m^2-min or 40mU/m^2-min), somatostatin (0.1 μg/kg-min) to inhibit endogenous insulin and glucagon release, and 1-^{13}C glucose (20% ^{13}C enriched) to establish one of three conditions: A) Hyperglycemia (10mM)-basal insulin (30pM), n=6; B) Euglycemia (5mM)-hyperinsulinemia (480pM), n=5; C) Hyperglycemia (10mM)-hyperinsulinemia (480pM), n=8. In a fourth group (D) rates of hepatic glycogenolysis and glycogen turnover were monitored during an overnight fast under basal conditions of glucose (5mM) and insulin (30pM), n=5. Hyperglycemia *per se*(A) caused a 92% inhibition of net hepatic glycogenolysis compared to basal conditions (D) (from basal 0.25±0.09 to 0.02±0.03mmol/liter liver-min, $p<0.05$) mainly through inhibition of glycogen phosphorylase flux. In contrast, hyperinsulinemia *per se* (B) caused a 100% inhibition in net hepatic glycogenolysis exclusively through activation of glycogen synthesis (0 to 0.43±0.05mmol/liter liver-min, $p<0.05$). Hyperinsulinemia *per se* had no inhibitory effect on phosphorylase (basal 0.25±0.09 vs. 0.27±0.06mmol/liter liver-min) resulting in extensive glycogen cycling. The glycogenolytic rate (0.27±0.06 mmol/liter liver-min) was ~55% of the glycogen synthetic rate (0.43±0.05mmol/liter liver-min, $p<0.05$) and rates of net hepatic glycogen synthesis were relatively low [0.16±0.01mmol/liter liver-min]. Combined hyperglycemic-hyperinsulinemia (C) resulted in relatively high rates of net hepatic glycogen synthesis (0.36±0.03mmol/liter liver-min) through stimulation of glycogen synthesis (0.40±0.04mmol/liter liver-min) and inhibition of glycogenolysis (0.04±0.02mmol/l liver-min). Conclusions: 1) Insulin and glucose work through different mechanisms to promote hepatic glycogen synthesis, 2) Both substrate and hormonal signals are simultaneously required to cause significant rates of net hepatic glycogen synthesis, 3) Promotion of hepatic glycogen cycling may represent the principal mechanism by which insulin suppresses net hepatic glycogenolysis and glucose production in man.

Beta-Cell Development and Function under Normal and Pathological Conditions

91

CHARACTERIZATION OF THE BETACELLULIN RECEPTOR IN PANCREATIC AR42J-B20 CELLS

N.Ishiyama, M.Kanzaki*, M.Furukawa*, J.Miyagawa**, T.Hanafusa**, M. Seno#, H.Yamada#, I.Kobayashi and I. Kojima*. Dept of Lab Med, *Inst for Mol & Cell Regl, Gunma University,**2nd Dept of Med, Osaka University, # Dept of Biosci & Biotech, Okayama University, Japan.

Betacellulin (BTC) is a member of the EGF family and is shown to exert its mitogenic action via the EGF receptor (Erb-B1). In pancreatic acinar AR42J cells, BTC induces differentiation and converts them into insulin-secreting cells. The effect of BTC is not reproduced by the same concentration of either EGF or TGF-α, suggesting that BTC acts on its own receptor. The present study was conducted to identify the receptor system through which BTC induces differentiation in AR42J-B20 cells. In these cells, two classes of binding sites for ^{125}I-recombinant human BTC with the Kd values of $4.6x10^{-11}$ and $2.9x10^{-10}M$ were observed. When affinity crosslinking was done by using ^{125}I-BTC and disuccinimidyl suberate, followed by immuno-precipitation using antibodies against Erb-B1,2,3, and 4, only Erb-B1 was crosslinked with ^{125}I-BTC. BTC induced tyrosine phosphorylation of the Erb-B1, B2 and B4 whereas EGF induced tyrosine phosphorylation of the Erb-B1 and B2 but not B4. In the presence of activin A, nearly 100 % of AR42J-B20 cells converted to insulin-producing cells by 100 pM BTC. In contrast, only about 20% of the cells became insulin-positive by much higher concentrations of EGF. The results suggest that the differentiation-inducing activity of BTC is exerted via both Erb-B1 and other type of receptor possibly Erb-B4.

92

DISTURBED DIFFERENTIATION, MIGRATION AND PROLIFERATION OF PANCREATIC ß- CELLS IN MICE LACKING EGF RECEPTORS

P.J. Miettinen, J. Ustinov, T. Koivisto, S. Rasilainen, M. Huotari, E. Lehtonen and T. Otonkoski, Transplantation Laboratory, Department of Pathology and Children's Hospital, University of Helsinki, Helsinki, Finland.

All pancreatic epithelial cell types, including acini and islets, are believed to differentiate from common ductal precursors. Little is known about the regulators of these processes. Epidermal growth factor receptor (EGF-R) is expressed throughout the developing pancreas and its ligands, particularly transforming growth factor-alpha, are also abundantly present. We have now analyzed the pancreatic phenotype of EGF-R deficient mice (E-), which generally die within the first postnatal week from epithelial immaturity. The knock-out mice were identified from their open-eye phenotype and their normal littermates were used as controls. The E- pancreata were smaller but otherwise appeared normal. Although the DNA content of E- pancreata was 33% lower, the insulin/DNA ratio was 34% higher than in controls. Based on BrdU labelling, proliferation of neonatal ß-cells was only half of that in controls (2.6±0.4 vs. 5.8±0.9 %, $p<0.01$) and the difference persisted even at the age of 7-10 days. A similar proliferation defect was present also in the exocrine pancreas. The most striking feature of the islets in the E- pancreata was that instead of forming circular clusters, the islet cells were mainly located in streak-like structures directly associated with pancreatic ducts (direct duct-association 63±8 % in E- vs. 36±9 % in contr, $p<0.05$). All endocrine islet cells were detected in 6-day cultured explants of E12 embryonal pancreata. However, in E- the most common cell was the glucagon cell (39 % of all endocrine cells) and the proportion of insulin cells was lower than in controls (27±6 vs. 48±8 %, $p=0.05$). PP cells were nearly as abundant as insulin cells in E- (24 % vs. 14 % in controls) and somatostatin cells were equally frequent (8 vs. 10 %). Our findings suggest that the absence of EGF-R mediated signalling leads to a generalized proliferation defect of gastrointestinal epithelia, a moderate delay in ß-cell development, and possibly to disturbed migration of the developing islet cells as they differentiate from their precursors. As a whole the pancreatic islet phenotype is relatively mild, possibly due to an important contribution of signalling through the other three EGF-R (erb-B) tyrosine kinases.

93

IMPAIRED B CELL DEVELOPMENT IN THE FETAL GK RAT: IMPACT OF DIABETIC INHERITANCE

P. Serradas, M.-N. Gangnerau, M.-H. Giroix and B. Portha - *Lab. Physiopath. of Nutrition, CNRS URA 307, University Paris 7, Paris, France.*

We have previously reported that the lack of insulin secretory response to glucose is a very early defect in the GK rat since it is detectable in vivo as early as fetal age. GK fetuses had an increased plasma glucose concentration, a decreased plasma insulin level and a reduced pancreatic ß-cell mass. The aim of the current study was an attempt to discriminate between gestational effects (such as maternal hyperglycemia) and genetic factors on this defect. For this purpose two crosses were performed: normoglycemic Wistar (W) female with GK male (W/GK) and hyperglycemic GK female with W male (GK/W). Fetuses were named respectively f-W/GK and f-GK/W and they were compared to fetuses issued from W mother and father (f-W/W) and GK mother and father (f-GK/GK). In hybrids f-W/GK plasma glucose and plasma insulin levels were almost normal and their pancreatic ß-cell mass was slighty reduced. Hybrids f-GK/W exhibited higher plasma glucose levels than f-W/W but plasma insulin levels and pancreatic ß-cell mass were normal. In vivo ß-cell reactivity to glucose was studied in the fetuses using an hyperglycemic clamp protocol applied to the mothers during 60min. This techique allowed to obtain a steady-state hyperglycemia in the corresponding fetuses. Under these conditions after 5min hyperglycemia f-W/W increased their plasma insulin level which remained high at 60min compared to basal level before hyperglycemia. By contrast, plasma insulin in the GK fetuses remained at the basal level despite hyperglycemia similar to that in f-W/W. Hybrids f-W/GK and f-GK/W increased their plasma insulin levels in response to hyperglycemia in vivo. The incremental insulin response to glucose over the 60min experiments period were normal (18.4±3.7, 17.2±2.3 and 22.1±3.4ng/ml in f-W/GK, f-GK/W and f-W/W respectively). In summary, our data suggest that hyperglycemia *in utero* does not influence the severity of the decrease of the ß cell mass, neither the lack of the insulin secretory response to glucose. Moreover, they indicate that conjunction of both maternal and paternal genes are necessary in order these defects to appear in the GK model.

94

IAPP (AMYLIN) NULL MUTANT MICE; PLASMA LEVELS OF INSULIN AND GLUCOSE, BODY WEIGHT AND PAIN RESPONSES

S Gebre-Medhin[1], H Mulder[2], M Pekny[1], Y-Z Zhang[2], J Törnell[3], P Westermark[4], F Sundler[2], B Ahrén[5] and C Betsholtz[1]. Medical Biochemistry[1] and Physiology[3], Göteborg; Physiology & Neuroendocrine Science[2], Lund; Pathology[4], Linköping and Medicine[5], Malmö. Sweden.

Islet amyloid polypeptide (IAPP), also termed amylin, is stored and released together with insulin in response to nutrient stimuli. IAPP-expression is also found in the sensory nervous system. Several biological effects have been reported for IAPP such as inhibititon of insulin release and action, food intake and gastric emptying. To assess the physiological role for IAPP, we have investigated the consequences of a targeted disruption of the IAPP-gene. Until 7 months of age, mice lacking IAPP (*IAPP*-null) had normal basal levels of glucose. However, in IVGTT tests (1g/kg), the glucose elimination rate was found to be increased in *IAPP*-null animals. Thus, at 30 minutes after glucose administration, plasma glucose levels were 10.9±0.4 mmol/l (n=60) in *IAPP*-null animals versus 12.3±0.4 mmol/l (n=65) in controls ($p<0.001$), the difference being more pronounced in males. *IAPP*-null males also presented a simultaneous increase in plasma insulin response to glucose (at 1 minute: 4.2±0.6 nmol/l in *IAPP*-null animals, n=6 versus 1.9±0.3 nmol/l in controls, n=6, $p<0.01$). Moreover, *IAPP*-null males developed a 29% increase in body weight by the age of 18 weeks (44.2±1.7g, n=16 versus 34.2±0.7g in controls, n=25, $p<0.001$). We also report that *IAPP*-null mice (n=12) reacted less to pain stimuli than controls (n=10) showing a 24% reduced licking duration ($p=0.025$) in the late phase of the paw formalin test. The *IAPP*-null phenotype described, relate to two major expression sites for IAPP; the pancreatic β-cells and dorsal root ganglion neurons, and suggests a dual role for IAPP as a regulator of glucose metabolism and insulin release and as a novel sensory neuropeptide.

95

REDUCED ISLET AMYLOID POLYPEPTIDE RELEASE IS A CHARACTERISTIC OF IMPAIRED GLUCOSE TOLERANCE AND NIDDM.

S.E. Kahn, C.B. Verchere, S. Andrikopoulos, P.J. Asberry, D.L. Leonetti, E.J. Boyko, R.S. Schwartz, M.A. Austin, W.Y. Fujimoto, University of Washington, Seattle WA, U.S.A.

Islet amyloid is a characteristic feature of NIDDM. Its major component is the normal B-cell secretory peptide islet amyloid polypeptide (IAPP) or amylin which is normally coreleased with insulin in a molar ratio of approximately 1:100 or 1%. To determine whether increased release of IAPP may explain the propensity for amyloid deposition in NIDDM, we measured plasma IAPP-like immunoreactivity (IAPP-LI) and immunoreactive insulin (IRI) release in response to an oral glucose load in 78 Japanese-American subjects with normal glucose tolerance (N: n=43), impaired glucose tolerance (I: n=10) and NIDDM (D: n=25) as defined by WHO criteria, who were matched for age (mean±se: 56.0±1.4 y) and body adiposity (BMI: 25.6±0.5 kg/m^2). The incremental increase in IAPP-LI, IRI and glucose (G) at 30 minutes following oral glucose ingestion was used to calculate ΔIAPP-LI/ΔG and ΔIRI/ΔG as measures of B-cell function. As expected, plasma glucose concentrations at both fasting (N: 5.1±0.5, I: 5.5±0.1, D: 6.1±0.3 mM, $p<0.0001$) and 2 hours (N: 6.7±0.1, I: 9.3±0.3, D: 13.2±0.5 mM, $p<0.0001$) were elevated in individuals with IGT and NIDDM. In response to glucose ingestion, plasma IAPP-LI and IRI increased in all subjects but these increments were lower in individuals with reduced glucose tolerance as reflected in the ΔIAPP-LI/ΔG (N: 2.8±0.2, I: 2.0±0.3, D: 1.2±0.2 pM, $p<0.001$) and ΔIRI/ΔG (N: 118±10, I: 90±29, D: 49±6 pM, $p<0.0001$). Moreover, these reductions in the 30 minute incremental IAPP-LI and IRI responses were proportionate such that the molar ratio of IAPP-LI to IRI was not different among the three groups (N: 2.5±0.2, I: 2.6±0.4, D: 2.7±0.4 %, p NS). We conclude that the reduced B-cell function of impaired glucose tolerance and NIDDM includes proportionate reductions in both IRI and IAPP-LI release. Thus, it is unlikely that the development of islet amyloid in NIDDM is the result of increased release of IAPP-LI.

96

PROLONGED EXPOSURE OF PANCREATIC B-CELLS TO FREE FATTY ACIDS IN VIVO INCREASES GLUCOSE-INDUCED INSULIN SECRETION AND B-CELL MASS IN RATS

C. Magnan*, M.F. Berthault*, M.C. Laury*, J. Leveteau**, L. Penicaud†, A. Ktorza* and °F. Assimacopoulos-Jeannet, *Université Paris 7, **Université Paris 6, Paris, †Université Paul Sabatier, Toulouse, France, °Centre Médical Universitaire, Genève, Suisse

Free fatty acids (FFA) exert divergent short and long term effects on insulin secretion. To investigate the mechanisms of long term effects of FFA on glucose-induced insulin secretion, intralipid and heparin (hyperlipidemic rats, HL rats) or saline (control rats, C rats) was infused to normal rats for 48h. At the end of infusion, intra gastric glucose tolerance test (500 mg/kg) was performed. Insulin secretion calculated as the insulinogenic index (ΔI/ΔG), was dramatically increased in HL rats compared to C rats (C rats: 2.17±0.4; HL rats: 14±2, $P<0.001$). B-cell responsiveness to glucose was related at least in part to an increase in the B-cell mass which was ~1.5 fold higher in HL rats than in C rats, as measured by an histomorphometric method (C rats: 4.6±0.4, HL rats: 7.1±1.3 mg, $P<0.05$). These data contrast with the rather deleterious effect of FFA on B-cell function in vitro and may therefore reflect the role of extrapancreatic factors, especially nervous factors controlling insulin secretion. To test this hypothesis we recorded parasympathetic and sympathetic firing rate at the end of infusion at the level of the thoracic branch of the vagus nerve and the superior cervical ganglion, respectively. We found a decrease in both parasympathetic (C: 2.20±0.3; HL: 0.60±0.07 spikes/s, $P<0.001$) and sympathetic nervous activity (C: 2.80±0.30; HL: 0.24±0.03 spikes/s, $P<0.001$) in HL compared to control rats. This decrease was more marked in sympathetic nerve. In conclusion, prolonged exposure of pancreatic B-cell to high FFA levels in vivo results in an increase in both B-cell mass and insulin response to glucose, which can be related in part to alterations of autonomic nervous system activity, especially a sharp decrease in the sympathetic one.

97

CCAAT/ENHANCER-BINDING PROTEIN BETA (C/EBPβ) IS INDUCED BY HYPERGLYCEMIA AND INHIBITS TRANSCRIPTION OF THE RAT INSULIN I GENE THROUGH INTERACTION WITH E2A TRANSCRIPTION FACTORS

J. Seufert, M. Lu and J. F. Habener. Massachusetts General Hospital, Howard Hughes Medical Institute, Harvard Medical School, Boston, MA

A reduction of insulin gene transcription by sustained high glucose levels is due in part to a loss of the stimulating transcription factors IDX-1 and RIPE3b1 as has been shown in the β-cell lines HIT-T15 (1), β-TC6, INS-1 and in the rodent diabetes model of partial pancreatectomy (2). We recently reported the inhibitory actions of the stress induced transcription factor C/EBPβ on insulin gene transcription (3). Here we examine the regulation of C/EBPβ in response to sustained high glucose levels in β-cell lines as well as during the time course of development of diabetes in the Zucker diabetic fatty (ZDF) *(fa/fa)* rat. C/EBPβ expression was asessed by Western blotting in HIT-T15 and INS-1 cells , exposed to high glucose levels (11.1, 25mM) for 25 weeks (long term) or 96 hours (short term). Expression in pancreatic tissue sections of ZDF rats *(fa/fa)* at the age of 6 and 12 weeks, Lean Littermates *(fa/+)* (ZLC) or Wistar Rats (WR) were examined by fluorescence immunocytochemistry and image quantitation. Interaction of C/EBPβ with E47 on the rat insulin I promoter was examined by Electrophoretic Mobility Shift, GST-pulldown, and immunoprecipitation assays. In β-cells exposed to high glucose for long term, C/EBPβ expression is irreversibly upregulated whereas a reversible upregulation is observed during short term exposure. A similar upregulation of C/EBPβ concomitant with the loss of insulin expression is seen in ZDF rats during the development of diabetes at 6 and 12 weeks of age, as opposed to ZLC and WR controls. GST-pull down and immunoprecipitation from INS-1 cells with GST-C/EBPβ and antibody to E47 provide evidence for a direct interaction of these two factors. Our *in-vitro* and *in-vivo* findings suggest that C/EBPβ may contribute to the glucotoxic reduction of insulin gene transcription via inhibitory interactions with the E47 transcription factor on the Far- and Nir-elements of the rat insulin I gene promoter. 98

THE GLP-1 RECEPTOR ANTAGONIST, GLP-1 (9-36AMIDE), IS A PRIMARY PRODUCT OF THE INTESTINAL L-CELL.

JJ Holst, L Hansen and CF Deacon. Department of Medical Physiology, the Panum Institute, University of Copenhagen, Denmark.

The initial metabolism of exogenous GLP-1 consists of deletion of its 2 N-terminal amino acid residues catalyzed by the enzyme dipeptidyl peptidase IV (DPP IV). The product GLP-1 (9-36amide) acts as a GLP-1 receptor antagonist with sufficient potency to influence GLP-1 activity and occurs in equal or higher concentrations than GLP-1 in the circulation. We studied the molecular nature of newly released GLP-1 using isolated perfused porcine ileum (n = 7), stimulated by either intraluminal glucose or intraarterial bombesin infusion, both robust stimuli for GLP-1 secretion. The stimuli were repeated in the presence of specific DPP-IV inhibitors (diprotin A or pyrrolidide derivatives) infused a) intravascularly and b) intraluminally. GLP-1 was analysed by differential radioimmunoassay techniques, capable of measuring intact or intact plus degraded GLP-1 and by analytical HPLC. Newly released GLP-1 consisted of 54 ± 10 % intact GLP-1 and 44 ± 9 % GLP-1 9-36 amide (no other metabolites identified). Addition of DPP-IV inhibitors , regardless of route, completly prevented cleavage of GLP-1. All stored GLP-1 (extracted from ileum before and after experiments) was intact. Measurable degradation neither occurred in perfusion medium sampled from the arterial nor the venous line. We conclude that large amounts of GLP-1 9-36 are formed at the stage of L-cell exocytosis. Being a primary secretory product, specific actions of GLP-1 (9-36amide) should now be sought.

OP 14

Hypoglycemia and Protein Metabolism

99

EFFECT OF RECENT, ANTECEDENT HYPOGLYCAEMIA AND RESPONSE OF CORTISOL PER SE', ON RESPONSES TO SUBSEQUENT HYPOGLYCAEMIA IN HUMANS.

S.Pampanelli, C.Lalli, P.Del Sindaco, M.Lepore, M.Ciofetta, C.Fanelli, P.Brunetti and Geremia B.Bolli. University of Perugia, Perugia, Italy.

Cortisol response to antecedent hypoglycaemia (hypo) mediates some of the suppressive effects of hypo on responses to subsequent hypo, but the relative roles of antecedent response of cortisol "per sè" and hypo are not known. To establish the effect antecedent response of cortisol independent of hypo, 5 normal volunteers were studied on 4 occasions at 1 month intervals (Studies 1-4) with the hyperinsulinaemic-hypo clamp (plasma glucose, PG, decreased stepwise from 5.0 to 2.2 mmol/l). On the day prior to study, either euglycaemia was maintained (S1); or 2 episodes of insulin-induced hypo (PG 2.7 mmol/l, 13.00-15.00 and 21.00-23.00 h) (S2); or S2 + blockade of cortisol response (oral metyrapone, S3), or S3 + cortisol replacement to mimic cortisol response of S2 (S4) were performed. As compared to S2, lack of response of cortisol to antecedent hypo in S3 resulted in greater adrenaline (4.51±0.64 vs 3.1±0.45 nmol/l) and glucagon (150±18 vs 118±15 pg/ml) ($p<0.05$), but not growth hormone and cortisol responses, although all responses remained more suppressed than in S1 ($p<0.05$). In S3, autonomic (but not neuroglycopenic) symptom score was greater than in S2 (10.5±2.5 vs 6.4±1.9, $p<0.05$) and no longer different from S1 (p=NS). However, deterioration of cognitive function (CF) was not affected in S3 vs S2, and was consistently less evident than in S1 ($p<0.05$). In S4 responses were no different from those of S2 (p=NS). Conclusions: responses of cortisol to antecedent hypo largely mediate suppression of adrenaline and glucagon and autonomic symptoms. In contrast, responses of growth hormone and cortisol and neuroglycopenic symptoms, and deterioration of CF are mediated by antecedent hypo "per sè" independent of cortisol responses.

100

SYMPTOMS, COUNTER-REGULATORY HORMONE RESPONSES AND COGNITIVE FUNCTION DURING HYPOGLYCAEMIA IN NIDDM

D. Hopkins[a], A. Korzon-Burakowska[a], J. Lomas[a], A. Pernet[a], M. Evans[a], K. Matyka[a], I. Macdonald[b] and S. Amiel[a]. [a]King's College School of Medicine & Dentistry, London, [b]Queens University Medical School, Nottingham, UK.

To determine the effects of glycaemic control on responses to hypoglycaemia in NIDDM, we have measured hormones, symptoms and cognitive function during stepped hypoglycaemia (nadir 2.4 mmol l^{-1}) in 7 poorly controlled patients (mean HbA_1c 11.3 ± 0.5 %) before and after improving control with insulin treatment, and in 7 non-diabetic control subjects. In poorly controlled NIDDM, counter-regulatory hormone responses were brisker than in health (AUC for adrenaline 690 ± 107 vs. 391 ± 57 nmol(180 min)l^{-1}, p= 0.027), and started at higher plasma glucose (PG) levels (adrenaline 4.4 ± 0.2 vs. 3.7 ± 0.2 mmol l^{-1}, p= 0.023; growth hormone 4.2 ± 0.2 vs. 3.4 ± 0.1 mmol l^{-1}, p= 0.018). Following insulin treatment, significantly improved glycaemic control (mean HbA_1c 8.1 ± 0.4 %, p <0.001) was achieved without severe hypoglycaemia. Hormonal responses were significantly reduced (AUC adrenaline 306 ± 93 vs. 690 ± 107 nmol(180 min)l^{-1}, p= 0.036; AUC cortisol 50822 ± 10050 vs. 85211 ± 7646 nmol(180 min)l^{-1}, p= 0.010) and started at much lower PG (adrenaline 3.5 ± 0.3 vs. 4.4 ± 0.2 mmol l^{-1}, p= 0.005; growth hormone 3.2 ± 0.2 vs. 4.2 ± 0.2 mmol l^{-1}, p <0.001; cortisol 3.7 ± 0.2 vs. 2.9 ± 0.1 mmol l^{-1}, p= 0.004). PG at which hypoglycaemic symptoms developed fell from 3.6 ± 0.2 to 3.0 ± 0.2 mmol l^{-1} (p= 0.019). In contrast, PG at which cognitive impairment occurred did not change significantly (3.1 ± 0.1 vs. 2.8 ± 0.1 mmol l^{-1}, p= 0.125). We conclude that:(1) counter-regulatory responses but not cognitive impairment begin at normoglycaemia in poorly controlled NIDDM; (2) glucose thresholds for responses to hypoglycaemia are determined by recent antecedent glycaemic experience; (3) intensified therapy lowers PG threshold for hypoglycaemic symptoms to levels associated with cognitive impairment; (4) severe hypoglycaemia is not an inevitable association with this change but patients are likely to be at increased risk of asymptomatic hypoglycaemia.

101

Hyperglucagonemia Accelerates Protein Catabolism in Type 1 Diabetes Mellitus. Charlton MR and Nair KS. Mayo Clinic and Foundation and the University of Vermont. USA

Background: Hyperglucagonemia in the presence of insulin deficiency increases leucine oxidation in nondiabetic subjects. Patients with type I diabetes have both high glucagon levels and increased rates of leucine oxidation. **Hypothesis:** We hypothesized that increased glucagon levels contribute to the increased leucine oxidation seen during insulin deficiency. **Methods:** To test this hypothesis we used a primed continuous infusion of L[1-13C] leucine to measure leucine oxidation in 6 insulin deprived, C-peptide negative type I diabetic patients during a) insulin deprivation and suppressed endogenous glucagon levels (INS DEP + SRIH) and b) insulin deprivation and suppressed endogenous glucagon levels with high level of glucagon replacement (INS DEP + SRIH + GGON). Paired t-tests were used to compare hormone levels and leucine kinetics between protocols. **Results:**

	INS DEP + SRIH		INS DEP + SRIH + GGON	
	baseline	**plateau**	**baseline**	**plateau**
insulin	< 35	< 35	< 35	< 35
glucagon	105 +/- 14	84 +/- 12*	110 +/-11	225 +/- 38†
leu oxidation	40 +/- 2.5	32 +/- 2.7*	36 +/- 1.6	48+/- 3.0 †

all results expressed +/- SEM, *denotes lower ($p<0.02$) vs. baseline, †denotes higher ($p<0.009$) than either baseline or INS DEP + SRIH plateau.

Leucine oxidation was significantly higher during the plateau period of the INS DEP + SRIH + GGON (when glucagon levels were high) studies than either baseline period or the plateau period of the INS DEP + SRIH studies (when glucagon levels were lower). The mean values of other hormones (GH, cortisol, IGF-1, epi- and norepinephrine) did not differ between studies. Leucine oxidation was seen, by multiple regression analysis, to correlate with glucagon levels (R^2=0.85). **Conclusions:** While insulin deficiency increases protein breakdown, hyperglucagonemia is primarily responsible for increased leucine oxidation. The protein catabolic state in insulin-deprived type I diabetic patients is contributed to not only by insulin deficiency but also by elevated glucagon levels.

102

EFFECTS OF HYPER- AND HYPOOSMOLALITY ON WHOLE BODY PROTEIN METABOLISM IN MAN

K. Berneis, S.Vosmeer, S.Sansano, R.Ninnis and U. Keller
Departments of Research and Internal Medicine, University Hospital Basel, Switzerland

Diabetic subjects frequently experience changes of extracellular osmolality. Cell volume alterations due to alterations of osmolality have recently been recognized to represent a new principle of metabolic control. To investigate the effects of acute hyper- and hypoosmolality on whole body protein metabolism, leucine kinetics were determined in 10 postabsorptive healthy male subjects 3 times in randomized order: hyperosmolality was induced by fluid restriction and additional NaCl 2-5% iv (w/v); hypoosomolality by i.v. administration of a synthetic analog of vasopressin (Minirin®), liberal water drinking and infusion of NaCl (0.4%); the control study consisted of water ad libitum. Whole body protein kinetics measured using the 1-^{13}C-leucine infusion technique, demonstrated that leucine flux-a parameter of protein breakdown-decreased under hypoosmolal conditions compared to controls (from 1.91±0.05 to 1.78± 0.06 µmol/kg/min, $p<0.02$). Leucine oxidation-a parameter of irreversible catabolism-decreased in the hypoosmolality group (from 0.34±0.01 to 0.27±0.01µmol/kg/min, -19±6% $p<0.005$ vs controls) and remained unchanged in the hyperosmolality group (+4±8%) and in controls (+9±7%). Plasma concentrations of insulin and glucose were lower, and plasma glycerol and ketone bodies higher under hypoosmolal conditions than in controls ($p<0.05$ or less). Indirect calorimetry demonstrated that utilization of fat as percentage of nonprotein energy expenditure was increased (54±9% vs. 34±5%) and that of protein and glucose decreased during hypoosmolality ($p<0.05$ or less vs controls). During hyperinsulinaemic euglycemic clamping glucose metabolic clearance rate was decreased during hypoosmolal conditions (4.39±0.35 vs 3.26±0.17 ml/kg/min $p<0.05$ vs controls). It is concluded that acute hypoosmolality exerts a protein sparing effect with increased utilization of fat and decreased insulin sensitivity of peripheral glucose metabolism; these alterations resemble those observed during prolonged starvation.

103

LEPTIN TREATMENT DOES NOT PREVENT THE DEVELOPMENT OF OBESITY IN BROWN FAT DEFICIENT TRANSGENIC MICE

A. Hamann, B. Büsing, C. Kausch, H. Greten and S. Matthaei.
Department of Medicine, University of Hamburg, Hamburg, Germany.

Transgenic mice (TG) in which the uncoupling protein promoter drives expression of diphtheria toxin A-chain in brown adipose tissue (BAT) have primary BAT deficieny and subsequently develop severe obesity, insulin resistance and late-onset hyperphagia. The aim of the present study was to investigate whether leptin treatment of BAT deficient mice could prevent the development of the obese phenotype. Starting at the age of 6 weeks, when body weight, food intake, plasma leptin, insulin and blood glucose of TG and controls were not significantly different, leptin (5 µg/g) or saline were injected i. p. once daily. During the following 6 weeks, leptin-treated controls lost 0.5 g of weight, while saline-treated controls gained 2.9 g. Saline-treated TG gained 13.5 g and leptin-treated TG gained 13.4 g body weight. Body lipid was 2.36 g compared to 0.65 g in leptin-treated controls ($p<0.01$), and markedly elevated in both TG groups after saline (11.3 g) or leptin treatment (10.7 g). This was accompanied by a 46% decrease in plasma leptin in leptin-treated controls, while both groups of TG revealed a ~9 fold increase in plasma leptin. In leptin-treated controls, total food intake was reduced by 10.6 % ($p<0.05$) while significant hyperphagia was observed in TG both under saline (+27.3%) and leptin treatment (+29.6%). Compared to controls, glucose, insulin, triglycerides and cholesterol levels were significantly elevated both in saline and leptin treated TG, but as for the data mentioned above, none of the measured parameters were significantly different between TG treated with either saline or leptin. In conclusion, chronic leptin administration cannot prevent the development of marked obesity, hyperphagia and abnormal glucose and lipid metabolism in BAT deficient mice. These data suggest that intact BAT function is of critical importance for leptin's role in the regulation of energy homeostasis. (Supported by DFG Ha 2093/2-1).

104

ACUTE HYPERGLYCEMIA WITHOUT HYPERINSULINEMIA CAUSES SYMPATHOEXCITATION AND VASODILATION.

RP Hoffman, CA Sinkey, M Hausberg, EA Anderson. University of Iowa Iowa City, Iowa, USA.

Chronic hyperglycemia plays a role in the development of autonomic neuropathy and macrovascular disease in diabetes. To learn more about the acute effects of hyperglycemia we measured muscle sympathetic nerve activity (MSNA, microneurography), forearm vascular resistance (FVR, air plethysmography) in 7 normal humans (age: 28±1 yrs; mean±se) before and during 60 min hyperglycemic clamp (12.5 ± 0.6 mmol L^{-1}). Octreotide (250 ug/hr), insulin (4 mU m^{-2} min^{-1}), and 20% dextrose infusions to maintain euglycemia (5.4 ± 0.2 mmol L^{-1}) and fasting plasma insulin levels (67±29 pmol L^{-1}) were started at least 90 min before the clamp. Subsequent studies with equal volume infusions of 20% mannitol and 0.2% saline to control for the effects of hyperosmolarity and volume of dextrose infusion were performed in each subject. Mean arterial and central venous pressures did not vary during any of the sessions. Results for MSNA (bursts/min) and FVR (units) are shown in the table below.

	Hyperglycemia		Mannitol		0.2% Saline	
	MSNA	FVR	MSNA	FVR	MSNA	FVR
Baseline	15±2	66±6	19±3	49±10	18±2	42±7
60 min	25±3*	45±7*	22±1	35±8*	22±3	43±8

*$p<0.01$ versus baseline

These results indicate that acute hyperglycemia causes sympathoexcitation and peripheral vasodilation even without changes in plasma insulin concentration. The increase in MSNA appears to be independent of both osmolar and volume effect but the vascular action may be partially mediated by increased osmolarity.

105

INSULIN AND GLUCOSAMINE INCREASE O-LINKED GLYCOSYLATION OF SKELETAL MUSCLE PROTEINS IN VIVO

Hannele Yki-Järvinen*, Antti Virkamäki**, Marc C. Daniels***, Don McClain***, and W. Kirby Gottschalk****. *University of Texas, San Antonio, Texas, USA **Minerva Foundation Institute for Medical Research, Helsinki, Finland, ***University of Mississippi Medical Center, Jackson, Mississippi, USA, and ****Glaxo Wellcome Research and Development, North Carolina, USA

O-linked N-acetylglucosamine (O-GlcNAc) is an abundant post-translational modification of serine/threonine residues of nuclear and cytoplasmic proteins. We determined whether insulin, or coinfusion of glucosamine (GlcN) with insulin alters O-linked glycosylation. Three groups of conscious fasted rats received 6-hour infusions of either saline (BAS), insulin (18 mU/kg·min) and saline (INS) or insulin and GlcN (30 μmol/kg·min, GLCN) during maintenance of normoglycemia. Insulin increased whole body glucose uptake from 49±5 to 239±8 μmol/kg·min, p<0.001), glycogen in abdominis muscle from 138±11 to 370±26 mmol/kg dry, p<0.001), the amount of cytosolic N- and O-linked glycosylation by 56 % from 362±30 to 564±45 dpm/μg protein·100 min (p<0.02), and O-linked glycosylation from 221±16 to 339±27 dpm/μg·100 min (p<0.02). Glycogen content was positively correlated with the amount of total (r=0.90, p<0.005) and O-linked glycosylation in the insulin infused animals. Coinfusion of GlcN with insulin increased muscle UDP-GlcNAc 3-4-fold (196±43 nmol/g) compared to insulin (56±10, p<0.05) or saline (66±11, p<0.05) infused animals. GlcN also decreased glucose uptake over 6 hours by 30 % to 168±8 μmol/kg·min (p<0.001 for GLCN vs INS), and muscle glycogen to 292±24 mmol/kg dry (p<0.05 for GLCN vs INS). Both total (635±60 dpm/μg·100 min, p<0.002) and O-linked (375±36 dpm/μg·100 min, p<0.002) cytosolic glycosylation were significantly higher in the GLCN (635±60 dpm/μg) than the BAS rats (p<0.002). As in the INS rats, muscle glycogen and O-linked glycosylation were positively correlated in GLCN rats (r=0.54, p<0.05). Variation in total and O-linked glycosylation in the GlcN infused rats was due both to glucosamine (p<0.02) and variation in the glycogen content (p<0.005).

106

EFFECT OF LIVER TRANSPLANTATION (LTx) ON INSULIN RESISTANCE IN CIRRHOTIC-DIABETIC PATIENTS.

G. Perseghin, D. Baratti, L. Piceni Sereni, E. Regalia, V. Mazzaferro and L. Luzi. San Raphael Scientific Institute and Liver Transplantation Unit, National Cancer Institute, University of Milan, Italy.

Liver cirrhosis is frequently complicated by overt diabetes mellitus and the most important pathogenic mechanism is considered to be insulin resistance. The aim of this study was to assess the effect of successful LTx on glucose homeostasis and on insulin action in 19 cirrhotic-diabetic. 14/19 subjects (74%) withdrew insulin therapy within 10±2 ms and the remaining 5 patients (26%) reduced the insulin regimen by 28% and 60% respectively 12 and 18 ms after Tx. 7 cirrhotic-diabetic (CIR: Child Pugh B, age=53±2 ys, BMI=27±2 kg/m^2, plasma glucose=156±13 mg/dl), 5 transplanted patients still on insulin treatment (DM-LTx: age=54±2 ys, BMI=27±1 kg/m^2, PG=114±9 mg/dl, Insulin Dose=28±6 U/day, Tx age=8±2 ms, prednisone=5±3 mg/day, cyclosporin A=4.4±0.7 mg/[kg·day]) and 4 transplanted patients who discontinued insulin treatment 12±4 ms following the transplant (LTx: age=56±3 ys, BMI=24±2 kg/m^2, PG=100±8 mg/dl, Tx age=33±12 ms, CyA=3.4±0.4 mg/[kg·day] but no prednisone) were studied by means of the euglycemic-hyperinsulinemic (40 mU/[m^2·min]) clamp to measure glucose uptake (GU) in combination with bolus-continuous infusion of [3-^{3}H]glucose to measure endogenous glucose production (EGP). 6 subjects with chronic uveitis on the same immunosuppressive therapy of transplanted patients and 6 normal healthy subjects (NOR) served as controls. CIR showed hyperinsulinemia (29±5 μU/ml; p=0.01), insulin resistance (GU: 2.3±0.2 mg/[kg·min]; p=0.01), increased EGP at both fasting (3.2±0.3; p=0.01) and clamp (1.0±0.2 mg/[kg·min]; p=0.01) conditions, when compared to NOR. DM-LTx normalized EGP (2.1±0.3 mg/[kg·min]; p=0.002 vs CIR and p=0.87 vs NOR), reduced insulin levels (8±1 μU/ml; p=0.01 vs CIR and p=0.91 vs NOR) and improved, but did not normalize insulin resistance (GU: 3.5±0.3 mg/[kg·min]; p=0.03 vs CIR and p=0.04 vs NOR). Finally, LTx normalized insulin levels, EGP and moreover insulin sensitivity when compared to NOR (GU: 6.2±0.4 vs 7.5±0.9 mg/[kg·min]; p=0.41). In summary, liver transplant normalizes 1) insulin levels, 2) endogenous glucose production and 3) peripheral insulin sensitivity. In conclusion liver transplant is capable to cure diabetes mellitus in 74% of cirrhotic-diabetic patients mainly acting via a marked improvement of hepatic and peripheral insulin action.

OP 15

Cardiovascular Risk Factors and Atherosclerosis

107

FACTORS ASSOCIATED WITH FIRST CORONARY EVENTS IN PATIENTS WITH NON-INSULIN-TREATED DIABETES IN A COMMUNITY SETTING

HW de Valk, JG Blankestijn, HJ de Bruin and DW Erkelens. University Hospital, Utrecht, The Netherlands.

Coronary heart disease is a major source of morbidity and mortality in patients with non-insulin-dependent diabetes mellitus (NIDDM). Identifying factors associated with the occurrence of coronary heart disease can provide directions for preventive strategies. Since most patients with NIDDM are treated in general practice, studies concerning this setting are needed. We have studied 728 patients with NIDDM treated in general practice without previous clinically manifest cardio-vascular disease. Mean age at baseline: 64.3 years (25-93); male: 336; median duration of clinical disease: 1.5 years (0-34). Median follow-up: 24 months (1-79). New coronary events were defined as objectively-proven angina pectoris, myocardial infarction, coronary artery bypass grafting, percutaneous transluminal angioplasty, and sudden unexpected death. Association between events and baseline variables were tested using the log rank test. Continuous variables were dichotomised using median or accepted cut-off points. Variables tested: sex, age ≤65 years, duration of disease >1.5 years, smoking, alcohol use, plasma creatinine >90 μmol/l; glycemic control: HbA1c>7.0%; lipids: total cholesterol >6.5 mmol/l, LDL-cholesterol >4.5 mmol/l, triglycerides >2.0 mmol/l, low HDL; blood pressure: systolic hypertension (>150 mm Hg), diastolic hypertension (>90 mm Hg), or high pulse pressure (PP) (>60 mm Hg); obesity (Body Mass Index >27); high fasting C-peptide (>1.10 nmol/l); use of sulphonurea or biguanides. Significant factors were entered into the Cox model to test for independence. A total of 34 events were observed. Younger age (p=0.01), low HDL (p=0.001), systolic hypertension (p=0.006), and high PP (0.0009) were associated with events, with creatinine>90 (p=0.058) of bordeline significance. Low HDL, high PP, and creatinine>90 were independently associated with events (p=0.001, p=0.004, and p=0.042). Substituting systolic hypertension for high PP yielded similar results. First coronary events in non-hospital-treated patients with NIDDM initially not on insulin are independently associated with low HDL, elevated systolic pressure or pulse pressure, and higher plasma creatinine. Preventive intervention strategies aimed at these factors are warranted to assess their benefit.

108

DETERMINANTS OF SEVERITY AND EXTENT OF CORONARY DISEASE IN TYPE 2 DIABETIC AND NONDIABETIC PATIENTS

M. Syvänne, P. Pajunen and M-R. Taskinen. University of Helsinki, Helsinki, Finland.

To elucidate whether the determinants of the severity and extent of coronary artery disease (CAD) differ in Type 2 diabetic CAD patients (DM) compared with nondiabetic CAD patients (non-DM), we used quantitative coronary angiography (QCA) to grade the severity (tightness of stenoses) and extent (proportion of the coronary tree involved in stenoses) in 55 DM patients (48 men and 7 women) and in 55 non-DM patients matched for sex, age, and body mass index. We also calculated per-patient global atheroma burden indices, which incorporate both severity and extent. We used stepwise multivariate linear regression analysis to select determinants of the angiographic characteristics in each group from a large number of potential risk factors, including demographics, lifestyle variables, glucose and insulin levels, lipoproteins separated by ultracentrifugation, major apolipoproteins, and apoE phenotype. In the DM group, the models selected accounted for 19%, 2%, and 11%, and in the non-DM group, 39%, 32%, and 35% of the variability in severity, extent, and atheroma burden, respectively. For the DM group, severity was associated with duration of diabetes (p=0.073) and IDL-cholesterol (C) (p=0.080); extent had no predictors; and atheroma burden had an inverse relation to HDL-C (p=0.017). The following predictors were found in the non-DM group: for severity, duration of CAD (p<0.001), smoking (p=0.002), and LDL-C (p=0.008); for extent, apoE phenotype (4/3 associated with milder CAD than 3/3, p=0.001) LDL-C (p=0.004), and apoA-II (inverse, p=0.011); and for atheroma burden, respective predictors were apoE phenotype (p=0.003), apoA-II (inverse, p=0.010), LDL-C (p=0.020), and HDL_2 triglycerides (inverse, p=0.040). We conclude that determinants of CAD severity and extent are different in Type 2 diabetes compared with nondiabetics and that conventional risk factors have greater predictive power in nondiabetics than in diabetic patients.

109

VISCERAL ADIPOSITY, BLOOD PRESSURE, AND GLUCOSE ARE INDEPENDENT RISK FACTORS FOR CORONARY HEART DISEASE

W. Fujimoto, E. Boyko, K-W. Chen, D. Leonetti, L. Newell, and P. Wahl, University of Washington, Seattle, WA, USA

The "insulin resistance syndrome" is associated with increased risk for coronary heart disease (CHD) and non-insulin-dependent diabetes mellitus (NIDDM). Baseline risk factors were examined in relationship to the development of CHD (clinical history or ECG consistent with Minnesota Code categories 1.1, 1.2, or 7.1) over 10 yr of followup of 174 Japanese-American men without CHD at baseline, 54 of whom also had NIDDM at baseline (clinical history or WHO criteria for a 75-g oral glucose tolerance test). Fasting plasma was collected at baseline to measure insulin, C-peptide, glucose, cholesterol, LDL-cholesterol, HDL-cholesterol, and triglycerides (TG). Computed tomographic scans of the thorax, abdomen, and thigh were done to assess body fat distribution. Body mass index (BMI) was calculated from weight (kg)/height^2 (m^2). There were 51 new cases of CHD. NIDDM and hypertension (systolic blood pressure [BP] ≥140 and/or diastolic BP ≥90 mm Hg) at baseline were significantly related to CHD. Univariate logistic regression analysis showed these baseline variables to be associated with CHD, adjusting for NIDDM at baseline (odds ratio for 1 S.D. increase, 95% C.I.): intra-abdominal fat (IAF, 1.52, 1.06-2.16), glucose (1.82, 1.12-2.95), HDL (0.66, 0.45-0.97), TG (1.49, 1.03-2.16), systolic BP (1.72, 1.20-2.47) and diastolic BP (1.97, 1.33-2.91). Notably, insulin, C-peptide, cholesterol, and LDL-cholesterol were not significantly associated with CHD. IAF, BP, and glucose remained independent risk factors in multivariate age- and BMI-adjusted logistic regression analysis of models that included IAF, NIDDM, insulin, C-peptide, glucose, hypertension, BP, HDL, and TG. Thus the association between IAF and CHD is very strong and independent of lipids and hyperinsulinemia. Both BP (hypertension) and glucose (diabetes) were also independently associated with CHD risk. Conclusion: These findings are consistent with the hypothesis that visceral adiposity and not insulin resistance (hyperinsulinemia) is central to the development of the metabolic syndrome associated with CHD.

110

PREDICTORS OF CORONARY ARTERY DISEASE (CAD) AND CEREBROVASCULAR DISEASE (CVD) IN NON-INSULIN DEPENDENT DIABETES MELLITUS (NIDDM)

H. Abu-Lebdeh, D. O. Hodge, T.T. Nguyen, Mayo Clinic, Rochester, USA

Classical risk factors do not fully explain the increased risk CAD and CVD in NIDDM. The aim of this study was to assess the risk of future CAD and CVD in relation to classical risk factors and other possible factors such as hyperglycemia and Lipoprotein(a) [Lp(a)]. From 1968-82, glucose, cholesterol (chol), triglycerides (TG) and Lp(a) were obtained in 449 Olmsted County residents with NIDDM and were free of CAD or CVD at baseline. Lp(a) was measured by a semi-quantitative method based on electrophoretic patterns. This cohort was followed for the incidence of CAD and CVD events using medical index (ICD9) codes. The cohort consisted of 47% men , 53% women and 45.7% smokers. The prevalence of hypertension was 37.4%. Mean age was 57 years, mean body mass index (BMI) 29.2, mean chol 6.34 mmol/L, mean TG 2.40 mmol/L and mean glucose 9.2 mmol/L at baseline. Mean duration of diabetes was 4 years. The frequency of distribution of Lp(a) scores 0, 1, 2, 3 (0=absent, 1= mild, 2= moderate, 3=maximally increased) were 55.9%, 26.1%, 16.5% and 1.6% at base line respectively. Mean follow up was 11.6 years. There were 216 CAD events and 115 CVD events. On multivariate analysis significant predictors of CAD were age (p=0.0001, HR 1.04), baseline glucose levels (p=0.0004, HR 1.63), TG (p=0.0038, HR 1.49) and smoking (p=0.0078, HR 1.45). Duration of diabetes, gender, hypertension, BMI and Chol did not predict CAD events. Significant predictors of CVD were age (p=0.0001, HR 1.07), baseline glucose levels (p=0.0264, HR 1.69), hypertension (p=0.0018, HR 1.89) and smoking (p=0.0296, HR 1.57). Duration of diabetes, gender, BMI, Chol and TG did not predict CVD events. Increments in Lp(a) levels were not associated with increased risk for developing either CAD or CVD. Conclusion: In NIDDM, baseline glucose levels, TG levels, smoking status and age were the only significant predictors of developing CAD, while baseline hypertension, glucose levels, smoking status and age were the only significant predictors of developing CVD. We did not find an association between baseline Lp(a) measurements and future risk of developing CAD or CVD.

111

INCREASED RISK FOR HEART DISEASE BY HIGH HOMOCYSTEINE LEVEL IS RELATED TO GLUCOSE TOLERANCE: THE HOORN STUDY

E.K. Hoogeveen[1], R.J. Heine[1,2], P.J. Kostense[1], P.J. Beks[1], C. Jakobs[3], L.M. Bouter[1] and C.D.A. Stehouwer[1,2]. [1]Institute for Research in Extramural Medicine, [2]Department of Internal Medicine and [3]Clinical Chemistry, Vrije Universiteit Amsterdam, The Netherlands.

High serum total homocysteine is an important risk factor for cardiovascular disease. To investigate the relationship between high serum total homocysteine and ischaemic heart disease independent of glucose tolerance we studied an age-, sex- and glucose tolerance stratified sample (n=631) of a 50-74 year old general Caucasian population. Glucose tolerance was assessed by means of two oral glucose tolerance tests, except in subjects with non-insulin-dependent diabetes mellitus (NIDDM) who were treated with insulin and/or hypoglycaemic agents. Cardiovascular history and an ECG were obtained from 288 subjects with normal glucose tolerance (NGT), 170 with impaired glucose tolerance (IGT), 173 with NIDDM. Any ischaemic heart disease was defined as a history of angina pectoris, myocardial infarction, coronary artery bypass grafting, (a) Minnesota Code(s) indicative of possible ischaemic heart disease and/or a Cardiac Infarction Injury Score > 20. High serum total homocysteine was defined as > 14 μmol/l. After stratification of the three glucose tolerance categories, we performed a logistic regression analysis. After adjustment for age, sex, hypertension, smoking and serum total cholesterol, the odds ratios (95% CIs) for any ischaemic heart disease for high serum total homocysteine were 0.96 (0.47–1.96) in NGT, 1.49 (0.66–3.35) in IGT and 2.72 (1.18–6.28) in NIDDM. We conclude that a high serum total homocysteine level is a stronger risk factor for ischaemic heart disease in non-insulin-dependent diabetes mellitus independent of classical risk factors, compared with normal and impaired glucose tolerance.

112

IMPACT OF RAMIPRIL ON LEFT VENTRICULAR HYPERTROPHY IN NORMOTENSIVE NON-ALBUMINURIC NIDDM PATIENTS.

F. S. Nielsen, A. Sato, S. Ali, L. Tarnow, U. M. Smidt and H.-H. Parving. Steno Diabetes Center, Gentofte, Denmark.

NIDDM patients have raised cardiovascular morbidity and mortality even in the absence of albuminuria and hypertension. Left ventricular hypertrophy (LVH) which is an ominous prognostic sign and an independent risk factor for cardiac events is often present in NIDDM patients. Therefore the aim of our six months randomized, double blind, parallel study was to compare the effects of Ramipril (R) 5 mg/day (n = 16, 10 males, 60 (9) years) with placebo (P) (n=15, 8 males, 55 (10) years) on left ventricular mass index (LVMI, echocardiography, Vingmed CFM725) and 24-h ambulatory blood pressure (ABP, A&D TM2420) in normotensive (repeated clinic blood pressure < 140/90 mm Hg), non-albuminuric (albuminuria < 100 mg/24-h) NIDDM patients with LVH (LVMI > 131 g/m^2 in males and > 100 g/m^2 in females). ABP was almost identical at baseline, mean (SE), 132/76 (3/1) vs 133/74 (5/2) mm Hg and remained stable during treatment 134/76 (3/1) vs 136/74 (6/2) mm Hg in the R and P group, respectively. LVMI was comparable at baseline, mean (SE), 137.1 (7.0) vs 129.6 (3.7) g/m^2 in the R and P group, respectively, and decreased significantly more in the R group as compared with the P group, mean (SE) 17.6 (3) vs 5.7 (4.6) g/m^2, respectively, mean difference (95% CI) 11.9 (0.7 to 23.1) g/m^2, (p = 0.027). In conclusion: Ramipril induces regression of LVH in normotensive, non-albuminuric NIDDM patients, independent of systemic blood pressure.

113

MICROALBUMINURIA AND CAROTID WALL THICKNESS IN NONDIABETIC AND DIABETIC SUBJECTS: THE IRAS STUDY

L Mykkänen, DJ Zaccaro, DH O'Leary and SM Haffner, University of Texas Health Science Center, San Antonio, TX, USA

Microalbuminuria (MAB) is associated with cardiovascular mortality and prevalent atherosclerotic vascular disease. Recent studies using ultrasound have shown that carotid atherosclerosis, expressed as an increased intima-media thickness (IMT), correlates with coronary disease. It is not known whether MAB is related to an early stage of atherosclerosis manifested as asymptomatic intimal thickening of arterial wall. Therefore, we investigated the relationship between MAB and IMT of the common carotid artery (CCA) in 991 nondiabetic (nonDM) and 450 NIDDM subjects aged 40-69 years and participating in the Insulin Resistance Atherosclerosis Study (IRAS). Altogether 14% of nonDM and 28% of NIDDM subjects had MAB and 31% of nonDM and 51% of NIDDM subjects had hypertension. Subjects with MAB had greater IMT of the CCA compared to those without MAB (nonDM: 0.84±0.01 vs. 0.79±0.01 mm, p=0.010; NIDDM: 0.89±0.02 vs. 0.86±0.01 mm, p=0.152; combined: 0.86±0.01 vs. 0.82±0.01 mm, p = 0.005). The relationship between MAB and IMT was independent of age, gender, ethnicity, clinic, lipid and lipoprotein levels, and smoking. Further adjustment for systolic blood pressure in the multiple linear regression analysis decreased the difference in IMT of the CCA between subjects with and without MAB to borderline significant level (combined: 0.86±0.01 vs. 0.83±0.01 mm, p=0.056). In conclusion, MAB was associated with increased IMT of the CCA. This relationship was partly mediated by systolic blood pressure. Our results suggest that MAB is related to atherosclerosis already at an early stage of the disease process.

114

RISK FACTORS FOR STROKE IN NON-INSULIN DEPENDENT DIABETIC SUBJECTS.

H. Millns, I.M. Stratton, R.R. Holman and R.C. Turner for UK Prospective Diabetes Study (UKPDS) Group, University of Oxford, Oxford, UK.

Newly diagnosed, white Caucasian, subjects with NIDDM, were studied after three months' diet to determine risk factors for subsequent stroke (fatal or non-fatal). Of 3776 subjects, 99 had a stroke within 10 years. Cox proportional hazards models, adjusting for age and gender, assessed the effect of each of body mass index, waist-hip ratio, systolic and diastolic blood pressure (BP), hypertension (systolic BP>160mmHg, diastolic BP>90mmHg, or on antihypertensive therapy), fasting plasma glucose, haemoglobin A_{1c}, total, LDL and HDL cholesterol, triglyceride, insulin, exercise and smoking. Systolic BP (p=0.009) and hypertension (p=0.001) were significantly associated with risk of stroke. In a stepwise procedure only hypertension was included in the model in addition to age and gender. The estimated hazard ratios (95% confidence interval) for subjects aged 50–54, 55–59 or ≥60 relative to <50 years were 1.37 (0.62, 3.00), 3.22(1.68, 6.19) and 4.78(2.56, 8.92) respectively. The estimated hazard ratio for men relative to women was 1.63 (1.08, 2.47) and for subjects with hypertension relative to those without was 2.47 (1.64, 3.74). When systolic BP was included instead of hypertension, the hazard ratios for the middle and upper tertiles, relative to the lower tertile were 1.96(1.01, 3.81) and 2.99(1.57, 5.69) respectively. In summary, in non-insulin dependent diabetic subjects, hypertension was the major modifiable risk factor for stroke.

INHIBITION OF PROTEIN KINASE C CORRECTS NERVE CONDUCTION AND BLOOD FLOW DEFICITS IN DIABETIC RATS.

N.E. Cameron[1], M.A. Cotter[1], A. Jack[1] and T.C. Hohman[2]. [1]Aberdeen University, Aberdeen, Scotland UK and [2]Wyeth-Ayerst, Princeton NJ, USA.

Increased activation of the protein kinase C (PKC) / diacylglycerol (DAG) system has been implicated in the aetiology of vascular complications in experimental diabetes. The aim was to test whether this mechanism was important for peripheral nerve function in streptozotocin-diabetic rats by examining the effects of a specific PKC inhibitor, WAY151003 (2,6-Diamino-*N*-([1-(1-oxotridecyl)-2-piperidinyl]methyl) hexanamide), which is active at the regulatory domain, and the effects of cremophor EL, a lipid formulation that complexes DAG to prevent PKC activation. Treatment was for 2 wk following 6 wk of untreated diabetes. An approximately 20% deficit ($p < 0.001$) in sciatic motor nerve conduction velocity (NCV) in diabetic rats was corrected by 92.4 ± 5.0% ($p < 0.001$) by WAY151003 (3 mg/kg) and 81.3 ± 6.3% ($p < 0.001$) by cremophor EL (100 mg/kg) treatment. Similarly, a 19.2 ± 2.4% deficit in sensory saphenous NCV was 72.3 ± 7.6% ($p < 0.001$) and 66.1 ± 9.3% ($p < 0.001$) corrected by WAY151003 and cremophor EL respectively. Sciatic nutritive endoneurial blood flow was 50.4 ± 3.5% ($p < 0.001$) reduced by untreated diabetes. This was completely ($p < 0.001$) corrected by WAY151003 treatment and 69.4 ± 7.2% ($p < 0.001$) corrected by cremophor EL. PKC inhibitor effects on motor NCV and blood flow were completely abolished ($p < 0.001$) by co-treatment with the nitric oxide synthase inhibitor N^G-nitro-L-arginine (10 mg/kg). PKC inhibition did not alter motor or sensory NCV and blood flow in non-diabetic rats. Thus, the data implicate the PKC-DAG mechanism in the aetiology of impaired neurovascular function in diabetic rats, perhaps by causing a deleterious effect in the nitric oxide system of vasa nervorum.

116

A DOUBLE BLIND PLACEBO TRIAL OF THE EFFECT OF AN ACE INHIBITOR, TRANDALOPRIL ON DIABETIC POLYNEUROPATHY.

RA Malik, CA Abbott, S Williamson, B Abu-Aisha, AJM Boulton. Department of Medicine, Manchester Royal Infirmary, Manchester, UK.

There is accumulating evidence that vascular factors are important in the pathogenesis of diabetic neuropathy. One animal study and two open label studies have shown benefit with Angiotensin converting enzyme (ACE) inhibitor. A double blind placebo controlled trial was undertaken in 41 diabetic patients who received either Trandalopril (T) 2mg od (n=21) or Placebo (P) (n=20) over 12 months. All patients were well matched for age and degree of glycaemic control (HbA1c (%), T(10.1± 0.43) and P(10.7 ± 0.29)). Baseline Peroneal motor nerve conduction velocity (PMNCV-m/s)(T(38.5 ± 0.98), P(37.42±1.1)), Sural nerve amplitude (SNAP-μv)(T (8.2 ± 1.40), P(6.1 ± 1.4)), Neuropathy symptom score (NSS) (T(3.6 ± 0.5), P(3.3 ± 0.5)), Neuropathy deficit score (NDS) (T(3.1 ± 0.28), P(3.8 ± 0.2)), Vibration perception threshold (VPT-volts)(T(20.9 ± 2.5), P(22.8 ± 2.5)), 30:15 ratio (T(1.08 ± 0.02), P(1.07 ± 0.01)) and Heart rate variation during deep breathing (HRV)(T(11.33 ± 1.3), P(9.2 ± 1.1)) did not differ significantly between the two groups. After 12 months of treatment a trend for improvement was observed. PMNCV improved by +0.91 ± 0.52 in T and decreased by -0.85 ± 0.62 in P (P<0.04). SNAP also showed a trend for improvement in T (+1.21 ± 0.78) compared to P (-0.48 ± 0.73) (p= 0.12). Clinical evaluation of the NSS showed no significant difference between T (-0.24 ± 0.64) and P (-1.2 ± 0.66) (P= 0.3). The NDS also did not change significantly between T (+0.7 ± 0.42) and P (+0.7 ± 0.33) (P= 1.0). VPT decreased in T (-1.26 ± 1.29) and increased in P (+0.32 ± 1.2) (P= 0.66) favouring active treatment. Autonomic function evaluated by the 30:15 ratio decreased by the same amount in T (-0.04 ± 0.02) and P (-0.04 ± 0.02 (p= 0.92) and the HRV increased more in T (+1.43 ± 1.13) than P (+0.7 ± 0.92) (p= 0.62). This short term study has shown a beneficial effect of ACE inhibition in diabetic patients with mild to moderate neuropathy with a positive trend for improvement in parameters assessing peripheral and autonomic neuropathy but not symptoms or signs. The results support the potential role of ACE inhibition in the treatment of diabetic polyneuropathy.

117

A MULTICENTRE DOUBLE-BLIND TRIAL OF GAMOLENIC ACID IN DIABETIC PERIPHERAL SENSORIMOTOR NEUROPATHY

A.J.M. Boulton[a], D. Ziegler[b], J. Scarpello[c], G. Jamal[d], H. Keen[e], L.O. Almer[f], A. Gamstedt[g]. [a] Department of Medicine, Manchester Royal Infirmary, Manchester, UK, [b]Diabetes Forchungs Institut, Dusseldorf, Germany, [c]Department of Diabetes and Endocrinology, City General Hospital, Stoke-on-Trent, UK, [d]Department of Neurology, Southern General Hospital, Glasgow, UK, [e]Guys Hospital, London, UK, [f]University of Lund, Malmo General Hospital, Sweden and [g]Department of Internal Medicine, Orebro Medical Centre Hospital, Sweden.

Two trials have previously reported improved electrophysiological function in patients with diabetic neuropathy after treatment with gamolenic acid (GLA). This study aimed to compare the effect of gamolenic acid and placebo in neuropathic patients. 291 patients (7 centres) were randomised double blind to GLA (n=146) or placebo (n=145) for twelve months, subsequently all patients received GLA single blind for a further twelve months. At entry all subjects had clinical signs of peripheral neuropathy with either abnormal electrophysiological (peroneal nerve mcv $< 42 ms^{-1}$) function and/or thermal perception. Twenty eight variables were assessed: 4 thermal threshold, 12 electrophysiological and 12 clinical assessments. After 12 months 23 out of 28 assessments had improved on GLA (10 at $2p < 0.05$). All 28 variables on placebo had worsened (19 at $2p < 0.05$). Differences between GLA and placebo were in favour of GLA ($2p < 0.05$) in 21 of the 28 assessments. During the second year, those previously on GLA significantly further improved in 8 variables ($2p < 0.05$), those previously on placebo showed a trend to improvement in 18 assessments. GLA did not affect glycemic control and side effects (mainly GI) were minor. GLA appears to improve nerve function in established diabetic neuropathy and is well tolerated.

118

BENEFICIAL EFFECT OF DIETARY OMEGA 3 FATTY ACIDS ON Na,K-ATPase AND NERVE FUNCTION IN DIABETIC NEUROPATHY.

A. Gerbi, J-M. Maixent, O. Barbey, T. Coste, M. Pierlovisi, A. Nouvelot, P. Vague and D. Raccah, Division of Diabetology, University of Marseille, Marseille, France.

Omega 3 fatty acids from fish oil may help in the amelioration of cardiovascular disease. However, there are very few studies about their preventive effects during diabetes-induced neuropathy. The objective of this study was to assess the preventive ability of a fish oil rich diet (rich in omega 3 long chain fatty acid) on diabetes induced abnormalities in Na,K-ATPase activity, isoenzyme expression, fatty acid content in sciatic nerve membranes, nerve conduction velocity (NCV) and morphological lesions. Three groups of 15 rats were studied. In two groups diabetes was induced by streptozotocin (STZ). Diabetic animals were fed standard rat chow supplemented with either fish oil (MaxEPA) (DM) or olive oil (DO) at a daily dose of 0.5g/kg by gavage during 8 weeks. Non-diabetic control animal were fed standard rat chow supplemented with olive oil (CO). The results show that in olive oil treated diabetic rats compared to controls, membrane phospholipids fatty acid composition was altered, Na,K-ATPase $\alpha 1$ and $\alpha 3$ isoforms activity ($\alpha 1$: CO ; 2,41±0.23 µmol Pi/h/mg Prot vs DO ; 1,09±0,07 $p<0,05$/ $\alpha 3$: CO ; 1,18±0,19 vs DO ; 0,11±0,03 $p<0,05$), expression and conduction velocity of sciatic nerve were decreased (CO ; 48,33±1,17 m/s vs DO ; 34,35±0,55 m/s, $p<0,05$). Morphological abnormalities in sciatic nerves were also observed. In diabetic rats fish oil restored Na,K-ATPase activity (CO ; 4,8±0,7 vs DO ; 2,18±0,1 $p<0,05$ and DO vs DM ; 3,56±0,16 $p<0,05$), $\alpha 1$ and $\alpha 3$ isoforms expression and activity ($\alpha 1$: DM ; 1,72±0,18 vs DO $p<0,05$/ $\alpha 3$: 0,97±0,1 vs DO $p<0,05$), partially conduction velocity (DM ; 39,1±0,96 m/s vs DO, $p<0,05$) and some morphological lesions. These results suggest that fish oil treatment could normalize fatty acid composition in membrane phospholipids, and thus has beneficial effects on diabetes-induced alterations in sciatic nerve.

119

LONG-TERM EFFECTS OF ACETYL-L-CARNITINE ON MYOCARDIAL SYMPATHETIC INNERVATION IN DIABETIC PATIENTS

AK Turpeinen[1], JT Kuikka[2], E Vanninen[2], J Yang[2] and MIJ Uusitupa[1], [1]Dept. of Clinical Nutrition, University of Kuopio and [2]Dept. of Clinical Physiology and Nuclear Medicine, Kuopio University Hospital, Kuopio, Finland

L-carnitine and its derivative, acetyl-L-carnitine (ALC) may have beneficial effects on cardiac performance and nerve function in diabetes mellitus. To investigate the effects of ALC on myocardial sympathetic innervation and autonomic nervous function (ANF), we studied 19 patients (placebo group: n = 6, age 56 ± 5 years, HbA_{1c} 9.0 ± 0.5 %; ALC group: n = 13, age 57 ± 2 years, HbA_{1c} 9.4 ± 0.6 %, mean ± SEM) in a randomized placebo-controlled double-blind one-year trial. The dose of ALC was 1500-3000 mg/day. A dual-tracer isotope single-photon emission tomography (SPET) was performed before and after the one-year treatment to assess myocardial sympathetic innervation (^{123}I-metaiodobenzylguanidine, MIBG) in relation to perfusion (^{99m}Tc-methoxyisobutylisonitrile) at rest. Autonomic nervous function tests and power spectral analysis of heart rate variability were also performed. The two groups did not differ with respect to their ANF results or plasma catecholamine levels. In patients with placebo, global myocardial MIBG uptake (100 ± 16 % vs. 77 ± 6 %, p = 0.03 before vs. after treatment) deteriorated during the one-year trial, whereas in ALC-treated patients MIBG uptake (100 ± 10 % vs. 102 ± 6 %, p = NS) remained constant. Similarly, resting myocardial perfusion was lower at the one-year examination in the placebo group, but remained unchanged in the the ALC group. No changes were observed in myocardial MIBG/perfusion ratio or ANF results in either group. We conclude that long-term treatment with ALC might prevent the progressive loss of myocardial sympathetic innervation in diabetic patients. MIBG-SPET is a sensitive and reproducible method in assessing the development of myocardial sympathetic denervation.

120

Insulin affects Cardiac Sympatho -Vagal Balance: a clamp study.

I. Balzani , M.De Marco, G. De Masi, * C.Macor , *E. Rella, ** K. Thomaseth, •M. Carruba, * G. Federspil, * R. Vettor and F. Bellavere. Autonomic Nervous System Physiopath. Unit ,1st Dept. of Medicine, S. Antonio City Hospital, *Institute of Semeiotica Medica - University of Padova ** Institute of System Science and Biomedical Engineering (C.N.R.) Padova, • Pharmacology Dept. , Milano, Italy.

The effects of insulin on cardiac neural regulation were studied in 15 subjects aged 30(5.1) (M(SD)), 8 normals aged 31.5(5.7) and 7 obese aged 29(3.9) who underwent a euglycaemic clamp with a three step insulin infusion-rate: a) 20 mU/min/m2, b) 40 mU/min/m2, c) 80 mU/min/m2 . Power Spectral Analysis (PSA) of Heart Rate (HR) quantified cardiac Sympatho-Vagal balance throughout the study. While there was no significant variation (before and after insulin infusion) in HR and HR Variance, a linear correlation was found between progressive insulin infusion rate and the percentage increase of Low (LF) - High (HF) Frequency ratios of HR spectral components ($b = 30.4$, $r = 0.30$, $p < 0.02$). This correlation was significantly higher in the obese group ($b = 52.13$, $r = 0.45$, $p < 0.001$) but it was not statistically significant in the normal group ($b = 21.09$, $r = 0.21$, p = n.s.). Specular correlation was found between HF values and steps of insulin infusion rate in all subjects ($b = -8.64$, $r = -0.26$, $p < 0.04$) and to a greater extent in the obese group ($b = -13.6$, $r = -0.37$, $p < 0.007$) while statistical significance was not reached in the normal group ($b = -4.8$, $r = -0.14$, p = n.s.). However no significant increases in plasma Noradrenalin and Adrenalin concentrations were found in all subjects nor in both groups before and after any step of insulin infusion rate. As the LF and HF components of PSA are commonly thought to be related, mainly to the sympathetic and entirely to the vagal influences respectively on the cardiac autonomic drive, we found evidence that insulin per se affects the Sympatho-Vagal cardiac balance leading to a vagal withdrawal as well as to a relative sympathetic predominance related to the insulin infusion rate . These effects have been shown to predominate in obese rather than in normal subjects . Specular data on hypoglicaemic clamp in the same subjects are available but have not been discussed here.

121

INCREASED AUTONOMIC DYSFUNCTION IN IDDM PATIENTS AT HIGH RISK OF CARDIOVASCULAR MORTALITY: A POPULATION STUDY.

O. Eshoj, K.Borch-Johnsen, B. Feldt-Rasmussen and H. Beck-Nielsen. Department of Endocrinology, Diabetes Research Center, Odense University Hospital, Odense, Steno Diabetes Center, Gentofte and Department of Nephrology, Rigshospitalet University Hospital, Copenhagen, Denmark.

BACKGROUND: IDDM patients with macroalbuminuria have a high cardiovascular mortality and microalbuminuria is a strong predictor for the development of macroalbuminuria. In IDDM patients, impaired autonomic function is related to sudden cardiac death. Thus, the aim of the present study was to investigate if patients with IDDM and raised urinary albumin excretion rate (AER) had autonomic dysfunction more frequently compared to controls. *STUDY POPULATION AND METHODS:* In an epidemiological study of IDDM patients we identified all with raised AER and divided the material into three groups: 1. *Microalbuminuria*: AER=20-200 μg/min (n=74),2. *Macroalbuminuria*: AER>200 μg/min (n=53), and 3. *Raised AER*: >20 μg/min (n=127). From the same material three control groups with normal AER, matched to the above groups according to sex, age, duration of diabetes and HbA1c (n=148, 106 and 254, respectively) were identified. AER was based upon three overnight urine collections and autonomic function was determined by beat-to-beat variation during deep breathing, where ≤ 10 beats/min was defined as definite abnormal (Ewings criteria). *RESULTS:* In the microalbuminuria group vs. control group we found 35(47%) vs. 59(40%) with autonomic dysfunction (Kruskal-Wallis chi-square=163.56, p<0.0001), in the macroalbuminuria group vs. control group 39(74%) vs. 54(51%) (Kruskal-Wallis chi-square=119.37, p<0.0001) and in the group with raised AER vs. control group 74(58%) vs. 108(43%) (Kruskal-Wallis chi-square=290.02, p<0.0001). *CONCLUSION:* We conclude, that IDDM patients at high risk of cardiovascular mortality have increased autonomic dysfunction, which may contribute to cardiovascular death.

122

DECREASED MOTOR NERVE CONDUCTION VELOCITY (MNCV) IN DIABETIC RATS IS LINKED TO CYTOSOLIC REDUCTIVE STRESS

Y. Ido[1], E. Ostrow[1], B.L. Mylari[2], P.J. Oates[2], and J.R. Williamson[1], [1]Washington University, St. Louis, and [2]Pfizer Inc., Groton, USA.

Aim. To assess the role of sorbitol pathway-induced reductive stress (a decrease in cytosolic free NAD/NADH) in mediating impaired MNCV in diabetic rats. The effects of sorbinil (50 mg/kg bwt day in the chow), an aldose reductase inhibitor (ARI), and CP-166,572 (200 mg/kg bwt/day in the drinking water), an inhibitor of sorbitol dehydrogenase (SDI), were assessed on MNCV in sciatic peroneal (SP) and distal tibial nerves (DT) 4 months after induction of diabetes (D) by iv injection of 50 mg/kg bwt of streptozotocin in male Sprague-Dawley rats (bwt ~300 g). On the day of sacrifice rats were anesthetized with thiopental and sciatic nerves were quickly sampled for measurement of lactate, pyruvate, malate, acetoacetate, and β-hydroxybutyrate for estimating cytosolic and mitochondrial free NAD/NADH and cytosolic NADP/NADPH. D rats gained less weight and had plasma glucose levels of 33-40 mM vs ~7 mM for controls (C). MNCV in D was ~11 % slower (p<0.005) than in C in both SP (65.3±4.2 m/sec in C, n=12, vs 59.0±5.0 in D, n=8) and DT (59.2±5.2 in C vs 52.3±4.1 in D). SDI and ARI prevented the decreased MNCV in both SP (68.4±7.1 for SDI, n=11, and 65.1±4.8 for ARI, n=10) and DT (58.2±5.2 for SDI and 57.1±6.6 for ARI). Cytosolic free NAD/NADH was decreased 46 % (p<0.001) in D (272±95) vs C (508±132). SDI and ARI prevented this decrease (478±195 for SDI and 438±142 for ARI). Cytosolic free NADP/NADPH was decreased 44 % (p<0.005) in D (0.0090±0.0032) vs C (0.0161±0.0048); this decrease was prevented by SDI and ARI. Mitochondrial free NAD/NADH was decreased 37% (p<0.02) in D (16.4±4.6) vs C (26.1±7.9); it was not normalized by SDI (16.2±3.5) or by ARI (17.1±5.0). In conclusion, in rats with diabetes of 4 months duration, decreases in MNCV and in cytosolic NAD/NADH and NADP/NADPH (but not the decrease in mitochondrial NAD/NADH) were prevented by ARI and by SDI. These observations suggest a potentially important role for sorbitol pathway-induced reductive stress in mediating decreased MNCV in diabetic rats.

Inflammatory Mediators and Beta-Cell Destruction

123

ROLE OF TGFβ SECRETED FROM A CD4+ SUPPRESSOR T CELL CLONE IN THE PREVENTION OF IDDM.

H.S. Jun, H.S. Han, C.S. Yoon, A. Kim, H.Y. Bae, T. Utsugi, S.J. Kim, and J.W. Yoon. University of Calgary, Calgary, Alberta, Canada; Ajou University, Suwon, Korea; NIH, Bethesda, Maryland, USA.

We have previously shown that a CD4+ suppressor T cell clone (NY4.2) isolated from islet- infiltrating lymphocytes of NOD mice prevented the development of autoimmune IDDM. This investigation was initiated to determine the mechanisms involved in the prevention of IDDM by the CD4+ suppressor T cell clone NY4.2. First, we examined whether the suppressive activity of NY4.2 T cells results from the cytokines secreted from the cells. Measurement of several cytokines from the supernatant of NY4.2 T cell culture using ELISA revealed that NY4.2 T cells secrete substantial amounts of TGFβ, IL-10, and IFN-γ , but not IL-2 or IL-4. Next, we examined which of the cytokines, TGFβ, IL-10 or IFN-γ are involved in the suppression of immune responses. We treated the supernatant from the culture of NY4.2 cells with antibody against TGFβ, IL-10 and IFN-γ and the immunosuppressive activity of the supernatant was measured. Most of the immunosuppressive activity of the supernatant was abrogated after treatment with anti-TGFβ antibody, but not by treatment with anti-IL-10 or anti-IFN-γ antibodies. Finally we examined whether TGFβ suppression resulted in a loss of suppressive activity by transducing TGFβ -expressing NY4.2 cells into TGFβ-suppressed NY4.2 cells using a retroviral vector which expresses antisense TGFβ genes. We found that these transduced NY4.2 cells no longer suppress cell-mediated autoimmune IDDM in NOD mice. On the basis of these observations, we conclude that TGFβ secreted from CD4+ NY4.2 T cells plays a major role in the prevention of IDDM in NOD mice.

124

MODULATION OF CYTOKINE-INDUCED APOPTOSIS IN NEONATAL RAT ISLETS. N.John J.Mabley,S. Thomas, A-M Dunger * D. Schröder *S. Schmidt, * M. Di Matteo, and I.Green, Univ. of Sussex, Brighton UK and *Univ. of Greifswald, Germany.

We have previously shown that treatment of rat islets with the cytokine combination IL-1ß, TNF and IFN inhibited ß cell function and decreased cell number. The aim of this study was to determine if cytokines caused programmed cell death by apoptosis in islet beta cells and whether pretreatment with growth factors could prevent cytokine-induced chromatin condensation. Islets from rats aged 8-16 days were cultured for at least 2 days prior to growth factor pretreatment (TGFß (3.3 x 10^{-11}M), IGF-1 (10^{-8}M) or insulin (4nM) (24h) followed by cytokine treatment (IL-1ß, TNF (both 100pM) and IFN 2U/ml) for 24-48h. Dissociated single cells were harvested and analysed; intact islets were dispersed into single cells. Cell suspensions were mixed with acridine orange (10μg/ml) and apoptotic nuclei were counted by fluorescence microscopy. This methodology was validated using additional features of electron microscopy and DNA laddering in both cytokine and free radical treated cells. An increased number of apoptotic nuclei 11.6% was observed following 24-48h combined cytokine treatment versus 2.7% in control cells, [nuclei viewed 855 and 703 respectively; 7 experiments P<0.001]. This increase was partially blocked by 24h pretreatment with growth factors (apoptotic cells cytokine treated 15.5%; TGF+ cyt 7%; IGF-1+ cyt 6.9%; INS +cyt 5.3%. Confirmation that beta cell nuclei were showing chromatin condensation was made by use of a beta-cell specific antibody in conjunction with acridine cytochemical analysis. We conclude that cytokines accelerate programmed cell death in beta cells and that growth factors maintain cell viability.

125

DESTRUCTION OF BETA CELLS IS ASSOCIATED WITH APOPTOSIS IN NON-OBESE DIABETIC (NOD) MICE

K. Anzai, S. Nagafuchi* and J. Ono. Department of Laboratory Medicine, Fukuoka University School of Medicine, *First Department of Medicine, Faculty of Medicine, Kyushu University, Fukuoka, Japan

To clarify how beta cell is injured in autoimmune diabetes, we studied apoptosis of beta cells in cryostat sections of pancreas from non-obese diabetic (NOD) mice by an in situ apoptosis detection methods. After DNA unveiling preparation, slides were incubated with terminal deoxynucleotidyl transferase and digoxigenin labeled nucleotides. The catalytically added nucleotides were visualized with a peroxidase labeled anti-digoxigenin antibody. Female NOD mice (4-35 wk-old) were split into three groups according to age and existence of diabetes: non-diabetic mice (group I; 4-10 wk and group II; 11-35 wk), and diabetic mice (group III, 11-35 wk). The diabetic mice were sacrificed the day after the plasma glucose level exceeded 14 mM. The apoptotic cells were detected within islets of non-diabetic mice of group II, and these cells were also stained with anti-insulin antibody. No apoptosis was observed in islets of both non-diabetic young mice (group I) and diabetic mice (group III). The absence of apoptosis in diabetic mice suggest that the apoptotic beta cells are rapidly removed. Apoptotic lymphocytes were detected among infiltrating lymphocytes in all three groups. We conclude that apoptosis plays an important role in the beta cell injury in autoimmune diabetes.

126

NF-κB ACTIVITY IS REQUIRED FOR TNF-α-INDUCED APOPTOSIS OF NIT-1 INSULINOMA CELLS.

L.A. Stephens, H.E. Thomas and T.W.H. Kay. The Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia.

TNF-α is a potential mediator of β cell destruction in IDDM. We have investigated the cytotoxic effects of TNF-α in NIT-1 insulinoma cells. Apoptosis was induced in NIT-1 cells after treatment with murine TNF-α (1-1000U/ml) for 24 hrs, and was potentiated by IFN-γ. Human TNF-α also induced apoptosis in NIT-1 cells, implying the involvement of the p55 TNF-R in delivering the apoptotic signal. TNF-α-induced apoptosis is generally considered to involve activation of the Caspase (formerly ICE) family of cysteine proteases, but not the TNF-inducible transcription factor NF-κB. NIT-1 cells transfected with crmA, a cowpox virus-encoded inhibitor of ICE, were protected from TNF-α-induced apoptosis. Unexpectedly, NIT-1 cells stably transfected with a dominant negative inhibitor of NF-κB (Δsp), which lacked TNF-inducible NF-κB activity in a gel mobility shift assay, were also protected from TNF-α-induced cell death. Δsp-expressing NIT-1 cells were deficient in ICE mRNA compared with parental cells, consistent with a role for NF-κB in ICE regulation, and potentially explaining their protection from TNF-mediated apoptosis. Inducible nitric oxide synthase (iNOS) is a gene known to be regulated by NF-κB. NO does not, however, appear to play a role in TNF-α-induced apoptosis of NIT-1 cells, as treatment with 0.5mM N^G-Methyl-$_L$-Arginine, a competitive inhibitor of iNOS, did not protect cells against TNF-α-induced death. Our results show that both NF-κB and ICE activity are required for TNF-induced apoptosis of NIT-1 insulinoma cells, and these molecules are therefore potential targets for prevention of cytokine-mediated beta cell destruction in IDDM.

127

ERK1/2 AND p38 MITOGEN ACTIVATED PROTEIN KINASE (MAPK) INHIBITION BLOCKS IL-1 INDUCED RAT ISLET NITRIC OXIDE (NO) SYNTHESIS.

T. Mandrup-Poulsen[1], C.M. Larsen[1], K. Wadt[1], L. F. Juhl[2], H.U. Andersen[1], J. Raingeaud[3], K. Seedorf[2] and C.A. Dinarello[4]. [1]Steno Diabetes Center and [2]Hagedorn Research Institute, Gentofte, Denmark, [3]University of Massachusetts Medical School, Worcester, and [4]University of Colorado Health Sciences Center, Denver, USA.

Interleukin-1ß (IL-1) is selectively cytotoxic to rat pancreatic ß-cells by inhibiting glucose oxidation, causing DNA damage and inducing apoptosis. Nitric oxide (NO) is a necessary, but not sufficient mediator of these effects. We have previously reported that IL-1 causes phosphorylation of Elk-1, activation transcription factor (ATF) 2 and heat shock protein (Hsp) and activates the extracellular signal-regulated kinase (ERK) 1/2 and the p38 MAPK in rat islets and rat insulinoma (RIN) cells. Here we show that mitogen activated protein kinases (MAPK) are involved in IL-1 signalling of NO dependent and independent effects in ß-cells. Specific ERK1/2 and p38 MAPK inhibition using the PD and VK compounds blocked Elk-1 and Hsp25 phosphorylation, respectively, demonstrated by phosphotransferase activity assay of lysates of IL-1 exposed rat islets, and when combined completely prevented IL-1 induced phosphorylation of Elk-1, ATF2 and Hsp25, indicating that ERK1/2 and p38, but not c-Jun NH2 terminal kinase (JNK) are responsible for the phosphorylation of these substrates. The ERK1/2 and p38 MAPK inhibitors individually reduced, but in combination blocked IL-1 mediated islet NO synthesis determined as nitrite by the Griess method. p38 MAPK, but not ERK1/2 inhibition prevented IL-1 mediated inhibition of glucose-stimulated insulin release. We conclude that ERK1/2 and p38 MAPK activation is necessary, but not sufficient for IL-1 mediated ß-cell NO synthesis and that p38 MAPK is involved in signalling of NO independent effects of IL-1 ß-cells.

128

ROLE OF MACROPHAGE-DERIVED SOLUBLE MEDIATORS IN THE PATHOGENESIS OF EMC VIRUS-INDUCED DIABETES IN MICE.

K. Hirasawa, H.S. Jun, K. Maeda, Y. Kawaguchi, S. Itagaki, T. Mikami, H.S. Baek, K. Doi, and J.W. Yoon. University of Calgary, Calgary, Alberta, Canada; University of Tokyo, Tokyo, Japan; Ajou University, Suwon, Korea.

We have previously shown that the major population of infiltrating cells, in mice, at an early stage of encephalomyocarditis (EMC) virus infection are macrophages. The inactivation of macrophages prior to viral infection resulted in the prevention of diabetes, whereas activation of macrophages prior to viral infection resulted in the enhancement of β-cell destruction. This investigation was initiated to determine whether macrophage-produced soluble mediators play a role in the destruction of pancreatic β-cells in mice infected with a low dose of diabetogenic EMC-D virus. When we examined the expression of the soluble mediators interleukin -1β (IL-1β), tumour necrosis factor- α (TNF-α) and inducible nitric oxide synthase (iNOS) in the pancreatic islets, we found that these mediators were clearly expressed at an early stage of insulitis and this expression was evident until the development of diabetes. We confirmed the expression of these mediators by *in situ* hybridization using digoxygenin-labelled RNA probes or immunohistochemistry in the pancreatic islets. Mice treated with antibody against IL-1β and TNF-α, or the iNOS inhibitor aminoguanidine, exhibited a significant decrease in the incidence of diabetes. Mice treated with a combination of anti-IL-1β antibody, anti-TNF-α antibody and aminoguanidine exhibited a greater decrease in the incidence of disease when compared to mice treated with one of the antibodies, or aminoguanidine. On the basis of these observations, we conclude that macrophage-produced, soluble mediators play an important role in the destruction of pancreatic β-cells, resulting in the development of diabetes in mice infected with a low dose of EMC-D virus.

129

CHANGES IN PROTEIN EXPRESSION DURING DISEASE OCCURENCE IN ISLET SYNGRAFTS IN BB-DP RATS AND DURING REJECTION OF BB-DP ISLET ALLOGRAFTS.

U. Bjerre Christensen, P. Mose Larsen[1], S. J. Fey[1], H. Ullits Andersen, T. Mandrup-Poulsen, J. Nerup.
Steno Diabetes Center, Gentofte, Denmark, [1]Institute of Medical Microbiology, Århus University, Århus, Denmark.

IL-1 is cytotoxic to rat ß-cels, and increased expression of IL-1 mRNA is found in the islets of Langerhans during development of diabetes in BB-DP rats and NOD mice. IL-1 has been proposed to induce a race between protective and deleterious proteins in the ß-cells.

In this study we investigated *1)* changes in protein-expression during IL-1 stimulation of islets in vitro, *2)* if these changes are also induced in vivo during disease occurrence in islet syngrafts in BB-DP rats, *3)* and during islet allograft rejection. Two-hundred neonatal BB-DP rat islets were grafted under the kidney capsule of either 30 days old BB-DP rats killed at onset of diabetes or of 30 days old Wistar Kyoto (WK) rats, killed 12 days after grafting. The excised islet grafts or in vitro IL-1 exposed neonatal BB-DP rat islets were labeled with [^{35}S]-methionine, and processed for two dimensional gel electrophoresis. Fluorographs of the gels were analyzed by computer. Significant changes in protein expression were defined as $p<0.01$ (Student's t-test).

Interleukin-1 was found to change level of expression of 82 proteins (22 up- and 60 down-regulated) in neonatal BB-DP rat islets in vitro. Of these 35 (5 up- and 30 down-regulated) also changed level during disease occurence in syngeneic islet grafts from diabetic BB-DP rats, and 33 (5 up- and 28 down-regualted) during rejection of BB-DP islets grafted to WK rats. Changes in the level of expression of 17 (4 up- and 13 down-regulated) of the 82 proteins altered by IL-1 in vitro were found only in syngeneic islet grafts in diabetic BB-DP rats, and changes in the expression level of 11 (3 up- and 8 down-regulated) were found only in BB-DP islet allografts in WK recipients.The identity these proteins are unknown and under study.

Identification of these proteins may be important in understanding the mechanisms of islet destruction and be new possible immunological markers for the development of IDDM, and islet graft rejection.

130

GALECTIN-3, A LECTIN INVOLVED IN CYTOKINE-MEDIATED BETA-CELL DESTRUCTION AND IDDM?

A.E. Karlsen*, H.U. Andersen*, P. Mose Larsen°, S.J. Fey°, M. Larsen¤, F. Pociot*, T. Whitmore♦, K. Nielsen*, and J. Nerup*. *Steno Diabetes Center, Gentofte, °Center for Proteome Analysis and ¤Dept. Molecular Biology, Odense University, Denmark, ♦,ZymoGenetics Inc., Seattle, USA

Beta cells are exquisitly sensitive to the toxic effect of cytokines, especially interleukin-1 beta (IL-1). Understanding of the molecular background for this may identify new intervention strategies in IDDM.

Analysis of control and IL-1 exposed isolated rat islets by 2D-gel electrophoresis revealed up-regulation of 52 protein-spots, three of which were identified by mass-spectrometry as three different phosphorylation stages of galectin-3 (gal-3), a 27 kd lectin involved in the development of the endocrine pancreas, inhibition of apoptosis and stimulation of monocyte IL-1 and superoxide radical formation. Chromosome mapping localized the gene for gal-3 to human chromosome 14q21, thus a potential candidate gene for IDDM11. The gal-3 gene was cloned from rat islets and stably expressed in the rat insulinoma cell-line RIN-5AH under a CMV promoter. Two-D-gel analysis of the stable transfectants showed high expression of two different phosphorylation stages of the gal-3 protein. Functional analysis of the transfectants induced a significantly increased proliferation rate of the RIN-5AH cells and high the gal-3 expression level had a protective effect on the cytokine induced (IL-1, TNFa and IFNg) cytotoxicity otherwise seen in non-transfected RIN-5AH cells.

In conclusion: A 2D-gel identified, IL-1 upregulated islet protein demonstrated to be gal-3, was cloned, expressed and partially characterized. Our in vitro studies suggest that intracellular expression of this protein have protective effects agains the cytotoxic effect of cytokines. Further analysis will establish its potential role in the pathogenesis of IDDM in vitro and in vivo.

OP 18
Endothelial Function

131

BASAL INSULIN LEVELS MODULATE ENDOTHELIAL FUNCTION BY REGULATING FREE FATTY ACID LEVELS.

H. Steinberg, M. Tarshoby, R. Leaming, J. Cronin, A. Johnson, G. Hook and A.D. Baron, Indiana University and VA Medical Centers, Indianapolis, IN, USA

Euglycemic hyperinsulinemia causes endothelium dependent vasodilation (EDV) and enhances vasodilation to the endothelium dependent vasodilator Methacholine Chloride (MCh). It is unclear whether basal insulin contributes to EDV. We studied leg blood flow (LBF) responses to graded intrafemoral artery infusions of the endothelium dependent vasodilator Mch in 8 lean subjects, age 35±2, body mass index 22±1, mean blood pressure (86±3 mmHg) and cholesterol (175±13 mg/dl). Each subject was studied during systemic infusion of saline (SAL) and after 2 hours of systemic somatostatin infusion (SRIF) designed to lower basal insulin levels. During SRIF, basal insulin levels decreased from 11±1 to 5±1 mU/L ($p<0.05$), basal glucose level was 95±2 and was clamped during SRIF infusion at 94±6 mg/dl (p=ns). Free fatty acid levels (FFA) rose from 474±22 to 1042±116 mmol/L ($p<0.01$), and LBF rose from 0.211±0.018 to 0.268±0.023 L/min ($p<0.05$). In response to MCh doses of 5.0, 10.0 ,and 15.0 mg/min, LBF increased by 79±19,120±31 and 165±25% during SAL and by 24±8, 54±15, and 83±15% during SRIF ($p<0.02$, SAL vs SRIF, ANOVA). To examine the role of the SRIF induced rise in FFA on EDV, circulating FFA levels were raised in a separate group of 7 normal subjects by infusion of Intralipid+heparin to achieve FFA levels similar to that in the SRIF infused group(1275±224 mmol/L) and EDV measured by graded intra-arterial infusion of Mch. Compared to basal, EDV was impaired by 50%($p<0.01$), thus to a similar degree as in the SRIF infused group. These data suggest that 1) circulating FFA elevations cause endothelial dysfunction and 2) basal insulin action to regulate lipolysis is an important indirect modulator of EDV. Given insulin's impaired ability to suppress lipolysis and the elevated FFA levels observed in insulin resistant subjects, it is reasonable to suggest that elevated FFAs are responsible at least in part for the impaired EDV observed in these patients and thus may contribute to their increased risk of macrovascular disease.

132

ROLE OF CHRONIC HYPERGLYCEMIA AND OXIDIZED LDL IN ENDOTHELIAL DYSFUNCTION IN PATIENTS WITH IDDM

S. Mäkimattila, J. Luoma, S. Ylä-Herttuala, R. Bergholm, T. Utriainen, M. Mäntysaari, P. Summanen and H. Yki-Järvinen. Universities of Helsinki and Kuopio, Finland.

Chronic hyperglycemia and oxidized LDL have been implicated as risk factors for impaired vascular function in IDDM. We determined the concentration of autoantibodies against oxidized LDL (ratio between antibodies to native vs oxidized antibodies, oxLDLab) and blood flow responses to intrabrachial infusions of acetylcholine, sodium nitroprusside and L-NMMA in 23 male patients with IDDM (age 33±1 yrs, body mass index 24.3±0.6 kg/m^2, HbA_{1c} 8.5±0.3 %) and in 33 matched normal males. Total (4.7±0.2 vs 4.4±0.2), LDL (2.8±0.1 vs 2.8±0.1) HDL (1.3±0.1 vs 1.3±0.1) cholesterol (mmol/l, IDDM vs normal subjects) concentrations were comparable between the groups. OxLDLab were 41 % higher in patients with IDDM than in the normal subjects (1.74±0.21 vs 1.23±0.07, $p<0.01$). Within the group of IDDM patients, HbA_{1c} but not oxLDLab or LDL cholesterol, was inversely correlated with forearm blood flow response to acetylcholine ($r=-0.51$, $p<0.02$) but not to sodium nitroprusside ($r=0.06$, NS). These data implicate that oxidative modification of LDL is increased in normolipidemic patients with IDDM compared to normal subjects. Despite this, chronic hyperglycemia, but not oxLDLab, is an independent determinant of impaired endothelium-dependent vasodilation in patients with IDDM. These changes could contribute to the increased cardiovascular risk in IDDM.

133

RETINAL AND GLOMERULAR ENDOTHELIAL CELL MONOLAYER PERMEABILITY IS INCRESED BY HIGH GLUCOSE

F. Pricci [1], G.Pugliese [1], G. Romeo [1], G. Leto [2], P. Barsotti [1], G. Galli [3], C.M. Rotella [3], G. Mazza [2], G. Fuiano [2], and U. Di Mario [2]
Univ. of [1] Rome "La Sapienza", [2] RC-Catanzaro and [3] Florence, Italy

Vascular permeability was shown to be increased in tissues targets of diabetic complications, including the retina and the kidney. This study was aimed at assessing whether the diabetic milieu is capable of impairing retinal and glomerular endothelial cell barrier function directly, independent of other factors affecting permeability. Bovine retinal endothelial cells (BREC) and human glomerular endothelial cells (HGEC) were cultured for 10 days under high glucose (HG) vs. iso-osmolar mannitol (M) and normal glucose (NG) conditions on permeable PET membranes inserted in 35-mm culture dishes. To assess the time-course or HG-induced changes, BREC were exposed to the above conditions also for 30 days (through 3 passages) and 5 hours (i.e. during the assessment of permeability). At confluence, monolayer permeability was measured by a radiotracer technique using ^{125}I-labelled horseradish peroxidase (HRP), bovine serum albumin (BSA), IgG or fibrinogen (FBG, to exclude an abnormal leakage of monolayers), which were added to the upper chamber at time 0. Medium was sampled from both chambers at 1, 2, 3 and 5 hours and percent leakage was then calculated. BREC grown for 10 days under HG, but not M, showed increased leakage of HRP (+35%), BSA (+44%), and IgG (+60%), but not FBG, compared with NG control cells ($p<0.001$). The increases vs. NG in HRP and BSA (but not IgG) leakage were even more pronounced in BREC grown in HG for 30 days, whereas no change was evident in BREC exposed to HG for 5 hours. HGEC cultured in HG for 10 days also showed significant increases vs. NG ($p<0.001$) in the transendothelial passage of HRP (11.7±0.5 vs. 8.1±0.9), BSA (7.9±1.2 vs. 5.4±0.7), and IgG (5.8±1.2 vs. 4.1±0.5). DNA synthesis and cell number did not change in response to HG, thus ruling out the possibility that the increased permeability observed under these conditions was dependent on reduced cell density. These results show that the diabetic milieu directly impairs retinal and glomerular endothelial cell barrier function.

134

ALTERATIONS OF GLYCOSYLATION BY GLYCATED PRODUCTS IN RETINAL MICROVASCULAR CELLS.

N. Rellier, D. Ruggiero, M. Lecomte, E. Michoud, M. Lagarde and N. Wiernsperger. Diabetic Microangiopathy Research Unit, LIPHA-INSERM U352 INSA-LYON, Villeurbanne, France.

Diabetic retinopathy is a complication characterized by alterations of specific cell-cell interactions in the retinal capillaries. Glycation, as a result of reactions between sugars and proteins, produces advanced glycosylation end products (AGEs), known to accumulate in basement membranes and to affect the retinal cell proliferation in vitro. However, at the cellular level, little is known concerning the effects of the diabetic environment on the structure and/or biosynthesis of the glycoconjugates, making up the glycocalix, a key-structure for cellular interactions. So, we decided to study the **effects of AGEs on the glycoprotein profiles of retinal cells.** Endothelial cells (BREC) and pericytes from bovine retinal microvessels were separately cultured in the presence of glycated albumin (AGE-BSA). The cell homogenates were analyzed by lectin affino-blotting. The total protein content was not affected by the glycated products. However, the lectin analysis of the glycoprotein profiles showed specific alterations of the glycosylation pattern for the BREC cultured with AGE-BSA. A significant decrease of α(2,3) sialylation, β–galactosylation and α-fucosylation was observed mainly for a 210 kDa glycoprotein, localized in a membrane-rich fraction. Similar alterations were obtained by metabolic labelling of endothelial cell cultures with labelled sugars ([^{3}H]ManNac, [^{3}H]Fuc, [^{14}C]Gal). The alterations appeared AGE dose-dependent. In contrast, The 210 kDa glycoprotein was only weakly modified in pericytes. The enzymatic glycosylation was then studied through glycosidase and glycosyltransferase assessments : a similar trend was observed in various enzymatic activities. Our results show for the first time that **glycated products can affect carbohydrate structures resulting from enzymatic glycosylation.** They suggest that post-translational protein modifications can be further modulated by a subsequent change such as glycation. The resulting altered glycoforms might exhibit modified biological properties.

135

MODULATION BY HIGH GLUCOSE AND TNF-α OF APOPTOSIS ASSOCIATED MOLECULES IN CULTURED ENDOTHELIAL CELLS

S.M. Baumgartner-Parzer, M. Artwohl, W. Waldhäusl. Dept. Med.III, Div. Endocrinology&Metabolism, Währinger Gürtel 18-20, 1090 Vienna, Austria.

Using human umbilical vein endothelial cells (HUVECs) we have previously shown 30 mM glucose and TNF-α to induce apoptosis and to upregulate protooncogene p53 expression, probably involved in the development of vascular complications in diabetes mellitus. In this study we evaluated the effects of high (30 mM) glucose and TNF-α on "p53-dependent genes" p21, an inhibitor of cyclin dependent kinases, and thrombospondin (TSP), a mitogen for smooth muscle cells and a "bridging molecule" between phagocytes and apoptotic cells. Exposure of HUVECs to 30 mM glucose (13±1 days) significantly increased p21 (133±29% of control, $p<0.01$;n=15) and TSP (120±23% of control, $p<0.05$;n=10) mRNA expression versus control cells in 5 mM glucose.Determination of p53 and p21 in the identical individual isolate after 30mM glucose long term culture exhibited a more pronounced stimulation of p21 (+30%) compared to p53 gene expression with a range between 93 and 176%, suggesting at least in part p53-independent upregulation by hyperglycemia of p21. High glucose long term culture of HUVECs (13±1 days, n=7) previously to TNF-α (1300U/ml/24 h) exposure further stimulated cytokine induced p21 mRNA upregulation from 133±33% to 167±31% of control ($p<0.05$ each). Both, increase in p21 and observation of reduced (-95%) hyperphosphorylation of the retinoblastoma protein (pRb), analyzed by Western blotting, seem to mediate the antimitogenic effects of TNF-α in HUVECs. Parallel cell cycle studies indicate more pronounced susceptibility of HUVECs to TNF-α induced apoptosis in G1- than in S-phase. The extent to which p21, TSP and pRb affect induction of apoptosis or growth arrest, remains to be elucidated. These data, however, suggest hyperglycemia and TNF-α to locally exhaust the replicative potential of endothelial cells due to apoptosis and growth arrest, and thus could be prerequisite for vascular lesions.

136

ENDOTHELIAL CELL DYSFUNCTION IN MICROALBUMINURIC IDDM PATIENTS; FURTHER IMPAIRMENT WITH ADDITIONAL COMPLICATIONS

AC Shore, SJ Morris and JE Tooke. University of Exeter, Exeter, U.K.

Haemodynamic abnormalities have been described in microalbuminuric IDDM patients, however the mechanisms involved are unclear. The aim of this study was to investigate the skin perfusion responses to acetylcholine (ACh) (an endothelium-dependent vasodilator) and sodium nitroprusside (SNP) (a smooth muscle relaxant) in microalbuminuric IDDM patients (albumin excretion rate of 20-200 μg min^{-1} on at least 2 out of 3 occasions). In 12 microalbuminuric IDDM patients (age 41.1 ± 3.3 years (mean ± sem); 4 female) and 12 age and sex matched controls forearm skin blood flow responses to iontophoretically applied 1% ACh and 0.01% SNP were recorded by laser Doppler perfusion imaging. ACh significantly increased forearm skin perfusion ($P<0.001$, ANOVA), however the vasodilatation was significantly lower in the IDDM patients with microalbuminuria compared with the controls ($P<0.001$), e.g. the maximum vasodilatation to ACh was 1.25 ± 0.11 V in IDDM patients *vs* 1.86 ± 0.11 V in the controls. Skin perfusion increased following SNP ($P<0.001$) but was not significantly different between the 2 groups, e.g. at the fifth measurement point the vasodilatation to SNP was 0.28 ± 0.06 V in IDDM patients *vs* 0.32 ± 0.07 V in healthy volunteers. The response to ACh was further impaired in microalbuminuric patients with (pre)proliferative retinopathy and/or peripheral neuropathy (n=7) compared to IDDM patients with microalbuminuria and background retinopathy (n=5) ($P<0.05$). Diabetes duration was also significantly longer in microalbuminuric patients with (pre)proliferative retinopathy and/or peripheral neuropathy (32.2 ± 2.5 years) compared to IDDM patients with microalbuminuria and background retinopathy (19.2 ± 3.7 years ($P<0.011$), however the maximum response to ACh did not significantly correlate with duration of diabetes. These data suggest that skin microvascular endothelial cell function but not smooth muscle cell function may be abnormal in IDDM patients with microalbuminuria. The level of endothelial cell dysfunction may be related to the degree of diabetic microangiopathy and/or diabetes duration.

137

THE EFFECT OF EXERCISE ON THE ENDOTHELIAL FUNCTION OF THE MICRO- AND MACRO- CIRCULATION IN IDDM.

R. Saouaf, R.A. Fielding, V.M. Donaghue, E.S. Horton and A. Veves. Deaconess-Joslin Foot Center, Harvard Medical School and Boston University, Boston, MA, USA.

Exercise is beneficial in diabetes and can reduce cardiovascular disease. We have examined the effect of regular, intense exercise on the endothelial function in both the micro- and macro- circulation in IDDM. For this we studied four groups of patients matched for age, sex and Body Mass Index: 1. Non-diabetic control regular exercisers (CE) (n=12, 9 Males, mean age 33 years) , 2. IDDM exercisers (DE) (n=15, 13 M, age 34 yrs, DM duration 16 yrs) 3. sedentary controls (CS) (n=17, 10 M, age 34 yrs) and 4. sedentary diabetic patients (DS) (n=4, 3 M, age 32 yrs, DM dur. 21 yrs). Autonomic neuropathy was present in 5 DE and 0 DS patients, retinopathy in 4 DE and 4 DS and macro-proteinuria in none. There was no difference in the weekly energy expenditure from exercise, evaluated by the Harvard Alumni Health Questionnaire, between CE (6497 ± 1374 kcal/week) (mean ± sd) and DE (6437 ± 3036) but both groups were higher compared to CS (281 ± 501) and DS (150 ± 300, p <0.0001). Similar results were found in maximal oxygen uptake (VO_2 max) (CE 55.3 ± 8.0 ml/kg/min, DE 52.4 ± 10.7, CS 38.4 ± 6.0, DS 34.8 ± 10.0, p <0.0001). The endothelial function in the microcirculation was assessed by measuring the changes in the erythrocyte flux after the iontophoresis of acetylcholine and in the macro-circulation by assessing the changes in the brachial artery diameter induced by reactive hyperemia. When all diabetic patients were considered as one group the micro-circulation endothelial function was reduced compared to the controls (91 ± 49 % flux increase vs 122 ± 41, p <0.05) but no difference existed between DE (95 ± 51) and DS (73 ± 42) and between CE (117 ± 44) and CS (125 ± 40). Similarly, in the macro-circulation a reduced response in the diabetic patients (7.0 ± 4.5 % diameter increase vs 11.2 ± 6.6, p< 0.05) while no difference existed between DE (6.7 ± 4.6) and DS (8.0 ± 4.7) and between CE (12.0 ± 5.8) and CS (11.5 ± 7.3). We conclude that regular exercise does not prevent the diabetes-induced impairment of the endothelial function.

138

INSULIN INDUCED VENODILATATION IS FURTHER IMPAIRED IN TYPE II DIABETES MELLITUS WITH HYPERCHOLESTEROLEMIA.

A. Chaudhuri, S. Rao, P. Mohanty, C. Padginton, K. Thusu, B.H. Sung, M.F. Wilson and P. Dandona. State University of New York at Buffalo, Buffalo, N.Y.

We have shown that insulin induces venodilatation via the endothelial dependent NO-cGMP pathway and that this effect is impaired in NIDDM, a disease associated with endothelial dysfunction. As hypercholesterolemia increases the risk of cardiovascular diseases in NIDDM, we have studied the venodilatory response to insulin in NIDDM subjects with cholesterol > and ≤ 200 mg/dl. Sixteen healthy caucasians, 19-67 years old (Group 1), nine normotensive NIDDM 42-77 years old, with cholesterol 251 ± 22 mg/dl, and LDL cholesterol 147 ± 23 mg/dl (Group 2) were compared to nine matched NIDDM with cholesterol 173 ± 12 mg/dl, and LDL cholesterol 107 ± 12 mg/dl (Group 3). Cephalic vein of the left hand was visualised 1cm distal to the cannula tip using an Acuson 128XP ultrasonograph with 7.5 Mhz linear array transducer. Norepinephrine was infused at 12.5, 25, 50 and 100 ng/min and this was followed by a coinfusion of norepinephrine at 100 ng/min with regular insulin at 8, 16, 24, and 32 μu/min, each dose for 5 mins. A blood pressure cuff was inflated at the arm to 40 mm of Hg 3 minutes into each infusion and the venous diameter was measured between 4 to 5 minutes using the M-mode image.

	Baseline	$N_{12.5}$	N_{25}	N_{50}	N_{100}	Mean	SEM	I_8	I_{16}	I_{24}	I_{32}	Mean	SEM
Group 1	100 (2.8)	80	70	57	47	72	2.9	71	77	90	95	87	2.0
Group 2	100 (2.5)	67	52	57	57	67	3.0	45	55	64	57	64*	2.4
Group 3	100 (3.5)	76	66	61	55	72	2.7	65	60	64	68	72*+	2.4

Data expressed as percentage of baseline diameter (mm); *p<0.05 when compared to Group 1. +p<0.05 in comparison to Group 2. Analysis by twanova. These data show that hypercholesterolemia further impairs the venodilatory response to insulin in NIDDM subjects. Coexistence of these disease states have a synergistic effect on endothelial dysfunction and this correlates clinically with the increase in vascular risk seen in such conditions.

OP 19

Better Care for People with Diabetes

139

Measurements of glycated haemoglobin and microalbuminuria in West-Germany from 1988 to 1994

Hartmann, P.[1], Gruesser, M.[2], Heuer, J.[2], Joergens, V. [1]. [1]Dept. of Nutrition and Metabolism, Heinrich-Heine-University, Duesseldorf (WHO-Collaborating Centre, Dir. Prof. M. Berger) [2]Central Institute for Ambulatory Health Care, Cologne

The number of measurements of glycated haemoglobin and microalbuminuria is an indicator of process quality of care in people with diabetes. In Germany the number of all determinations of glycated haemoglobin and microalbuminuria is available through a nationwide account and information system. This system summarises all determinations in ambulatory care for patients, who are members of the compulsory health insurances in West-Germany (57.5 million persons). Based upon epidemiological data the prevalence of diabetes can be assumed to be 5 % (2.875 million persons with diabetes). The number of measurements has increased significantly since 1988 (Tab.1). This increase cannot be attributed to an increase in the number of insured persons nor in the number of all medical acts (indicated by EKG).

Tab. 1. Number of insured persons, EKG and determinations of $HbA_{1(c)}$ and microalbuminuria from 1988 to 1994.

	1988	1989	1990	1991	1992	1993	1994
Insured persons (mill.)	55.1	54.7	55.9	56.8	57.2	57.5	
Diabetic patients (mill.)	2.76	2.74	2.80	2.84	2.86	2.875	
$HbA_{1(c)}$ (mill.)	1.0	1.3	1.6	1.9	2.2	2.5	2.6
Microalbuminuria (thousand)	0	2.6	8.4	33.9	72.2	77.3	125.5
EKG (mill.)	16.0	16.0	15.6	16.1	16.4	17.0	17.2

Guidelines state that glycated haemoglobin should be determined quarterly and microalbuminuria annually in persons with diabetes. During six years the number of $HbA_{1(c)}$ measurements increased by 160 %. It would be interesting to compare our data with population-based data of other countries, but to our knowledge such data are not yet available. If physicians adhered fully to guidelines a maximum of 11.5 million measurements of glycated haemoglobin and at least 8.6 million measurements of microalbuminuria would be necessary on an annual basis in West-Germany. Authors of guidelines for better care of persons with diabetes should be aware of the tremendous financial consequences of their application.

140

SPECIFICITIES OF ORGANISATION OF DIABETES HEALTH CARE DURING WAR TIME

Ž. Metelko, M. Prašek, G. Roglić, M. Pibernik-Okanović, I. Pavlić-Renar, N. Car, B. Ročić, M. Rogić, M. Granić, Z. Škrabalo

Vuk Vrhovac University Clinic for Diabetes, Endocrinology and Metabolic Diseases, Medical Faculty University of Zagreb, Dugi Dol 4a, 10000 Zagreb, Croatia

The Model of diabetes health care relies on the network of diabetes centres and continuous flow of information from highly specialised centres to primary health care and the flow of rationally referred patients from primary to tertiary health care. The model has shown its advantages during the war in Croatia. The register was the basis for planning the supplies of oral agents, insulin, and self- monitoring equipment in the war-struck regions. In 1991 there were 111.096 diabetic persons registered, 16% of them requiring insulin, 46% oral agents and 36% treated by basic principles of treatment only (education, exercise, diet). All patients were provided with a 60-day supply of insulin or oral agents. As destruction increased there was need to modify the existing system of information exchange which remained only on telephone communication. Use was made of existing PC compatible equipment and the computer network created to prepare for accepting and distributing of patients evacuated from destroyed hospitals or dialysis centres, and to learn of movements of larger groups of displaced persons. Written instructions were issued to patients on how to prepare themselves for long stays in shelters, disinfection of water, lack of drugs and food. For assessing glycaemic control, a simple method was developed for transporting blood samples in specially prepared tubes and transporting them at room temperature to the nearest lab for haemoglobin A1C determination. Except for diabetic gangrene, probably due to poor hygienic conditions in war areas, there were no more cases of acute diabetic complications. This could be attributed to good education of diabetic patients within the model of diabetes health care as a basic principle of treatment, especially in the regions far from specialised centres.

141

LIONS DIABETES MINNESOTA: A MODEL FOR COMMUNITY-BASED INTERVENTIONS IN PRIMARY CARE.

R. Mazze, R. Risley, G. Castle, S. Sundem, G. Simonson, R. Bradley, and E. Strock. International Diabetes Center, Minneapolis, Minnesota, USA.

In 1993 the Lions Clubs of Minnesota developed a community-based approach to public and professional education in diabetes. The purpose of this study was to determine to what extent this regional diabetes program changed diabetes practices. Lions Diabetes Minnesota (LDM) was created to reach all of the rural communities of Minnesota with a 3 part program: (1) to screen for diabetes in a high risk population; (2) to provide public education in the prevention of diabetes and its complications; and, (3) to assess care practices in order to provide professional education to improve care. A total of 1351 individuals came to the public screening program, of whom 629 were in treatment for diabetes. The remaining 722 had at least one risk factor for type II diabetes. Through the screening program and follow-up, 72 individuals were diagnosed with diabetes. The subsequent public education program (for 1846 individuals) focused on management of weight, exercise and life style to prevent diabetes. These individuals came from 30 clinics which agreed to participate in an assessment of current diabetes care. On the basis of 731 chart audits at these sites it was estimated that 70% of the patients were at a level of glycemic control (HbA1c >1.5% above normal) that would contribute to the development of microvascular complications and <15% of the patients were appropriately evaluated for complications. The follow-up professional education program at these sites focused on appropriate classification of diabetes, therapeutic goals, treatment options and surveillance for complications. It was attended by 684 physicians, nurses and dietitians. The overall goal was to improve glycemic control and surveillance for microvascular and macrovascular complications. One year follow-up showed a significant ($p<.001$) decrease in HbA1c (-1.4%) and a significant ($p<.01$) increase in surveillance for eye disease (23 to 34%) and foot disease (16 to 33%). A survey of the sites revealed: 77% increase in SMBG, 66% increase in HbA1c to 3-4/year, 77% increase in patient education and nutrition services and 55% increase in the rate of screening for microalbumin. LDM was able to identify persons at risk for diabetes, diagnose undetected cases and provide education which resulted in improved glycemic control and complications surveillance.

142

SHARED CARE FOR NIDDM PATIENTS IN GENERAL PRACTICE: SUSTAINED GOOD GLYCAEMIC CONTROL AFTER TWO YEARS.

JJJ de Sonnaville, LP Colly, D Wijkel and RJ Heine. Research Centre Primary/Secondary Health Care, Amsterdam Thrombosis service and Laboratory for General Practitioners and Department of Endocrinology, University Hospital Vrije Universiteit, Amsterdam, The Netherlands.

A prospective non-randomized cohort study was designed to assess the intermediate term (2 years) effect of structured NIDDM care with (study group=SG; 22 GPs) and without (control group=CG; 6 GPs) support from a 'diabetes service' on glycaemic control and well-being. The 'diabetes service', supervised by a diabetologist, included a registration system and consultation facilities of a dietitian and diabetes nurse educator. GPs of the SG received protocolized glucose lowering therapy advises. This included home blood glucose monitoring and insulin therapy. In the SG 350 known NIDDM patients above 40 years of age (206 women; mean age 65.3±SD 11.9 and diabetes duration 5.9±5.4 years) have been followed for at least 2 years. The CG consisted of 68 patients (28 women; age 64.6±10.3 and diabetes duration 6.3±6.4 years). Mean HbA1c (reference value 4.3-6.1%) fell from 7.4±1.6 to 7.0±1.3% after 1 and 2 year of follow-up in SG, but rose from 7.4 to 7.6 in CG ($p=0.004$). The part with poor HbA1c (>8.5%) decreased from 21.4 to 11.7% in SG but increased from 23.5 to 27.9% in CG ($p=0.008$). Good control (HbA1c <7.0%) was achieved in 54.3% (at entry 43.4%) in SG and in 44.1% (at entry 54.4%) in CG ($p=0.013$). Insulin therapy was initiated in 29.9% (SG) and 8.8% (CG) ($p=0.000$). The incidence rate of severe hypoglycaemia was low 0.019 /patient year in SG and not reported in CG. General well-being, as assessed with annual self-report questionaires, did not change during intensified therapy. In conclusion, implementation of structured care, including protocolized therapeutic advice, results in safe and sustained good glycaemic control in the majority of NIDDM patients in primary care.

143

CAN PRIMARY CARE BASED REVIEWS KEEP INDIVIDUALS WITH DIABETES OUT OF HOSPITAL?

E.C.Goyder, N.A.Spiers, J.L.Botha, P.McNally and M.Drucquer. University of Leicester, Leicester, UK.

It has been suggested that increases in routine diabetes review in primary care could reduce hospital admission rates for individuals with diabetes and that interventions should target those at highest risk of admission. However recent trials of intense primary care interventions in high risk groups have been unable to reduce overall admission rates. This observational study explored the relationship between routine diabetes review in primary care and risk of diabetes related hospital admission in groups with and without comorbidity. A historical cohort study of 1092 individuals with diabetes, from randomly selected general practices, collected information on service contacts and clinical, social and demographic variables using patient records and postal questionnaires. Logistic regression modelling was used to establish risk factors for admission during a five year period. The main predictors of admission were the number of non-diabetic drugs regularly prescribed (odds ratio=1.4 per drug on repeat prescription, $p<0.0001$) and type of diabetes treatment (odds ratio=1.6 for insulin, 0.9 for tablets, $p=0.0001$). Only in the subgroup without comorbidity (defined as those prescribed no regular treatment other than diabetes treatment) was general practice review associated with a lower risk of admission (odds ratio=0.30, $p=0.02$). Structured care for diabetes in primary care may in the long term reduce diabetes related hospital admissions. However interventions to increase frequency of routine review which target high risk groups which have high levels of comorbidity, are unlikely to reduce admission rates.

144

THE COST OF DIABETIC FOOT ULCERS IN A DEVELOPING COUNTRY

Zeynep Osar Ersanli, Taner Damci, Alev Yalaza, Mücahit Özyazar, Ugur Görpe, Hasan Ilkova and Nazif Bagriacik. Cerrahpasa Medical Faculty, Department of Internal Medicine, Division of Diabetes and Metabolism, Istanbul, Turkey.

The prevalance of diabetic foot ulcers is around 7 % and of amputations due to foot ulcers is 3 %. The total direct economic burden of diabetic foot problem in the USA is 150 million USD annually and the mean cost of a diabetic patient who undergoes lower extremity amputation is 24700 USD. The present study was done to disclose the main features and calculate the avarage cost of 60 randomly chosen inpatients treated for diabetic foot ulcers. 18 patients were female (30%) and 42 were male (70%), with mean age of 58.9+10.1 (31-84), diabetes duration of 13.5+7.6 years(0.3-30). Mean HbA1c was 9.4+2 (4.6-15). 14 patients previously had ulcers (23.3%) and 11 had (18.3%) previous amputations. All of the 14 patients previously had and were treated for ulcers, had received programmed education for foot care and prevention of foot ulcers. 54 patients had neuropathy as the predominant etiologic factor for foot ulcers (90%) , 4 (6.7%) had both ischemia and neuropathy and 2 (3.3%) had ischemia solely. 36 patients (60%) had grade 3 or more severe ulcers according to Wagner classification. Ulcers were localized on the toes in 27 patients, 9 (15%) of them being on the plantar surface of great toe, 19 (31.7%) on the metatarsal head, 9 (15%) on the heel, 3 (5%) on volar surface of the foot, 2 (3.3%) on the wrist. Swab culture of the ulcer yielded single microorganism in 33 (55%) patients and multiple organisms in the rest. 21(35%) patients received single antibiotic, 39 (45%) had combined antimicrobial therapy. 22 patients (36.7 %) treated conservatively whereas 7 (11.7%) underwent grafting, 11 (18.3%) transmetatarsal amputation, 15 (25%) wedge resection of the toes, 4 (6.7%) below knee amputation, 1 (1.7%) above knee amputation. Mean duration of hospitalisation was 5.45+ 4.22 weeks, grade of ulcer being the only factor affecting this. The mean total cost of a hospitalized patient was found to be 7000 USD. In our country where avarage income per family is below 200 USD per month and some 60% of total population is not covered by any kind of social security, diabetic foot is even a more severe economic and social problem than in the USA and European countries. This urgently mandates planning and implementation of diabetic foot clinics all over the country.

145

THE USE AND THE COSTS OF ALL MEDICATIONS OF DRUG-TREATED DIABETIC PATIENTS IN FINLAND

T Kangas [1], T Klaukka [2], J Martikainen [2] and A Reunanen [3], [1] City of Helsinki, [2] Social Insurance Institution, [3] National Public Health Institute, Helsinki, Finland

The aim of the study was to investigate the total use and costs of all kinds of medications used by persons with diabetes (PWD). The persons having purchased medications for diabetes were identified from the Central Drug Registry which codes and registers all prescriptions of medicines with a unique personal identification number. The use of all kinds of medicines by PWD was identified. The medications used in hospitals and sold over the counter were not included. There was a total of 125193 persons (2.25% of the population) having purchased diabetes medicines in 1995, out of whom only 73.7% used their right for reimbursement. The total cost of drugs used by PWD was 130.3 million US dollars (USD), or 1040.5 USD/PWD (vs. 264.5 USD/ inhabitant). 50000 had used insulin for 31.3 million USD and 91000 oral hypoglycemic drugs (OHD) for 20.4 million USD. Antidiabetic drugs totalled to 51.7 million USD (40% of total costs). 13000 had purchased both insulin and OHD. The costs of other medications was 78.6 million USD (60%). The cost of all cardiovascular drugs was 33.3 million USD. 19.6% of PWD used digitalis vs. 2.3% of population at large. Use of cholesterol reducing drugs was 5.3% vs. 3.1%, that of ACE inhibitors 25.1% vs. 9.7% respectively. The given figures are crude. The study has an age and sex matched control population, but the results are in preparation. Our preliminary results show that use and costs of medications by PWD are remarkably higher than those of population at large. The final results will give exact figures of the extra usage.

146

POTENTIAL COST-EFFECTIVENESS OF PRIMARY PREVENTION OF INSULIN-DEPENDENT DIABETES MELLITUS.

Richard C. Eastman , Catherine C. Cowie, Joan Harmon, and the DPT-1 Study Group. National Institutes of Health, Bethesda, Maryland, USA.

We analyzed the potential cost-effectiveness of primary prevention of IDDM, using a simulation model of IDDM . We used hazard rates for diabetes from the Diabetes Prevention Trial for Type 1 Diabetes (DPT-1) of 22.5%/year for the parenteral insulin protocol (P), and 6%/year for the oral insulin protocol (O). Screening costs ($1751/case found) and intervention costs ($3172/yr (P) and $1360/yr (O)) were estimated from DPT-1. Modeled patients receive intensive treatment if IDDM develops ($4545/yr). Incremental costs and benefits are in present value dollars (3% discount rate). Life years are adjusted for quality of life (QALYs) using utilities for blindness (0.69), renal failure (0.61), and amputation (0.8). We assume IDDM reduces quality of life by 5%. The perspective of the analysis is from a single payer responsible for all direct medical costs. The model predicts that 99% (P) and 97% (O) progress to IDDM. The predicted lifetime risks of visual acuity <20/100, renal failure, and amputation are 42%, 16%, and 5% (P) and 31%, 11% and 3.5% (O). Primary prevention that reduces the risk of progressing to IDDM by 50% delays the mean age at onset of diabetes from 12.5 years to 17 years (P), and from 22.9 to 28.8 years (O). Complications occur in later in life; cumulative incidence is reduced to 38%, 14%, and 4.8% (P), and 22%, 8%, and 2.4% (O). Reduced treatment costs for clinical IDDM, reduced lifetime risk of severe hypoglycemia, and reduced complications partly offset the costs of screening and preventive treatment. We estimate that parenteral insulin would cost ~$22,000/QALY gained , and oral insulin ~$5,800/QALY gained. Savings of ~$4,700/person treated are predicted if subcutaneous insulin alone is effective in the parenteral insulin trial. The cost/QALY gained is stable if the HbA1c assumed under intensive care is 7.2%-8.7%, assuming that the incremental costs of intensive care are proportional to the HbA1c achieved. Primary prevention is a reasonable goal to pursue from a health and economic perspective.

OP 20

Insulin Action in Vitro

147

IRS-2 IS THE MAIN DOCKING PROTEIN FOR PI 3-KINASE IN ADIPOCYTES FROM NIDDM PATIENTS.

U. Smith, L. M. Wang*, P. Lonnroth, C. Wesslau, J. H. Pierce* and C. M. Rondinone. Lundberg Lab. for Diabetes Research, Dept. Internal Medicine, Sahlgrenska University Hospital, Gothenburg, Sweden and *Lab. Cell and Molecular Biology, NCI, NIH, Bethesda, MD, USA.

IRS proteins are substrates for the insulin receptor tyrosine kinase and act as docking proteins. The aim of this study was to investigate the role of IRS proteins in the insulin signaling pathway in adipocytes from healthy subjects or NIDDM patients. We examined insulin-stimulated glucose transport, protein content of key proteins involved in insulin action and performed immunoprecipitation, immunoblotting and PI-3 kinase assays using specific antibodies to IRS-1 and 4PS/IRS-2. Glucose transport activity in response to insulin was reduced by 40-60% in NIDDM patients, IRS-1 protein content was reduced by 50-90% while 4PS/IRS-2 protein content was unaltered. In contrast, other key proteins such as the insulin receptor, PI 3-kinase (p85 and p110), SHC or MAP kinases were unchanged in NIDDM. Following insulin stimulation 4PS/IRS-2 was rapidly tyrosine phosphorylated, associated with the p85 subunit of PI 3-kinase and stimulated the activation of PI 3-kinase in NIDDM subjects. In contrast, in anti IRS-1 immunoprecipitates from NIDDM adipocytes no clear tyrosine phosphorylated band corresponding to IRS-1 or an associated PI 3-kinase activity was detected. Conclusion: IRS-1 is the dominant tyrosine phosphorylated protein which binds p85 and accounts for most of the phosphotyrosine associated PI 3-kinase activity in adipocytes from normal human subjects. In contrast, in cells from NIDDM subjects, which are deficient in IRS-1, 4PS/IRS-2 becomes the principal docking protein.

148

PI3-KINASE ACTIVATION ALONE IS NOT SUFFICIENT FOR THE MEDIATION OF INSULIN ACTION

A. Krook [a,b], J.P. Whitehead[a,b], S. Dobson[c], J. Tavare[c], M. Ouwens[d], J.A. Maasen[d], C. Baker[a,b], S. O'Rahilly[a,b]. Depts. of Medicine[a] and Clin. Biochemistry[b] Univ. of Cambridge, UK; Dept. of Biochemistry[c], Bristol Univ. UK; Dept. of Medical Biochemistry[d], Univ. Leiden, Holland.

Two naturally-occuring mutations (Pro1178Leu and Arg1174Gln) in the insulin receptor tyrosine kinase domain, found in patients with severe insulin resistance, retain the ability to phosphorylate IRS-1 yet fail to mediate insulin-stimulated glycogen synthesis or mitogenesis. Further studies were undertaken to examine the molecular basis for the defective signalling associated with these mutant receptors. The mutant receptors failed to stimulate any GLUT4-GFP translocation to the plasma membrane in microinjected 3T3 fibroblasts and were unable to stimulate activation of a reporter plasmid consisting of the fos promoter upstream of luciferase ($p < 0.001$ vs wild type receptor). Although at low concentrations of insulin these receptors were impaired in their tyrosine phosphorylation of IRS-1, at 100nM insulin cells expressing the 1174 and 1178 mutant receptors showed significantly enhanced tyrosine phosphorylation of IRS-1, association of the p85α subunit of PI3-kinase with IRS-1, and PI3-kinase activity in anti-IRS-1 immunoprecipitates compared to parental CHO cells. In contrast, at 100nM insulin, no significant enhancement of the tyrosine phosphorylation of Shc, GTP loading of ras, or map kinase activation was seen. These findings indicate that PI3-kinase activation alone may be insufficient to mediate the metabolic and mitogenic effects of insulin and suggest that additonal signalling events involving the shc-ras-map kinase pathway may be required for the full mediation of insulin's metabolic and mitogenic effects. Additionally, these data provide support for the notion that insulin's activation of ras is dependent on shc, rather than IRS-1, phosphorylation.

149

DIFFERENTIAL ROLES OF REGULATORY SUBUNITS OF PI 3-KINASE IN GLUCOSE HOMEOSTASIS IN THE P85α PI 3-KINASE KNOCKOUT MICE

Y. Terauchi, S. Sato*, H. Minoura, Y. Tsuji, K. Iwamoto, K. Murakami, A. Okuno, K. Tobe, H. Sekihara*, H. Nakajima§, T. Hanafusa§, Y. Matsuzawa§, Y. Akanuma#, Y. Yazaki, and T. Kadowaki. Tokyo University, *Yokohama City University, §Osaka University, and #Asahi Life Foundation. Japan.

The aim of this study is to investigate the role of phosphatidylinositol 3-kinase (PI3K) in glucose homeostasis by targeted disruption of a regulatory subunit of PI3K gene (p85α) in mice. Alternative isoforms of the p85α gene, p55α and p50α, were normally expressed in this knockout mice. Total PI3K activity associated with anti-phosphotyrosine antibody after an insulin injection was normal in the liver and 70% of the normal in the skeletal muscle. A 50kDa protein (p50) recognized by anti-p85 antibody, which was presumably p50α, played a compensatory role for p85α deficiency in insulin-stimulated PI3K activation by binding to IRS-1 and p110 catalytic subunit of PI3K. Mice lacking p85α showed lowered set point of glucose levels associated with decreased insulin levels. Steady state plasma glucose levels after somatostatin, insulin, and glucose infusion were 125±34 and 254±15 mg/dl in knockouts and the wild-type ($P<0.01$), although steady state plasma insulin levels were indistinguishable. Studies on glucose metabolism intermediates in the liver strongly suggested that glucose output was rather increased in response to enhanced glucose utilization by the peripheral tissues. In fact, 2-deoxy-glucose uptake into the soleus muscle was increased by 40% in knockouts compared with the wild-type, and 3-*o*-methyl-glucose uptake into the adipocyte was 2-3 fold increased with the physiological concentrations of insulin in knockouts. These results demonstrated that increased glucose utilization in the peripheral tissues, rather than primary reduction of glucose output by the liver, was the main cause of hypoglycemia and increased insulin sensitivity. Although PI3K activity associated with IRS-1 was essentially normal, efficient targeting of PI3K activity to the GLUT4 vesicle via p50/p110 complex may have resulted in efficient glucose transport in the p85α knockout mice. Thus, PI3K isoforms may play differential roles in glucose metabolism in the peripheral tissues, and p85α deficient mice should give important insight into the molecular mechanism linking PI3K activation and GLUT4 translocation.

150

DECREASED IRS-1 PHOSPHORYLATION AND PI 3-KINASE ACTIVITY IN MUSCLE FROM NIDDM PATIENTS.

J.R. Zierath, M. Björnholm, M. Lehtihet and H. Wallberg-Henriksson. Department of Clinical Physiology, Karolinska Hospital, Stockholm, SWEDEN.

We examined the effect of physiological hyperinsulinemia on IRS-1 tyrosine phosphorylation and PI3-kinase activity in skeletal muscle from six lean to moderately obese NIDDM and six healthy subjects. A rise in serum insulin levels from ~60 to ~650 pmol/l increased IRS-1 tyrosine phosphorylation 6-fold over basal levels in control muscle ($P<0.01$), whereas no significant increase was noted in NIDDM muscle. The reduced IRS-1 phosphorylation in the NIDDM muscle was not related to changes in IRS-1 protein content, since IRS-1 protein expression was similar between control and NIDDM subjects (16.0±1.7 vs. 22.9±4.0 arbitrary units/mg for control and NIDDM, respectively, N.S.). Physiological hyperinsulinemia increased PI 3-kinase activity in control muscle 2-fold, ($P<0.01$), whereas no increase in insulin-stimulated PI 3-kinase activity was noted in the NIDDM muscle. Furthermore, in vitro insulin-stimulated (600 pmol/l) 3-O-methylglucose transport was 40% lower in isolated muscle from NIDDM subjects ($P<0.05$). The present findings couple both reduced insulin-stimulated IRS-1 tyrosine phosphorylation and PI 3-kinase activity to the impaired insulin-stimulated glucose transport in skeletal muscle from lean to moderately obese NIDDM subjects.

151

HYPERINSULINEMIA POTENTIATES ACTIVATION OF p21Ras BY GROWTH FACTORS.

B. Draznin, M. Goalstone, and J.W. Leitner. University of Colorado Health Sciences Center and Denver VAMC, Denver, CO U.S.A.

Detrimental role of hyperinsulinemia has been suggested by numerous epidemiological studies correlating insulin resistance and/or hyperinsulinemia with atherosclerosis and hypertension. Biochemical evidence of the cause-and-effect relationship remains, however, elusive. We have recently discovered that insulin promotes phosphorylation and activation of the farnesyltransferase, FTase, an enzyme crucial for preparing the Ras signaling pathway for subsequent activation. FTase catalyzes farnesylation of p21Ras, a step necessary for anchoring p21Ras at the plasma membrane where it can be activated by various growth factors. Insulin in a dose- and time-dependent manner activated FTase in fibroblasts, adipocytes, vascular smooth muscle cells, and endothelial cells. In 3T3-L1 fibroblasts, this action of insulin on FTase activity led to a 3 fold increase in the size of the cellular pool of farnesylated p21Ras, which upon farnesylation is translocated to the plasma membrane. The effect of insulin was inhibited by the α-hydroxyfarnesyl phosphonic acid (HXPA) (1 μM), an inhibitor of FTase. The half-life of the farnesylated p21Ras at the plasma membrane appears to be six hours. Insulin and other growth factors stimulate GTP loading only of the membrane-associated p21Ras. An augmentation in the plasma membrane-associated farnesylated p21Ras by hyperinsulinemia resulted in 5-8 fold increases in p21Ras•GTP loading in response to EGF, IGF-1, or PDGF. This potentiation effect of insulin was also inhibited by the α-HXPA. We conclude that hyperinsulinemia increases the cellular pool of the plasma membrane-associated and farnesylated p21Ras available for activation by other growth factors. This increase creates a new background sufficient to elicit an exaggerated response to various circulating growth factors.

152

PROTEIN KINASE Cs βII, δ and ζ MEDIATE INSULIN-INDUCED GLUCOSE TRANSPORT IN CULTURED SKELETAL MUSCLE.

S. R. Sampson, L. Friedman and L. Wiksman, Bar-Ilan University, Ramat-Gan, Israel

The purpose of this study was to clarify the role of protein kinase C (PKC) in the mediation of insulin-induced glucose transport in skeletal muscle. Studies were performed on primary cultures prepared from skeletal muscle of 1-2 day old rat pups. Glucose uptake was determined by measurements of the uptake of [^{3}H]-2-deoxy-glucose (2DG), and identification and translocation of glucose transporters and PKC isoforms from the cytosolic compartment to the plasma membrane were determined by western blotting. Skeletal muscle expresses GLUTs 1, 3 and 4, and PKC isoforms βII, δ, and ζ, as well as α and θ. Insulin causes a significant increase in 2DG uptake within 20-30 min and this is associated with translocation of GLUTs 3 and 4. Insulin also translocates PKC isoforms βII, δ, and ζ, but not α and θ. PKC activation by phorbol esters (TPA) increases 2DG uptake, and is associated with translocation of GLUTs 1 and 3, but not GLUT4. TPA translocates PKCδ but not the other PKC isoenzymes. PKC inhibitors (staurosporine, chelerythrine) increase basal 2DG uptake and block effects of both TPA and insulin. Inhibition of PI3 kinase by wortmannin (WM) does not alter basal 2DG uptake and inhibits effects of both insulin and TPA. In addition, WM blocks the insulin-induced translocation of GLUTs 3 and 4 as well as TPA-induced translocation of GLUTs 1 and 3, and prevents insulin-induced translocation of PKCs βII and ζ but not TPA-induced translocation of PKCδ. Thus, WM appears to inhibit both PI3 kinase activated by the insulin receptor cascade, as well as GLUT 1 and 3 translocation induced by translocation of PKCδ. We conclude that insulin-induced translocation of GLUTs3 and 4 is mediated via PKCs βII and ζ which are activated by PI3 kinase probably through the intracellular release of diacyl glycerol. (Supported by funds from the Sorrel Foundation, Harvett-Aviv Research Fund and the Ben and Effie Raber Research Fund. SRS is the incumbent of the Louis Fisher Chair in Cellular Pathology.)

153

IS PHOSPHOLIPASE Cγ INVOLVED IN THE METABOLIC EFFECTS OF INSULIN IN 3T3-L1 ADIPOCYTES?

N.J.G. Webster, A. Kayali and J. Eichhorn. UCSD/Whittier Diabetes Research Program, University of California, San Diego and the VA Medical Center, San Diego, USA.

The role of phospholipase C in insulin action has been debated for a long time. Early studies used metabolic labelling to examine phospholipid levels following insulin treatment. However, these studies would not reveal transient changes or localized increases. Previously, we have identified a novel autophosphorylation site in the B isoform insulin receptor (IR) which is the isoform present in insulin target tissues. We also found that this site allows the B isoform IR to interact with phospholipase Cγ (PLCγ). The present study was designed to investigate whether PLCγ might be involved in the metabolic actions of insulin in 3T3-L1 adipocytes. PLC hydrolyzes phosphatidylinositol-bisphosphate to diacylglycerol (DAG) and inositol triphosphate (IP3). Insulin caused a biphasic increase in DAG levels in 3T3-L1 adipocytes with a transient peak (180%) at 30 sec. followed by a second larger increase (230%) at 30 min. While we did not measure IP3 levels directly, insulin did not cause an elevation in intracellular Ca^{2+} levels measured by single cell FURA2 imaging. Microinjection of PLCγ SH2 domains blocked GLUT4 translocation in an immunofluorescent localization assay suggesting a role in stimulation of glucose uptake. A specific PLC inhibitor U73122 and its weakly active analogue U73343 were tested for their effect on insulin action in 3T3-L1 adipocytes. U73122, but not U73343, inhibits insulin-stimulated glucose transport in primary adipocytes. This inhibitor also blocks insulin-stimulated GLUT4 translocation and MAPKinase activation in a dose-dependent manner but has no effect on IR tyrosine kinase activity, IRS1-associated PI-3Kinase activity or p70-S6Kinase activation. Based on this data, we hypothesize that the B isoform IR initiates an alternative signaling pathway to glucose uptake through a transient interaction with PLCγ.

SKELETAL MUSCLE GLYCOGENESIS AFTER EXERCISE IN TRANSGENIC MICE OVEREXPRESSING GLUT1 GLUCOSE TRANSPORTERS IN MUSCLE

J Ren*+, B Marshall#, M Mueckler# and G Shulman+
*Bristol-Myers Squibb, Princeton, #Washington University, St. Louis, and +Yale University, New Haven, U.S.A.

We have shown that skeletal muscle glycogen concentration in transgenic mice overexpressing GLUT1 is 10-fold higher than their littermates. This marked elevation of muscle glycogen concentration is associated with an increase in glucose transport activity. To examine the effect of increased glucose transport activity on the rate of muscle glycogenesis, both GLUT1 transgenic mice and their littermates underwent 3 h of swimming. Gastrocnemius muscle glycogen concentration (n=6) was determined before exercise, at 0, 5 and 24 hr post-exercise, during which food and water were provided. Exercise resulted in a 90% reduction of muscle glycogen in both controls (11.2±1.4 to 2.1±1.3 umol/g) and transgenic mice (99.3±4.7 to 11.8 umol/g). During recovery, the glycogen concentrations were 38.2±7.3 (5h post) and 40.5±2.8 (24h post) in controls and were 57.5±7.4 (5h post) and 152.1±15.7 (24h post) umol/g in transgenic mice respectively ($p<0.01$). Plasma insulin was lower in transgenics than in controls at all time points post exercise, while plasma glucose was lower only at 0 hr after exercise. There is no difference in glycogen synthase activity between control and transgenic mice ($p>0.05$). CONCLUSIONS: These results demonstrate that the rate of glycogenesis after exercise is increased in transgenic mice and the level of muscle glycogen is determined by muscle glucose transport activity.

Insulin Secretion in Vitro: Secretagogue Recognition and Signal Transduction

155

MITOCHONDRIAL ACTIVATION DIRECTLY TRIGGERS THE SECRETION OF INSULIN IN RAT PANCREATIC β-CELLS.

P. Maechler, E.D. Kennedy and C.B. Wollheim. Div. de Biochimie Clinique, University Medical Centre, Geneva, Switzerland.

The mitochondria of the β-cells are crucial in the generation of signals coupling glucose recognition to insulin secretion. The production of reducing equivalents by substrates in the mitochondria causes hyperpolarization of the mitochondrial membrane potential ($\Delta\psi_m$) permitting the rise in mitochondrial Ca^{2+} ($[Ca^{2+}]_m$) to the concentration range for activation of the NADH-generating dehydrogenases. The mitochondrial Ca^{2+} uptake is mediated by a uniporter and driven by the $\Delta\psi_m$. To elucidate the mechanism underlying the metabolism-secretion coupling in the β-cell we have monitored 1) the $\Delta\psi_m$ by Rhodamine-123 fluorescence, 2) the $[Ca^{2+}]_m$ by transient transfection of the Ca^{2+}-sensitive photoprotein aequorin targeted to the mitochondria, and 3) the insulin secretion by radioimmunoassay. Part of these experiments were performed in permeabilized rat islet cells with Staphylococcus α-toxin, permitting the study of cell-impermeant metabolic substrates such as the Krebs cycle intermediate succinate under conditions of clamped, saturating [ATP] (10 mmol/L) and stimulatory cytosolic $[Ca^{2+}]$ (800 nmol/L). In intact cells, 5 mmol/L of the cell-permeant methyl-ester form of succinate (met-Suc) caused a hyperpolarization of the $\Delta\psi_m$ and a transient peak of $[Ca^{2+}]_m$. These changes in mitochondrial metabolism were accompanied by a 4-fold stimulation of insulin secretion in perifused islet cells. In permeabilized cells kept in an intracellular-type buffer containing permissive $[Ca^{2+}]$ (800 nmol/L), 5 mmol/L succinate induced a rapid hyperpolarization of the $\Delta\psi_m$ and a 4-fold stimulation of insulin secretion in perifused cells. These results provide evidence that activation of mitochondrial metabolism in rat pancreatic islet cells generates factors other than Ca^{2+} and ATP which are capable of triggering insulin secretion.

ATP-DEPENDENCE OF EXOCYTOSIS IN MOUSE PANCREATIC β-CELLS

Lena Eliasson, Carina Ämmäla, Erik Renström and Patrik Rorsman
Dept of Medical Biophysics, Göteborg University, Sweden

Cytoplasmic ATP, via closure of the ATP-sensitive K-channels, plays a central regulatory role in glucose-stimulated insulin secretion. However, there is also evidence that ATP interacts with the insulin secretory process at more distal stages. Here we have explored the effects of cytoplasmic ATP on Ca^{2+}-induced exocytosis in individual mouse pancreatic β-cells by a combination of the patch-clamp technique, capacitance measurements, microfluorimetry of the cytoplasmic Ca^{2+}-concentration ($[Ca^{2+}]_i$) and flash photolysis of caged ATP and Ca^{2+}. The standard whole-cell configuration was used and all intracellular media were supplemented with 0.1 mM cAMP. The steady-state rate of capacitance increase observed at a $[Ca^{2+}]_i$ of 2 μM amounted to 20±4 fF/s in the presence of 3 mM ATP. Replacement of ATP with the stable analogue AMP-PCP resulted in 80% reduction of exocytosis. The latter effects could be mimicked by inclusion of 5 mM ADP in the pipette solution in the continued presence of 3 mM ATP. In experiments utilizing photorelease of caged ATP, exocytosis elicited by 170 nM $[Ca^{2+}]_i$ increased (after a delay of 11 s), from an initial 1.7±0.7 fF/s to 5.1±0.8 fF/s after appliciation of ATP ($P<0.001$; n=12).In the presence of intracellular ATP, elevation of $[Ca^{2+}]_i$ by photorelease from Ca/NP-EGTA produced a biphasic stimulation of exocytosis consisting of a rapid (<200 ms) first phase and a protracted (≥10 s) second phase. Whereas the initial phase (limited to 100 fF which corresponds to the release of 50 secretory granules) was resistant to replacement with AMP-PCP and NEM (an inhibitor of NSF), the late phase was abolished by either of these maneouvres. We interpret the biphasic stimulation of exocytosis as the release of granules from two different pools: a readily releasable pool, situated in the close vicintiy of the release site, and a reserve pool located further away from the membrane.Whereas the replenishment of the readily releasable pool requires 10 s and ATP-hydrolysis, exocytosis of granules already sitting in the readily releasable pool is rapid and proceed in an ATP-independent fashion. The small exocytotic response obtained after suppression of granule mobilization finally suggests that the pool of release-competent granules in the β-cell is <1% of the total population of granules.

MUTIPLE EXOCYTOTIC PATHWAYS REVEALED BY AMPEROMETRIC AND CAPACITANCE MEASUREMENT IN PANCREATIC β-CELLS.

N.Takahashi, T.Kadowaki, K.Yasuda, Y.Yazaki and H.Kasai. University of Tokyo, Tokyo, Japan.

Precise time- and Ca^{2+}-dependence of exocytosis from single cultured mouse β-cells were investigated using membrane capacitance measurement and amperometric detection of vesicular contents. Serotonin was pre-loaded into large dense-core vesicles for the amperometry. Exocytosis was induced with rapid elevation of cytosolic Ca^{2+} concentrations ($[Ca^{2+}]_i$) using caged-Ca^{2+} compounds. We revealed two major components in increase of membrane capacitance, reflecting exocytosis, only the slow one of which was associated with serotonin secretion, indicating that the slow component represent exocytosis of the large dense-core vesicles. Consistent with this idea, the fast (~100 ms) and slow (100ms~) exocytoses induced the characteristic endocytoses that often followed exocytoses of small-clear and large dense-core vesicles, respectively. The two exocytotic pathways exhibited similar Ca^{2+} dependencies; the half-maximal rates of secretion were achieved at 18-26 μM in $[Ca^{2+}]_i$, suggesting physiological involvement of both pathways. Interestingly, the slow exocytosis was further decomposed into two phases. Serotonin secretion was associated with both of the two phases in 30% of cells, while only with the slower phase in the rest of the cells. These suggest the presence of two types of large dense-core vesicles with distinct time constants of exocytosis. Our data for β-cells provide a new theoretical basis for mechanisms by which the biphasic insulin secretion takes place, and emphasize the existence of multiple exocytotic pathways with divergent fusion kinetics in endocrine cells

GLUCOKINASE OVEREXPRESSION INDUCES GLUCOSE REGULATION OF INSULIN PRODUCTION AND STIMULATION OF MITOGEN ACTIVATED PROTEIN KINASE.

S. Ferber, Y. Grimberg, R. Hemi, H. Kanety, A. Karasik and Y. Cohen. Institute for Endocrinology, Sheba medical ctr. Tel-Hashomer Israel.

Glucokinase (GK) is suggested to play a crucial role in the glucose sensing ability of pancreatic islets. Distal events to glucose phosphorylation have still to be elucidated. In the present study we evaluate the role of GK in mediating the glucose sensing ability of the rat insulin promoter-1 (RIP) activity in RIN1046-38 (RIN-38) cells, and make a first attempt to figure out whether this effect is mediated by activation of mitogen activated protein kinase (MAPK). Beta-cell type GK gene as well as the RIP-CAT (the reporter gene chloramphenicol acetyl-transferase) and the control CMV-CAT and CMV- luciferase (cytomegalovirus promoter, not affected by glucose) were introduced by adenoviral infection as a gene transfer tool. We found out that RIP activity in RIN-38 cells of passage 19 is glucose regulated, insulin promoter activity is 2-3 fold higher in 20mM glucose as compared to 0.2mM glucose (21.89±0.8 vs.7.88±0.5 $p<10^{-4}_{M.W.}$). The promoter activity gradually decreased with time in culture and its glucose regulation was lost together with specific dramatic decrease in GK gene expression and enzymatic activity. RIN-38 cells of passage 30 and 52 exhibited RIP activity levels which were 2 and 5 fold lower, respectively, as compared to cells at passage 19. Overexpression of GK in RIN-38 increased total glucose phosphorylating activity 4 fold (3.3±0.78 to 11.55±1.1 u/mg prot.) GK activity increased 5 fold (1.67±0.094 to 8.25±1.8 u/mg prot.), glucose regulation of insulin promoter activity increased 2-3 fold. 20mM glucose caused a several fold increase in endogenous activated MAPK levels in RIN-38 cells of passage 30 (by immunobloting with antibody which recognizes activated MAPK, Promega) overexpression of GK further increased the activated MAPK levels. **In conclusion,** GK plays an important role in induction of glucose sensing ability of insulin production. The glucose signaling pathway may be mediated via activation of MAPK, the effect of specific inhibitors of MAPK activity on glucose regulation of insulin promoter activity should supply important information on the signaling pathway leading to glucose regulation of insulin production and secretion in pancreatic islets.

159

CHARACTERIZATION OF THE DISTAL REGION OF THE β-CELL PROMOTER OF THE RAT GLUCOKINASE GENE

Tilo Moede, Ingo B. Leibiger, Per-Olof Berggren and Barbara Leibiger
The Rolf Luft Center for Diabetes Research, Dept. of Molecular Medicine, Karolinska Institute, Stockholm, Sweden

Previous studies on the promoter of the β-cell specific transcription unit of the rat glucokinase gene have shown the involvement of at least two distinct promoter regions in the transcriptional regulation. Whereas the proximal promoter region up to nucleotide -300 bp, contains *cis*-elements which are necessary for transcription in β-cells, the distal promoter region, at least up to nucleotide -609 bp, allows maximal transcriptional activity in HIT M2.2.2 cells, but seems to exhibit no cell type specific properties.

In order to characterize the distal promoter region in more detail, we performed 5'- and 3'-deletion ana-lysis and *in vitro* as well as *in vivo* DNA-protein binding studies to delineate *cis*-elements contributing to transcriptional control. Deletional analysis revealed that both positive and negative acting *cis*-elements contribute to the action of the distal promoter region. Positive acting elements have been mapped between -277 bp/-206 bp and -609 bp/-63 bp. Due to the combination of 5'- and 3'-deletion studies

the localization of the negative acting *cis*-element could be determined between -373 bp and -359 bp. This region contains a perfect N-box motif, which has been described as a binding site for the negative acting factor HES-1. The minimal -609/-n fragment which exhibits a positive effect on reporter gene expression was -609/-463. This fragment also conferred positive transcriptional activity in an orientation dependent manner when fused to a heterologous minimal promoter. The positive action of this fragment was observed in insulin-producing HIT M2.2.2 and non-insulin-producing BHK 21 cells. DNase I footprinting analysis of the region -609/-463 bp revealed the same protected region between nucleotides -562 to -516, when using nuclear extracts prepared from HIT M2.2.2 and BHK 21. This protected region which is highly enriched in AT-bases, is also involved in protein binding *in vivo*. By performing a MAR-assay we could show that the AT-rich region of the distal promoter part does not act as a Matrix Attachment Region. This region contains putative *cis*-elements, which show high homology to consensus motifs reported for the transcriptional factors Pit 1, NFMR 1, HINFA, HNF 1, HNF 3, BRN 2 and HSFA.

Site directed mutagenesis of the putative cis-elements within the distal promter part and DNA/protein interaction studies are in progress to study the contribution of the above mentioned transcription factors in the transcriptional control of the rat glucokinase gene in insulin-producing cells.

160

GLUCOSE CAUSES A COORDINATED INDUCTION OF GLYCOLYTIC AND LIPOGENIC GENES IN ß(INS-1) CELLS

E. Roche, F. Assimacopoulos-Jeannet, L.A. Witters, B. Perruchoud, S. Thumelin, G. Yaney, M. Asfari, T. Brun, B. Corkey, and M. Prentki. *Molecular Nutrition Unit, University of Montreal, Canada.*

Long term exposure ot the ß-cell to elevated glucose causes a high rate of insulin secretion at low glucose, ß-cell hypertrophy and hyperplasia. These actions of glucose are expected to be associated with changes in the expression level of a number of genes which must be identified. The exposure of ß(INS) cells from 5 to 25mM glucose for 3 days induced phosphofructokinase-1(isoforms C, M and L), glyceraldehyde 3-phosphate dehydrogenase, L-pyruvate kinase, acetyl-CoA carboxylase and fatty acid acid synthase proteins, whereas pyruvate dehydrogenase (subunits E1alfa and E3) malic enzyme, pyruvate carboxylase, ATP citrate lyase and carnitine palmitoyl-transferase I enzymatic activities remained constant. Similar patterns were observed at the mRNA level. These changes in metabolic genes expression were associated with an increased ß-cell metabolic activity (indicated by the reduction of the artificial electron acceptor MTT) at low glucose and a marked glycogen deposition which was readily mobilized upon lowering of the ambient glucose. Chronically elevated concentrations of citrate, malate and malonyl-CoA with an associated sustained inhibition of fatty acid oxidation and exaggerated fatty acid esterification as well as triglyceride deposition also ocured. The data provide a possible mechanism for the ß-cell hypersensitivity to glucose (also named "glucose toxicity") caused by the chronic exposure of the ß-cell to elevated glucose. It is proposed that a coordinated induction of metabolic genes by glucose causes pleiotropic alterations in ß-cell metabolism (glycogen and triglyceride deposition, glycolysis, Kreb's cycle activity, anaplerosis, fatty acid oxidation and esterification) resulting in the exaggerated production at low glucose of metabolic coupling factors regulating insulin secretion.

161

DIFFERENTIAL ROLES OF THE RHO SUBFAMILY OF GTP-BINDING PROTEINS IN GLUCOSE- AND CALCIUM-INDUCED INSULIN SECRETION.
A. Kowluru, G. Li, M. Rabaglia, V.Segu, K. Aktories**, F.Hofmann**, and S. Metz. University of Wisconsin, Madison, USA and **Institute of Pharmacology and Toxicology, Freiburg, Germany

We utilized clostridial toxins (with known specificities for modification of the rho subfamily of G-proteins) to ascertain the contribution of candidate GTP-binding proteins in physiologic insulin secretion from β cells. Exposure of normal rat islets or HIT-T15 cells to *Clostridium difficile* toxin A or B resulted in the glucosylation of Cdc42, rac and rho, accompanied by inhibition of glucose (>70%)- or potassium (>60%)-induced insulin secretion. *Clostridium sordellii* lethal toxin (LT) specifically glucosylated rac2 and rap1, but, like toxins A or B, attenuated glucose (-57%)- or potassium (-58%) induced insulin secretion. In contrast, *Clostridial* C3-exoenzyme (which fully ADP-ribosylated rho) did not affect either glucose or potassium-induced secretion. These data suggest that Cdc42, rac, and/or rap (but not rho) may be needed for glucose- or calcium-induced secretion. These toxin effects appear to be specific for relatively late steps in stimulus-secretion coupling, since no differences in metabolic viability were demonstrable between control or toxin -treated cells. Also, toxin-treatment did not alter glucose- or potassium-mediated rises in $[Ca^{2+}]_i$, suggesting that these G-proteins are involved in steps distal to elevations in $[Ca^{2+}]_i$. In intact cells, the carboxyl methylation of Cdc42 was stimulated by glucose, whereas that of rap and rac was regulated by glucose or potassium. Together, these findings provide direct evidence, for the first time, that rho subfamily of G-proteins play key, differential regulatory roles in insulin secretion. Furthermore, they suggest that Cdc42 may be required for early steps in glucose stimulation of insulin release (probably phospholipase activation), whereas rap and rac may be required for a later, calcium-dependent step(s) in insulin exocytosis.

162

EFFECT OF BOTULINUM NEUROTOXIN C1 ON EXOCYTOSIS OF INSULIN AND SNARE-PROTEIN CLEAVAGE IN PANCREATIC β-CELLS

J. Lang,*H. Niemann and C.B. Wollheim
Div. of Clinical Biochemistry, CMU, Université de Genève, Switzerland;
** Institut für Mikrobiologie, Tübingen, Germany*

The botulinum neurotoxin C1 cleaves the membrane proteins syntaxin 1,2 and 3 and thereby inhibits neurotransmission and neuroendocrine secretion. We investigated the effect of botulinum neurotoxin C1 (BoNT C1) on syntaxin 1 (*syx*) cleavage and insulin secretion/exocytosis in pancreatic β-cells to gain insight into the function of syntaxin. As the toxin cannot enter intact β-cells, cells were first permeabilized with streptolysin-O (SLO). Under those conditions recombinant BoNT C1 (3-100 nM) cleaves *syx* 1 in HIT-T15, INS-1 and primary islet cells. The levels of SNAP-25 or VAMP, known targets of BoNT A/E and tetanus toxin, remain unchanged. The cleavage of *syx* by BoNT C1 is accompanied by a progressive loss of Ca^{2+}-stimulated exocytosis (10 μM Ca^{2+}) in all three cell types without alterations in basal levels of insulin release (0.1 μM Ca^{2+}). GTPγS-induced exocytosis, which is calcium-independent, was not reduced by BoNT C1 in INS-1 or primary islet cells and was toxin-sensitive only in HIT-T15 cells. In contrast, BoNT E inhibited Ca^{2+} and GTPγS-stimulated exocytosis in all three cell types. To test whether BoNT C1 cleavage of *syx* interferes with different stimuli of insulin release in intact cells, we transiently expressed the light chain of BoNT C1 (BoNT C1 LC) together with human preproinsulin in hamster HIT-T15 cells and measured human C-peptide release as a marker of insulin release from transfected cells. Under those conditions BoNT C1 LC abolished secretion evoked by KCl, forskolin, glucose and forskolin or by the phorbol ester PMA. *Syx* cleavage and light chain expression was verified by transient cotransfection of BoNT C1 LC together with the green fluorescent protein GFP(S65T) and subsequent fluorescent activated cell sorting of the transfected cells. In conclusion are data demonstrate that (i) syntaxin is required for Ca^{2+}-, but not for GTPγS-dependent exocytosis of insulin and that (ii) β-cell impermeable neurotoxins can successfully be expressed in insulin-secreting cells, which will provide a valuable tool for further investigation of secretory mechanisms.

LOW BIRTHWEIGHT AND GLUCOSE INTOLERANCE: A ROLE FOR THE SYMPATHETIC NERVOUS SYSTEM?

DIW. Phillips and DJP. Barker. MRC Environmental Epidemiology Unit, (University of Southampton), Southampton, UK.

We have examined the hypothesis that persisting sympathetic nervous system (SNS) activity determined *in utero* could be one of the processes explaining the link between reduced fetal growth and raised blood pressure and glucose intolerance in adult life. We tested this by examining the relation between birth size and resting pulse rate, an index of SNS activity, in 449 men and women born in Preston, Lancashire, aged 46-54 years whose birth records have survived. Subjects were visited at home and resting heart rate recorded with an automated recorder. Resting pulse ranged from 44-108 (mean 73) beats per minute. It rose with increasing body mass index ($r=0.14$, $p=0.003$) and waist to hip ratio (adjusted for sex $r=0.10$, $p=0.003$) and correlated significantly with systolic and diastolic blood pressures ($p=0.001$), fasting glucose ($p=0.02$), split proinsulin ($p=0.001$) and triglyceride concentrations ($p=0.02$). Pulse rate fell progressively from 76/min among subjects who weighed 2.5kg or less at birth to 71/min among those who weighed 3.3kg or more ($p=0.01$). The association was independent of current body mass index, smoking habit, alcohol consumption and social class. These findings suggest that elevated SNS activity established *in utero* may be a mechanism linking small size at birth with raised blood pressure and glucose intolerance in adult life.

164

LOW BIRTHWEIGHT, GLUCOSE INTOLERANCE AND FAMILY HISTORY OF DIABETES IN SWEDISH MIDDLE-AGED MEN.

S. Carlsson, P-G. Persson, V. Grill, S. Efendic, A. Norman, C-G. Östensson and the SDPP study group. Departments of Epidemiology, Endocrinology, Social Medicine and Diabetes Prevention, Stockholm County Council, Sweden.

Low birthweight has been suggested as a potential risk factor for non-insulin-dependent diabetes (NIDDM). This could be due to the effect of fetal malnutrition. However, the impact of other possible factors influencing birthweight and glucose tolerance, such as family history of diabetes, particularly diabetes in the mother, and socio-economic status, have not been elucidated in detail. The aim of this study was to investigate the association between low birthweight and glucose intolerance taking into account family history of diabetes and socio-economic status. We performed a cross-sectional study of 3129 Swedish men in the age 35-56 years of whom 52% had a strong family history of diabetes (at least one first or two second degree relatives with diabetes). Information on birthweight and fathers' socio-economic status were obtained by questionnaire from 2237 (71%) of these men. Oral glucose tolerance testing detected 102 cases of impaired glucose tolerance (IGT) and 35 cases of NIDDM. After adjustment for family history of diabetes and body mass index the relative risk of NIDDM associated with low (≤3000 g) birthweight was 3.8 (95% confidence interval (CI) =1.7-8.4). Correspondingly, the relative risk of IGT and high 2-h glucose levels within the normal interval (5.8-7.7 mM) was 1.5 (95% CI=0.9-2.6) and 1.6 (95% CI=1.1-2.2). Men with low birthweight (≤3500g) and family history of diabetes had 8.1 times the risk of having NIDDM (95% CI=2.4-27.3). For IGT and high 2-h glucose levels within the normal interval, corresponding estimates were 2.8 (95% CI=1.5-5.1) and 2.0 (95% CI=1.4-2.8). Controlling for fathers' socio-economic status and diabetes in the mother left the results virtually the same as those already presented. We conclude that there is an association between low birthweight and glucose intolerance when family history of diabetes, diabetes in the mother and fathers socio-economic status are taken into account. Furthermore, family history of diabetes and low birthweight synergistically increase the risk of NIDDM.

165

ASSOCIATION OF LOW BIRTH WEIGHT WITH REDUCED BETA-CELL FUNCTION

JTE Shaw. Department of Diabetes and Endocrinology, Princess Alexandra Hospital, Brisbane, Australia* and Diabetes Research Laboratories, Radcliffe Infirmary, Oxford, UK. (* Address for correspondence)

Reduced growth in fetal and neonatal life has been linked with an increased risk of developing impaired glucose tolerance and type 2 diabetes in adult life. The pathophysiological basis of the association between impaired intrauterine growth and type 2 diabetes has been uncertain. The aim of this study was to define the relationship between birth weight and Beta-cell function in the first degree relatives of type 2 diabetic subjects. The study was cross sectional, and involved 101 Caucasian adults of known birth weight from 47 families which had at least one member with type 2 diabetes. The subjects were of mean age 43 ± 7 years (± 1 SD). Glucose tolerance was measured with the 5 mg.kg ideal body weight/min continuous infusion glucose tolerance test. Beta-cell function and insulin sensitivity were calculated from the fasting glucose and insulin concentrations with Homeostasis Model Assessment. Beta-cell function was standardised to allow for the confounding effects of age and obesity. Birth weight was expressed as a centile taking into account gestational age, gender, birth order, and maternal height. Twenty-seven of the subjects had type 2 diabetes, 32 had impaired glucose tolerance, and 42 were normoglycaemic. Birth weight correlated with the Beta-cell function in the complete cohort (r_s=0.29, p=0.005), in the type 2 diabetic subjects (r_s=0.50, p=0.023) and in the 74 nondiabetic subjects (r_s=0.29, p=0.013). There was no significant correlation between birth weight and insulin sensitivity. The diabetic (n=27) and nondiabetic (n=74) subjects had similar median (interquartile range) centile birth weight: 50% (19%-91%) and 53% (30%-75%) respectively. However the diabetic subjects had significantly lower Beta-cell function: 69% (48%-83%) vs 97% (86%-120%) p<0.001. The cause of the association between low birth weight and reduced Beta-cell function in adult life is uncertain. Nutritional factors determining fetal and infant growth may influence the size or vascularity of the adult pancreatic Beta-cell complement. Alternatively, lower birth weight may result from the phenotypic expression of genetic Beta-cell defects associated with reduced fetal insulin secretion and reduced anabolic effect in utero. The marked impairment of Beta-cell function in the type 2 diabetic subjects could not be accounted for by low birth weight alone, and additional genetic and environmental factors are likely to be necessary for the development of type 2 diabetes.

166

RELATIONSHIP OF MATERNAL BIRTH WEIGHT TO ORAL GLUCOSE TOLERANCE, INSULIN RESISTANCE AND NEONATAL WEIGHT IN NON-DIABETIC MOTHERS.

G. Seghieri, G. Gregori, S.Sani, M.C. Breschi, and R. Anichini. Dpt. of Internal Medicine, Hospital of Viareggio, and Diabetes Unit, Spedali Riuniti, Pistoia, Italy.

According to the hypothesis of *'thrifty phenotype'* a low birth weight is associated to the appearance of non-insulin-dependent diabetes mellitus, as well as of other clinical correlates of the insulin resistance syndrome in the adult life. Among known determinants of birth weight there is the status of glucose tolerance during the pregnancy either in mothers with gestational diabetes or in non diabetic women. Whether maternal birth weight could be in some way related to the weight of their neonates as well as to both glucose tolerance and insulin response after an oral glucose load, are the questions raised by this study. Both glucose and insulin plasma levels were evaluated basely, at 60 min and at 120 min after an oral 100 g-glucose load in a group of 96 non-diabetic pregnant women, between the 24th and the 28th gestational week. Neonatal weight was, on average, significantly higher in the group of the highest quartile of maternal birth weight (n=23; 3530±701(SD)g), as compared to the mean value of the women of the lowest quartile (n=29; 3103±661g; p=.03). This difference remained significant even after adjusting for gestational age, neonatal sex, maternal height or maternal caloric intake (p=.039). No significant differences were observed in both maternal and insulin area under the curve across the quartiles of maternal birth weight. The only further variable significantly associated to maternal birth weight was mean blood pressure recorded just before the oral glucose test, significantly increased in the highest quartile of maternal birth weight. (91±6 mmHg in the highest vs 87±7 mmHg in the lowest; p=.03). In conclusion these results demonstrate that a higher maternal birth weight predicts the delivery of fatter babies, being, moreover, associated with a higher mean blood pressure duiring the pregnancy, while no relationship is shown between maternal birth weight and glucose tolerance or insulin levels after an oral glucose load in non diabetic pregnant women.

167

IMPACT OF GESTATIONAL DIABETES ON INSULIN SECRETION, INSULIN SENSITIVITY AND GLUCOSE EFFECTIVENESS IN AFRICAN AMERICANS WITH FAMILY HISTORY OF NIDDM : K.Osei, and T. Gaillard, D.Schuster, The Ohio State University, Columbus, Ohio, USA.

Prior history of gestational diabetes mellitus(GDM) is an important risk factor for NIDDM. Nevertheless, the metabolic characteristics of African Americans (AA) with former GDM are unknown. In addition, whether a positive family history of NIDDM impact adversely on the putative metabolic defects in AA with former GDM is uncertain. We have measured, beta cell function, insulin sensitivity index(Si) and glucose - dependent glucose disposal(Sg) in 15 healthy, normal glucose tolerant former GDM females (mean±sem,38.5 ±2.0yrs) who were first degree relatives of AA patients with NIDDM and had average of 7 years after the index pregnancy. Their data were compared with those of 35 age -, weight -, BMI - and waist - hip ratio- matched healthy first degree AA females (mean age 43.0 ±1.8 yrs) but without prior history of GDM(CONT). Standard oral glucose tolerance test(OGTT) and insulin - modified, FSIGT were performed in each subject. Insulin sensitivity index(Si) and glucose effectiveness (Sg) were determined by the minimal model method. The mean fasting and postprandial (PP) serum glucose(G) levels were slightly greater but not significantly different in the GDM vs. CONT. While mean fasting serum insulin(INS) was no different, INS levels at 30-90 mins were significantly lower in former GDM vs. CONT. However, the mean fasting and PP serum c-peptide(C-P) were not different in the GDM vs. CONT. Following intravenous glucose load, serum G levels were not significantly different in the former GDM vs. CONT. Mean acute first phase insulin, but not C-P release, was blunted in the former GDM vs. CONT. Mean Si (1.87± 0.47 vs. 2.87± 0.35x10^{-4}. min^{-1}/uU/ ml^{-1}, p<0.05) and Sg (2.11 ± 0.15 vs 3.25 0.54 x 10^{-2}.$mins^{-1}$ p<0.05) were significantly lower in the post GDM than CONT. **Conclusion:** Our study demonstrates that defects in beta cell secretion, insulin clearance, Si and Sg persist 7 years after the index pregnancy in glucose - tolerant, first degree relatives of AA diabetic patients with former GDM. Thus,GDM confers greater metabolic derangement beyond that attributed to family history of diabetes alone and could partly explain the higher propensity for NIDDM in AA with former GDM.

168

GESTATIONAL DIABETES MELLITUS: DIFFERENT OUTCOME IN WOMEN WITH ISLET CELL ANTIBODIES

M. Albareda, R. Corcoy, A. Caballero, G. Badell, J. Morales, D. Mauricio, A. García, M. Puig and A. de Leiva. Hospital de Sant Pau, Barcelona, Spain

Gestational diabetes (GD) is an heterogenous entity, some women displaying positivity for islet cell antibodies (ICA). We aim to assess if glucose tolerance at follow-up differs in GD women with ICA. We have followed a cohort of 183 GD women for a mean of 7.34 ± 2.8 years. ICA were determined during pregnancy by indirect immunofluorescence with prolonged incubation: 22 women were ICA+ and 161 were ICA-. According to WHO criteria 17 have developed diabetes mellitus (DM) and 18 impaired glucose tolerance (IGT). Mean survival time for the whole cohort to develop IGT or DM is 14.75 years (95% CI 11.63-17.87). Despite a mean survival time of 14.46 years (95% CI 11.03-17.88) for ICA- and of 15.48 years (95% CI 11.51-19.45) for ICA+ GD women, the Breslow and Tarone-Ware statistics are significant (p<0.05) for a worse outcome in ICA+ women due to a faster deterioration in this group. We conclude that ICA+ GD women have an earlier deterioration of glucose tolerance than their ICA- counterparts.

169

IS THERE A THRESHOLD OF HYPERGLYCEMIA FOR INCREASED RISK OF CONGENITAL MALFORMATIONS IN DIABETIC PREGNANCIES?

K.Teramo, L.Suhonen and V.Hiilesmaa. Univ. Central Hospital, Helsinki, Finland

Several studies in humans have shown that first trimester hyperglycemia is associated with an increased rate of malformations (MF): the higher the hemoglobin A1c (HbA1c), the higher the risk of MF. However, a threshold of HbA1c, under which the MF rate is not increased, is unknown. We studied 540 consecutive pregnancies of 405 IDDM patients during an 8-year period (from 1988 to 1995). The mean (range) maternal age was 29.6 years (17-44). HbA1c was measured at least once before the end of the 15th week of pregnancy in 94 % of the patients by a HPLC method with a mean (SD) of 5.0 % (0.32) in healthy non-diabetic subjects. There were 26 cases (4.7 %) with major MF and 36 cases (6.5 %) with minor MF among the 552 offspring of the 540 pregnancies. There were 10 twin pregnancies and 1 triplet pregnancy. A malformation was considered major when it was lethal or needed major surgical correction. Four cases with severe MF had pregnancy interruption between 16 and 20 weeks of gestation after ultrasound diagnosis. These 4 cases were included in the study group. The Table shows the frequencies of major and minor MF at different levels of HbA1c in early pregnancy. Only 6.5 % of the diabetics had a HbA1c value within the non-diabetic range. They had the lowest MF rate, which is roughly the same as in the general population. The diabetics with the highest HbA1c levels had the highest MF rate (Table). Our results suggest that only diabetics with HbA1c levels within normal limits in early pregnancy do not have an increased risk of MF.

HbA1c		N	Major MF		Minor MF		Total MF	
%	SD-units		N	%	N	%	N	%
>9.5	>14.0	50	4	8.0	4	8.0	8	16.0
7.6-9.5	8.1-14.0	197	8	4.1	14	7.1	22	11.2
5.6-7.5	2.1-8.0	234	12	5.1	15	6.4	27	11.5

Unknown		35	1	2.9	2	5.7	3	8.6

170

POLYCYSTIC OVARY SYNDROME (PCOS) IN URBAN INDIAN WOMEN: ASSOCIATION WITH INSULIN RESISTANCE AND PARENTAL HYPERGLYCEMIA.

B.S.Sardesai, K.M. Shelgikar, S.S.Naik, K.J. Coyaji and C.S.Yajnik. Diabetes Unit, K.E.M. Hospital and Research Centre, Pune, India.

We studied 55 women with PCOS and their parents for glucose tolerance (WHO 1985), plasma immunoreactive insulin (IRI) & lipids, blood pressure and anthropometry. The PCOS women were 22 y old (mean), 11 were obese (BMI>25 kg/m^2), 13 (24%) had abnormal glucose tolerance [4 diabetic (3 obese), 9 IGT (4 obese)]. Fasting IRI was significantly higher in the PCOS women compared to controls [149 vs 90 pmol/l, median, p<0.001]. Fasting IRI correlated with BMI (p<0.001), WHR (p<0.001), blood pressure (p=0.029), triglycerides (p<0.001) and luteinising hormone (p=0.036). Thirty six of sixty four (56%) parents studied were hyperglycaemic[27 diabetic (13 fathers,14 mothers); 9 IGT (2 fathers, 7 mothers)]. In 27 PCOS girls (50%) either or both parents were hyperglycaemic. Thus, Indian PCOS women suffer metabolic syndrome even though a large proportion are non-obese. High prevalence of parental hyperglycaemia suggests that the insulin resistance in PCOS may be familial.

OP 23

New Approaches in the Management of NIDDM

171

Comparative effects of A-4166, sulfonylureas and repaglinide on meal induced glucose excursions in normal rats.

C.J. de Souza, P. Russo, R. Lozito and B. Dunning. Sandoz Pharmaceutical Inc., East Hanover, USA.

The ability of A-4166, a rapid onset/short acting insulin secretagogue, to augment the early insulin response and thereby curb prandial glucose excursions during a meal was tested and compared to glibenclamide (GB) (slow onset/long acting), glipizide (GP) (rapid onset/short acting) and repaglinide (RP) (rapid onset/short acting). Chronically catheterized male SD rats acclimated to a meal feeding regime were administered the compound orally 10 min. before a 30 min. meal. Blood samples were obtained via the jugular cannula at -10, 0, 1, 3, 5, 10, 20, 30, 45, 60, 90 and 120 min. after commencement of feeding. Food consumed during the meal was unaffected by the compounds. In the controls, the 30 min. meal resulted in an increase in plasma glucose and insulin with peak levels occurring at 15 and 20 min. respectively. GB did not augment the early insulin response ($\Delta AUC_{-15 \text{ to } 3 \text{ min}}$) and glucose excursions paralleled those in the control. Total insulin release during the 120 min. test period ($\Delta AUC_{-15 \text{ to } 120 \text{ min.}}$) was not significantly higher (5±0.7 *v/s* 7±1.4 mU•min/ml, control and GB) but postprandial glucose levels were 30 mg lower than in controls. Conversely, A-4166 (60 and 120 mg/kg), GP (1.0 mg/kg) and RP (0.2 mg/kg) all augmented the acute insulin secretory response while glucose excursions during the meal ($\Delta AUC_{-15 \text{ to } 30 \text{ min}}$) were eliminated (814±91, 11±177, -415±106, 13±202 and -122±203 mg•min/dl for controls, A-4166 at 60 and 120 mg, GP and RP respectively). Total insulin release and postprandial glucose levels in the A-4166 treated groups were comparable to the controls. Conversely, GP and RP resulted in greater total insulin release and postprandial glucose levels were 33-34 mg lower that in the controls. A lower dose of RP (0.02 mg/kg) resulted in total insulin release comparable to the higher dose of A-4166 (10±2.3 and 10.1±1.6 mU•min/ml respectively). However, this lower dose of RP failed to augment the early insulin secretory response and eliminate the glucose excursion during the meal but postprandial glucose levels tended to be lower than in the controls albeit not significantly (-5±6.1 and 11±2.8 mg/dl respectively). In conclusion, the rapid onset of A-4166 allows for an augmentation of the early insulin response and an elimination of prandial glucose excursions while its extremely short duration of action prevents excessive insulin secretion and postprandial hypoglycemia in normal rats.

172

GLP-1 tablet in NIDDM

M. Gutniak, H. Larsson, S. Sanders, O. Juneskans, JJ Holst and B. Ahrén. Vällingby Med. Center, Karolinska Institute, Stockholm, Dept. of Medicine, Lund Univ., Malmö, TheraTech Inc. Salt Lake City, USA, Karolinska Pharmacy, Stockholm, Sweden, Dept. of Medical Physiology, PANUM Institute, Copenhagen, Denmark.

For establishing GLP-1 as a therapeutic regimen in diabetes, another route of administration would be advantageous. We showed that in healthy volunteers, a buccal tablet containing 400 µg of GLP-1 delivered potential therapeutic levels of the peptide. Furthermore, it reduced fasting glycaemia and increased plasma insulin. Now we have used that delivery system for studying the effect of GLP-1 in patients with NIDDM and poor metabolic control. In addition, we have evaluated the effectiveness of the insulinotropic effect versus the gastro-intestinal effect in the lowering of glycaemia. Ten NIDDM patients received a single tablet under fasting conditions and before a standard meal in this randomized, placebo controlled study. The mean peak GLP-1 concentration was 139.4±17 pmol/L and occurred 30 min following application. The mean placebo adjusted AUC was 5940±764 min•pmol/L consistent with a relative bio-availability of 6% vs i.v. injection and 46% vs s.c. injection. Half-life of total peptide activity after buccal administration was 17 min. Placebo adjusted glucose concentrations decreased by 1.4±0.4 mmol/L in fasting experiments and by 4.7±0.7 mmol/L after a standard mixed meal. In fasting state, plasma insulin increased by 185% and glucagon decreased by 20% consistently with the increase in plasma GLP-1 concentrations. The peptide exerted a significant insulinotropic effect during meal (calculated as an insulinogenic index) 93.1±27 vs 45.7±19 in placebo experiments. The calculated gastro-intestinal effect of the peptide (gastric emptying etc.) was 70% compared to 30% effect on pancreatic islets (insulin, glucagon, etc.). **We conclude** that potential therapeutic plasma levels of GLP-1 were achieved after administration of a single buccal tablet in NIDDM patients. The peptide had marked glucose lowering effect mostly by inhibiting gastric emptying. This new alternative treatment form may therefore be feasible in the future for NIDDM, although a more prolonged pharmaco-kinetic profile is required.

173

INFLUENCE OF GLUCAGON-LIKE PEPTIDE 1 ON FASTING GLYCAEMIA IN NIDDM PATIENTS TREATED BY INSULIN (SULFONYLUREA FAILURE)

A. Sauerwald, M.A. Nauck, J.J. Holst, W.H. Schmiegel, Medizinische Universitätsklinik (Knappschaftskrankenhaus) Bochum, Germany and Panum Institute, University of Copenhagen, DK.

Glucagon-like peptide 1 (GLP-1) has glucose-dependent insulinotropic and glucagonostatic actions in NIDDM patients on diet and on oral agents. It is not known, whether after secondary sulfonylurea failure GLP-1 is still effective. Therefore, 10 NIDDM patients (6 female, 4 male; 65 ± 10 years, BMI 30.4 ± 5.1 kg/m^2; HbA_{1c} 8.2 ± 1.5 %; 6 ± 3 years, range 2-13 years, after starting insulin treatment) were examined in the fasting state after discontinuing NPH insulin on the evening before the two study days. GLP-1 [7-36 amide] (1.2 pmol·kg^{-1}·min^{-1}) or placebo (NaCl with 1 % HSA) were infused over 6 h. Plasma glucoe (glucose oxidase) insulin (IMx), and C-peptide (ELISA) were measured. Statistics: repeated measures analysis of variance. Fasting plasma glucose was 9.4 ± 0.7 mmol/l, and was reduced by GLP-1 to 5.4 ± 0.4 (range 3.9 - 7.3) mmol/l (placebo: 8.2 ± 0.7 mmol/l; $p < 0.0001$). GLP-1 transiently increased insulin (from 114 ± 31 to 222 ± 65 pmol/l at 150 min; $p < 0.0001$) and C-peptide (from 1.00 ± 0.12 to 1.90 ± 0.23 nmol/l at 120 min; $p < 0.0001$) with no effect of placebo. After normalization of plasma glucose, insulin and C-peptide concentrations became lower again during the ongoing administration of exogenous GLP-1. It is concluded that exogenous GLP-1 effectively lowers plasma glucose concentrations also in advanced NIDDM (long after sulfonylurea secondary failure). These findings may broaden the applicability of GLP-1-derived drugs as a new treatment to nearly all NIDDM patients.

174

THE AMYLIN ANALOGUE PRAMLINTIDE DECREASES POSTPRANDIAL PLASMA GLUCOSE AND GLUCAGON IN IDDM PATIENTS.

B. Nyholm[1], L. Ørskov[1], K.Y. Hove[1], C.H. Gravholt[1], N. Møller[1], K.G.M.M. Alberti[2] and O. Schmitz[1]. [1]Dept. of Medicine M, Aarhus Kommunehospital, Denmark and [2]Dept. of Medicine, Framlington Place, Newcastle-upon-Tyne, UK.

Previous reports have suggested that administration of the amylin analogue pramlintide to IDDM subjects improves glycemic control. To further explore the effects of treatment with pramlintide (Pr) vs placebo (Pl) on glucose control and postprandial responses of glucose, glucagon and various metabolites following standardised meals in IDDM patients, we examined 13 male IDDM patients in a double-blind, placebo controlled, cross-over study. Patients were treated with Pr (120 μg/day, 30 μg qid) or Pl for 4 weeks. On the last day of this period, a diurnal profile (08.00-16.30 h) was performed, focusing on the postprandial response to a carbohydrate rich breakfast. Mean serum insulin (49.5±6.5 vs 46.6±5.0 pmol/l) on the diurnal day were comparable between treatment periods, however, mean plasma glucose was lower after Pr (8.4±0.7 vs 10.2±0.8 mmol/l, $0.05 < p < 0.10$). Furthermore, after Pr treatment, blood glycerol was lower (0.030± 0.003 vs 0.039±0.005 mmol/l, $p < 0.05$) and blood alanine higher (0.28±0.01 vs 0.25±0.01 mmol/l, $p < 0.05$), whereas no significant differences were observed in serum NEFA (0.26±0.02 vs 0.31±0.03 mmol/l) or blood lactate (0.73±0.03 vs 0.71±0.05 mmol/l)(Pr vs Pl). Following the carbohydrate rich breakfast, mean plasma glucose (9.3±1.0 vs 12.5±1.0 mmol/l) and glucagon (49.4±6.6 vs 65.4 ±7.5 ng/l) were lower after Pr vs Pl ($p < 0.05$), and area under the curve for both plasma glucose and glucagon were reduced by 26 % ($p < 0.05$). In conclusion, treatment of 13 male IDDM subjects with pramlintide (30 μg qid) for 4 weeks resulted in reductions in plasma glucose and glucagon as well as blood glycerol following a carbohydrate rich breakfast, while serum insulin remained constant. These observations suggest, that Pr mediated suppression of glucagon secretion may contribute to the reduction in postprandial hyperglycaemia observed during Pr treatment. Longer term studies are required to ascertain whether these findings are sustained over time.

175

VANADYL SULFATE IMPROVES METABOLIC CONTROL AND INSULIN SENSITIVITY IN PATIENTS WITH NIDDM.

K. Cusi, S. Cukier, R.A. DeFronzo, J.C. Pereira Redondo, M. Torres.
CEMIC, Buenos Aires,Argentina & UTHSCSA, San Antonio, TX, USA

Vanadium salts have significant insulin-like actions *in vitro*, reduce hyperglycemia and insulin resistance in animal models of diabetes and may be useful to treat subjects with NIDDM. STUDY AIM: to examine the effects of 6 weeks of treatment with vanadyl sulfate ($VOSO_4$) in 10 patients with NIDDM (age 59±2y, BMI 28.6±0.9 kg/m^2, fasting glucose (FPG) 187±15 mg/dl, HbA_{1c} 8.4±0.4%). We evaluated glycemic control, glucose tolerance (OGTT), insulin sensitivity (euglycemic insulin clamp, 40 mU/m^2•min, with 3-^{3}H glucose), lipids and 24h ambulatory blood presure (ABP) before (following a 4 week run-in period) and after follow-up for 6 weeks with $VOSO_4$ (150mg/day). Caloric intake and physical activity were constant. RESULTS: $VOSO_4$ reduced FPG(191±15 to 155±11mg/dl), HbA_{1c} (8.2±0.4 to 7.7±0.4%) and fructosamine (359±22 to 291±15 umol/L, all $p<0.01$). During OGTT, the mean plasma glucose conc was reduced by 30 mg/dl; this was entirely accounted for by a decrease in FPG and hepatic glucose production. Insulin clamp: glucose uptake (M) increased by 22% (2.7±0.3 to 3.3±0.4 mg/kg•min, $p<0.02$), but remained less than in non-diabetic controls (5.8±0.4 mg/kg•min, $p<0.001$). Total and LDL-cholesterol decreased (223±14 vs. 202±16, $p<0.01$; 141±14 vs. 129±14 mg/dl, $p<0.05$). Mean 24hr ABP was unchanged, but $VOSO_4$ enhanced the nocturnal MAP drop ($p<0.05$) and restored a normal circadian rhythm in 4/6 pts. Weight remained stable (76.1±4.2 vs. 75.9±4.1kg,NS). CONCLUSIONS: $VOSO_4$ treatment for 6 weeks in NIDDM is well tolerated, improves metabolic control and attenuates cardiovascular risk factors. Improvements in whole body insulin-mediated glucose disposal (muscle) and hepatic sensitivity to insulin contribute to enhanced glucose tolerance. The results suggest that $VOSO_4$ may be helpful in the treatment of NIDDM.

176

THE PPARγ AGONIST, BRL 49653, PREVENTS PROGRESSION TO DIABETES IN ZUCKER DIABETIC FATTY RATS.

SA Smith, CA Lister, MG Hughes and RE Buckingham, SmithKline Beecham Pharmaceuticals, Welwyn, U.K.

The Zucker Diabetic Fatty (ZDF) rat, an animal model of NIDDM, progresses from an obese, hyperinsulinemic and glucose intolerant state to one of overt diabetes, with attendant impaired weight gain and secondary complications such as nephropathy and cataract formation. In an attempt to influence the course of the disease process, the PPARγ agonist, BRL 49653 (~10 μmol/kg body weight daily), was given via the diet to ZDF rats, aged 6 weeks (Prevention group; n=8) or 21 weeks (Intervention group; n=7) until termination at aged 28 weeks. Untreated ZDF and lean (ZL; n=10) rats were used as controls. ZDF control rats (n=16) were hyperglycemic at aged 11 weeks (15.2±6.1 vs ZL 5.7±0.4 mmol/L; mean±SD; $p<0.001$) and thereafter blood glucose fluctuated between 29.0±2.0 (22 weeks; n=8) and 17.9±6.8 mmol/L (25 weeks; n=8) until termination. The Prevention group, however, maintained a normoglycemia (eg 3.7±0.8 mmol/L vs ZL 3.0±0.9 mmol/L at 27 weeks; p=NS). Late Intervention with BRL 49653 at aged 21 weeks failed to influence the hyperglycemia. ZDF controls also developed marked glycosuria and proteinuria, neither of which were seen in the Prevention group. At aged 27 weeks, ZDF controls excreted in 24h 9.4±1.0g glucose and 1.0±0.1g protein. By contrast, glycosuria was barely detectable in Prevention group rats (~0.01g/24h) and proteinuria was similar to that in ZL controls (0.081±0.013 vs 0.051±0.008 g/24h; p=NS). Late Intervention treatment, however, failed to influence the established glycosuria and proteinuria. These data show that early treatment with BRL 49653 prevents the progression to diabetes in ZDF rats and simultaneously affords protection against the development of proteinuria.

177

TROGLITAZONE AND METFORMIN ENHANCE GLUCOSE DISPOSAL THROUGH DISTINCT MOLECULAR MECHANISMS.

J. M. Lenhard, M. A. Paulik, K. D. Plunket, S. A. Kliewer, J. M. Lehmann and J. E. Weiel. GlaxoWellcome, Inc., Research Triangle Park, U. S. A..

Troglitazone and metformin are antidiabetic agents that belong to the thiazolidinedione and biguanide classes of drugs, respectively. These agents enhance glucose disposal and insulin sensitivity in both animal models and patients with NIDDM. To determine if these agents act through similar molecular mechanisms we compared their effects in several *in vitro* assays. Both drugs stimulated glucose transport and utilization in C3H10T1/2 cells, a pluripotent mesenchymal stem-cell line capable of differentiating into adipocytes. Troglitazone treatment stimulated glucose incorporation into lipids (*i.e.*, lipogenesis) and β_3-adrenergic receptor-mediated lipolysis but inhibited basal lipolysis and aerobic respiration. In contrast, metformin had no effect on lipogenesis or adrenergic-mediated lipolysis but increased basal lipolysis, β-oxidation of palmitoyl-CoA and aerobic respiration. Metformin was also more efficacious than troglitazone at decreasing the extracellular pH (*i.e.*, increasing acidosis) and increasing lactate accumulation in the medium (*i.e.*, anaerobic respiration). Insulin enhanced the effects of troglitazone, but not metformin, on glucose and lipid metabolism. Moreover, we show that troglitazone, but not metformin, binds and activates the nuclear receptor peroxisome proliferator activated receptor gamma (PPARγ). Taken together, these observations provide evidence that troglitazone and metformin affect distinct molecular pathways involved in carbohydrate and lipid metabolism. In sum, troglitazone had an anabolic effect while metformin had a catabolic effect on C3H10T1/2 cells. It is proposed that the antidiabetic action of troglitazone involves PPARγ-mediated transcription of genes involved in lipid and carbohydrate metabolism.

THE METABOLIC EFFECTS OF TROGLITAZONE IN NON-INSULIN DEPENDENT DIABETES (NIDDM). Troglitazone Study Group (USA), Yale New Haven, CT, USA.

In a multicenter, double-blind trial, we studied the metabolic effects of 6 months troglitazone (TGZ) in 93 NIDDM patients (age 52±1yr, fasting plasma glucose 11.3±0.3mM, body mass index 33±1kg/m^2) randomized to take either 100, 200, 400 or 600mg of TGZ, or placebo; and assessed with a meal tolerance test and a 5h hyperinsulinemic (120 mU/m^2.min) euglycemic clamp with systemic di-deuterated glucose, before and after treatment. TGZ lowered fasting ($p<0.0001$) and post prandial ($p<0.02$) plasma glucose by ~25% and ~20% respectively at the high treatment doses (400 & 600mg) and lowered fasting ($p<0.02$) and post prandial ($p<0.01$) triglycerides, and fasting free fatty acids but only at the highest treatment dose (600mg, $p<0.02$). There was a lowering of plasma insulin in the higher treatment groups (200-600mg), whereas, c-peptide levels fell across all groups including placebo ($p<0.0001$). Of interest, basal hepatic glucose production was unaffected by TGZ in all treatment groups ($p<0.001$) except with the highest treatment dose (600mg) where basal hepatic glucose production fell. More importantly, TGZ had a most striking effect on insulin-mediated glucose disposal rates; increasing glucose disposal ($p<0.005$) by ~45% above pre-treatment levels in the 400 & 600mg treatment groups. Determining factors that predicted a favorable glucose lowering effect, regression analysis confirmed that the stongest predictor of a glucose lowering effect either fasting ($p<0.0001$) or post prandially ($p<0.02$) was treatment with TGZ itself. Controlling for TGZ effect, fasting c-peptide level was the next strongest predictor. To conclude, TGZ has powerful glucose lowering effects in fasting and post prandial states in NIDDM, especially in patients with good insulin secretory reserve; this effect is mediated by enhancing insulin-mediated glucose disposal in peripheral tissues.

ARE ATTRIBUTABLE RISK ESTIMATES IMPORTANT FOR IDDM PREVENTION?

J.S. Dorman and the WHO DiaMond Molecular Epidemiology Sub-Project Group, University of Pittsburgh, Pittsburgh, PA, USA

The WHO DiaMond Molecular Epidemiology Sub-Project, which is based on standardized IDDM incidence registries, is determining the contribution of host susceptibility to the occurrence of disease within and between populations from across the world. Using a case-control design, data from Japan, China, Mexico, USA (PA and AL), New Zealand and Finland have been analyzed to estimate absolute and attributable IDDM risks. This information is important not only for understanding the epidemiologic patterns of IDDM, but also for developing strategies for the prediction and prevention of the disease. Such approaches have typically been targeted towards first degree relatives, known to be at high genetic risk. However, most individuals who develop IDDM have no other affected family members. Thus, the definition of 'susceptible' individuals in the general population remains a complex and controversial issue that may be addressed, in part, by the DiaMond Molecular Epidemiology Sub-Project. For each racial group in these seven population, IDDM susceptibility was uniquely defined by the specific HLA-DQ genotypes that were significantly more prevalent among the cases than controls. Although it was consistently observed that individuals with two high risk genotypes were most likely to develop IDDM in all populations (1-33% through age 35 years), only 26-55% of the incidence of the disease in any of the areas could be accounted for by these high risk genotypes. One can, therefore, conclude that natural history studies and clinical trials, which are based upon the enrollment of only high risk individuals, identified by similar genetic screens, represent less than ½ of future incident cases. Therefore, even if other markers, such as autoantibodies, were subsequently utilized to improve predictive value, more than 50% of the individuals who will develop IDDM would be missed with strategies targeted towards those who screen at high genetic risk. Thus, attributable risk estimates provide important information that should be utilized, in conjunction with relative and absolute IDDM risk estimates, for the development of clinical and public health practices targeted towards the prediction or prevention of IDDM in populations from across the world.

180

CONCORDANCE FOR IDDM IN IDENTICAL TWINS IS AFFECTED BY THE 'LOAD' OF BOTH MHC AND NON-MHC SUSCEPTIBILITY GENES.

K. Metcalfe[a], G. Hitman[a], R. Rowe[a], M. Hawa[a], T. Stewart[b], R.D.G. Leslie[a]
[a] *St Bartholomew's and The Royal London School of Medicine and Dentistry.*
[b] *Genentech, USA.*

The environmental component of susceptibility to IDDM is reflected in the discordance for disease found in monozygotic twins. Twin studies have also provided valuable evidence for the genetic contribution to disease and might also help elucidate the potential importance of markers for IDDM in individuals who are 'genetically susceptible' to disease. We have examined the hypothesis that discordance in identical twins might also reflect a decreased load of diabetes predisposing genes in discordant compared to concordant twins. We studied 40 discordant and 40 concordant identical twins at 2 polymorphisms of the insulin gene region on chromosome 11p (INS) : the 3' untranslated region 1,127 Pst 1 and the 5' -23 Hph 1 restriction sites. Of the concordant twins 87.5% possessed the disease associated INS genotype at both polymorphisms; of the discordant twins it was only 60% at the 5' and 68% at the 3' polymorphisms (for Hph 1: $p=0.005$, RR=4.67; for Pst 1: $p=0.036$, RR=3.37). The stronger association with the 5' Hph 1 locus is consistent with reports implicating a functional effect of the VNTR in disease susceptibility. INS thus appears to have an effect on disease concordance. We also studied these twins at HLA-DQB1 and found a higher frequency of the disease associated 0302 allele in the concordant than in the discordant twins (67.5 v 42.5%; $p=0.027$, RR=2.8). The higher frequency of DQB1 0201/0302 heterozygosity in the concordant twins (50 v 30%) did not, however, reach statistical significance. Our results suggest that the 'load' of both MHC and non-MHC susceptibilty genes has an impact on the disease penetrance of IDDM.

181

ROLE OF DQA1*0102/DQB1*0602 IN RISK CHARACTERIZATION: THE DIABETES PREVENTION TRIAL-TYPE 1 DIABETES (DPT-1).

G.S. Eisenbarth, J. Krischer, C. Greenbaum, D. Schatz, J. Skyler, for the DPT-1 Study Group, Nationwide, USA.

The aim of the study was to determine the role of DQA1*0102, DQB1*0602 (0602+) in risk characterization in relatives of patients with type 1 diabetes. This haplotype was previously found "protective" for type 1 diabetes, and is an exclusion criteria for DPT-1. Of >40,000 relatives screened, 3.44% are ICA positive (≥ 10 JDF U). Of 909 ICA+ relatives DQ typed, 62 (6.8%) were 0602+. Of 250 subjects with low first phase insulin response (FPIR) to IVGTT, 8 (3.2%) were 0602+, in comparison to 54 of 659 (8.2%) with FPIR that was not low ($p<0.001$). This suggests that the protective 0602+ haplotype may also be associated with lack of progression to low FPIR. We also analyzed expression of insulin (IAA), GAD65 (GAA), and ICA512bdc (ICA512AA) "biochemical" autoantibodies (AAs) for the first 52 ICA+ relatives with 0602+, and compared the results to analysis of a randomly chosen 52 similar relatives lacking 0602. Of the subjects studied in depth, 34% percent of the 0602+ relatives were ICA- (<10 JDF U) upon repeat ICA testing, as compared to 17% of 0602- relatives. The second DQ "haplotype" was either 0501/0201 or 0301/0302 in 81% of the confirmed ICA+ relatives with 0602+ in comparison to only 35% of relatives with 0602 but with negative repeat ICA. The remainder of analyses were done only on relatives with confirmed ICA positivity. Expression of biochemical AAs was greater amongst 0602- than 0602+ relatives (e.g. 60% of 0602+ relatives versus 21% of 0602- relatives expressed none of the "biochemical" AAs, $p<.001$).

	GAA	IAA	ICA512AA	0Ab	≥2Ab	3Ab
0602+	23%	23%	13%	60%	20%	6%
0602-	61%	59%	50%	21%	57%	30%

Amongst ICA+ first degree relatives of patients with type 1 diabetes, DQB1*0602 appears to dramatically "delay" rather than permanently suppress the expression of IAA, GAA, and ICA512AA.

NON-Asp 57 RESIDUES IN THE HLA-DQB1 GENE CONTROL SUSCEPTIBILITY TO IDDM IN INDIA.

N.Tandon, R.Rajalingam*, N.K.Mehra*. Departments of Endocrinology and Histocompatibility & Immunogenetics*, All India Institute of Medical Sciences, New Delhi-110 029, India.

Strong association of HLA-DR3/DR4 has been reported in IDDM patients around the world. Using PCR-SSOP, we have studied the polymorphism of HLA-DRB1, DQA1 and DQB1 genes in 38 patients with IDDM and 154 unrelated healthy controls from the homogeneous population of North Indian Hindus. A strong association of DRB1*03012 encoding HLA-DR3 was observed in IDDM as compared to controls (60.5% vs 8.4%, Pc<0.000000001, RR=16.6). HLA-DR4 did not reveal any deviation from controls in these patients. On the other hand, DR2 molecules showed a significant negative association (13.2% vs 40.3%, Pc<0.01, RR=0.2) in patients which is consistent with earlier studies. All HLA-DR2 positive IDDM patients were found to be DRB1*1502-DQA1*0103-DQB1*0601 which is the most common DR2 haplotype in Asian Indians (30%). Among DQA1 alleles DQA1*0501 occurred more frequently in diabetics as compared to controls (73.3% vs 40.3%, Pc<0.001, RR=4.1). Of the 4 DQA1 alleles that carry Arg 52 (0301, 0501, 0401, 0601), two i.e., 0301, 0501 were found to occur in 80% of IDDM patients as compared to controls (55.2%, Pc<0.05, RR=3.2). Similarly, non-Asp 57 carrying DQB1 alleles particularly, DQB1*0201 were found to be significantly increased in patients as compared to controls (78% vs 36%, Pc<0.000001, RR=6.5). Upto 95% of IDDM patients in this study had non Asp 57 residues in their DQ beta molecules (DQB1*0201, 0302, 0501, 0604, 0102) as compared to controls (55.2%, X^2=19.8, Pc<0.00001) thus giving a very high relative risk of 14.2. Further, a strong linkage disequilibrium was observed between DRB1*03012-DQA1*0501-DQB1*0201 in all patients and controls. The study indicates that i) IDDM in Asian Indians is primarily associated with HLA-DR3 and not DR4, ii) that the primary susceptibility genes lies in the DQ region represented by DQB1*0201 in strong linkage disequilibrium with DRB1*03012 and other non-Asp 57 containing alleles.

EVIDENCE FOR ASSOCIATION OF SHORTER CLASS 1 ALLELES OF INSULIN GENE 5′ MINISATELLITE WITH IDDM IN JAPAN

T. Awata[1], C. Kikuchi[1], S. Kurihara[1], S. Katayama[1], Y. Kanazawa[2] and R. Hagura[3]. Saitama Medical School, Saitama, Japan[1], Omiya Medical Center, Saitama, Japan[2] and Asahi Life Foundation, Tokyo, Japan[3].

The role of the insulin gene-linked IDDM susceptibility (*IDDM2*) still remains unclear in Japanese: majority (~95%) of Japanese are homozygous for class 1 alleles of the variable number of tandem repeat (VNTR) in the 5′ region of the insulin gene. Therefore, we determined their exact length in number of repeat units (RUs) of class 1 alleles by PCR amplification of the VNTR of 152 IDDM patients and 167 control subjects in Japan. We found that the distribution of class 1 alleles in Japanese was bimodal with one peak located at 32/33 RUs and the other peak located at 41 RUs, and that 1S (25~38 RUs) alleles were significantly increased in the IDDM group compared with the control group (0.55 vs 0.46, p=0.032). The 1S/1S genotype was significantly increased in the patients (0.34 vs 0.20, p=0.005, RR2.1). Transmission disequilibrium test (TDT) of 21 Japanese families confirmed the association of 1S alleles with IDDM: 18 1S alleles and 7 1L (39~44 RUs) alleles were transmitted to affected offspring (p=0.028) while 1S and 1L allele transmission to non-affected offspring were 6 and 6. The present study suggests that shorter class 1 alleles may have a role in IDDM susceptibility in Japan. Because difference between 1S and 1L alleles is characterized by element sequence variations as well as repeat numbers, we prefer a possibility that sequence variations of class 1 alleles influence the disease susceptibility.

HLA-DQB1^{57} BUT NOT *HLA-DQA1*^{52} ALTERATION IS ASSOCIATED WITH THE DISEASE IN POLISH IDDM FAMILIES

H.W.Witas, M.Różalski, K.Jędrychowska-Dańska, W.Młynarski and J.Bodalski
Molecular Biology Unit, 2nd Clinic of Children Diseases, Institute of Pediatrics, Medical University of Lodz, Lodz, Poland

Allele-specific amplification PCR method (*ASA-PCR*) allows to follow codon polymorphism at *HLA-DQA1*^{52} and *HLA-DQB1*^{57} thus giving a possibility of expressed amino acid identification. Frequency analysis of codon variants was performed in IDDM children (n=97) and control subjects (n=78) of Polish origin. 45 IDDM children, their parents (n=65) and healthy siblings (n=17) were also analyzed. Obtained results revealed aliphatic and hydrophobic amino acid residues (phenotypes: Val/Ala and Ala/Ala) to be present at significantly higher frequency at DQβ^{57} in IDDM children (63%) compared to control subjects (17%; RR=8,472) Values for parents and siblings were established at the level of 38% and 29%, respectively. Heterozygous Asp was present in 28% IDDM patients v. 47% control subjects (RR=0.784); in parents and siblings percentage did not exceed 58% and 65%, respectively. Homozygous Asp *was not found* in IDDM children while present in 28% of controls (RR=0.014). Only one parent and one sibling (1.5% and 6%, respectively) exhibited it. This suggests its enhanced protective effect. Simultaneous typing of both studied codons revealed that DQα^{Arg52+}/DQβ^{Asp57-} accompany IDDM phenotype at much higher frequency (64%) than the physiological one (20,5%), RR=6.86; respective values for parents and siblings are 38% and 29%, respectively. The correlation between IDDM and number of susceptible dimers DQα^{Arg52+}/DQβ^{Asp57-} one individual can assemble has been observed in dose respective manner. The highest relative risk (RR=4.87) was obtained for individuals who can express IV (100%) those dimers. *Amino acid residue at DQα*^{52} *concerned alone was of no importance in respect to IDDM.* The crucial role of DQβ^{57Asp} in respect to the disease was confirmed in second approach. 16 families with at least one affected and one non-affected child were selected from the set of subjects and subsequently analyzed. DQβ^{57Asp} was present in 12/17 (71%) healthy siblings, 16/31 (52%) parents, and only in 5/17 (29%) IDDM children.

INSULIN GENE 5' VNTR POLYMORPHISM IN BASQUE TYPE I DIABETICS

L. Castaño, I. Urrutia, JR Bilbao, B Calvo and GEPVN group*, Hospital de Cruces, Barakaldo, Spain

Genetic analysis have shown association between several polymorphic genomic regions and susceptibility or protection to type I diabetes (IDDM). In addition to *IDDM1* (HLA class II region on chromosome 6p), a polymorphic region spanning 4.1 kb around the insulin gene on chromosome 11p (*IDDM2*) has been strongly related to the disease. Basques are a population living in the W-Pyrenees (SW France and N Spain), that has been isolated in the past. Anthropological studies have pointed out allelic frequency differences in polymorphic genes in Basques. Our aim was to characterize *IDDM2* among Basque families with IDDM. We studied 62 families of Basque ethnic origin, including 71 diabetic patients and 203 first-degree relatives, as well as 42 healthy and unrelated controls. For genetic analysis we studied the Variable Number of Tandem Repeats (VNTR) region 5' to the insulin gene using Southern blot hybridization of *Pvu* II digested genomic DNA with radiolabelled Phins 310 probe. Restriction fragments were classified according to size in class 1 (<600bp), class 2 (600-1600bp), and class 3 alleles (>1600 bp). Linkage analysis were performed with TDT (Transmission Disequilibrium Test). Comparison of the allelic frequencies between diabetic and non-diabetic alleles, using affected family based control alleles, and of the genotypic frequencies between diabetics and healthy controls are:

ALLELES	class 1	class 3
IDDM (n= 126)	84.1%	15.9%
Non-IDDM (n=110)	59.1%	40.9%

p= 0.000017

GENOTYPES	1/1	1/3	3/3
IDDM (n= 62)	71.0%	27.4%	1.6%
Controls (n= 45)	31.1%	51.1%	17.8%

p= 0.000054

Relative risks (RR) for each genotype were 5.41 for 1/1, 0.36 for 1/3 and 0.08 for 3/3. TDT analysis performed on heterozygous parents showed linkage of the VNTR region to diabetes susceptibility: 35 transmissions of class 1 *vs.* 9 of class 3 (p= 0.000089). There was no difference of allelic transmission between heterozygous mothers and fathers (p= n.s.). In conclusion, the VNTR region is linked to type I diabetes in Basques, and class 1 allele is associated with the disease. No evidence of imprinting has been observed.

THE EFFECT OF HLA-B ALLELE ON THE IDDM RISK DEFINED BY DRB1*04 SUBTYPES AND DQB1*0302

S. Nejentsev[1,2], H. Reijonen[1], B. Adojaan[3], L. Kovalchuk[4], A. Sochnevs[4], V. Vasina[2], E. Schwartz[2], HK. Akerblom[5] and J. Ilonen[1]
1-Turku Immunology Centre and Department of Virology, University of Turku, Turku, Finland; 2-Department of Medical Genetics, Pediatric Medical Academy, St.Petersburg, Russia; 3-Department of Endocrinology, Tartu University Hospital, Tartu, Estonia; 4-Laboratory of Immunogenetics and Immunology, Latvian Medical Academy, Riga, Latvia; 5-Children's Hospital, University of Helsinki, Helsinki, Finland

In this study we analyzed at the population level the effect of DR4 subtypes and class I, HLA-B alleles, on the IDDM risk when the influence of DQ locus was equalized. The genes encoding HLA-DQ heterodimer molecules, DQB1 and DQA1, have been found to have the strongest association with IDDM risk, although there is cumulative evidence for the effect of other gene loci within MHC gene region. HLA-DR locus besides HLA-DQ has most often been suggested to contribute to the disease susceptibility. In our research DRB1*0401 and DRB1*0404 were the common subtypes associated with DQB1*0302 in all three studied populations (Estonian, Latvian, Russian). DRB1*0401 was increased and *0404 decreased among IDDM patients. DRB1*0402 was also relatively common among Russian haplotypes, but was not associated with IDDM risk. When HLA-B alleles were analyzed, strong association between the presence of specific B alleles and DRB1*04 subtypes were detected. HLA-B*39 allele was found significantly more often in DRB1*0404-DQB1*0302 positive patients than healthy control subjects positive for this haplotype: 27/54 (50%) vs. 4/49 (8.2%), P<0.0001 in the combined series. The result demonstrates that DQ and DR genes cannot explain all of the HLA-linked susceptibility to IDDM and the existence of a susceptibility locus telomeric to DR is probable.

188

IDDM2 ALLELE EFFECTS ON *IGF2* mRNA LEVELS IN THE MAJOR TISSUES IMPLICATED IN TYPE I DIABETES AUTOIMMUNITY.

P. Vafiadis, R. Grabs, C. Polychronakos. McGill University, Montréal, Canada.

It has been shown that a polymorphism consisting of a variable number of tandem repeats, situated 5' to the insulin gene (*INS*-VNTR), is associated with type I diabetes (*IDDM2* locus). The shorter alleles (class I) predispose to diabetes, while the longer ones (class III) have a dominant protective effect. Since the VNTR is not transcribed, its contribution to *IDDM* susceptibility must be mediated by transcriptional effects on adjacent genes. We have presented evidence of strong VNTR allele effects on thymic (but not pancreatic) insulin expression, that may explain the effect on diabetes risk. In addition to --or even instead of-- effects on insulin, diabetes risk could be modulated by transcriptional effects on *IGF2*, the closely linked gene encoding insulin-like growth factor II. This gene is parentally imprinted, with exclusive expression from the paternal allele in most tissues, including pancreas and thymus. Parental effects have been described in the transmission of *IDDM2* alleles to diabetic offspring. We therefore, analyzed the effect of VNTR alleles on mRNA level in samples of human pancreas, thymus and leukocytes by quantitative-competitive-RT-PCR. *IGF2* mRNA level was 4.7 ±0.9 (mean ± SEM, arbitrary units) in thymi with a paternal class III *INS-VNTR* compared with 4.7 ± 1.3 in samples with a paternal class I. The same absence of a significant difference was found in pancreas: 28.4 ±4.2 vs. 29.5 ±5.2. We also examined control of *IGF2* expression in leukocytes where, as we have previously reported, *IGF2* imprinting is variably relaxed. A transcribed *ApaI* polymorphism was used to distinguish paternal from maternal alleles in heterozygous individuals. The (+) allele of this polymorphism was found to be associated with higher *IGF2* mRNA levels, when parental origin was taken into account. However, VNTR class had no effect on *IGF2* mRNA levels, as the paternal/maternal ratios were not significantly different between subjects with a maternal class I and a paternal class III vs. maternal class III and paternal class I (4.2±1.5 vs. 3.1 ±1.3). Thus, we found no VNTR effects on *IGF2* mRNA levels in three tissues relevant to diabetes autoimmunity. This corroborates our previous report suggesting that the gene involved in *IDDM2* is insulin.

189

HLA ASSOCIATED GENETIC SUSCEPTIBILITY TO IDDM IN ORIENTAL AND CAUCASOID ETHNIC GROUPS IN RUSSIA

A.Zilov*, L.Alexeev, M.Boldyreva, D.Trofimov, I.Demidova*, I.Dedov* (Institute of Immunology, *-Dept. of Endocrinology MMA, Moscow, Russia).

A comparative study, using SSP method, on the association between HLA alleles and genotypes of the HLA DQ locus and IDDM susceptibility was conducted on two ethnic groups - Russians (Caucasoids) and Buriats (Orients). This choice is due to the fact that IDDM morbidity in Buriats is tenfold low as compared to Russians at the same region. Eight of HLA DQA1 and fourteen DQB1 specificities were discriminated. The genotyping had undergone quality control in term of the XII IHWC "HLA and IDDM" component. Among Russians the most frequent associations to IDDM are DQA1-0301 (RR=4,21), -0501 (RR=2,90),-0301 (RR=0,01) alleles and the genotype DQA1 0501/0301 (RR=9,13). In HLA DQB1 gene IDDM associated are HLA DQB1-0302 (RR=6,38), - 0602 (RR=0,42) and DQB1-0302/0201 (RR=9,60). The following genotypes were found to be IDDM associated: DQA1-0301/DQB1-0302 (RR=4,2), DQA1-0501/DQB1-0302 (RR=8,4) and DQA1-0103/DQB1-0201 (RR=0,03). In IDDM Buriat patients the associations with some "classical" HLA DQA1 and DQB1 "alleles-markers" we revealed which are typical for both Oriental and Caucasian populations. So alleles DQA1-0301 and DQB1-0302 were determined IDDM "markers" in spite of their extremely high frequency (cca. 25% for DQA1-0301) in healthy controls. On the other hand in IDDM Buriat patients the allele markers are typical for the subjects of Oriental origin and include HLA DQB1-0303 as IDDM "marker" and DQB1-0601 as the desease resistance "marker" were found. The most important conclusion of present observations is the total absence of the genotype HLA DQA1-0103/DQB1-0201 in healthy Buriat controls whereas that one is most frequently detected in Buriat IDDM patients (13,75% at RR=35,75%).

190

INTERLEUKIN-1 RECEPTOR TYPE 1 GENE POLYMORPHISM IN SPANISH SUBJECTS AFFECTED WITH IDDM

E.Mato, M.Puig-Domingo, J.Morales, Mª A. Ortiz, L.Gallart, D.Mauricio, F.Pociot*, J.Nerup* and A. de Leiva.
S.Endocrinologia, H. de Sant Pau, Barcelona,Spain and Steno Diabetes Center, Copenhagen, Denmark.

A diallelic polymorphism of the interleukin-1 receptor type 1 (IL1R1) gene has been differentially associated to IDDM according to the racial origin of the populations studied. A positive association has been found in British diabetics while not in Finnish and South Indians. We have studied the polymorphism of the 5'untranslated promoter region of the IL1R1 gene by using PCR-RFLP assay in the intermediate risk Spanish population. Analysis of samples from 100 type 1 diabetic subjects and 130 controls showed the following allelic distribution using sthe nomenclature from Southern analysis: 1.2kb/1.2kb 44% in diabetics and 40% in controls, 1.2kb/3.2kb 45% and 49% in diabetics and controls respectively, and 11% in both for 3.2kb/3.2kb (X^2=ns). Neither association was found when diabetic subjects were selected according to the presence or abscense of a high risk haplotype (DQA1*0301-B1*0302 and/or DQA1*0501-B1*0201). In conclusion, these results suggest that the polymorphism of the IL1R1 gene is not a valuable genetic risk factor for IDDM in Spanish subjects. **FISS 95/1065**

191

ANALYSIS OF HLA-DRB1,-DQA1 AND -DQB1 GENOTYPE OF KOREAN IDDM PATIENTS

H.S. Son, M.I. Kang, J.M. Lee, S.J. Yoo, K.H. Yoon, B.Y. Cha, K.W. Lee, H.Y. Son and S.K. Kang. Catholic University Medical College, Seoul, Korea

To evaluate the association of IDDM and HLA class II genes in Korea, we compared allelic constitutions at HLA-DRB1, -DQA1, -DQB1 loci of IDDM patients with that of ethnically matched nondiabetic individuals by PCR-based reverse dot hybridization method. In IDDM patients, the frequency of DRB1 *03, *04 (RR=5.4;2.3) and DQA1 *03, *05 (RR=3.5;2.3) was significantly high and that of DQA1 *01 (RR=0.3) and DQB1 *06 (RR=0.4) was significantly low. Three haplotypes HLA-DRB1 *03 - DQA1 *05 - (DQB1 *02), HLA-DRB1 *04 - DQA1 *03 - (DQB1 *04) and (HLA-DRB1 *13) - DQA *01 - DQB1 *06 were in the state of linkage disequilibrium in IDDM. Of these three haplotypes, two (DRB1 *03-DQA1*05-DQB1*02 and DRB1*04-DQA1*03-DQB1*04) appear to be susceptible haplotypes, whereas the third (DQB1*13-DQA1*01-DQB1*06) appears to be protective haplotype. These findings suggest that DRB1*03-DQA1*05-DQB1*02 and DRB1*04-DQA1*03-DQB1*04 can be markers of IDDM in Korea.

HLA DQA1 AND DQB1 ALLELES IN IDDM PATIENTS OF AN ARGENTINIAN CAUCASIAN POPULATION.

MULTICENTER TRIAL: PREDI-C-DIAB:
L.Litwak, M. Herrera, V.Bernarth, A.Alvarez, A.Cayssials, A.Doval, M.Ferraro, L.Grosembacher,M.Migliano, M.Pando, R.Papassian, G.Perichon, H.Raizman, O.Ramos, J.Surpik,M.Tarruela,M.Tonietti, L.Trifone,M.Vacarezza, L.Satz. Laboratory of Molecular Biology of the Laboratorio de Medicina and Service of Inmunogenetic of the Hospital de Clinicas. Services of Endocrinology and/or Nutrition of the: Hospital Italiano, Hospital Posadas, Hospital Gutierrez and Hospital P.Eleizalde, Buenos Aires, Argentina.

The frequency of HLA class II alleles was analzyed in a population of 118 IDDM Argentinian patients and compared to that of 198 controls. Patients and controls belonged to an homogeneous Caucasian individuals with Spanish and/or Italian ancestry. Class II alleles were determined by DNA typing using primers and probes of the 12th International Histocompatibility Workshop. Results: 86.3% of the patients and 19.4% of the controls were homozygous for non-Asp_{57} - DQB1 alleles (odds ratio, OR: 26.2, X^2: 64.3, $p<10^{-5}$). To investigate the contribution of HLA-DQA1 to the susceptibility in this population, DQA1 alleles were determined in 64 patients and 180 controls: 43% of the patients and 1.7% of the controls were homozygous for non-Asp_{57} - DQB1/Arg_{52} -DQA1 susceptible alleles (OR: 38.9, X^2: 38.1, $p<10^{-6}$). On the other hand, DQB1*0602 was significantly decreased among patients (0,85% vs. 18,7% in controls, OR: 0.04, X^2:20.6, $p<10^{-5}$). These results confirm for this population the primary association of IDDM with DQA1 and DQB1 alleles. In addition DQB1* 0602 seems to be a protective allele also in our population.

194

A *CTLA4* POLYMORPHISM AFFECTS LYMPHOCYTE mRNA LEVELS BUT IS NOT ASSOCIATED WITH TYPE 1 DIABETES IN A CANADIAN DATASET.

R. Barnes, R. Grabs and C. Polychronakos, McGill University, Montreal, Canada.

The susceptibility locus *IDDM12*, mapped to 2q33, is linked to and associated with type 1 diabetes (IDDM) in Italian families. Association was confirmed in a Spanish dataset and, although it did not reach statistical significance in US and UK datasets, it was highly significant in combined data from all sources. The marker is an A/G polymorphism at nucleotide 49 of the coding sequence (threonine/alanine in the leader peptide) of *CTLA4*, a gene encoding a membrane receptor that mediates apoptosis in activated T lymphocytes. We sought to confirm the association in a group of diabetic children from Montréal. A PCR-based *Fnu4HI* RFLP was used to compare the frequency of the G allele in 128 IDDM patients to the control frequency in the two parental chromosomes not transmitted to the child. There were 161 A alleles transmitted (tr), vs 153 not tr and 95 G alleles tr vs. 103 not tr. This lack of association in our population may be due to different linkage disequilibrium of A/G with the susceptibility locus. Alternatively, if A/G is the true susceptibility locus, the population differences may be due to interactions with other loci. As a first step in examining possible differential biologic function of the A vs. G alleles, we measured relative, allele-specific *CTLA4* mRNA levels in human peripheral mononuclear cells (PBLC) from five A/G heterozygous diabetic subjects. The G/A allele intensity ratio in the internally radiolabeled RT-PCR product, measured in triplicate, was compared to the same ratio in genomic DNA, where both alleles are present in equal concentrations. The genomic DNA ratio was 0.419±0.024 (mean±SEM.) as expected by the smaller size of the digested G allele. The ratio was higher in RNA from both unstimulated (0.709±0.064, p=.002) and stimulated (0.568±0.022, p=.003) lymphocytes (paired *t*-test). This indicates a higher level of the G allele in *CTLA4* mRNA, which can be due an increase in either transcription level or mRNA stability. It provides a plausible mechanism of susceptibility to diabetes and other autoimmune disease, such as Grave's. The lack of association in our population may be due to population differences at other loci.

195

IS THERE A METABOLIC, GENETIC OR IMMUNOLOGICAL CONNECTION BETWEEN IDDM AND NIDDM IN SOUTH INDIAN FAMILIES

Ramachandran A[1], Snehalatha C[1], Sanjeevi C.B[2], Tuomilehto-Wolf E[3], Vidgren G[4], Ogunkolade W[4], Hitman GA[4].

[1]Diabetes Research Centre, Madras, India.[2] Karolinska Institute, Sweden.[3] National Public Health Institute, Helsinke, Finland. [4]The Royal London School of Medicine, London, UK.

We studied 170 south indian families consisting of parents and a proband with IDDM (Type 1) to investigate whether there would be an increase in prevalence of NIDDM in the parents and the relationship of glucose tolerance with either HLA-DQ or GAD65 antibodies (GADA). Among the parents 11.2% had NIDDM and 13.6% had IGT on oral GTT and this was similar to that in age matched population of South India. DNA samples were typed for allelic variation at HLA-DQB1 in the families and studied using the transmission disequilibrium test. Both HLA-DQB1 *0201 (p=0.0003) and DQB1 *0302 (p=0.002) were associated with IDDM. There was no correlation of *0201 or *0302 with glucose tolerance in the parents excluding a genetic link between NIDDM and IDDM in these families. GADA were measured by a radiobinding assay. GADA was positive in 56.5% of the probands against 7% of control (p<0.0001) and in 33% of the parents. There was no correlation of GADA with glucose tolerance in parents. In conclusion,in South Indian families with an IDDM proband, there is no overlap between IDDM and NIDDM. The high rates of GADA in the parents are yet to be explained.

NO LINKAGE OF THE *CTLA-4* GENE REGION (*IDDM12*) TO TYPE 1 DIABETES IN THE DANISH POPULATION

Z.M. Larsen, O.P. Kristiansen, J. Johannesen, J. Nerup, F. Pociot, DSGD and DIEGG. Steno Diabetes Center, Gentofte, Denmark

Insulin-dependent diabetes mellitus (IDDM) is a multifactorial disease with polygenic susceptibility. Results from genome-wide screenings and partial ones have presented some evidence of linkage with several non-HLA linked loci. Recently, *IDDM12* was mapped to chromosome 2q making this chromosomal region particularly abundant of IDDM-linkage markers. *CTLA-4* is the candidate gene for *IDDM12*. We have analysed this locus in Danish IDDM family materials. Initially, we typed 152 families (688 individuals) with at least 2 IDDM affected siblings for the $(AT)_n$ microsatellite in the 3'untranslated region of the *CTLA-4* gene. An extended transmission disequilibrium test (TDT) for multi-allele marker loci was used to assess transmission from heterozygous parents to offspring. No evidence for neither allele-wise or genotype-wise transmission disequilibrium was found (p=0.6 and p=0.2, respectively). However, a distorted transmission of the $(AT)_{17}$ -allele was observed; p=0.007 (uncorrected). A point mutation in exon 1 of the *CTLA-4* gene (A→G transition) was analysed as well. Previously this polymorphism has revealed transmission disequilibrium in Italian and Spanish populations, but not in UK and US populations. In this analysis, the 152 sib-pair families and additionally 105 families (429 individuals) with only one IDDM affected offspring were included. Although a tendency towards a skewed transmission: 145 'A' passed and 166 'G' passed to IDDM offspring and 96 'A' and 88 'G' passed to unaffected offspring, this did not reach statistical significance (p=0.2 for IDDM offspring). In conclusion, we were not able to replicate the observation of linkage of the *IDDM12* locus to disease in a large Danish IDDM family data set. If the *CTLA-4* gene is important for conferring susceptibility to IDDM, the present data combined with previous data from UK and US, indicate that the A→G transition is unlikely to be the aetiological mutation.

GENETIC AND ENVIRONMENTAL FACTORS IN TYPE I (INSULIN-DEPENDENT) DIABETES MELLITUS IN CHILEAN CHILDREN.

Pérez-Bravo F (1), Santos JL (1), Calvillán M (2), Carrasco E. (2).

(1) Molecular Biology and Epidemiology Department. Nutrition and Food Technology Institute (INTA), University of Chile. (2) Faculty of Medicine, Diabetes Unit, Hosp. SJ. de Dios. University of Chile. Santiago, Chile.

HLA class II alleles play an important role in the genetic susceptibility to develop insulin-dependent diabetes mellitus (IDDM). Some environmental factors such as viruses prevalence and breast-feeding duration have been associated with the disease. Our objective was to clarify what heterodimers account for the higher risk of IDDM, and assess their interaction with the breast feeding duration (BFD). 63 IDDM children and 74 non diabetic children were recruited for this study. Alleles determinations were performed by means of PCR with oligospecific probes, while BFD and prevalence of infectious diseases were ascertained by retrospective survey. In diabetic patients, we found a significant different frequency of risk heterodimers (H4) regard to non diabetic children (0.59 vs 0.19, p<0.0001) with an OR=13.7 (IC 95%: 4.4-42.7) respect to the H0 group that serves as the reference category. H0 was more frequent between controls children (0.35 vs 0.08, p<0.01). In relation of the environmental factors, both groups had a similar prevalence for rubella, measles and mumps. For the BFD, the IDDM group showed a reduced average of effective breast feeding compared with the control group (21.5±15 vs 33.8± 20 weeks, p<0.01) and a early exposure to cow milk (15.9± 12 vs 21± 13, weeks, p<0.05). When stratifying by BFD, we observed a high OR for H4 respect to H0 in the group of children with breast-feeding < 3 months (OR 20.25, p<0.0001). For BFD > 3 months, the OR comparing H4 with H0 was 14 (IC 95%: 1.5 - 128). In conclusion, the H4 combinations is strongly associated with high risk for IDDM, and the long period of BFD could be very important as protector factor in the low incidence of IDDM in Chilean children.

ASSOCIATION OF CTLA-4 GENE POLYMORPHISM WITH AUTOIMMUNE THYROID DISEASE BUT NOT WITH IDDM IN JAPAN

S. Kurihara[1], T. Awata[1], S. Katayama[1], Y. Kanazawa[2] and R. Hagura[3]. Saitama Medical School, Saitama, Japan[1], Omiya Medical Center, Saitama, Japan[2] and Asahi Life Foundation, Tokyo, Japan[3].

CTLA-4 (cytotoxic T lymphocyte associated-4) gene on chromosome 2q33 (*IDDM12*) is a good candidate for autoimmune disease. Recently, associations of CTLA-4 gene polymorphisms with Graves' disease and IDDM were reported in Caucasian populations. Therefore, in this study, we determined an A/G polymorphism in exon 1 of CTLA-4 gene in Japanese patients with IDDM (n=97), autoimmune thyroid disease (AITD; Graves' or Hashimoto's disease)(n=142) or both(n=23). Allele frequencies of the G allele, which was increased in Caucasian patients with Graves' disease and IDDM, were 0.67 in the IDDM group, 0.71 in the AITD group (0.70 in Graves, 0.73 in Hashimoto) and 0.65 in the IDDM+AITD group. Compared with the control group, in which the frequency was 0.63, significant increase of the G allele was only observed in the AITD group (p=0.031). The G/G genotype was significantly increased in the AITD group (p=0.017, RR 1.7). Although further confirmation is required, the CTLA-4 gene region may have a susceptibility role in AITD but not in IDDM in Japan.

DNA ANALYSIS OF HLA CLASS II GENES IN INDONESIAN IDDM PATIENTS

***Judajana FM*[1], Askandar Tjokroprawiro[1], Suhartati IS[1], Netty EP[1], DeVries R[2], Verduyn W[2], Schipper. R.[2], Claas FHJ[2].**

[1] Diabetes & Nutrition Center Medical School, Airlangga University, Surabaya, Indonesia

[2] Dept of Immunohematology, Hospital Univ. of Leiden, Netherlands

The incidence of Diabetes Mellitus in Indonesia is obviously increasing every year, this is due in part to the following factor effect of different gene system, race, sex and patient age at the time of onset. The aim of this study was to determine the distribution of HLA Class II polymorpnism based on molecular investigation in Indonesia IDDM patients. Although, serological studies have investigated the association of HLA DR-3 and DR-9 antigen with the predisposition to IDDM, furthermore HLA DR-5 has been associated with a protection from IDDM.

In this study HLA class II alleles (DRB, DQA and DQB) were determined by PCR-SSO method in 64 unrelated IDDM patients, and 82 unrelated healthy controls. All samples originated from Java and Bali island. The results were observed in particular, a predisposing effect of the HLA DRB1 * 0301 (RR 14.8 p = 0.0014), DQA * 0501 (RR7.5, p = 0.00256), DQB1 * 0201 (RR 11.7, p = 0.000002) DRB3 * 0202 (RR 3.5, p = 0.04). Based on these study, it is shown in Indonesian IDDM patients , that DRB1 * 04 was not associated with a susceptibility to IDDM and HLA DRB1 * 1202, DRB3 * 0301 DQA * 0601, DQB1 * 0301 with a protection from IDDM. Conclusion : the data in Indonesian diabetics together with data on European IDDM patients, suggest agradient of various HLA class II predisposing and spesific protective markers link these populations.

200

CTLA-4 GENE (*IDDM12*) POLYMORPHISM IN JAPANESE PATIENTS WITH IDDM

T. Yanagawa[1)], T. Maruyama[2)], K. Gomi[1)], H. Hirose[3)], S. Nakano[3)], K. Nakamura[3)], H. Maruyama[3)] and T.Saruta[3)]. Nerima General Hospital[1)], Saitama Chuo Hospital[2)], Keio University[3)], Tokyo, Japan.

Susceptibility to IDDM is determined by environmental and genetic factors. The main gene associated with a predisposition to IDDM is HLA and at least 12 other genes-unlinked to HLA contribute to the development of IDDM. Recent studies described linkage and association of IDDM to the CTLA-4 gene (*IDDM12*) in Caucasians. CTLA-4 is a candidate gene for T cell mediated autoimmune diseases because it is a negative regulator of T cell proliferation. As CTLA-4 association with IDDM may be influenced by the racial composition of the population, it is important to study it in other ethnic groups. We investigated the distribution of CTLA-4 gene polymorphism in 59 Japanese patients with IDDM and 59 controls. An A/G transition at position 49 of exon 1 was analyzed by the PCR-RFLP method. There was no significant difference in the distribution of CTLA-4 alleles between patients and controls (χ^2=1.69, P=0.43, 2 d.f.). The present study did not support the association of CTLA-4 gene with IDDM in Japanese, however this negative finding should be confirmed with increased number of subjects.

201

THE FREQUENCY OF HLA-DR4 IS NOT INCREASED IN FAMILIES WITH IDDM MOTHERS AND MALFORMED CHILDREN

P Onkamo, E Tuomilehto-Wolf, J Tuomilehto, J Mills, K Teramo (National Public Health Institute, Helsinki, Finland)

The association between IDDM of the mother and the risk of congenital malformations of her children has been acknowledged for decades. The metabolic control of the IDDM mother is known to have a major effect on the risk. Despite the improvement in metabolic control of pregnant IDDM women achieved this far, the risk of malformations still continues to be 2-3 times higher than the risk of non-diabetic women. This study was undertaken to find out whether HLA, the major genetic contributor to the IDDM susceptibility, also exerts an additional risk for congenital malformations. Twenty families with an IDDM mother having child or children with congenital malformations were PCR-typed for DR and DQ loci. The malformations included different types of both minor and major birth defects. We expected that the strongest diabetogenic alleles, DR4 and DR3 would be more frequent in the case children and/or in their mothers. However, compared with our population-based study of HLA haplotypes of diabetic families, there were no differences between the diabetic malformation case families and the diabetic families with non-malformed offspring. Of the diabetic mothers of the malformed offspring, 15/19 (79 %) were DR4-positive; of the diabetic mothers with the non-malformed offspring 56/74 (76 %) were DR4-positive. Interestingly, 6/16 cases with malformations were DR4-positive, whereas the expected number based on mendelian segregation of DR antigens in the families would be 10. The frequencies of DR4 in the families with malformed offspring were the following: diabetic mothers 0.42, non-diabetic fathers 0.22, malformed offspring 0.28. In conclusion, it seems as if the DR4-antigen is not increased in the children with malformations, nor in the diabetic mothers of the malformed cases.

202

CHROMOSOME 2 MARKERS AND IDDM IN SOUTH INDIAN FAMILIES

W. Ogunkolade, G.A. Hitman, M.F. McDermott, *C. Snehalatha and *A. Ramachandran. The Royal London Hospital, London, United Kingdom and *Diabetes Research Centre, Madras, India.

A number of IDDM chromosomal regions have been assigned to the long arm of chromosome 2 including around the interleukin 1 gene cluster, HOXD8, D2S152 and CTLA4. We have previously investigated a South Indian population and failed to find an association between IDDM and either the insulin gene or the interleukin-1 receptor type gene using a case control study design. The aim of our studies was to investigate 82 IDDM probands and their parents for excess transmission of microsatellites in the regions on chromosome 2 that might harbour IDDM susceptibility genes. DNA was amplified by the polymerase chain reaction and primers for D2S160, D2S410, D2S326, D2S1244, D2S152, D2S72 and D2S206. Microsatellites were run on a polyacrylamide gel using an ABI373 sequencer and alleles sized using GENESCANNER software. The data was analysed using the extended transmission disequilibrium test (TDT). To date we have full data sets for D2S326, D2S1244 and D2S152; the Chi squared for allele wise TDT was 0.58, 0.59 and 0.21 for each of the loci respectively. In conclusion, the current results suggest that an IDDM locus is not located around HOXD8 or D2S152 on chromosome 2 in the South Indians.

203

DOES INSULIN-DEPENDENT DIABETES MELLITUS OCCUR TOGETHER WITH MULTIPLE SCLEROSIS IN FINLAND?

G. Vidgrén, E. Tuomilehto-Wolf, and J. Tuomilehto. Diabetes and Genetic Epidemiology Unit, National Public Health Institute, Helsinki, Finland.

Finland has the highest incidence of diabetes mellitus (IDDM) in the world (40/100 000/year in 1991). The prevalence of multiple sclerosis (MS) is also high in different parts of the country. The genetic susceptibility to both IDDM and MS is conferred by genes in the HLA region on chromosome 6 although by different - mutually exclusive - alleles. Certain DR4,DQ8 haplotypes are specific markers for IDDM whereas DR15(2),DQ6 haplotypes - supposedly "dominant protective" in IDDM - are markers for MS. Our aim was to find out wheather IDDM and MS occur together in Finland and wheather DR17(3),DQ2 haplotypes might play a role in both diseases as suggested by Olerup. IDDM and MS were found to co-segregate in 23 of the 801 families (3%) ascertained in the DiMe Study, a nationwide population-based IDDM study of children under the age of 15 years. Second degree relatives of the DiMe probands were most likely to have MS. In three families the fathers had MS and in one family an IDDM mother had a child with MS. None of these parents transmitted known IDDM susceptibility haplotypes. DR17(3),DQ2 was not observed more frequenty in these Finnish families whereas B18 (or B35),DR1,DQ5 haplotypes were.

204

LINKAGE ANALYSIS OF *IDDM13* IN DANISH IDDM MULTIPLEX FAMILIES

O.P.Kristiansen, Z.M. Larsen, J. Johannesen, T. Mandrup-Poulsen, J. Nerup, F. Pociot, DSGD and DIEGG. Steno Diabetes Center, Gentofte, Denmark

Genetic susceptibility to insulin-dependent diabetes mellitus (IDDM) is polygenic and caused by both HLA and non-HLA loci. Several studies of linkage between non-HLA loci and IDDM have focused on the long arm of chromosome 2. Recently a locus at 2q34 providing some evidence for linkage to IDDM in a mixed population from UK and Australia was described and denominated *IDDM13*. The **aim** of the present study was to investigate if linkage between *IDDM13* (D2S164) and IDDM could be demonstrated in a large Danish IDDM multiplex **material** comprising 149 IDDM sibpair multiplex families with at least 2 IDDM affected siblings per family and a total of 676 individuals. **Genotyping** of the D2S164 microsatellite was performed by PCR followed by PAGE, blotting and visualization utilizing a streptavidine-peroxidase catalysed ECL reaction. **Statistical analysis** was performed using the extended transmission disequilibrium test (ETDT Version 1.1) for multi-allele marker loci. Borderline evidence for allele-wise transmission disequilibrium to affected offspring was found (χ^2=24.7; 15 df: p=0.054). No evidence for genotype-wise transmission disequilibrium to affected offspring was found (p=0.13). Normal allele- and genotype-wise transmission to unaffected offspring were observed. Transmission analysis of individual alleles, revealed a distorted transmission of the 285bp and the 297bp alleles to affected offspring. The 285bp allele was transmitted 62 and non-transmitted 42 times: p_{td}=0.05 (uncorrected) and the 297bp allele was passed 5 and non-passed 15 times: p_{td}=0.016 (uncorrected). Both alleles displayed normal transmission to unaffected offspring. In **conclusion**, marginal evidence for linkage of *IDDM13* to IDDM in a Danish IDDM multiplex population was demonstrated. The data suggested that the 285bp and the 297bp alleles may be in linkage disequilibrium with aetiological mutations that confer susceptibility and (partial) protection to IDDM, respectively.

205

NO INDEPENDENT ASSOCIATION OF HLA-DP POLYMORPHISMS WITH SUSCEPTIBILITY TO DEVELOP IDDM IN NORWAY

B.A. Lie[1], H.E. Akselsen[1], G. Joner[2], O. Søvik[3], K.S. Rønningen[4], E. Thorsby[1]and D.E. Undlien[1]. [1]Institute of Transplantation Immunology, The National Hospital, Oslo, Norway. [2]Aker Diabetes Research Center, Aker University Hospital, Oslo, Norway. [3]Department of Pediatrics, University of Bergen, Bergen, Norway. [4]Department of Population Health Sciences, National Institute of Public Health, Oslo, Norway.

It is well established that the HLA complex (in particular DR and DQ) is involved in genetic susceptibility to develop IDDM. Polymorphisms within the HLA class II gene DPB1 have in recent studies been suggested to be associated with disease susceptibility. These studies have found the DPB1*0301 allele to be increased among patients, apparently independently of linkage disequilibrium to high risk HLA-DR or DQ alleles. To overcome the problem of linkage disequilibrium we have genotyped 237 IDDM patients and 285 HLA-DRB1-DQA1-DQB1 carefully matched controls, carrying high risk DR-DQ genotypes, from an ethnically homogenous population. We observed no significant differences between patients and controls comparing DPA1 or DPB1 allele frequencies. The frequency of DPB1*0301 is 12% in patients and 10% in controls (p_{nc}=0.2) in this selected population. Among DRB1*0301-DQA1*0501-DQB1*0201/DRB1*0404-DQA1*03-DQB1*0302 individuals there is a tendency of increased frequency of DPB1*0301 (19% in patients vs. 11% in controls; p_{nc}=0.07) among patients. Taken together, our data suggests that there is no independent effect of DPB1*0301 on IDDM susceptibility, suggesting that the DPB1 associations observed in previous studies may not reflect an independent effect of DPB1, but rather be secondary to linkage disequilibrium to high risk HLA-DQ and/or DR alleles. In conclusion, our data do not support previous reports on a primary association between HLA-DP polymorphisms and IDDM developmentand suggests that if such an association exists, it has to be a very minor one.

206

THE VITAMIN D RECEPTOR; A CANDIDATE GENE FOR IDDM

G.A. Hitman, M.F. McDermott, *A. Ramachandran, E. Aganna, W. Ogunkolade, D. Curtis, B. Boucher and *C. Snehalatha. The Royal London Hospital, London, United Kingdom and *Diabetes Research Centre, Madras, India.

Vitamin D has important immunomodulatory properties and prevents the development of diabetes in the NOD mouse. We have investigated 96 probands with IDDM and their parents for an association with the Vitamin D receptor (VDR) gene (12q14). DNA was amplified using two separate pairs of primers to the VDR gene and at D12S85 (within 2 Cm from VDR). The VDR gene fragments were digested with BsMI, ApaI and TaqI and RFLPs, subjected to agarose gel electrophoresis and detected by ethidium bromide staining. D12S85 was analysed by polyacrylamide gel electrophoresis on a ABI 373 DNA sequencer using GENESCANNER software. Excess transmission of polymorphic markers was tested using the extended transmission disequilibrium test (TDT). There was significant excess transmission of VDR alleles containing the BsMI restriction site to affected offspring in these families ($p = 0.016$) as well as BsMI/TaqI haplotypes ($p = 0.01$). In contrast, in the first 60 families no excess transmission of D12S85 alleles were found. In conclusion, the vitamin D receptor gene or a nearby locus on 12q14 determines susceptibility to IDDM in South Indian subjects.

207

Analysis of the HLA-DMB gene frequency in Japanese IDDM patients by PCR-RFLP method.

Shizuhiro NIIHIRA, Emi WATUKA, Kumiko HIRANO, Noboru NABEYA, Kengo NISHIMAKI, Kyoko YAGAWA, Hirosi INADA, Tomoyuki KAWAMURA, Gen ISSHIKI (Osaka City University, Osaka, JAPAN), Yoshisuke NOSE (Hyogo Red Blood Center, Hyogo, JAPAN), Taeko NARUSE, Hidetoshi INOKO (Tokai University, Kanagawa, JAPAN)

The role of HLA class II antigens (DR, DQ, DP) is important to the onset of IDDM. We newly analized of HLA-DMB gene by PCR-RFLP methods (Tissue antigens 1996: 47: 530).

Materilas and methos: The genomic DNAs were isolated by phenol extraction of SDS-lysed and proteinase K-treated cells. After PCR-amplification of the third exon of DMB gene using a pair of primers, aliquots from reaction mixtures were digested with restriction endonucleases, ApaLI, BsrI, and HinpII (PCR-RFLP methods).

Results: The Japanese 89 IDDM patients typed for HLA-DMB alles by PCR-RFLP methods (TABLE). We compared the frequency of the normal Japanese populations (by Naruse etc.) to Japanese IDDM and listed. The DMB*0101 frequence of IDDM is higher than normal populations. The DMB*0102 of IDDM is significantly ($P<0.035$) lower than normal.

Discussions: HLA-DM is required for peptide loading into other HLA class II molecules, so by our data, it is possible to be related to the onset of IDDM.

TABLE. The HLA-DMB allels (%) in normal and IDDM Japanese.

	IDDM	normal	X2	P value
DMB*0101	56.2 %	49.3 %	2.6	p<0.105
DMB*0102	17.4 %	23.2 %	4.4	p<0.035
DMB*0103	26.4 %	23.2 %	0.004	NS
DMB*0104	0.0 %	0.4 %	---	---

208

POLYMORPHISM OF ALDOSE REDUCTASE GENE IN RUSSIAN JUVENILE IDDM AND NIDDM PATIENTS: COMMON RISK MARKER?

D.A.Chistyakov[1], R.I.Tourakoulov[1], N.M.Gorashko[1], L.M.Demurov[1], Y.Y.Kondratiev[1,2], L.N.Scherbacheva[2] I.I.Dedov[2], and V.V.Nosikov[1]. [1]National Research Centre "GosNII genetika" and [2]Endocrinology Research Centre, Moscow, Russia

Aldose reductase (ALR2) is a key enzyme of polyol (sorbitol) pathway of glucose metabolism which activation results from hyperglycaemia in diabetes condition. Polymorphism of (CA)n dinucleotide microsatellite at the 5' region of ALR2 gene in DNA from 112 healthy Russian controls, 64 childhood IDDM and 46 NIDDM patients was studied using PCR technique. Seven alleles (from Z-6 to Z+6) were observed. The Z+4 allele was shown to be the most frequent in the Russian healthy subjects. A Russian population was characterized by strongly increased frequency of the Z+4 allele in comparison with one in British Caucasians (24.6% vs. 2.3%). Frequency differences between groups were estimated using two-tailed Fisher's exact test. The significant decrease of Z+4 allelic frequency was observed in both diabetic groups compared to healthy controls (10.2% vs. 24.6%, p=0.00056, and 15.2% vs. 24.6%, p=0.04443, for IDDM and NIDDM patients, respectively). Patients with juvenile IDDM had significantly increased frequency of both Z/Z-4 (10.9% vs. 2.7%, p=0.02845) and Z/Z-2 (21.9% vs. 10.7%, p=0.0387) genotypes compared to those in the non-diabetic group. The Z/Z-4 genotype was also increased in NIDDM subjects compared to normal controls (10.9% vs. 2.7%, p=0.04685). These preliminary data allow us to suggest that in a Russian population the particular ALR2 gene alleles might be associated with susceptibility or resistance to diabetes mellitus of both types, or to vascular complications characterized for IDDM and NIDDM in different extent.

INVESTIGATION OF THE NON-HLA-DR-DQ CONTRIBUTION TO *IDDM1*

CL Perry, CH Mijovic, C Cockram, D Jenkins, and AH Barnett. Dept Medicine, Birmingham University, Birmingham, England.

The major histocompatibility complex (MHC) on chromosome 6 encodes the major determinant of genetic susceptibility to IDDM, (*IDDM1*). The HLA-DR and DQ genes are likely to contribute to this susceptibility but there is evidence that one or more additional MHC-encoded genes are also involved. Our previous studies have identified a DR/DQ haplotype (DR4/DQ4) which is predisposing to IDDM in the Japanese but is neutral in the Chinese. The aim of this study was to compare DR4/DQ4 haplotypes from each race at other MHC loci. Any allelic differences would implicate that locus as a candidate susceptibility determinant, this could then be tested in a case/control study. The Japanese subject was homozygous at all loci studied: DR4-DQ4-TAP2*0201-DMB*0101-DMA*0102-DPA1*02022-DPB1*0501. The Chinese individual was also homozygous at DR, DQ, TAP1, LMP7 and LMP2 with alleles identical to the Japanese individual, but heterozygous at the other loci: TAP2*0201/0302-DMB*0101/0103-DMA*0102/0101-DPA1*0103/N-DPB1*-N/N (N = new allele). One Chinese DR4-DQ4 haplotype identified is thus identical to the Japanese DR4-DQ4 haplotype from DRB1 to DMA. The divergence at DP is consistent with the recombination hotspot between DMA and DPB1. This study excludes a role for the TAP1, LMP7 and LMP2 alleles in determining the difference in susceptibility noted between Japanese and Chinese DR4/DQ4 individuals. Our previous population study of TAP2 alleles excluded a role for this locus. The DM and DP loci cannot be excluded as susceptibility determinants without population studies. Further population studies and comparison of other MHC loci on these haplotypes should allow us to map non-DR/DQ loci contributing to *IDDM1*.

210

GLN-ARG 192 POLYMORPHISM OF PARAOXONASE IN IDDM

E.Schwartz, T.Markova, D.Demidova, S.Akhmedova and S.Nejentsev.
St. Petersburg Institute of Nuclear Physics, St. Petersburg, Russia.

Paraoxonase (PON) is an enzyme protecting organism from organophosphate poisoning and capable of lipid peroxides hydrolyzing. According to relative enzyme activities, two isotypes, A and B, have been defined. The actual molecular basis for the PON polymorphism is a Gln→Arg substitution. Serum paraoxonase activity is decreased in IDDM and NIDDM. We investigated 206 unrelated IDDM patients from St.Petersburg with mean age 18±9 years and 148 age-related healthy controls. In order to determine the amino acid 192 substitution the fragment 99 bp of genomic DNA was PCR amplified, then digested by MboI restrictase and subsequently analyzed on a 12% polyacrilamide gel. In PCR amplified fragment we have one original MboI restriction site and the second one forms in case of Gln-Arg (A-G) substitution. We have found the following PON genotype distribution : AA-50.5%, AB-41.25%, BB-8.25% in IDDM and AA-56.1%, AB-37.1%, BB-6.8% in control group. We used χ^2 test to compare frequencies in analyzed groups. No any statistically significant differences were obtained in IDDM patients compared to healthy controls, though there was a tendency of Arg allele increase in IDDM. Thus, the observing decrease of PON activity may be due the present of some epigenetic factors.

211

EXAMINATION OF HUMAN β_2-MICROGLOBULIN (β_2-m) GENE AS A CONTRIBUTOR TO DEFECTIVE IDDM ANTIGEN PRESENTATION·

A. Penfornis*, L. Ma and D. Faustman. *University of Franche-Comté, Besançon, France and Massachusetts General Hospital, Boston, Ma, USA.

We have shown that IDDM patients have a defect in antigen-presentation, in part, characterized by an altered conformation of surface class I molecules. Besides MHC class I genes themselves and genes coding for proteins involved in the processing of endogenous peptides (LMP and TAP), the β_2-m gene which encodes for the L chain of class I molecules, is a candidate for a polymorphism contributing to this altered conformation. β_2-m is required for normal class I surface expression and, in the mouse, can regulate the cell surface conformation and expression of class I H chains. The mouse β_2-m locus is polymorphic with 8 alleles. Some studies have suggested that one of these alleles can affect class I molecules/antigen conformation, and presentation and recognition by T cells. Furthermore, mouse β_2-m is linked to the autoimmune diabetes non-MHC locus Idd 13. In humans, 6 nucleotide discrepancies, including 2 with amino acid (AA) substitution, have been reported. It is not known whether they are true polymorphisms. Here, we report the β_2-m sequences from 4 IDDM patients shown to have the antigen presentation defect characterized by altered class I conformation. mRNA was isolated from B cell lines, RT-PCR was performed and a β_2-m cDNA probe was used for Northern blots. Specific PCR products of the β_2-m cDNA were transfected into E. Coli vectors and 5 inserts sequenced. The level of IDDM β_2-m mRNA was identical to non-diabetic control, making the presence of a functional polymorphism in the promoter region unlikely for constitutive β_2-m mRNA expression. The sequences of 4 β_2-m cDNA coding regions uncovered no difference and the deduced AA sequence is in agreement with the commonly submitted one. We have not found any of the previously reported nucleotide discrepancies. In conclusion, the HLA class I presentation defect observed in our patients is unlikely to be explained by a β_2-m gene polymorphism. We cannot rule out a mutation affecting the induced β_2-m mRNA expression or yet unreported alternative splicing with induction with interferon-α.

212

ANALYSIS OF THE FAMILIES OF IDDM-MOTHERS WHOSE CHILDREN SUFFER FROM DIABETES

L. Dvořáková and H. Přibylová. KlinLab Ltd Prague and Institute for the Care of Mother and Child,Prague,Czech Republic

The aim of our study was to analyse the occurrence of diabetes and its types in the families of IDDM-mothers with diabetic children (15 families A) and without them (115 families B). In our long-term follow-up of 177 adult children of IDDM mothers (CDM) we found 15 diabetic CDM: 9 IDDM and 6 NIDDM from 11 mothers, another 4 CDM of 4 mothers had transient gestational diabetes. In group A the diabetic girls were more frequent (73.7%) than in group B (46.7%), p <0.01. In A mothers IDDM manifested in 21.1±2.1 years, in B mothers in 17.1±0.6 years. IDDM was diagnosed in pregnancy in 46.7% of A mothers and in 13.9% of B mothers (p<0.001). In families A the occurrence of diabetes, mostly NIDDM, was higher than in families B. A mothers had also diabetic mothers (60%) and their parents (26.6%), B mothers had lower frequency of diabetic mothers (18.3%) and their parents (5.2%), p<0.001 and <0.01 resp. A mothers had diabetic fathers in 26.7%, B mothers in 16.5%. Diabetes in fathers of CDM (husbands of diabetic mothers) in 20% of group A and in 10.4 % of group B was present. Conclusion: We found high risk of diabetes of both types in offspring of those mothers, in whose families the high occurrence of diabetes is present and whose IDDM began in pregnancy. The special attention to this families should be paid.

213

LACK OF MHC CLASS I POLYMORPHISMS IN NON-OBESE DIABETIC MICE

W. Karges[1], R. Gaedigk[2], B. O. Boehm[1], J. C. Gorga[3], and H. M. Dosch[2] *[1]Dept. of Internal Medicine I, Univ. of Ulm, Germany. [2]Dept. of Immunology, Hospital for Sick Children, Univ. of Toronto, Canada. [3]Children's Hospital, University of Pittsburgh Medical School, U.S.A.*

Genetic susceptibility to autoimmune diabetes is predominantly linked to the major histocompatibility complex (MHC) genes. While the role of polymorphic MHC class II antigens in human and murine experimental diabetes has been extensively studied, the contribution of class I MHC is less defined. We here cloned and analysed MHC class I antigens of the non-obese diabetic (NOD/Lt) mouse, an animal model immunogenetically related to human autoimmune diabetes. From a (dT) primed NOD brain cDNA phage library 34 independent clones containing H-2 K^d, H-2 D^b and class I associated genes were isolated. When compared to wild type sequence, all H2-K^d NOD clones showed a single base exchange (T→G) at position 430, leading to a non-conservative amino acid substitution at position 114 (His→Gln^{114}) located in the extracellular α2 domain involved in antigen presentation and TAP interaction. To confirm this finding, wild type K^d cDNA was RT-PCR generated from DBA/2 mice and cloned. Complete sequence identity to NOD derived K^d was found, thus correcting the previously published DBA/2 sequence. In addition, no base exchanges were detected in NOD H2 D^b and class I associated cDNAs. In conclusion, MHC Class I antigens are not polymorphic in NOD mice compared to non-autoimmune strains, further emphasizing the contribution of class II polymorphisms to MHC associated diabetes risk.

214

NUMBERS OF SAMPLES DESIRABLE IN LINKAGE DISEQUILIBRIUM MAPPING FOR DIABETOGENIC GENES.

Y. Kawaguchi, H. Ikegami, Y. Nakagawa, H. Ueda, J. Fu, G.-Q. Shen and T Ogihara, Department of Geriatric Medicine, Osaka University Medical School, Suita, Osaka, Japan

To isolate disease-predisposing genes for insulin-dependent diabetes mellitus (IDDM), linkage disequilibrium mapping is essential. It is desirable to estimate the number of subjects which is enough to detect significant results before conducting linkage disequilibrium mapping, and it is important to use an analytical method with a higher statistical power, especially when subjects available for analysis are limited. To investigate the number of subjects necessary to obtain significant results, and to compare the power of case-control study and transmission disequilibrium test (TDT), we conducted simulation studies. Genetic parameters, such as allele frequencies and penetrances, are calculated using the data from our extensive analysis on *IDDM2* (*TH*) and *IDDM7* (*D2S152*), which showed significant association with IDDM in Japanese population. In *IDDM2*, when 0.001 is adapted as the significance level, the power of case-control study using 200 patients and 200 control subjects is 0.70, and that of TDT using 200 patients and their parents was 0.50. In case of *IDDM7*, the power of case-control study using 400 patients is 0.38, and that of TDT using 400 patients is 0.26. Case-control study had higher power than TDT in any case studied, suggesting that it is a powerful method provided that there is no population stratification.

215

ASSOCIATION OF TUMOR NECROSIS FACTOR-B IN INSULIN-DEPENDENT DIABETES (IDDM) PATIENTS FROM LATVIA.

P. Dhabadghao, A. Shtauvere, I. Rumba, I. Dzivite, P. Hjelmström and CB. Sanjeevi. Dept of Molecular Medicine, Stockholm; Dept of Pediatrics, Riga; Sweden, Latvia.

TNF -A and -B genes have been shown to be associated with IDDM in Caucasians. TNF genes are located close to the HLA-B genes in the short arm of chromosome 6. The aim of our study was to determine the frequency of TNF-B gene polymorphism in IDDM patients (n=105) and healthy controls (n=114) from Latvia.. TNF-B was genotyped by PCR-RFLP which identifies two alleles, allele 1 and allele 2. Allele 1 is positively associated with IDDM in Latvian patients and is present in 87/105 (83%) patients and 80/114 controls (Odds ratio 2.05; $p<0.05$). Analysis of TNF-B genotypes showed positive association for genotype 1/2 present in 77/105 (73%) patients and 68/114 (60%) controls (OR = 1.86; $p<0.05$). The genotype 2/2 is negatively associated, seen in 18/105 (17%) patients and 34/114 (30%) controls (OR = 0.49; $p<0.05$).

TNF-B is a cytokine gene that plays an important role in the inflammation and immune regulation. The polymorphism of the TNF-B gene linvolves NcoI polymorphism in intron 2 and is associated with substitution at amino acid position 26 encoded in exon 3 of the TNF-B gene. It is not clear how this polymorphism influences the secretion of TNF-β. We conclude that in IDDM patients from Latvia, TNF-B allele 1 and TNF-B genotype 1/2 is positively associated and TNF-B genotype 2/2 is negatively associated with the disease. It is not clear whether this association is primary or secondary to linkage with HLA-class II or class I region.

GENETIC ANALYSIS OF AUTOIMMUNE TYPE I DIABETES IN THE KDP RAT

N. Yokoi[1], M. Kanazawa[2], K. Kitada[1], A. Tanaka[2], Y. Kanazawa[3], S. Suda[2], H. Ito[2], T. Serikawa[1], and K. Komeda[4], [1]Institute of Laboratory Animals, Faculty of Medicine, Kyoto University, Kyoto, [2]Third Department of Internal Medicine, Tokyo Medical College, Tokyo, [3]Omiya Medical Center, Jichi Medical School, Omiya, [4]Division of Laboratory Animal Science, Animal Research Center, Tokyo Medical College, Tokyo, Japan

Komeda Diabetes-Prone (KDP) rat has been established as a diabetes-prone substrain of the Long-Evans Tokushima Lean (LETL) rat, a desirable animal model for human IDDM. An MHC-linked gene has been reported to be involved in the pathogenesis of insulitis of the LETL rat. To detect non-MHC IDDM susceptibility genes in the KDP rat, we generated the three crosses: (TM x KDP) x KDP, (LETO x KDP) x KDP and (BN x KDP) x KDP backcrosses. Animals were checked for glycosuria and non-fasting blood glucose levels until 18 weeks of age. We genotyped markers throughout the rat genome on animals generated from the TM cross (54 diabetics, 114 non-diabetics), and detected strong evidence of linkage to IDDM on chromosome (Chr) 11 (D11M16Mit14, $\chi^2=62.0$, $p<0.001$). To confirm these findings, we genotyped Chr 11 markers on animals generated from the LETO (64 diabetics, 127 non-diabetics) and BN (9 diabetics, 48 non-diabetics) crosses. In these crosses, strong evidence of linkage to IDDM was found in the same region on Chr 11 (D11Mgh5 in the LETO cross, $\chi^2=64.8$, $p<0.001$; Mox2 in the BN cross, $\chi^2=9.0$, $p<0.01$), indicating that a recessively-acting gene on rat Chr 11, termed *Iddm/kdp1*, is a major diabetogenic factor in the KDP rat irrespective of the cross. Comparative mapping suggests that homologs of *Iddm/kdp1* are located in the region between D16Mit14 and D16Mit46 on mouse Chr 16 and in the human Chr 3p11-q13 region. To our knowledge, there are no potential candidate genes around these regions. *Iddm/kdp1* on rat Chr 11, therefore, seems to be a novel IDDM susceptibility gene.

217

THREE TNF MICROSATELLITE MARKERS IN FINNISH IDDM HAPLOTYPES

S. Koskinen, M. Sjöroos, H. Reijonen, J. Ilonen, H.K. Åkerblom and Childhood Diabetes in Finland Study Group. Departments of Virology and Biotechnology, University of Turku, Turku, Finland, Childrens' Hospital, University of Helsinki, Helsinki, Finland

The polymorphic gene region encoding and regulating tumor necrosis factor is located between class I and class II HLA genes. It is a candidatefor an additional susceptibility gene in IDDM. We studied within HLA gene region three TNF microsatellite markers (a-b-c) in DiMe (Childhood Diabetes in Finland Study) families. TNFabc markers were identified in 249 IDDM associated and 202 control haplotypes. We used PCR and ABI PRISM 377 DNA sequencer GENESCAN fragment analysis program to identify these markers. TNF2-3-1 was significantly increased among IDDM haplotypes 16.4 % vs 8.9 % (p=0.0260) and TNF5-5-2 decreased 11.4 % vs 5.6 % (p=0.0408). TNF2-3-1 was associated with DQB1*0201 allele and there was no significant difference in the frequency of this TNF combination between IDDM associated and control DQB1*0201 posite haplotypes. When TNF microsatellite markers were compared in other haplotypes with defined DQB1 alleles with IDDM risk, no significant differences were found. In conclusion, we didn't find any conclusive evidence for an independent role of TNFabc microsatellite polymorphism in IDDM susceptibility.

Environmental Factors, Epidemiology and Prevention

218

THE INCIDENCE OF INSULIN DEPENDENT DIABETES MELLITUS (IDDM) IN THE UNDER 16'S IN DEVON AND CORNWALL FROM 1985 TO 1996

H Zhao , C Soper, P Hughes, E Sanderson, H Baumer, AG Demaine and BA Millward. Departments of Diabetes, Paediatrics and Medicine, University of Plymouth, Plymouth, UK.

We aimed to study the incidence rates of insulin dependent diabetes mellitus (IDDM) in children under 16 years of age living in Cornwall (C)and Plymouth Health District (PHD) from 1985 to 1996. 310 children with IDDM were identified from 2 independent sources; a)paediatric and adult diabetes registers from Treliske and Derriford Hospitals, b) admissions for IDDM recorded in hospital records. All were diagnosed between 01/01/1985 - 3/12/1996. Ascertainment was 99%. Overall incidences were calculated using the 1991 census. The average annual incidence rates per 100,000 in C was 17.1 (boys 17.8, girls 16.5); in PHD was 19.7(boys 17.4, girls 22.3). The incidences differed between districts , lowest in the far south-west (10.2 Restormal), and highest in Caradon (25.4) around the Tamar Valley . These differences in incidence mirrored the prevalence of the HLA haplotype conferring low risk for IDDM (B44 DR4 *0301) which are most prevalent in the Celtic population . These observations may help us tounderstand the aetiology of IDDM

219

THE RISK OF INSULIN-DEPENDENT DIABETES MELLITUS IS INDEPENDENT OF BIRTH WEIGHT - A DANISH TWIN-CONTROL STUDY.

Instituttet, Copenhagen and Odense University, Denmark. I. Bache, K.O. Kyvik, K. Buschard, A. Green and H. Beck-Nielsen. Bartholin

A relationship between birth weight and risk of developing insulin-dependent diabetes mellitus (IDDM) has been suggested. We conducted a nested twin-control study in order to investigate this. Twin partners of discordant pairs are matched for gestational age, maternal age, weight and parity. Furthermore, monozygotic twins are genetically identical.

In the 1953 through 1982 birth cohorts of the population-based Danish Twin Register, 95 twin pairs (26 monzygotic and 69 dizygotic) where one or both had IDDM were identified. These twins were found by sending questionnaire to the 20888 pairs of these birth cohorts. Zygosity was determined by questionnaire and by using serological methods. Information about birth weight and -length, prematurity, maternal age and parity was obtained from mid-wives records for the birth cohorts 1953 - 72 (incl.) and from the Danish Medical Birth Registry for the cohorts 1973 - 82 (incl.). Data regarding birth were available for 82 diabetic and 50 healthy twin individuals (67 twin pairs: 21 monozygotic and 46 dizygotic).

A paired t-test of discordant twins showed no difference in mean birth weight between diabetic and non-diabetic twin partners (2538 g *vs* 2549 g, $p > 0.05$, $n = 51$ pairs). Twin pairs divided according to zygosity showed a similar pattern. Paired t-test of twins who were born full term did not show any significant difference in birth weight between diabetic and non-diabetic twin partners (2911 g *vs* 2904 g, $p > 0.05$, $n = 20$ pairs). Concordant and discordant twin pairs did not differ significantly in gestational age ($p > 0.05$). In conclusion, no significant differences were found in birth weight between the twin individuals who later developed IDDM compared to the non-diabetic individuals in this material.

220

INCIDENCE OF IDDM IN MERIDA, SPAIN, DURING THE PERIOD 1983-92.

A.Becerra, A.Colorado, V.Lechón, G.Piédrola, R.Villar, O.González and G.Maldonado. Ramón y Cajal Hospital, Madrid, Spain.

We studied prospectively the IDDM incidence in Mérida Health Care region of Extremadura, Spain, during 10 years (1983-92). Inclusion criteria of cases were those of IDDM, age at onset less than 30 years and residence in Mérida at diagnosis. All cases were identified by four sources: endocrinologists, general physicians, diabetes societies and diabetic summer camps (criteria of WHO). Population at risk (0-29 y) was 71.233 inhabitants (total population 158.296). The degree of ascertainment was 95%. Male/female ratio was 1.08. Age specific incidence rate/100.000 in the age group 0-14 were 8.00 (C.I. 95%: 7.95-8.07) and in the age group 0-29 were 7.80 (C.I. 95%: 7.79-7.94), with great variations between the years of study. There was a seasonal onset pattern, with highest incidence in spring (Mar-May). The highest incidence occurred in the age group 10-14 years. We conclude that incidence of IDDM observed in Mérida during the period 1983-92 is lower than that previously reported in other Spanish regions (Madrid or Catalonia), but similar to those of some Mediterranean countries (France, Portugal or Algeria). The highest incidence was observed in the age group 10-14 years, as in other studies. The hypothesis of the called "north-south gradient" in diabetes risk remains to be confirmed, having important regional differences in the same country.

221

IDDM IN CHILDREN IS ASSOCIATED WITH EARLY NEONATAL COMPLICATIONS, LOW APGAR SCORE AND HIGHER MATERNAL AGE.

R Parslow, PA McKinney, K Gurney, G Law, HJ Bodansky and DRR Williams. Paediatric Epidemiology Group, Centre for Health Services Research, University of Leeds, UK.

Environmental risk factors for childhood IDDM may operate early in life. This study aimed to investigate neonatal exposures of children (0-15) diagnosed with IDDM in Yorkshire, UK, during 1993-4, using data from obstetric records of 521 mothers participating in a population-based case control study. Using 196 case control sets, matched for age and sex, univariate analyses were conducted on variables including birthweight, Apgar score, vitamin K, neonatal complications, jaundice and admission to a Special Care Baby Unit. Significant odds ratios (OR) were restricted to illness in the neonatal period (cases n=61; controls n=73; OR 1.61, 95% CI 1.06-2.44) and an Apgar score between 4 and 7 at one minute (cases n=49; controls n=57; 1.62, 1.04-2.51). No specific condition accounted for the risk of neonatal illness. Adjusting for mothers with pre-existing IDDM (cases n=4; controls n=0) did not effect the OR or significance of neonatal illness but removed statistical significance for low Apgar score. In a multivariate model, including mother's age *a priori*, only higher maternal age retains a significantly positive association. This study suggests complications in the neonatal period may contribute to the risk of IDDM in childhood, already associated with older mothers.

222

PRELIMINARY DATA ON THE INCIDENCE OF DIABETES MELLITUS TYPE 1 IN THE PROVINCE OF BADAJOZ (SPAIN); Morales Pérez, FM., Barquero Romero J., Aguila López MA., Diaz Pérez de Madrid J. and Group of study of IDDM in the province of Badajoz(GEDIDB). Hospital "Infanta Cristina", Badajoz, Spain.

Introduction: The incidence of IDDM in Spain (10.6-12-5/100.000) has been shown to be higher than expected for countries in the south Europe area. Badajoz is the largest of Spanish provinces with a highly rural or semi-rural population.
Objective: To detect the incidence, geographic distribution, and seasonal variation of insulin-dependent diabetes mellitus (IDDM) in the province of Badajoz (Spain). **Research design and methods:** The study population involve all persons aged 0-29,9 years and diagnosed in the province of Badajoz since the 1st of January 1992 to 15th December 1996. IDDM was defined on the basis of a clinical diagnosis of idiopathic diabetes by a physician. Cases meeting these criteria were included if insulin treatment was started before their 30th birthday and had been living in the study area during at least six months before the diagnosis was made. The primary source of ascertainment were reports made by adult and pediatric diabetologists, and second source was the notification of Diabetes Associations. We present results of data referred to one of the four sanitary areas of the province, which includes Badajoz city, and comprising 251.520 of the 671 774 inhabitants of the province. **Results:** Sixty-eight patients (39 males and 29 females) up to 30 years of age have been diagnosed of IDDM in this sanitary area during the study period. The age-adjusted incidence of IDDM was 10,8/100.000 (males: 11,8/100.000; females: 9,8/100.000). The sex-specific incidence ratio was 1.34. The incidence in the pubertal age-group of 10 to 14,9 years of age (16,58/100.000) was higher than for other age-groups. The incidence was higher in metropolitan (13,01/100.000) than in rural (6,2/100.000), semi-rural (9,2/100.000), or urban areas (11,3/100.000). A seasonal variation in the incidence of IDDM was observed with the lowest rates during the spring and summer. **Conclusion:** Awaiting results for the whole province, preliminary data on one complete sanitary area suggest that the incidence of IDDM in the province of Badajoz is similar to that of other regions of Spain. There was a significant pubertal peak and an impressive clustering of cases was observed in metropolitan area of the Badajoz city (117. 834 citizens) compared with the rural (< 2.000 citizens) and semirural areas (2.000-10.000 citizens).

223

COMPLICATED PREGNANCY AND LABOUR MAY PREDISPOSE TO THE DEVELOPMENT OF IDDM IN CHILDHOOD.

PA McKinney, R Parslow, K Gurney, G Law, HJ Bodansky and DRR Williams.Paediatric Epidemiology Group, Centre for Health Services Research, University of Leeds, UK.

Environmental risk factors for childhood IDDM have been investigated in Yorkshire, UK, using data from hospital obstetric records of mothers participating in a population-based case control study of children (0-15), diagnosed with IDDM during 1993-4. Univariate analysis of 196 age and sex matched sets of cases and controls gave significantly raised odds ratios (OR) for mothers over 35 years (OR 2.13, 95%CI 1.04-4.36). Antenatal risk factors included amniocentesis (3.85, 1.34-11.04), 'oedema, proteinuria and hypertension' (1.62, 1.03-2.54), excessive weight gain (7.12, 1.50-33.79) and labour complications (1.49, 1.00-2.21). The risk associated with oedema, proteinuria and hypertension was greatest when present throughout pregnancy. For the first trimester none of the cases (n=8) or controls (n=2) had IDDM but 4/8 cases and 1/2 controls had pre-existing hypertension. Caesarean delivery increased risk (1.90, 1.12-3.23), particularly for elective procedures (2.23, 1.03-4.81). Adjustment for mothers with IDDM (4 cases, 0 controls) did not affect the pregnancy risk factors or caesarean delivery but for labour complications and elective caesarians statistical significance was lost. In a multivariate model of significant OR, only excessive weight gain retained significance. This study presents a risk profile of older mothers whose babies may be exposed to adverse intrauterine conditions and caesarean delivery.

224

INCIDENCE OF CHILDHOOD TYPE 1 (INSULIN-DEPENDENT) DIABETES IN COIMBRA, PORTUGAL,1987-95

F.J.C. Rodrigues[a], F.G. Costa[b], L.S. Moura[c], B. Pinto[d], L. Gomes[a], M. Carvalheiro[a], M.M.A. Ruas[a] and Coimbra Diabetes Epidemiology Study Group. [a]*Serviço de Endocrinologia e Diabetes, University Hospital of Coimbra,* [b]*Coimbra Regional Health Administration,* [c]*Children's Hospital of Coimbra,* [d]*Hospital of Figueira da Foz. Portugal.*

In order to investigate the epidemiology of insulin-dependent diabetes in the age group 0-14 years, a prospective, population based registry was established in Coimbra in 1990 (WHO DIAMOND project). Prior to the institution of that registry we undertook a retrospective study for the period 1987-89. Included were cases diagnosed between 1987-95, with age at onset less than 15 years and residence in the district of Coimbra at diagnosis. The population at risk was 76,784 and the total population 427,839 at the 1991 census. As the primary source of cases we used hospital admissions. Two other independent sources were used for validation of case ascertainment by the primary source (general practitioners of the Public Health System and endocrinologists who have a private practice in the region). The degree of ascertainment by the hospital source alone was 100%. The overall incidence rate (/100,000/year) was 8.5 (Poisson 95% CI: 6.5-11.0). The age-adjusted (world standard) incidence rate was 7.5 per 100,000 per year. The age group 10-14 years showed the highest incidence rate, 10.8 (95% C.I.: 7.3-15.4). The incidence rate was slightly higher in females, 8.7 (95% C.I.: 5.9-12.5) than in males, 8.2 (95% C.I.: 5.5-11.8). This difference was not statistically significant. The incidence of IDDM in the district of Coimbra is in the middle range of the incidence observed throughout the world and is comparable to those found in several Southern European countries and Brazil.

225

FAMILIAL, PERINATAL AND DIETARY RISK FACTORS FOR INSULIN-DEPENDENT-DIABETES-MELLITUS (IDDM) IN CHILDREN AND JUVENILES IN VIENNA, AUSTRIA

Rami B.[1], Schneider U.[1], Imhof A.[1], Waldhoer T.[2], Patterson C.[3], Schober E.[1]
[1]University Children's Hospital, [2] Institute for Tumorbiology, Vienna Austria, [3] Queens University, Belfast, Northern Ireland

Environmental factors seem to play a role in the pathogenesis of insulin-dependent-diabetes-mellitus. In our case-control study the parents of all IDDM-patients with manifestation of the disease between 1989 and 1994 in Vienna were asked to complete a questionnaire (n = 119, mean age = 11.9 ± 3.4 yr). Control children (n = 476, 11.8 ± 3.4 yr) were recruited by random from all schools in Vienna matched for age and sex. The response rate was 87.4% in diabetics and 79.8% in controls. Additionally the obstetric hospital records could be traced in 72.3 and 68.1% respectively.

Both, fathers (mean age = 31.7 ± 6.7 yr) and mothers (27.8 ± 5.5 yr) of diabetic children were significantly older ($p<0.05$) than parents of controls (fathers: 30.0 ± 6.1 yr, mothers 26.9 ± 5.1 yr). There was no significant difference concerning duration of gestation (39.5 ± 1.5 vs 39.4 ± 1.8 weeks), birth weight (3348 ± 457g vs 3289 ± 510g), percentage (80.8% vs 81.3%) and duration (5.4 ± 4.4 vs 4.6 ± 4.3 months) of breast feeding. Neonatal icterus (40% vs 26%, $p<0.05$) and neonatal infections (7.1% vs. 2.6%, $p<0.05$) were significantly more often observed in children who later on developed IDDM.

Our results do not support the hypothesis of early introduction of cow milk and IDDM-development. Larger multicenter studies (EURODIAB) may help to clarify whether there are regional differences in the importance of trigger factors for the manifestation of IDDM.

226

THE INCIDENCE OF INSULIN-DEPENDENT DIABETES MELLITUS IN SOUTH BRAZIL;THE PASSO FUNDO REGISTRY REPORT.

HRK Lisboa, R. Graebin, L. Butzke C. Rodrigues and LA. Kurtz. Universidade de Passo Fundo. Faculdade de Medicina. Passo Fundo RS Brazil.

The frequency of Insulin-Dependent Diabetes Mellitus (IDDM) varies among countries. The WHO is trying to access these differences, through standardised recommendations of the Multinational Project for Childhood Diabetes (DIAMOND), in order to identify possible environmental causes. In this context, we have studied the incidence of IDDM in Passo Fundo, a city with 152, 110 inhabitants in highland region in Southern Brazil (latitude 28.10S, longitude 52.20W) in 1996. The eligibility criteria were that the person had to be born in the city or be a resident for at least one year, be under 15 years old, using insulin and his diagnosis of IDDM had to be made by a physician. The technique of capture and recapture was used. The primary source (capture) consisted of paediatricians (n=39) and endocrinologists (n=5) who were contacted by mail and telephone calls and, the secondary source (recapture) was information obtained at basic and nursery-schools. Also for recapture, a message was sent to the whole population in December through the newspapers, the radio and the television reaching respectively 20, 60 and 84% of the local population. The primary source identified 6 patients and all the 3 patients from secondary source were common to both sources. The variance and confidence intervals were not computed since all cases from the secondary were included in primary source. This situation indicates the necessity tp improve our secondary source in the future using hospital registries and insulin selling The incidence of IDDM was 12 cases/100,000/year. The degrees of ascertainment were 100, 50 and 100% for the primary, secondary and both sources. Therefore, our preliminary findings places our city in the middle range of incidence, together with Italy, Spain, New Zeland and Netherlands.

227

PANCREATIC FIBROCALCULOUS DIABETES BUT NOT MALNUTRITION RELATED DIABETES HAS DISTINCT FEATURES WHEN COMPARED TO IDDM.

P.Aschner, I.Escobar, J.Guerrero and C.Rosselli. Colombian Diabetes Association and Javeriana University, Bogotá, Colombia.

Malnutrition related diabetes mellitus (MRDM) may be difficult to identify among our patients with insulin-dependent diabetes mellitus (IDDM) who have low income, deficient nutrition and difficulty to obtain adequate control with moderate insulin doses. We selected 35 patients who additionally had shown to be resistant to ketosis. 14 had pancreatic calculi on X Rays and their diabetes was classified as fibrocalculous (FPD). Their age range was 14 to 37 yrs at onset and 10 were males. 7 had been initially diagnosed as NIDDM but finally required insulin. 7 out of 10 could recall manutrition during childhood and all had a BMI < 20 at onset.12 had a history of abdominal pain.10 had neuropathy, 2 had retinopathy (after 6&12yrs) and 4 had nephropathy (after 3,5,7&12yrs). When compared with 48 IDDM patients matched for age at onset and duration, FPD patients were leaner (BMI 16.8±2.9 vs. 20 ±2.5 kg/mt2,$p<0.001$), required higher insulin dose (1.08±0.61 vs. 0.70±0.20 units/kg.day, $p<0.001$) and still had higher blood glucose (252±72 vs. 192±51 mg/dL,$p=0.001$). On the contrary, the 21 patients suspected to have MRDM but with negative X Rays, although also leaner (BMI 18.6±2.6,$p=0.01$) required similar insulin dose as IDDM patients (0.78±0.28 units/kg.day) for a not so high blood glucose (215±75 mg/dL). We conclude that FPD is a distinct entity which may only be recognized if searched systematically (including X Rays). On the contrary, we believe that MRDM may just be the reflection of poor environment and poorer treatment among IDDM patients.

228

ONE OF THE LOWEST VALIDATED INCIDENCE RATES OF INSULIN DEPENDENT DIABETES MELLITUS IN THE AMERICAS: SANTIAGO, CHILE

Carrasco E (1), Pérez-Bravo F (2), Santos JL (2), López G (1), Calvillán M (1), Wolff C (1), García de los Ríos, M (1).

(1) Faculty of Medicine, Diabetes Unit, Hosp. SJ. de Dios. University of Chile (2) Molecular Biology and Epidemiology Department. Nutrition and Food Technology Institute (INTA), University of Chile. Santiago, Chile.

There is an extraordinary variation in the incidence rates of Insulin-Dependent Diabetes Mellitus (IDDM) in different countries and ethnic groups. Little is known, nevertheless, about the incidence of IDDM in Latin America, and Chile. These are the first reported data from Chile using the standardized methodology from the Multinational Project in Childhood Diabetes (DiaMond). The goal of this study was to estimate the average annual incidence rate of IDDM in Santiago from 1 January 1986 to 31 December 1992. The rates were calculated among subjects under 15 years of age, through a retrospective search and confirmation method from Hospitals and private offices of endocrinologists and specialists. A total of 252 registered cases were found, 118 boys and 134 girls, for an annual incidence of 2.36/100,000 hab.year (IC95%: 2.07 - 2.67). The maximum incidence was found in girls 10 - 14 years (3.91; IC95%: 3.0 - 5.02). The estimated incidence in Santiago de Chile represents one of the lowest validated rates in the Americas.

229

FOOD/NUTRIENT CONSUMPTION AND THE INCIDENCE OF INSULIN-DEPENDENT DIABETES IN CHINA.

Z. Yang [1], K. Wang [1], T. Li [1], YF. Chang [2], J. Dorman [2], R. LaPorte [2]. [1]Chinese Academy of Preventive Medicine, Beijing, China. [2] University of Pittsburgh, Pittsburgh, USA.

The association of insulin-dependent diabetes mellitus (IDDM) incidence and 25 food items and 25 nutrients was examined in China. The China IDDM registry had 22 centers and monitored more than 20 million children under age 15. There was an enormous geographic variation in the IDDM incidence rates across China. People living in different areas of China have quite different eating habits; thus this study provided a good opportunity to investigate the relationship of IDDM and food consumption. The food and nutrient consumption data were obtained from the third Chinese National Nutrition Survey. A three-consecutive-day dietary survey was carried out by a weighing method and a 24-hour dietary intake recall. Among the food items studied, 9 were found to be significantly correlated with IDDM incidence (5 positively and 4 negatively correlated with IDDM). These food items were milk (r =0.72), vegetable oil (r =0.5), cake/dessert (r = 0.51), sugar (r =0.77), paste/seasoning (r =0.46), dark colored vegetable (r = -0.46), animal fat oil (r = -0.42), rice (r = -0.41) and dry legume (r =-0.4). There were also 4 nutrients identified to be significantly positively correlated with IDDM (energy intake (r =0.46), fat (r =56), alpha tocopherol (r =53), vitamin E (total) (r =0.46). However, no nutrients were found to be negatively correlated with IDDM. The current study suggested that the huge geographic differences of IDDM incidence rates across China could be in part contributed to certain food consumption which is consistent in part with known risk factors (e.g. milk) but in an extremely low risk country. The existence of possible susceptible and protective foods toward IDDM may provide us directions to the prevention and treatment of IDDM.

230

STUDY ON THE INCIDENCE OF INSULIN-DEPENDENT DIABETES IN THE LAZIO REGION (CENTRAL ITALY) FROM 1989 TO 1995.

N. Visalli*, L.Sebastiani*, E. Adorisio*, A.L. De Cicco*, P. Pozzilli** and the IMDIAB Group**. *Institute of Hygiene, **Institute of II Clinica Medica, University of Rome "La Sapienza", Rome. Italy.

As part of the EURODIAB Subarea A, the study was carried out over a period of seven years, from January 1, 1989 to December 31, 1995. Evaluation of new cases of IDDM under 15 years of age was conducted at the region's antidiabetic centers and validated at centralized health centers. In seven years, 467 new cases of IDDM were identified, 230 female patients and 237 male patients; the average **annual incidence** was 8.43/100000 (in males 8.34/100000 and in females 8.53/100000). The incidence rates for each year, standardized on the data of Italian Statistical Year Book (1991) were: 8.09/100000 in 1989; 7.96/100000 in 1990; 7.84/100000 in 1991; 9.74/100000 in 1992; 7.58/100000 in 1993; 8.47/100000 in the 1994 and 9.36/100000 in 1995; differences by years are not significant. The incidence by age group was 6.84/100000/year in the 0-4-year-old age group, 10.09 in the 5-9-year-old age group and 8.33 in the 10-14-year-old age group. The **age** at which the most cases were shown was 9 years (10.7%). No statistical differences were observed in **sex** distribution. Place of residence of patients varied within the region, but the majority (66%) of them live in main towns in the Lazio region, 24% in smaller towns and 10% in rural areas, thus reflecting the distribution of the population in this region. The **seasonal trend** of incidence confirms that cases occurred more frequently during the winter (35.8%) and in spring (25.3%), whereas they diminished during summer and autumn (20.1% and 18.8%, respectively). 72.1% patients had been **breast fed** while the remaining 27.9% had been bottle fed. **Family history** of patients revealed that 23% of them have relatives who suffer from type 1 diabetes, while 55% have relatives with type 2 diabetes. With regard to the **disease severity at diagnosis**, the majority of patients (86.9%) were in ketosis and only 18 (3.9%) patients were in a state of coma. In conclusion, incidence of IDDM was found to be remarkably constant over the period of observation, higher in the 5-9-year-old age group, and in the winter period.

231

COW'S MILK CONSUMPTION ASSOCIATED WITH DISEASE SPECIFIC AUTOANTIBODIES IN SIBLINGS OF CHILDREN WITH IDDM

S.M.Virtanen, E.T.Hyppönen, M.Knip, P.Vähäsalo, P.Kulmala, H.K.Åkerblom and Childhood Diabetes in Finland Study Group. Tampere School of Public Health and Medical School, University of Tampere, Tampere, Department of Pediatrics, University of Oulu, Oulu, The Children's Hospital, University of Helsinki, Helsinki, Finland.

The association of infant feeding patterns and milk consumption with IDDM specific autoantibodies was studied in initially non-diabetic siblings of children with IDDM. The siblings were followed at half-year intervals for 4 years since the diagnosis of IDDM in the index child. At the end of follow-up 17.2 % (127/737) of the siblings were positive for ICA (≥2.5 JDF-units), GADA (>6.6 relative units), or IAA (>54 nU/ml). Those children who were positive for at least one IDDM specific auto-antibody at the end of follow-up (n=99) were compared to antibody negative ones (n=376) so that only one child from each family was included. Overall or exclusive duration of breast feeding were not associated with antibody positivity, neither was the age at introduction of cow's milk supplementary feeding. Cow's milk consumption during childhood was positively associated with antibody positivity, also when adjusted for age and sex (highest quartile vs. lowest OR=2.6, 95 % CI 1.2-5.5). To conclude, high consumption of cow's milk during childhood may be a risk determinant of seroconversion to positivity for IDDM specific autoantibodies.

232

LOW INCIDENCE OF IDDM DURING 1985-1995 IN THE REPUBLIC OF MACEDONIA

M. Kocova, M. Konstantinova and A. Demirdzieva. Pediatric Clinic, Medical Faculty, Skopje, Republic of Macedonia

Nation wide registry for IDDM in childhood (0-14 years of age) has been set up for the Republic of Macedonia since 1985. This country is a cold spot for IDDM incidence in Europe and among Caucasian populations as a whole, since the overall incidence for the period 1985-1991 was 2.45 (95%CI 2.03-2.96) per 100 000 per year. Majority of the population is of Slavic origin. Genetic analysis of HLA DQB1, DQA1 and DR genes has confirmed high percentage of resistant and neutral haplotypes in the general population. The objective of the present study was to evaluate the dynamics of IDDM incidence over an eleven year period. Overall yearly IDDM incidence in the period 1985-1995 was in the range 1.84-4.11 (3.11+0.79)/per 100 000 per year. The IDDM incidence was lowest in the age group 0-4 years, 1.50 (95% CI 0.55-2.45), and highest in the age group 10-14 years, 4.46 (95% CI 2.84-6.08). Although the incidence among females was slightly higher 3.43 (95% CI 2.24-4.62), sex difference was not statistically significant. There were two sharp increments of the number of newly diagnosed patients during September 1995 and February 1996 (3-4 times compared to the number of cases in those months during previous years). Enteroviruses were isolated from all blood cultures at diagnosis during these events. Concerning the seasonality, the lowest incidence in this population appears in the period March-May, and the highest in December -February. We conclude that overall incidence during the last 11 years shows stable patterns in this population with a very low IDDM incidence.

233

IMMUNOSUPPRESSING EFFECT OF COW MILK BETA-CASOMORPHINE IN PREDIABETIC MICE AND HUMANS

R.B. Elliott*, H. Wasmuth* and J. Hill**. * Dept Paediatrics, School of Medicine, Auckland, New Zealand and the **Dairy Research Institute of New Zealand, Palmerston North, New Zealand.

Type 1 (IDDM) diabetes results from a genetically determined immune destruction of islet beta-cells, following early exposure to a diabetogenic environmental agent. The strong correlation of national milk consumption with diabetes incidence suggests cow milk (CM) as such an environmental agent. This notion is supported by the promotion of diabetes in the NOD mouse by CM casein in a diabetes prone rodent model (NOD mouse). This diabetes promoting activity is found solely in A1 beta casein not the A2 variant. A1 beta casein alone yields beta-casomorphine-7 (BCM) after intestinal digestion. The diabetogenic effect of A1 casein is neutralised by the u-opioid antagonist naloxone. Synthetic BCM is shown to inhibit the PMA stimulated oxidative burst of macrophages derived from prediabetic NOD mice or (islet antibody positive) children, but not Swiss mice or control children. BCM depresses lymphoblastic responses to Con-A by normal human peripheral blood and intestinal cells.
The primary immune response to ovalbumin is totally extinguished by co-administered BCM in the NOD mouse, but not Swiss mice.
The marked opioid like immunosuppression found with this peptide product of cow milk A1 beta casein digestion, in IDDM predisposed mice and humans is likely to be causally related to the specific diabetogenic effect of the A1 cow milk variant.

234

THE INCIDENCE OF CHILDHOOD-ONSET INSULIN-DEPENDENT DIABETES IN ROMANIA

V. Serban and A. Green, for the ONROCAD study group,
University of Medecine and Pharmacy, Timisoara, Romania

A Romanian collaborative study group (ONROCAD) has been established to provide descriptive epidemiological information on insulin-dependent diabetes mellitus (IDDM)in nationwide Romania. Based upon submission of data from all 41 Romanian districts, 706 new cases (302 boys and 404 girls) of IDDM with onset 0-14 years were registered during 1992-1995 (4 years). The overall completeness of ascertainment was estimated at 93.5% (91.6%- 95.3%) with no major differences between the 3 main regions of Romania (Transilvania, Moldova and Muntenia). For whole Romania, the incidence of childhood onset was estimated at 3.57 per 100 000 per year. We found statistical differences in the incidence of IDDM between these 3 regions, after stratification for sex ($p < 0.05$). Girls had higher incidence than boys for each of the age groups 0-4, 5-9 and 10-14 years ($p < 0.05$). Between these age groups, the incidence showed statistically significant heterogeneity ($p < 0.0001$), due to a low rate for the age group 0-4 years. The incidence at district level showed significant variation, evident in girls, but not particularly in boys. We conclude that the incidence of childhood- onset IDDM is among the lowest recorded in Europe, with so far unexplained variability between Romanian districts.

235

INSULIN-DEPENDENT DIABETES MELLITUS AND MILK'S CONSUMPTION: A CASE-CONTROL STUDY IN SÃO PAULO, BRAZIL

S. G. A. Gimeno; J. M. P. de Souza. Department of Epidemiology, School of Public Health, University of São Paulo, São Paulo, Brazil

A case-control study was conducted to test the assumption that breast feeding protects against insulin-dependent diabetes mellitus, and that the early introduction of cow milk into the infant diet is a risk factor for the disease. Three hundred and forty-six diabetic children, less than 18 years old at the moment of the interview, were identified in two institutions in the city of São Paulo. The duration of exclusive breast feeding and the age of introduction of cow's milk products in the infant feeding of the cases were compared with 346 paired control cases for sex, age and place of residence. The ages of the parents when the child was born, the history of congenital rubella, the duration of gestation, the weight and the height at birth, the vaccination status, the child's viral disease history, the child's history of severe attacks of diarrhoea, the date of insulin therapy, previous familial history of insulin-dependent diabetes mellitus and non-insulin-dependent diabetes mellitus, the per-capita income of the family, and the order of birth of the child were considered as possible confouding variables. All comparisions between diabetic and control children were done using paired tests. The findings of this study indicate that the lack of exclusive breast feeding, particularly during the first week of life, is a risk factor to insulin-dependent diabetes mellitus (OR=2.13; 95% IC:1.28-3.55) and that the age at introduction of milk products, particularly when these products are introduced during the first seven days of life, is a risk factor for the disease (OR=2.29; 95% IC: 1.37-33.83).

Grant 94/0943-0 from Fundação de Amparo a Pesquisa do Estado de São Paulo (FAPESP)

EPIDEMIOLOGY OF DIABETES: INCIDENCE, PREVALENCE AND MORTALITY IN MOSCOW CHILDREN.

Gubanov N., Cherbatheva L., Sunzov U., Dedov I.

Endocrinology Research Center, Moscow, Russia

Epidemiolodgy study incidence, prevalence and mortality in group children with IDDM aged 0-15 years in Moscow population. Two sources of information were used: Children Hospitals' records and annual reports from all city's pediatric endocrinologists, to estimated we used capture-recapture method. Incidence was 5.17 per 100000 in 1967 - 1977 and during 1978-1990 - 9.7., 1990-1995 - 12.6 The increase in epidemiological "peak" was noted in 1985; number of new cases of IDDM 149, (incidence 10.1 per 100000). In the end of 1992 the prevalence was 50.9 per 100000 in Moscow-city, (children population was 1.772.581), the 1995 61,6. Mortality survival rate (Jan.1980- Dec.1989). All cases were verified by autopsy reports. In whole 28 deaths (20 girls and 8 boys) were revealed 12 cases occurred at the clinical onset of diabetes, and this makes 1.07 % of all diabetic children diagnosed during this 10 years. Mortality in 1995 was 0,06 per 100000. The remaining 16 deaths were classified as following: diabetic ketoacidosis -9,cases, infections-3, accident-1, cancer-1, others-2. Diabetic ketoacidosis was the main reason of death in analysed group. The above study is the first step of the National Register IDDM in Russia.

237

NO IDDM PROTECTIVE EFFECT OF BREAST FEEDING IN ISRAEL.

A.Arbel, E.Sprecher, Z.Josefsberg, N.Weintrob, M.Karp and P.Vardi, SCMCI, Petah-Tikva, Israel.

This study's aim was to evaluate effects of breast feeding and cow's milk introduction and their interaction with ethnicity on incidence of IDDM in Israel. Environmental factors, in addition to major genetic effects, likely have a crucial role in triggering beta cell autoimmunity in IDDM. Early introduction of cow's milk is suggested to predispose for, and breast feeding (BF) to be protective against, IDDM development. In Israel IDDM incidence varies among the different ethnic groups; thus, we initiated a study to evaluate the role and interaction of genetic and non-genetic factors in this disease. We obtained data concerning BF and cow's milk introduction in 199 IDDM patients (mean age 15.7 yrs±10.6 s.d.) and in 151 healthy controls (15.5±6.6). We applied several logistic regression models which initially examined feeding factors and their interaction with ethnic factors. As ethnic factor interactions had no significant effects, subsequent regressions applied reduced factor models as appropriate. The final resulting model contained only independent variables describing whether or not subjects were breast fed, and delay (months) of introduction of cow's milk. The overall regression model was significant (-2 log likelihood chi-square=9.575, df=2, p=0.0083; Score chi-square=9.497, df=2, p=0.0087). BF was significant (Wald chi-square=4.66, p=0.0309), with an odds ratio of 2.018 (95% CI 1.066 to 3.818) indicating BF as *predisposing* to development of IDDM. Delay of cow's milk introduction was also significant (Wald chi-square=7.08, p=0.0078), with odds ratio of 0.924 (95% CI 0.873 to 0.980) indicating a protective or sparing effect of 0.924 per month's delay. In conclusion, our results show that both BF and early cow's milk introduction are associated with development of IDDM in all ethnic groups in Israel,suggesting that the effect of feeding on IDDM development is not associated with a specific factor and that it spans across ethnicity.

238

EPIDEMIOLOGICAL ASPECTS IDDM IN MOSCOW REGION

A.V.Dreval, Yu. A.Redkin and I.V.Misnikova. Moscow Regional Research Clinical Institute, Moscow, Russia.

OBJECTIVE: This study was designed to estimate the prevalence and incidence of IDDM and its main complications in Moscow Region. METHODS: During 1994-1995 years was created Regional Diabetes Register (RDR). RDR include all patients with IDDM in Mytishinsky District of Moscow Region. RESULTS: the prevalence of IDDM was 85,39 per 100 000. The prevalence level among teenagers from 14 to 17 years (88,11 per 100 000) was little high than among adults (85,22 per 100000). Study of IDDM distribution on age has shown heaviest prevalence in the age groups 20-24 years old (221,45 per 100 000), 35-39 years old (123,26 per 100 000) and 45-49 years old (158,12 per 100 000). We have estimated the incidence of Type 1 diabetes. The IDDM incidence in 1994 was 3,28 per 100 000, that is comparable with data of the national registers of many countries. The high incidence level was in age groups 14-15 years old and 18-19 years old (22,66 and 39,22 per 100 000). The analysis of a structure of IDDM complications has shown, that 59.23 % of patients has retinopathy, 55.38 % - neuropathy and 23,84 % - nephropathy. The HbA1 level was 14.86±3.40% (n=50). The prevalence of microalbuminuria was 52.28%.

239

BREAST FEEDING; DEVELOPMENT OF DIABETES MELLITUS.

T.H.KURBANOV and A.A.GAISINA. Institute of Physiology, Baku, Azerbaijan.

The aim of this study was to determine the prevalence of infant feeding patterns and to compare the humoral immune response to bovine serum albumin (BSA) in patients with IDDM and NIDDM in Azerbaijan population. By the randomize method performed epidemiological analysis of 324 patients card. This data were the basis of study of serum samples from 90 patients with IDDM and 50 patients with NIDDM for anti-BSA-antibodies level by enzyme-linked immunosorbent assay (ELISA). By us was establish that nonexclusive breastfeeding was prevalent amongst patients with IDDM and constituted 60,5% and was rare occurence among patients with NIDDM (only 4,8%), P<0,001. The patients with IDDM who have had nonexclusive breast feeding in infancy had higher level of antibodies to BSA (in 1,5 time more) than did patients with IDDM but were exclusively breast fed. Furthermore, the level of anti-BSA-antibodies did not significantly differ between patients with NIDDM and IDDM, who have had only breast feeding in infancy. Results of researches confirm the provoke role of nonexclusive feeding in manifestation of IDDM and immediately participation of BSA in the autoimmune pathophysiological processes of induction of this disease.

240

THE PECULIARITY OF TYPE 1 DIABETES INCIDENCE AT NOVOSIBIRSK AREA ACCORDING TO REGISTRY DATA

J.Choubnikova,L.Kalashnikova and E.Shubnikof. Center "SibDiab", Institute of Therapy, Novosibirsk, Russia

The main aim of the study was to compare the Type 1 diabetes incidence at big Novosibirsk City and other smaller places of Novosibirsk Area. The analysis of incidence among children from 0 to 14 years was conducted for 1980-1994 years according to "DIAMOND" protocol. We have revealed significant statistical difference in incidence of IDDM among children from industrial Novosibirsk-City(total population about 1,5 million) in comparison with children living in smaller places: 6.1±0,5 (95% CI:5,0 - 7,1) and 3.9±0,4 (95% CI:3,1-4,6) cases per 100 000 children respectively. Also the mean annual incidence of Type 1 diabetes was significantly higher in 1990-1994 study period-7,9 per 100 000(95% CI:6,0-9,8) than in 1980-1984 study period where it was 4,4 per 100 000(95% CI:3,2-5,6) only among Novosibirsk City children. We have not found the time trends of incidence of Type 1 diabetes among children of small towns and villages (with the same genetic background) around the Novosibirsk City. The most likely reason for these phenomena are presence and increasing power of still unknown casual agents at the big Cities in Siberia.

241

ENHANCED T-CELL RESPONSE TO COXSACKIE VIRUS B4 IN PATIENTS WITH NEWLY DIAGNOSED IDDM

P.Klemetti, M.Roivainen, H.Hyöty, J.Ilonen, H.K.Åkerblom and O.Vaarala. The Children's Hospital, University of Helsinki, National Public Health Institute, Helsinki, University of Turku, Finland.

Enterovirus infections are associated with insulin-dependent diabetes mellitus (IDDM). We studied T-cell proliferation response from patients with newly diagnosed IDDM and from healthy children to a purified Coxsackie virus B4 (CBV4) (1 µg/ml) and to two vaccine antigens, a purified polio virus 1 (PV1) (1 µg/ml) and tetanus toxoid (TT) (10 µg/ml). IgG-antibodies to CBV4 were measured by RIA. HLA DQB1 genotyping was done in a subgroup of patients (n=36) and controls (n=23). T-cell reactivity to CBV4 was found in 27% patients and in 10% control children (20/74 vs 5/48 p=0.04), when the cut off was three multiples of median SI (SI>7.1) in the controls. No difference in the T-cell reactivity to PV1 (4/28 vs 0/16; p=0.3), or to TT was found between the groups. In IDDM patients, T-cell responses to enteroviral antigens, CBV4 and PV1, correlated (r=0.70, p<0.0001); the correlation was weaker in controls (r=0.49, p=0.05). The levels of antibodies to CBV4 did not differ between the groups (16.5 EIU vs 21.0 EIU; p=0.8). Correlation between humoral and cellular responses to CBV4 was better in patients than in controls (r=0.23 and r=-0.04). T-cell reactivity to CBV4 was found in 9 of 30 patients with HLA DQB1*0201 and/or 0302, whereas in none of 6 patients without risk alleles. Enhanced T cell reactivity to CBV4 was found at the time of IDDM diagnosis, although no increased levels of IgG-antibodies to CBV4 could not be demonstrated. Our results suggest that HLA risk alleles may influence to T cell reactivity to CBV4. Alternatively, enhanced T-cell response may reflect preceding enteroviral infection(s) as suggested by prospective studies.

DATA FROM IDDMREGISTRY- BANGALORE DISTRICT (URBAN)

Mala Dharmalingam, Aravind S, Munichoodappa C and Prasanna kumar K M, M.S.Ramaiah Medical College, Bangalore, India.

Aim to know incidence and mortality of IDDM in Bangalore district Urban and other data. The IDDM registry is maintained at M.S.Ramaiah Medical College, as per the specification of Diamond Project. The primary objective is to register all known cases of childhood diabetes in Bnagalore, to know incidence and mortality. Secondary objective to analyze other data. The area studied - Bangalore district Urban- 2,1990 sq km with population 4,807,019 (census 1991) covering Anekal, Bangalore North and South and Bagalore city. Registry maintained by capture recapture method from primary and secondary sources. 214 patients registered till Nov 1996. 116 boys and 98 girls. In the year 1995 -96 18 new cases registered. Incidence 1.68/100,000/year. Age group 0 - 4 yr. - 6%, 5 - 9 yr. - 68%, 10 - 14 yr. 36%. Maternal age 21 - 25 yr. 26 %, 26 - 30 yr. - 54% more than 30 yr. - 30%. Rural urban ratio 52:162. Socioeconomic status 48.15% - middle income group 23.56% lower income group, 28.29%, upper income group. Complications- Nephropathy 3, Hypertension 1, Diabetic foot 3.retinopathy-3. Mortality -DKA 2 Nephropathy 1, Lung abscess 1, GI Bleed 1. Intensive insulin treatment 53.1% other endocrine abnormalities 15% had positive thyroid antibodies, 82.1% showed positive height compared to parental height. 11.1% height less than 3 SD. PCOS -1, Turner 1. Conclusion incidence of IDDM in Bangalore distirct Urban a south Indian district of Karnataka is 1.68%/100,000/year. Mortality is 2.33%.The age group most coomonly presenting is 5-9 yr.The maternal age and income was not significant.There was a positive corellation for height in 82.1% of IDDM.DKA was the most common cause of death.

243

HLA RESTRICTED T-CELL RESPONSE TO ENTEROVIRUS ANTIGENS IN NEWLY DIAGNOSED IDDM PATIENTS

S. Juhela, H. Hyöty, M. Roivainen, O. Simell, J. Ilonen. Turku Immunology Centre and Departments of Virology and Pediatrics, University of Turku, Turku; National Public Health Institute, Helsinki, Finland.

Enterovirus infections may trigger the beta cell damaging process leading to clinical IDDM. Cellular immune response is important both in the elimination of the virus and in the autoimmune destruction of beta cells. In the present study lymphocyte proliferation responses to enterovirus antigens were analysed in 46 newly diagnosed IDDM patients and in 25 control subjects using standard blast transformation test and highly purified coxsackievirus B4, poliovirus types 1 and 3 and adenovirus hexon protein as antigens. There was no significant difference in enterovirus or adenovirus responses between IDDM patients and control subjects. However, proliferation responses to coxsackievirus B4 and poliovirus types 1 and 3 were significantly modulated by the HLA genotype. HLA- DRB1*03 positive patients had significantly lower responses than DRB1*03 negative patients (p<0.05-p<0.001). Median stimulation indices for coxsackievirus B4, poliovirus types 1 and 3 were 7.0, 3.0 and 1.6 in DRB1*03 positive patients compared to 11.4, 11.0 and 13.1 in DRB1*03 negative patients. No HLA association was found in adenovirus responses. T cell responses were not correlated with antibody levels to corresponding virus antigens. The results suggest that the DRB1*03 genotype is associated with weak cellular immune responsiveness to enterovirus antigens.

INSULIN DEPENDENT DIABETES IN CHINA AS PART OF THE WHO DIAMOND PROJECT.

Z. Yang [1], K. Wang [1], T. Li [1], YF. Chang [2], J. Dorman [2], R. LaPorte [2]. [1]Chinese Academy of Preventive Medicine, Beijing, China. [2] University of Pittsburgh, Pittsburgh, USA.

The current study investigated the incidence rate of insulin-dependent diabetes mellitus (IDDM) in China. The China IDDM registry was established in 1991 as part of the WHO DiaMond project. Twenty-two centers were setup to monitor the IDDM incidence cases for children under age 15. The population under investigation was more than 20 million, which represents about 7% of children in China. Seven major ethnic groups were involved in the study. At least two sources were employed to identify IDDM cases and capture-recapture method was used to adjust for the underascertainment. The primary source was the hospital medical records. The secondary source includes the records from school health program, Family Planning Committee, insurance company, Child-Woman Care Network and anti-epidemic station. The investigation period was from 1985 to 1994. A retrospective registration by reviewing the records from the primary and secondary sources was employed to identify the cases diagnosed before 1991. In total, 592 IDDM cases were identified from 22 centers with an annual crude incidence rate 0.48/100,000. The capture-recapture method estimated that there were 630 IDDM cases with an ascertainment corrected incidence rate of 0.51/100,000. The sex-specific rates were 0.47/100,000 for boys and 0.59/100,000 for girls. There was a 12-fold difference among 22 centers (0.13 - 1.61/100,000), the largest within country variation even seen. In general, the incidence rates were higher in the north and in the east. There was also a 7-fold difference among various ethnic groups (highest: Mongol 2.12, lowest: Zhuang 0.32/100,000). The current study showed that China had the lowest IDDM incidence rate ever reported, as well as the largest within country variation in the largest IDDM registration system.

245

ENTEROVIRUS RNA AND IDDM-RELATED AUTOANTIBODIES IN PREDIABETIC CHILDREN

M.Lönnrot, K.Salminen, M.Knip, T.Hyypiä, M. Hiltunen, H.K.Åkerblom, H.Hyöty and the DiMe Study Group

Dept. Virology, Univ. Turku, Dept. Pediatrics, Univ. Tampere,Dept. Int.Medicine, Univ.Tampere, Second Dept. Pediatrics, Univ. Helsinki, Finland

We have previously shown that enterovirus infections may initiate and accelerate the beta cell damaging process several years before clinical IDDM. In the present study the presence of enterovirus RNA was studied in the sera of initially healthy children who were followed until they manifested clinical IDDM, as well as in newly diagnosed IDDM patients and age- and sex-matched control subjects.

Altogether 33 follow-up samples from 7 prediabetic children were analysed using an RT-PCR method able to detect 1 PFU of virus per serum sample. Enterovirus RNA was found in 3 of these children in altogether 6 samples, taken 0.75 -3.4 years before the diagnosis of IDDM. In two children increases in IDDM-related autoantibodies were observed coincidently with the presence of enterovirus RNA in their serum. These findings are in line with our previous findings of enteroviruses as initiating and accelerating factors in the pathogenesis of IDDM. However, our analyses did not show an excess of enterovirus RNA in children with newly diagnosed IDDM (4 positive out of 35) as compared with control subjects (5/35). This suggests that the diabetogenic effect of enteroviruses may be most important during the early phases of the pathogenesis.

EPIDEMIOLOGY OF CHILDHOOD DIABETES IN HONG KONG: A PROSPECTIVE STUDY

G.W.K. Wong and T.F. Leung. Department of Paediatrics, The Chinese University of Hong Kong, Shatin, Hong Kong.

Epidemiological data on childhood diabetes in Chinese are limited. A registry of childhood IDDM was established in 1991 to collect new cases of childhood IDDM from four districts in the northeast region of Hong Kong. Data were collected according to the WHO DIAMOND protocol. The registry currently covers a population base of approximately 1.1 million. Of these, 250,000 are under 15 years of age. Data were collected retrospectively from 1986 to 1990 and prospectively from 1991 onwards. Primary ascertainment was based on review of medical records at a regional hospital serving the area. Independent school surveys validated the registry data. Capture-recapture estimates indicated the overall level of ascertainment was 94%. A total of 35 cases of childhood IDDM were diagnosed between Jan, 86 to Dec, 95. The mean yearly incidence rates of childhood IDDM were 1.7/100,000 (95% CI 0.5-4.3) during 1986 to 1990 and 1.3/100,000 (95% CI 0.3-3.8) during 1991 to 1995. The yearly incidence rate for females was 1.9/100,000 (95% CI 0.2-7.0). For males, it was 1.0/100,000 (0.0-5.7). In conclusion, the incidence for childhood IDDM in Hong Kong Chinese is low and females appear to have a slightly higher incidence rate than males.

247

CHILDREN WITH DIABETES SHOW NO TIME-SPACE CLUSTERING AT BIRTH

G. Law, P.A. McKinney, H. J. Bodansky, and D.R.R. Williams, Paediatric Epidemiology Group, Centre for Health Services Research, University of Leeds, UK.

The aetiology of IDDM remains largely unclear, but it is known the disease process involves an environmental component. Recent research has suggested perinatal events may be important, and the present study aimed to detect evidence of space-time clustering of births in children subsequently developing IDDM. Such a pattern would be suggestive of an infectious agent acting around the time of birth. The population basedYorkshire Childrens Diabetes Register collected details of children diagnosed with IDDM between 1978-1994 and is estimated as 97% complete. The residential address of the mothers at the time of birth of each child on the register was ascertained from birth certificates via the National Health Service Central Register and assigned a National Grid Reference. The Knox-Mantel test was applied to detect space-time clustering in the births of 1711 cases. Forty-two combinations of a wide range of spatial and temporal thresholds were tested (90-900 days, 1-20km). No evidence for space-time clustering was found ($p<0.05$) in the pattern of births of those children going on to develop IDDM during childhood. This the first UK study examining this issue and the results do not support the hypothesis of perinatal infections having an aetiological role in childhood IDDM.

248

PREVALENCE OF INSULIN-DEPENDENT DIABETES MELLITUS AMONG YOUNG FINNISH MALES IN 1975-1995

V.Jormanainen, M.Korpela, J.Tuomilehto and T.Sahi. Finnish Defence Forces and National Public Health Institute, Helsinki, Finland.

Finland has the highest incidence of insulin-dependent diabetes mellitus (IDDM) in the world. In Finland, all the males are ordered by the law to enter call-ups for common military service at the age of 18 years. The aim of the study was to describe the prevalence of IDDM among Finnish males at call-ups by municipality and year (birth cohort), during the study period 1975 - 1995. We used data provided by Finnish Defence Forces, Division of Health Care (FDF). The data contained aggregated information by district, service class, diagnoses, and numbers of checked males at annual call-ups. IDDM persons are without exceptions classified into service categories C or D (relieved from service in peace or war time, respectively) since 1973, and they enter call-ups only once.A case of IDDM was defined as a person, who at the time of the check-up had a well verified diagnosis of diabetes (ICD-8 or ICD-9: 250), and was classified into service category C or D. We calculated prevalence (i.e. cumulative incidence) per 1,000 persons by municipality and in the whole country. During the study period of 1975-1995, there were 4,281 IDDM cases among 715,212 males producing a crude prevalence of 6.0 per 1,000. The crude prevalence corresponds to an approximate annual incidence of 33.3 per 100,000. The lowest annual prevalence of 5.1 was observed in 1977, while the highest (6.9) in 1987. There was no clear trend in prevalence. By administrative municipality, the highest prevalences of IDDM were found in Eastern and Central Finland, and the lowest in Northern Finland. The observed variation between municipalities by study year was small as was variation by year within municipalities. Thus, the cumulative risk of IDDM in boys by age 18 remained unchanged while in young children the incidence has clearly increased during this period.

MORTALITY IN YOUNG DIABETIC SUBJECTS. A TWELVE - YEAR LITHUANIAN CHILDHOOD COHORT STUDY

B.Urbonaitė, R.Žalinkevičius and R.Lounamaa*. Kaunas Medical Academy, Institute of Endocrinology, *Bristol University, UK

Patients with IDDM are known to have increased risk of dying mainly because of acute and late complications of diabetes. The aim of present study was to determine mortality and causes of death among young patients with IDDM in Lithuania. The patients (n=698) were identified through the childhood register from 1983 to 1995. All these patients were young subjects: 360 males, age range (1.21-25.83 yrs) and 338 females (3.49-25.15 yrs). M/F ratio - 1.065. Cohort distribution by age was normal (skewness-0.096). Standard DIAMOND criteria for the diagnosis of IDDM were used. During the period of 01.01.95 - 01.06.95 the status of the cohort members was checked for 'alive' status. Search for IDDM onset deaths was a separate activity of mortality study in Lithuania. All deaths were coded according ICD-9 criteria. Totally, 25 deaths (2 onset) were registered. Hyperglycaemic coma was registered as a cause of death for 10 cases (40%). The observed/expected numbers of deaths (O/E ratio) of all cause mortality was 7.71 (CI 95% 2-sided 4.83-11.67, $p<0.001$), and 4.91 (CI 95% 2-sided 2.68-8.23, $p<0.001$) not directly attributed to diabetes. O/E ratio of all cause-mortality depending on duration of diabetes - for 0-5 yr duration group - 6.45 (CI 95% 2-sided 3.33-11.27, $p<0.001$), 6-13 yr duration group - 10.07 (CI 95% 2-sided 4.83-18.51, $p<0.001$). O/E ratio for causes not directly attributed to diabetes - 3.23 (CI 95% 2-sided 1.18-7.02, $p=0.012$) and 8.05 (CI 95% 2-sided 3.48-15.86, $p<0.001$), respectively. Conclusions: 1. Mortality risk for childhood onset diabetes in Lithuania is very high; 2. Mortality risk increases with longer duration of diabetes.

SEASONAL VARIATION OF INSULIN-DEPENDENT DIABETES MELLITUS IN SARDINIA AND FINLAND

Sa. Muntoni*, M. Karvonen, V. Elomaa, M. Stabilini*, L. Stabilini*, S. Muntoni* and J. Tuomilehto. * Centre for Metabolic Diseases and Atherosclerosis, Cagliari, Italy. Department of Epidemiology and Health Promotion National Public Health Institute, Helsinki, Finland.

The aim of this study was to compare the seasonal variation at the clinical onset of IDDM based on 1405 cases in Finland and 425 cases in Sardinia diagnosed at 14 years of age or under during 1989 to 1992. The average annual incidence of IDDM in Finland was 36.4/100,000 and 34.4/100,000 in Sardinia. Seasonal patterns were estimated presenting the data as short Fourier series up to three harmonics together with a possible linear trend. Likelihood ratio tests and Akaike's information criterion were used to determine the number of harmonics necessary to model the seasonal pattern. Seasonal patterns in both countries were compared between sexes and between the three 5-year age groups each controlling for the other's effect. In both countries, during a calendar year a significant seasonal pattern was found for the sexes combined and for two age groups (0-9 and 10-14 years). In Sardinia, two distinct cycles were found among the younger age group with a decreased incidence during May-August and a higher incidence during the autumn months. Two cycles were apparent for the older group with a nadir occurring during June-September. In Finland, one cycle with a decreased incidence in the summer was found in the younger age group. In the older age group, there were two distinct cycles with a decreased incidence in June and in the September-December period. The seasonal variation in the incidence of IDDM was clear in both countries, however, the pattern of variation was different. Although Finland and Sardinia have the highest IDDM incidence in the world, they are geographically remote from each other and therefore the difference in seasonal variation of IDDM incidence can be explained by climatic factors.

252

CLINICAL CHARACTERISTICS OF TYPE 1 DIABETES AT ONSET IN CHILDREN AND ADOLESCENTS

J. Rosenbauer, A. Dobroslavski and G. Giani. Department of Biometrics and Epidemiology, Diabetes Research Institute at Heinrich-Heine-University Düsseldorf, Germany.

Objective: Aim of this study was to describe the clinical presentation of Type 1 diabetes at diagnosis in a population-based cohort of children and adolescents and to analyse the association of clinical characteristics and age at onset. **Methods:** During 1993-95 291 new cases of Type 1 diabetes diagnosed under the age of 15 years were prospectively registered via an active surveillance system in a geographically well defined region around Düsseldorf. Detailed information on demographic data, duration of symptoms before onset, and clinical and biochemical presentation at diagnosis were obtained from hospital records. **Results:** Hospital records of 233 patients (80% of all eligible, 123 boys) could be evaluated. The distribution of age at onset was 0-4yrs: 22.7%, 5-9yrs: 34.3%, and 10-14yrs: 42.9%. The most frequently reported symptoms were polyuria (93,6%), fatigue (66.1%), weight loss (59.7%), and abdominal pain (15.9%). Polyuria was the first symptom in 85.8% of the patients with a mean duration of 3.3 ± 3.0 (± SD) weeks. Mean weight loss before diagnosis was 9.3 ± 5.7% of body weight. Weight loss was significantly higher in the youngest age group ($p < 0.05$). 35% of the children had a reduced skin turgor at clinical examination and 21.7% an impaired consciousness. Mean values of plasma glucose and glycosylated haemoglobin (relative to upper normal value) at diagnosis were 451 ± 197 mg/dl and 191 ± 50.6 %, respectively. Whereas glucose levels were significantly higher in the youngest age group ($p < 0.05$), glycosylated haemoglobin values were significantly higher in the oldest age group ($p < 0.05$). Ketonuria was present in 80.5%, plasma bicarbonate values < 20 mmol/l in 48.3% and acidosis (pH ≤ 7.2) in 16.8% of the children. Prevalence of acidosis was more common in children under 5 years than in the older age groups (0-4yrs: 20.8%, 5-9yrs: 15.1%, 10-14 yrs: 15.6%). **Conclusions:** This population-based analysis showed less severe clinical symptoms and metabolic dearrangement at disease onset than previously reported in other studies. For the most part the degree of metabolic decompensation was relatively minor. Ketonuria and acidosis were more frequent in the youngest age group.

253

THE SEASONAL DISTRIBUTION OF BIRTH OF PATIENTS WITH IDDM IS IDENTICAL TO ALL BIRTHS IN FINLAND

S. Väänänen, M. Karvonen and J. Tuomilehto
National Public Health Institute, Helsinki, Finland

It has been suggested that environment, e.g. virus infections, very early in life or even in utero would be important for the causation of IDDM. The aim of this study was to compare the seasonal distribution of birth of children with IDDM with all births in order to examine the possible differences in these distributions. The seasonal distribution of birth of 3604 children with IDDM diagnosed <15 years of age during 1987-1995 and born during 1976 to 1995 was compared with the seasonal distribution of births of 1,283,306 healthy children (children without IDDM) born in the same period. The fitting of the monthly distribution of births of children with IDDM and healthy children was tested using the X^2-test. The test was carried out for both sexes together and for boys and girls. Results showed that these two distributions did not differ from each others. Thus, in Finland, the monthly distribution of births of children with IDDM followed the monthly distribution of the healthy children born in the same period. The clear seasonal variation of IDDM incidence in Finland can hardly be explained by climatical factors or early exposure to certain infectious agents which are seasonal in the environment.

Distribution of births of children with IDDM and healthy children per month during 1976 to 1995 in Finland

		J	F	M	A	M	J	J	A	S	O	N	D	Tot

THE DIABETES PREVENTION TRIAL-TYPE 1 DIABETES (DPT-1): PROGRESS REPORT.

DPT-1 Study Group, Nationwide, USA

The DPT-1 is a nationwide study designed to determine whether insulin based therapies can delay or prevent the clinical onset of Type 1 diabetes in relatives found to be at high risk of development of the disease. Parenteral insulin is used in relatives with >50% projected 5-year risk. Oral insulin is used in relatives with 26-50% projected 5-year risk. Screening began in February 1994. Randomization began in December 1995 for the parenteral protocol and in September 1996 for the oral protocol. By November 30, 1996 there were 43,544 samples received for screening, of which 40,657 (93.4%) were eligible samples, a rate consistent with initial projections of screening 15,000-20,000 subjects per year. Of the 40,381 samples analyzed for islet cell antibodies (ICA) by 11/30/96, 1391 were positive. The rate of positive samples, 3.44%, is virtually identical to that projected in calculating sample size (3.6%). Of the 937 individuals who were staged for risk, 259 (27.6%) had low first phase insulin response (FPIR) to IVGTT, a slightly lower percentage than projected (35%), but within an acceptable range. Of the subjects who completed Staging for risk categorization, 141 were eligible for the parenteral study, and of these 131 (92.9% of those eligible) were randomized to the parenteral study. Of the 28 subjects eligible for the oral study, 26 (92.9% of those eligible) were randomized. Overall enrollment rates are 74.4% of that projected for the parenteral study and 89.7% of that projected for the oral study, by this point in time. These enrollment rates are comparable to those found in most multi-center randomized clinical trials. These data indicate that the statistical projections used in the design of DPT-1 are appropriate. DPT-1 is proceeding as planned.

255

MOLECULAR MECHANISMS FOR THE PREVENTION OF AUTOIMMUNE IDDM BY TREATMENT WITH A SUPERANTIGEN IN NOD MICE.

M. Lee, H.S. Jun, H.W. Lim, and J.W. Yoon. University of Calgary, Calgary, Alberta, Canada; Ajou University, Suwon, Korea.

We have previously shown that exogenous superantigens prevent the development of autoimmune IDDM in NOD mice. This investigation was initiated to determine the mechanisms involved in the prevention of IDDM by the superantigen staphylococcal enterotoxin B (SEB). First, we examined whether clonal deletion or clonal anergy of T cells is involved in the prevention of IDDM. We observed a mild but selective expansion of Vβ8 cells at three days after SEB injection, followed by a deletion of T cells at 14 days after injection. However, the number of Vβ8 cells and the proliferative responses of splenic T cells return to normal four weeks after SEB injection. Thus, the mild and transient effect of SEB is not a major factor in the prevention of autoimmune IDDM. Next, we examined whether SEB induces suppressor T cells when injected into NOD mice. We found that SEB induces CD4+ suppressor T cells. Finally, we examined the cytokine gene expression of the immunocytes that had infiltrated the pancreatic islets at different times after SEB treatment. We found an immediate increase in the expression of many cytokines, including IL-2, IFN-γ, IL-4, IL-10, IL-12 and TNF-α, as well as iNOS. With the exception of IL-4 and IL-10, expression of these cytokines and iNOS returned to normal three days after injection. At three weeks after injection a persistent increase in transforming growth factor β (TGFβ), IL-4, and IL-10 was observed. On the basis of these observations, we conclude that SEB persistently activates CD4+ suppressor T cells, which secrete increased amounts of IL-10, IL-4 and TGF-β. The increased secretion of cytokines may result in the prevention of cell-mediated autoimmune IDDM.

256

PREVENTION OF INSULIN-DEPENDENT DIABETES BY CD8 γδ T CELLS INDUCED BY AEROSOL INSULIN

L.C. Harrison, M. Dempsey-Collier, K. Takahashi, P. Augstein and D.R. Kramer, The Walter and Eliza Hall Institute, Parkville, Australia

Cellular immune hyporesponsiveness can be induced by the presentation of soluble protein antigens to mucosal surfaces. When we administered insulin aerosol to NOD mice even after the onset of sub-clinical disease, pancreatic islet pathology and diabetes incidence were both significantly reduced. Insulin-treated mice had increased circulating antibodies to insulin, and reduced splenic T-cell proliferation to the major epitope, insulin B chain amino acids 9-23, associated with increased IL-4 and particularly IL-10 secretion, as well as reduced proliferation to glutamic acid decarboxylase. The ability of splenocytes from insulin-treated mice to suppress adoptive transfer of diabetes by diabetogenic T cells were shown to be due to small numbers of CD8 γδ T cells. These cells also inhibit cyclophosphamide-accelerated diabetes and may be responsible for regulating the natural history of islet autoimmunity in NOD mice. Induction of regulatory CD8 γδ T cells by aerosol insulin has implications for the prevention of human IDDM.

257

THE EFFECT OF SUPERANTIGEN ADMINSITRATION ON THE NATURAL HISTORY OF IDD IN NOD MICE.

J. Schiffenbauer, T. Xie, M. Clare-Salzler and M.A. Atkinson. University of Florida, Gainesville, Florida, U.S.A.

A recent study examining islet infiltrating cells from patients who succumbed to diabetic ketoacidosis at the onset of IDD showed a selective expansion of T cells bearing the Vβ7 T cell receptor (TCR); an observation consistent with a superantigen driven expansion of lymphocytes. Such a superantigen (if any) responsible for initiating or exacerbating human IDD is unknown. In order to identify the potential effects of superantigen in the pathogenesis of IDD, split litters of female NOD mice (10 per group) were intraperitoneally injected with normal saline alone or with 50μg of staphylococcal enterotoxin B (SEB) in normal saline @ 4 (i.e., pre-insulitis), 10 (i.e., established insulitits), or 4 & 10 weeks of age. Functional studies of SEB administration demonstrated that Vβ8+/CD4+ T cells respond to this dose of SEB, although to a lesser degree than other mouse strains. Life-table analysis revealed that treatment of NOD mice with SEB at 4 (P=0.4) or 4 & 10 (P=0.5) weeks of age did not alter the natural history of progression to IDDM. Interestingly, SEB injection into 10 week old animals significantly delayed rather than exacerbated the onset of IDDM (P=0.04). In addition to contrasting the hypothesis suggested by the aforementioned human results, this observation was in marked contrast to our previous findings in experimental allergic encephalomyelitits (EAE) where SEB administration re-induced disease in mice which had resolved a previous clinical episode. Therefore while provocative, the role for a superantigen driven pathogenesis of IDD is not supported by these studies and remains controversial.

258

FEASIBILITY OF A MULTINATIONAL DIABETES PREVENTION TRIAL IN FIRST DEGREE RELATIVES OF A CHILD WITH IDDM

WP Moore, EAM Gale and the ENDIT Group, University of Bristol, U.K.

The European Nicotinamide Diabetes Intervention Trial (ENDIT) set out to screen 40,000 first degree relatives of individuals who developed IDDM before age 20 yrs, with the aim of recruiting 528 high risk relatives to a 5 year randomized placebo-controlled trial of nicotinamide. Recruits were aged 5-40 years, non-diabetic by OGTT, positive for ICA on two occasions with one value ≥ 20 JDF units (JDFu), and fulfilled other eligibility criteria. The end point is development of diabetes (WHO criteria). Primary ICA screening was carried out in 10 laboratories, and eligibility confirmed at a central reference laboratory. By December 1996, 449 individuals had been randomized in 16 countries. 62% were under the age of 20 and 48% female. 29% were parents, 59% siblings and 10% children of the proband. 29% had ICA ≥80 JDFu, 55% had GAD autoantibodies (Ab), 38% IA-2 Ab and 29% insulin Ab ≥99th centile of 3000 schoolchildren. 43% had at least 2 Ab ≥ 99th centile in addition to ICA. OGTT was normal in 88%, and showed IGT in 12%. Of 263 IVGTT analysed, 17% had FPIR (1'+3' insulin) < 50 mU/l (standardized to the Seattle assay). Individuals <20 yr had more risk markers than those ≥ 20 yr. ICA ≥ 80 JDFu were found in 31% vs 23% (p=NS); 3-4 Ab ≥ 99th centile in 41% vs 23% (p<0.001), and FPIR ≤ 50 mU/l in 26% vs 9% (p<0.001). 30 of those recruited have developed diabetes, and 35 withdrawn from the trial. Recruitment is expected to end in 1997, with completion of the trial in 2002. Conclusion: multinational collaborative intervention trials are feasible in pre-IDDM. Simple robust entry criteria are essential. ICA have proved their value, but future trial entry will probably be based on multiple antibody testing. The ENDIT group are currently planning their next intervention trial.

DOWN-REGULATION OF ISLET ANTIGEN EXPRESSION IN INSULIN STRATEGIES OF PREVENTION IN THE LD-STZ DIABETES MODEL.

E. Anastasi, F. Dotta, C. Tiberti, E. Ponte and U. Di Mario. Universities "La Sapienza" and "Sacro Cuore" of Rome/ University of RC-Catanzaro, Italy.

Aim of this study was to investigate in the LD-STZ mouse model of diabetes a preventive insulin administration evaluating its effects on disease onset, on the severity of the insulitis and on the pattern of islet antigen expression (ICA-target antigen, A2B5 monoclonal antibody recognizing islet glycolipids, GM3 and GM2-1 gangliosides) in different time points of the disease. Diabetes has been induced in male mice C57Bl6/J with LD-STZ. Seventy-one male C57Bl6/J mice were grouped as follows: Group A (n=25) injected i.p. with STZ only, Group B (n=21) injected subcutaneously with insulin in addition to STZ, Group C (n=15) injected with insulin only, Group D (n=10) used as normal control. Glycemia, insulitis and pancreatic islet antigen expression were evaluated at 12 and 24 days. At day 12 and 24 differences in mean glycemia and insulitis score between Group A and B were statistically significant (p<0.001, p<0.05), (p<0.001). At day 12 pancreas sections collected from Group B and Group C and incubated with 5 ICA+ human and normal mouse sera showed a lack of binding of these sera, at day 24 only sections from Group B showed positive reaction with the sera. At day 12 we observed in Group B and Group C the absence of the expression of monoclonal A2B5, in contrast at day 24 pancreata from both groups of mice showed positive binding to A2B5. Analysis of the pattern of ganglioside expression revealed that GM3 was equally expressed in all groups of treatment; in contrast expression of GM2-1 at day 12 was greatly reduced in Group B, while was not changed in animals belonging to Group C. At day 24, GM2-1 expression was reduced in Group C while was not unchanged in Group B of animals. In conclusion, our study confirmed that prophylactic insulin treatment is able to reduce diabetes and insulitis in the LD-STZ mouse model. Interestingly we showed that this effect was paralleled by a down regulation of the expression of some islet molecules, some of which, such as the cytoplasmic ICA antigens and the GM2-1 ganglioside, have been shown to be major targets of the autoimmune response leading to type 1 diabetes.

260

MULTI-CENTER RANDOMIZED TRIAL AT DIFFERENT DOSES OF NICOTINAMIDE IN PATIENTS WITH RECENT-ONSET IDDM. The IMDIAB Group, Rome, Italy.

Recent evidence has suggested that nicotinamide (NA) when given at IDDM diagnosis may protect against residual beta cell damage. Studies in animal models indicate that when high doses of NA are given, beta cells are better protected from destruction. The aim of this study was to compare the efficacy of standard doses of NA (25 mg/Kg b.w., GROUP A) vs. high doses of NA (50 mg/Kg b.w., GROUP B) on residual beta cell function and the parameters of metabolic control (insulin dose and HbA1c) in patients with recent-onset IDDM (less than 4 weeks after diagnosis). A multi-center trial was carried out in 42 IDDM patients (20 females and 22 males, mean age 13.6 ± 8.1 years), who were randomized to one or the other dose of NA which was administered daily in addition to intensive insulin therapy. Data on the integrated parameters of metabolic control were collected at entry and after 3- and 6-month intervals. Patients are expected to be followed-up for up to 1 year. No significant differences were observed in C-peptide secretion, insulin dose or HbA1c levels at each interval. C-peptide values were 0.77 ± 0.57 ng/ml (baseline), 0.86 ± 0.77 ng/ml (3 months) and 0.72 ± 0.4 ng/ml (6 months) in GROUP A vs. 0.55 ± 0.53 ng/ml (baseline), 0.90 ± 0.62 ng/ml (3 months) and 0.78 ± 0.59 ng/ml (6 months) in GROUP B (NS), with comparable good metabolic control (HbA1c = 6.2 % ± 0.8 in GROUP A and 6.3% ± 0.9 in GROUP B, after 6 months of therapy). Adverse effects were not reported in either group of patients. We conclude that NA is equally effective at doses of either 25 or 50 mg/Kg in maintaining residual beta cell secretion 6 months after diagnosis in patients with IDDM.

261

TROGLITAZONE REDUCES DIABETES INCIDENCE IN NOD MICE.

P.Beales, A.Giorgini, K.Batchelor and P.Pozzilli. Dept Diabetes & Metabolism, St Bartholomew's Hospital, London UK.

Troglitazone (TGL) is a thiazolidinedione compound which increases sensitivity to insulin and is used to treat insulin resistance in NIDDM. Insulin resistance is also a feature of IDDM and may have pathogenic relevance as increased antigen expression on beta cells may occur as a consequence of insulin release. TGL was given to NOD mice, a spontaneous model of IDDM, to determine if increasing insulin sensitivity using this compound could reduce diabetes incidence. TGL was given by gavage in a methyl cellulose carrier (MCC) to 32 female NOD mice 5 x per week from 3 to 30 weeks of age at a dose of 800 mg per kg body weight. A further group of 32 age, sex and litter matched NOD's served as controls and received MCC alone. By 16 weeks of age there was a significant reduction in diabetes incidence in the treated vs control group (0 vs 5)($p<0.03$ - comparison of proportions) this level of difference was maintained up to the conclusion of the study (treated vs controls = 5 vs 16). However there was no difference in insulitis levels, nor in the destructive pattern of insulitis between treated and control groups. In vitro data (presented elsewhere) suggests that lymphocyte activation is altered by TGL by changing cytokine secretion patterns. Therefore we conclude that TGL may be effective in preventing IDDM in NOD mice by modifying cytokine secretion of TH1/TH2 lymphocytes.

NICOTINAMIDE PREVENTS THE DEVELOPMENT OF INSULIN DEFICIENCY IN STREPTOZOTOCIN-TREATED NEWBORN RATS

N. Gorbenko, V. Poltorack, A. Gladkih and O. Borodina. Ukrainian Scientific Research Institute of Endocrine Diseases Pharmacotherapy, Kharkov, Ukraine

It has been shown that nicotinamide (NA), an inhibitor of poly (ADP-ribose)synthase and free radical scavenger, offers protection to pancreatic beta cells against a variety of toxic or immune-mediated insults. The aim of the study was to evaluate the protective effect of NA on the development of absolute and relative insulin deficiency in streptozotocin (STZ)-treated newborn rats. NA (500 mg/kg/day) was given to offspring's mother in diet for 10 days before and 5 days after STZ-injection (100 mg/kg i.p.). Pre- and postnatal treatment with NA prevented basal hyperglycemia (5.3±0.6 vs 11.4±0.5 mmol/l, $p<0.01$) and hypoinsulinemia (127.0±10.4 vs 78.0±5.5 pmol/l, $p<0.02$) on the absolute insulin deficiency stage (at day 5 after STZ-injection). NA administration also protected basal hyperglycemia ($p<0.05$) and forming of glucose intolerance on the relative insulin deficiency stage (at day 56): integral glycemia over the i.p. GTT was 32.1±1.4 vs 55.7±1.5 mmol/l, $p<0.02$ in untreated diabetic controls compared to 30.1±2.0 mmol/l in intact controls. All animals were sacrificed at 2 months of age and histological examination of pancreas revealed normalisation of morphological structure of islets with clear stimulation of beta-cells regeneration in rats treated with NA. Moreover, there were no differences in ascorbate and NADPH-dependent lipid peroxidation in liver of NA-treated animals and intact controls. We conclude that pre- and postnatal treatment with NA protects the development both absolute and relative insulin deficiency in STZ-treated newborn rats.

263

Effect of testosterone on development of diabetes

S. Takei[1], H. Toyoda[2], K. Negishi[1], T. Awata[1], S. Katayama[1] and J. Ishii[1] [1]4th Dept. of Int. Med., Saitama Med. Sch. Saitama, Japan [2]Cedars-Sainai Medical Center Los Angeles CA. U.S.A.

Nonobese diabetic (NOD) mouse strain has been utilized as a model for type 1 diabetes. The autoimmune diabetes is caused by lymphocytic infiltration and β -cell destruction mediated by inflammatory T-cells. The incidences of diabetes in female and male NOD mice are 65% and 5% at 30 weeks of age, respectively. This sexual dimorphism suggests that sex-steroid hormones may play an important role in the development of the disease. We, therefore, investigated the effect of a male steroid hormone, 5α -dihydrotestosterone(5DHT), on disease development, T-cell phenotype, T-cell proliferation, cytokine profiles and gene expression in female NOD mice. All mice (n=8) that recieved 5DHT for 120 days did not develop insulitis, whereas all untreated mice (n=8) developed the disease. The percentage of CD4+ T cells in peripheral blood mononuclear cells was decreased in the 5DHT treated mice compared to controls (37.1± 4.8% vs. 51.3± 9.3 %, $p<0.02$). Results of a syngeneic mixed lymphocyte reaction (SMLR) demonstrated an increased expression of a cytokine gene (IL-4) representing Th2 cell populations in splenic T cells obtained from 5DHT-treated mice. These results suggest that 5DHT may have direct effects on the expansion of Th2 cell populations with subsequent restoration of normal immune responses.

PORCINE BRAIN GAD AND CFA MAY PREVENT INSULITIS AND DIABETES IN NOD MICE

Z.G. Zhou, W.Yang, Z.L.Yang, and J.X.Wen. Institute of Metabolism & Endocrinology, Hunan Medical University, Changsha, China

This study aimed to investigate the preventive effect of glutamic acid decarboxylase (GAD) and complete Freund's adjuvant (CFA) on insulitis and diabetes in non-obese diabetic (NOD) mice. Six female NOD mice were injected once intraperitoneally with 10^{-3}g purified porcine brain GAD at 4 weeks of age, 4 female NOD mice as control were injected once intraperitonearily with 10^{-3}g bovine serum albumin (BSA) at the same age; 5 female NOD mice were injected in the hind footpad with 0.05 ml CFA at 4 weeks of age, 6 female NOD mice as control were injected in the hind footpad with 0.05 ml normal saline (NS) at the same age. The severity of insulitis of GAD-treated mice were less than that of BSA-treated mice by 19 weeks of age (insulitis scores: 1.28±0.51 vs 2.36±0.93, $P<0.05$). By 30 weeks of age, none of 5 CFA-treated mice, compared with 3 of 6 control mice, had developed diabetes. The severity of insulitis of CFA-treated mice were less than that of control mice (insulitis scores: 1.84±0.75 vs 3.00±0.80, $P<0.05$). These data showed that porcine brain GAD purified by our laboratory and CFA may be able to lessen insulitis severity of NOD mice, and CFA may decrease incidence of diabetes in NOD mice.

PS 3
Serological Markers of IDDM

265

Detection of autoantibodies to the diabetes-associated antigen IA-2 with non-radioactive assays compared to a validated radioligand assay

K. Löbner, N.G. Morgenthaler, U.Y. Khoo-Morgenthaler, M.R. Christie, J. Seissler and W.A. Scherbaum. Department of Internal Medicine III, University of Leipzig, Germany, and Department of Medicine, King's College London, UK.

Autoantibodies to the tyrosine phosphatase-like protein IA-2 (IA-2A) are important markers of IDDM. IA-2A are currently measured in radioligand assays (RIA) using *in vitro* synthesised ^{35}S-labelled antigen. We have investigated non-radioactive methods for the detection of these antibodies using E. coli derived IA-2 (Pinpoint, Promega). Intracytoplasmic IA-2 (IA-2ic) and a control protein (non-sense protein produced by a frameshift) were affinity purified, and used to coat ELISA plates. Additionally IA-2ic was dot-blotted directly onto nitrocellulose, or subjected to SDS-PAGE followed by Western blotting. We tested 45 sera of RIA positive or negative IDDM patients and 47 control sera. The results are summarized in the table; all sera were negative in assays using the control protein.

	RIA	ELISA	Dot blot	Westernblot
all IDDM patients	31/45(69%)	32/45 (71%)	32/45 (71%)	12/39 (31%)
RIA positive IDDM patients		29/31 (93%)	29/31 (93%)	11/31 (36%)
RIA negative IDDM patients		3/14 (21%)	3/14 (21%)	1/14 (7%)
healthy controls	0/47 (0%)	0/47 (0%)	1/17 (6%)	1/17 (6%)

The sensitivity of the ELISA and the dot blot was comparable to the radioligand assay, but the dot blot had a lower specificity. The values of the radioligand assay and the ELISA correlated ($r=0,75$; $p<0,0001$). Only one third of IDDM patients was positive in the Western blot, indicating that the majority of IDDM patients has autoantibodies to conformational epitopes, and autoantibody binding to IA-2 may be heterogeneous in some patients. These non-radioactive assays are potentially useful for the screening of antibodies to IA-2 where radioactive facilities are not available.

266

TEN DIABETES ASSOCIATED HUMAN MONOCLONAL GAD65-AUTOANTIBODIES DEFINE SIX DISTINCT EPITOPES IN GAD65.

K. Syren, *L. Lindsay , B. Stoehrer, K. Jury, *S. Baekkeskov and W. Richter, *University of Ulm, Ulm, Germany and Hormone Research Institute, University of California, San Francisco*

Autoreactive islet cell antibodies (ICA) directed to distinct target antigens are well-established markers for prediction and diagnosis of insulin dependent diabetes mellitus (IDDM). We attempted to isolate human monoclonal ICA to unknown islet cell antigens from patients newly diagnosed with IDDM but no stable ICA-reactive B cell lines could be obtained from 3 GAD-antibody-negative individuals. In contrast, four new human monoclonal ICA-reactive B cell lines (MICA 7-10) were stabilized from 2 out of 3 GAD-antibody-positive individuals tested. MICA 7 was derived from an HLA DR4/11^{+} patient, MICA 8-10 were isolated from an IDDM patient (HLA DR3/3) who also suffered from Graves' disease. MICA 7-10 were specific for GAD65. Therefore, they completed a set of six GAD65-reactive human monoclonal ICA (MICA 1-6) which were derived previously from an HLA DR1/7^{+} individual. This suggests a high frequency of GAD65-specific B cells compared to other ICA-reactive B cells in peripheral blood at diagnosis of IDDM. Analysis of 5 N-terminal and 3 C-terminal deletion mutants of GAD65 and blocking experiments by direct immunohistochemistry demonstrated that MICA 7-10 define three novel conformation dependent autoantigenic epitopes in GAD65. Using chimeric molecules constructed of GAD65 and GAD67 fragments we further narrowed down the epitopes of MICA 1-10. We identified three regions of distinct immunogenicity in GAD65: a) an NH_2-terminal region spanning amino acids (aa) 1-244 which was not sufficient for any epitope but contributed to the binding of MICA 8 and 9 requiring aa 39-585; b) the middle region encompassing aa 245-449 and harbouring the epitopes of MICA 4, 6 and MICA 10 and c) the COOH-terminal 135 aa which contained the epitopes recognized by MICA 1, 2, 3 and MICA 7. In sum, three analytical approaches demonstrated that MICA 1-10 define at least 6 distinct autoreactive epitopes associated with IDDM and detect two domain boundaries in GAD65.

IA-2 ANTIBODIES IN RELATION TO OTHER AUTOANTIBODIES AND GENETIC RISK MARKERS IN CHILDREN WITH RECENT-ONSET IDDM

K.Savola, E.Bonifacio, E.Sabbah, P.Kulmala, P.Vähäsalo, J.Karjalainen, E.Tuomilehto-Wolf, H.K.Åkerblom, M.Knip. University of Oulu, Oulu, Finland, Scientific Institute of San Raffaele, Milan, Italy, National Public Health Institute, Helsinki, Finland and the Children's Hospital, University of Helsinki, Helsinki, Finland.

To study the role of antibodies to IA-2 (IA-2A) in IDDM we analyzed 756 newly diagnosed patients younger than 15 years (mean age 8.5) for IA-2A, GAD65 antibodies (GADA) and insulin antibodies (IAA) with radiobinding assays, for islet cell antibodies (ICA) with immunofluorescence and for HLA DR alleles by serology. 73.4% of patients tested positive for IA-2A, 73.1% GADA, 48.6% for IAA and 84.2% for ICA. Boys and girls had similar frequencies and levels of IA-2A. There were no significant differences in the IA-2A frequencies between three age groups (0-4.99, 5.0-9.99 and 10.0-14.99), but patients aged 5.0-9.99 years had higher IA-2A levels ($p<0.05$) than the youngest children. There was a relatively strong correlation between IA-2A and ICA levels ($r=0.45$; $p<0.001$), while no relation was observed between IA-2A and GADA levels. A modest correlation was seen between IA-2A and IAA ($r=0.20$; $p<0.001$). A higher proportion of the patients tested positive for IA-2A and/or GADA than for ICA alone (91.5% vs. 84.2%; $p<0.001$). This difference was most conspicuous in the oldest age group (92.9% vs. 77.4%; $p<0.001$). An overwhelming majority of the patients (87.5%) tested positive for at least two disease associated autoantibodies. Only one antibody was detected in 8.8% of the children, and very few patients (3.7%) tested negative for all four autoantibodies. The patients carrying the DR4/x phenotype (x is other than DR3 or DR2) had higher antibody levels ($p<0.001$) than the other cases. Only about one third (35.3%) of the patients with DR 3/y phenotype (y is other than DR4 or DR2) tested positive for IA-2A and they had decreased antibody levels ($p<0.001$). These results indicate that the combination of IA-2A and GADA has a higher sensitivity for IDDM than ICA alone, especially in subjects older than 10 years. IA-2A are closely associated with the DR4 allele in contrast to GADA, which have been shown to associate with the DR3 allele.

EPITOPE SPECIFIC PRESENTATION OF GLUTAMIC ACID DECARBOXYLASE, GAD_{65}, IN HUMAN B-CELL LINES

Reijonen H [1], Masewicz S [1], Wicker L [2], Elliott J [3], and Nepom G [1]
[1] Virginia Mason Research Center, Seattle, USA [2] Merck Research Labs, Rahway, NJ, USA;[3] Department of Medical Microbiology and Immunology, University of Alberta, Edmonton, Alberta, Canada

Antigen processing and presentation of two immunogenic epitopes of GAD65 was analyzed using DRB1*0401 restricted murine T-cell hybridomas specific for peptides corresponding to GAD 274-286 and 114-126. Using immortalized B-lymphoblastoid cell lines derived from diabetic patients, subjects with GAD autoantibodies or healthy individuals, presentation of exogenously added GAD_{65} protein was investigated. Two B-cell lines pulsed with GAD protein were efficient for processing and presentation of both epitopes, but interestingly, four other B-cell lines displayed an epitope specific presentation pattern: The GAD 274-286 epitope was efficiently presented whereas stimulation of the T cell hybridoma specific for GAD 114-126 was not induced. All B-cell lines efficiently presented peptides corresponding to the particular epitopes, indicating that the differences occurred at the level of antigen processing. The deficiency of presentation in terms of epitope 114-126 generated from GAD protein was not due to a global defect in the processing machinery since these cell lines were capable of presenting exogenously added human serum albumin (HSA) protein equally well. These differences suggest either quantitative or qualitative variation in the intrinsic ability of antigen-presenting cells from different individuals to process and present specific antigenic peptides derived from an important autoantigen. Epitope specific presentation of GAD_{65} in human B-cell lines may have implications for events involved in triggering of the autoimmune response against dominant GAD_{65} epitopes or in determinant spreading towards subdominant epitopes during the disease course.

269

CAN BIOCHEMICALLY BASED ASSAYS FOR ISLET AUTOANTIBODY DETECTION REPLACE THE CLASSICAL ICA TEST?

D. Lazard, N. Weintraub, S. Assa, K. Bloch, N. Abramov, Z. Josefsberg, M. Karp and P. Vardi. The National Center for Childhood Diabetes, SCMCI, and FMRC, Tel Aviv University, Israel.

Islet cell antibodies (ICA) continue to serve as the principal serological test for definition of active autoimmunity of the beta-cells. In the last decade biochemically-defined beta-cell antigens were described, leading to the development of sensitive and specific autoantibody assays, to be used in prediction of insulin dependent diabetes mellitus (IDDM). The aim of our study was to examine the value of using combinatorial biochemically-based serological assays such as autoantibodies to insulin (IAA), glutamic acid decarboxylase (GAD) and ICA512 in replacement of the traditionally used ICA assay. Blood samples of 114 newly diagnosed IDDM patients aged 12±5yrs (range 2months - 29 years) taken at or soon after diagnosis (mean 5±4 days, range 0 -30 days) were tested for ICA (indirect immunofluorescence), IAA, GAD and ICA512 (radiobinding assay). The latter 2 assays were performed using recombinant human [^{35}S]-labelled antigen produced by in vitro transcription/translation. Using these tests we found that 90.3% (103/114) of our patients expressed 1 or more, 78.9% (90/114) 2 or more and 58.8% (67/114) 3 or more markers. Despite the improvement provided by an enlarged battery of assays, 9.6% of the tested sera did not react in any of the tests performed. We found that a lower number of sera scored positive for ICA and/or IAA (80.7%, 92/114) than for 1 or more of IAA, GAD, or ICA512 (88.6%, 101/114). Interestingly, only 2/114 (1.7%) were positive for ICA and negative for the other 3 markers. We conclude that combinatorial testing for IAA, GAD and ICA512 can advantageously replace the traditionally used ICA/IAA test for prediction of IDDM.

270

Molecular mimicry in IDDM: The PEVKEK motif of coxsackie B virus protein 2C and glutamate decarboxylase binds to HLA-DR3.

G.R. Vreugdenhil[1], A.Geluk[2], T.H.M. Ottenhoff[2], W.J.G. Melchers[1], B.O. Roep[2] and J.M.D. Galama[1]. University of Nijmegen, Nijmegen, The Netherlands;[2] University of Leiden, Leiden, The Netherlands.

Molecular mimicry between coxsackievirus B4 protein 2C and the autoantigen glutamic acid decarboxylase (GAD_{65}) has been proposed to play a role in the pathogenesis of insulin dependent diabetes mellitus. To investigate whether the sequence homology between GAD_{65} and p2C (PEVKEK) is restricted to coxsackie B4 we studied conservation of the homologous sequence within the family of enteroviruses. Sequence analysis of the p2C encoding genome of a number of coxsackie B-like enterovirus isolates showed that the mimicry motif and flanking sequences are highly conserved in different members of the coxsackie B-like group. In the polio-like enteroviruses no homology to GAD_{65} was found. Molecular mimicry is therefore restricted to the coxsackie B-like enteroviruses, which represent the most prevalent enteroviruses. Furthermore, the relevance of the mimicry motif for induction of autoimmunity to GAD_{65} was studied in an HLA-peptide binding assay using the diabetes-associated HLA-DR3, DR4 and DR1 molecules. Peptides derived from GAD_{65} and p2C, containing the PEVKEK motif, were found to bind with equal affinity to DR3. Replacement of amino acids in the motif showed that PEVKEK binds within the peptide binding groove of the DR3 molecule and thereby can be presented to the immune system. No binding was found with DR4 or DR1. These results suggest that molecular mimicry indeed may play a role in the development of diabetes. Furthermore, although exposure to the motif is frequent, molecular mimicry might be restricted to HLA-DR3 positive patients.

271

GAD65 AND ICA512 AUTOANTIBODIES AS DISEASE MARKERS AND THEIR NATURAL HISTORY IN A POPULATION OF YOUNG INSULIN-DEPENDENT DIABETIC PATIENTS.

M.M. Zanone, M. Pietropaolo*, E. Catalfamo, R. Quadri, M. Peakman*, S. James*, L. Chiandussi, F. Cerutti** and M. Trucco*. Depts. of Internal Medicine and **Paediatrics, Univ. of Torino, Italy; *Dept. of Immunogenetics, Children's Hospital, Pittsburgh, USA.

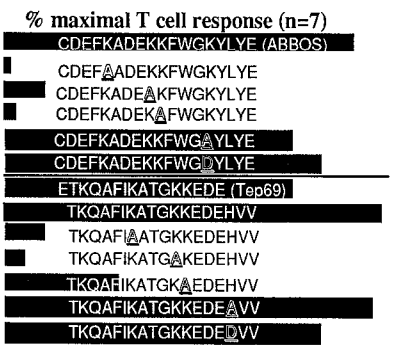
Circulating autoantibodies to islet autoantigens, glutamic acid decarboxylase (GAD65) and tyrosine phosphatase ICA512, measured in combination, have been proposed as predictive markers of IDDM. To analyse their potential for screening children with these markers, we examined their sensitivity in identifying IDDM in a population of 59 children at diagnosis of IDDM (mean (SD) age 7.5 (4) years). We also examined the natural history of the autoantibodies amongst childhood diabetics in 91 adolescents with IDDM (age 14.7 (1.6) years; mean duration of IDDM 7 (3.5) years). 42 normal adolescents (age 14.6 (1.8) years) without family history of IDDM were the control group. GAD65 and ICA512 autoantibodies were assessed by a quantitative radioimmunoprecipitation assay, using in vitro transcribed/translated proteins and expressed as indices derived using standard positive and negative sera. GAD65 and ICA512 autoantibodies were detected in 53% and 64% of newly diagnosed IDDM children. There was no correlation between levels of C peptide and levels of autoantibodies. 80% had at least one autoantibody, but the autoantibodies occurred together in only 37%. 24% of ICA negative patients had at least one of the two autoantibodies. 1/42 of controls (2%) had GAD65 autoantibodies and another control had ICA512 autoantibodies. GAD65 and ICA512 autoantibodies were present in 44% and 45% of diabetic adolescents, and occurred together in 21% of the adolescents. The mean ICA512 index was significantly higher amongst the newly diagnosed patients ($p<0.001$), and levels tended to decline with diabetes duration ($p=0.058$). At diagnosis, levels of GAD65 autoantibodies correlated with age ($p=0.05$), and in the adolescent patients levels did not decline with diabetes duration. In the adolescent patients, the presence of ICA512 was significantly associated with ICA ($p<0.05$) and mean ICA512 index was higher in ICA positive than in ICA negative patients ($p<0.005$). Our findings indicate that positivity for either GAD65 or ICA512 autoantibodies is a highly sensitive marker of IDDM in the paediatric age group, while positivity for both has a diagnostic sensitivity of 37%. The association between presence and levels of ICA512 autoantibodies and ICA suggests tyrosine phosphatase as one of the ICA target autoantigens, supported by the finding of higher levels of ICA512 at diagnosis, declining with diabetes duration.

272

STRUCTURAL PREREQUISITES OF ANTIGENIC MIMICRY BETWEEN ICA69 (TEP69) AND BSA (ABBOS)

H.-M. Dosch, J. C. Gorga*, R.K. Cheung, J. Gay* and D. J. Becker*, Departments of Pediatrics, Univ. of Toronto and *Pittsburgh

ICA69 is a neuroendocrine protein with maximal expression in β-cells. The function of the 4 ICA69 isoforms is unknown, but it is a frequent target of diabetic autoimmunity. There are 3 regions of homology between ICA69 and bovine serum albumin (BSA), one of several cow milk constituents that engender abnormal immune responses in diabetes. Studies of autoreactive T cells in newly diabetic children and NOD mice have delineated two dominant T cell epitopes in these two molecules that show fully reciprocal antigenic mimicry as well as cross-tolerance (in NOD mice): ABBOS (in BSA) and Tep69 (in ICA69). A model was proposed, where early exposure to dietary BSA would generate ABBOS-specific T cell repertoires that could target beta cell ICA69. As shown in the figure, the linear homology between ABBOS and Tep69 consists of 4 identically spaced amino acids (KA..KK). Here we have used ALA mapping with replacement peptides in patient T cell proliferation assays and find that these 4 residues are absolutely critical for the observed T cell mimicry. These and experiments in NOD mice define the structural constraints of mimicry between BSA and ICA69.



273

ANTIBODIES TO ICA512 AND GAD65 IN INSULIN-DEPENDENT DIABETES (IDDM) PATIENTS FROM LATVIA.

A. Shtauvere, I. Rumba, I. Dzivite, A Falorni and CB. Sanjeevi. Dept of Molecular Medicine, Stockholm; Dept of Pediatrics, Riga; Dept. of Internal Medicine, Endocrine & Metabolic Sciences, Perugia. Sweden, Latvia, Italy.

Antibodies to tyrosine pyrophosphatase (ICA512) and glutamate decarboxylase 65 (GAD65) are most prevalent in Caucasians with IDDM. The aim of our study was to determine the prevalence of ICA512 and GAD65 antibodies (Ab) in IDDM patients (n=87) and 90 healthy controls from Latvia.. ICA512Ab and GAD65Ab were evaluated by RIA using *in vitro* translated recombinant human 35S-ICA512 and 35S-GAD65 respectively. In controls, ICA512Ab were present in 5/90 (5%) and GAD65Ab in 3/90 (3%). In IDDM, ICA512Ab were present in 36/87 (41%)($p<0.001$ vs controls) and GAD65Ab in 58/87 (67%) ($p<0.001$ vs controls). The frequency of ICA512Ab in 0-5 years age was 8/16 (50%)which is higher than that observed in older (>5 years) patients (28/71,39%)(p=ns) whereas GAD65Ab was lower in patients with 0-5 years of age (6/16, 38%) than in older (>5 years) patients (51/71,72%)($p<0.01$). Both ICA512Ab and GAD65Ab were higherin frequency in female (20/42, 48% and 32/42, 76% respectively) than male patients (16/45, 35% and 26/45, 58% respectively). Both ICA512Ab and GAD65Ab were found simultaneously in 22/87 (25%); both Abs were absent in 15/87 (17%); either ICA512Ab or GAD65Ab was present in 72/87 (83%); A total of 12/87 (14%) IDDM patients was ICA512Ab+/GAD65Ab-, whereas 36/87 (41%) patients were ICA512Ab-/GAD65Ab+.

We conclude that IDDM patients from Latvia, have ICA512Ab and GAD65Ab at a significantly high frequency as compared to healthy controls. In conformity with previous observations in Swedish IDDM patients, GAD65 appears to be major autoantigen in Latvian IDDM.

274

CONSTRUCTION OF AN ANTIBODY PHAGE DISPLAY LIBRARY FROM 7 PATIENTS WITH TYPE - I DIABETES MELLITUS

K. M. Jury, P. Söhnlein, A. Kurkhaus, U. Scheidt, B.O. Böhm and W. Richter, University of Ulm, Ulm, Germany

The panel of human monoclonal IgG antibodies (hmabs) related to insulin dependent diabetes mellitus (IDDM) is still small. The prediction of IDDM and the standardization of islet cell autoantibody (ICA) assays will be improved when hmabs specific for diabetes-related autoantigens and their characteristic epitopes will be available. The phage display technology is a powerful tool for the generation of recombinant human antibody fragments (Fragment antigen binding, Fab). Aim of our approach was 1.) to generate a large combinatorial Fab phage display library characteristic for the humoral immune response at onset of IDDM and 2.) to isolate from this library new human islet cell autoantibody fragments directed to any relevant autoantigen in IDDM. To validate the applied techniques we established phage display of Fab and expression of soluble Fab molecules for MICA 2 and MICA 4, two human monoclonal GAD65-reactive IgG1 autoantibodies obtained by conventional methods. The genes of the light chains (L) and of the variable region plus first constant region (Fd) of the heavy chains (H) were cloned into phagemid pComb3HSS. The antibody fragments were expressed as fusion proteins with the coat protein cp III of bacteriophage M13 (Phab) and as soluble Fabs in E. coli. Phabs and soluble Fabs derived from MICA 2 and MICA 4 bound to human GAD65 in an indirect ELISA with immobilized antigen and in a dot blot analysis with immobilized phages. This demonstrates that the chosen phage display system is suitable for enrichment and production of IDDM-related Fab. The antibody phage display library was generated from 10^8 peripheral blood lymphocytes (PBL) pooled from seven individuals with high ICA titers at onset of IDDM. The library is now ready to be screened for high affinity Fabs to any autoantigen relevant for IDDM. The approach we described may be useful in identifying new IDDM-related antibody specifities to known and unknown islet cell antigens in type-I diabetes. Supported by grants of DFG Ri 707/1-2 and HFSP 361-95 to W.R.

275

ANTIBODIES TO ICA512 AND GAD65 IN INSULIN-DEPENDENT DIABETES (IDDM) PATIENTS FROM EASTERN INDIA.

CB. Sanjeevi, A. Shtauvere, A. Kanungo, K.C. Samal, B.B. Tripathy, and A. Falorni. Dept of Molecular Medicine, Stockholm; Dept of Endocrinology, Cuttack; Dept. of Internal Medicine, Endocrine and Metabolic Sciences, Perugia. Sweden, India and Italy.

Antibodies to tyrosine pyrophosphatase (ICA512) and glutamate decarboxylase 65 (GAD65) are frequently present in Caucasian patients with IDDM. The prevalence of ICA512 and GAD65 antibodies (Ab) in IDDM (n=74), and 123 healthy controls from Cuttack in Eastern India. was determined. ICA512Ab and GAD65Ab were evaluated by RIA using *in vitro* translated recombinant human 35S-ICA512 and 35S-GAD65 respectively. In controls, ICA512Ab were present in 3/123 (2%) and GAD65Ab in 8/123 (7%). In IDDM, ICA512Ab were present in 32/74(43%)($p<0.001$ vs controls) and GAD65Ab in 12/74 (16%)($p<0.001$ vs controls). In IDDM, the frequency of ICA512Ab was lower in patients with short term (0-4 years) (14/44,32%) than long term duration (>4 years)(18/30, 60%)($p<0,05$) whereas GAD65Ab frequency was higher in patients with short-term (0-4 years) (9/44, 20%) than with long-term duration (>4 years) (4/30, 13%)($p=0.42$). Both ICA512Ab and GAD65Ab were higher in frequency in male (20/42, 48% and 9/42, 21% respectively) than female patients (12/32, 38% and 3/32, 9% respectively). In IDDM patients, 30/74 (41%) were both ICA512Ab and GAD65Ab negative; 4/74 (5%) were both Abs positive; 36/74 (49%) were either ICA512Ab or GAD65Ab positive; 28/74 (38%) were ICA512Ab positive and GAD65Ab negative; and 8/74 (11%) were ICA512Ab negative and GAD65Ab positive.

We conclude that patients from Cuttack in Eastern India, have ICA512Ab and GAD65Ab in IDDM at a low but significant frequency compared to controls. ICA512 and not GAD65 is the major autoantigen in the IDDM patients from Eastern India. ICA512Ab and GAD65Ab account for only 49% of patients suggesting that an additional major autoantigen is involved in the etiopathogenesis of IDDM in this population.

276

ACTIVITY DEPENDENT BIOSYNTHESIS AND EXPRESSION OF SULPHATIDE IN ISLET CELLS

A.Ekblond, P.Fredmann and K.Buschard, Bartholin Instituttet, Kommunehospitalet, Copenhagen K, Denmark.

The aim of this study was to describe activity dependence of sulphatide, 3'-sulphogalactosylceramide, which has been identified in insulin granules of beta cells in the islets of Langerhans in the pancreas. Sulphatide is thought to play a role in the pathogenesis of IDDM, as circulating sulphatide antibodies are found in both BB rats and diabetic patients. It has been suggested, that beta cell activity is of importance during the development of IDDM. In fact, islet cell activity dependent cytotoxicity has been shown. This might be explained by certain antigens being co-released or expressed with insulin. By FACS analysis, glucose stimulated activity dependent islet cell expression of sulphatide was examined using a sulphatide specific monoclonal antibody, Sulph I. Activity dependent islet cell synthesis of sulphatide was also examined. This was done by adding radiolabelled precursors to islet culture medium followed by extraction of lipids and TLC-ELIZA of the purified sulphatide fraction. FACS analysis showed a significant influence of glucose stimulation upon sulphatide expression. After 12 h, the mean percentage ± SEM of Sulph I positive cells after glucose deprivation (4 mM) was 23 ± 8%, whereas the percentage of positive cells after glucose stimulation (18 mM) was 33 ± 7%, $P=0.01$ ($n=4$). After 18 h incubation the picture is reversed, as 42 ± 2% beta cells are positive after deprivation and only 37 ± 6% are positive after stimulation, $P=0.3$ ($n=4$). Chromatography and colometric scanning of the Sulph I positive bands showed, that after 24 h in culture, the sulphatide content in stimulated islets was half (1 nmol/600 islets) that observed in glucose deprived islets (2 nmol/600 islets). In conclusion, expression of the beta cell antigen sulphatide is activity dependent, but exhaustion after a longer period of glucose stimulation is acompanied by an insufficient capacity to synthesize and express sulphatide.

277

HIGH CONCORDANCE OF GAD 65 ANTIBODIES AND ISLET CELL ANTIBODIES IN RECENT ONSET IDDM PATIENTS AND IN IDDM OF LONG DURATION

C. Jaeger, J. Allendörfer, E. Hatziagelaki, K. Federlin and R.G. Bretzel. Medical Clinic III and Policlinic, Justus-Liebig University, Giessen, Germany

In recent onset IDDM most of the islet cell antibody positive patients are also positive for GAD 65 antibodies. In this study we investigated the frequency and levels of co-existence of GAD 65 antibodies and ICA in 105 longterm IDDM patients (median duration: 21 years; range: 10-46 years) compared to 259 recent onset IDDM patients. GAD 65 antibodies were detected in a radioligand-binding-assay, using recombinant human GAD 65 as tracer and islet cell antibodies were determined by indirect immunofluorescence on human pancreas. Among the long-term IDDM patients GAD 65 antibodies were present in 32%, whereas, islet cell antibodies were observed in 20% ($p<0.05$). By contrast, in the group of recent onset IDDM patients 78% were positive for GAD 65 antibodies but there was no significant difference in the frequency of islet cell antibodies which were found in 82% of the patients. In both groups of patients autoantibodies to GAD 65 were significantly more frequent in ICA positive individuals ($p<0.01$) and the index levels of GAD 65 antibodies were positively associated with higher ICA titres ($p<0.01$). In summary humoral autoimmunity to GAD 65 is closely associated with the presence and higher titres of ICA and tend to disappear more slowly than islet cell antibodies. The high concordance of GAD 65 antibodies with islet cell antibodies is striking supporting the hypothesis that there is an overlap in the humoral immune response directed to islet specific antigens although the time course appears to be different.

278

MONOCLONAL ANTIBODIES AGAINST THE SURFACE OF INS-1 INSULINOMA CELLS

C. Konidaris[1] and G.K. Papadopoulos[2]. Laboratory of [1]Biological Chemistry and [2]Immunology, University of Ioannina Medical School, Ioannina, GREECE

INS-1 is an established cel line from the rat (parent cell RIN tumour), β-mer- captoethanol dependent, characterised by functional and morphological properties similar to the rat β-cell. Confluence of cultured INS-1 cells is reached by 10-11 days and the doubling time is 100 hours. In this study we generated monoclonal antibodies to INS-1 in order to study the various functional and differentiation antigens of this line. Balb/c mice were immunised with whole cells and fusion of immune spleen cells with NSO myeloma cells generated several hybrids. Screening of hybridoma supernatants for reactivity in an ELISA assay of INS-1 extract or whole cells yielded a number of positive clones. After two rounds of cloning by limiting dilutions two clones, 2F8 and B2D6, that were positive in both assays were selected for further analysis. Both clones are of IgM class and are positive for cell surface immunofluorescence. Analysis by flow cytometry revealed that antibody 2F8 reacted with INS-1 cells in a time-of-culture-dependent manner (% positive cells from the 7th to the 11th day of culture 24 and 65 respectively). B2D6 was also reactive on this assay. Dilutions for flow cytometry for both assays were from 1:1000 to 1:4000, with a less than 10% decrease in staining at the latter dilution. By contrast, both antibodies were reactive with RIN-5AH cells throughout the culture period of 3 days (e.g. on day 2, 44.3% pos. with 2F8, and 75.0% with B2D6). Neither antibody reacted with rat splenic lymphocytes or monocytes. These antibodies could not inhibit the growth of RIN-5AH cells in culture, in three-fold dilutions of 1:2500 up to 1:202500, when added concurrently with or 24, or 48 hrs after the seeding of the cells. The antigenic specificity(ies) of these antibodies and their possible effect(s) on INS-1 and RIN-5AH function is currently under investigation.

279

FREQUENCY OF AUTOANTIBODIES AGAINST SIX DIABETES-RELATED AUTOANTIGENS IN NEWLY DIAGNOSED TYPE 1 DIABETIC PATIENTS.

C.Tiberti, E.Anastasi, P.Torresi, E.Vecci, M.L.Loffredi, F.Dotta and U.Di Mario. University of Rome "La Sapienza"and University of RC-Catanzaro. Italy.

Several autoantibodies have been found in sera of patients at or before the onset of type 1 diabetes; despite that various studies showed that a number of new onset type 1 diabetics at diagnosis (15-20%) seem to be autoantibody negative (whatever the test used); this finding could reflect the use of low sensitivity assays or more probably the study of an insufficient number of autoantigens in each patient serum. In this work we have combined the search for autoantibodies towards both protein and non protein antigens to better characterize this potential subgroup of autoantibody negative patients. Antibodies to islet pancreatic cells (ICA), glutamic acid decarboxylase (GAD65Abs), insulin (CIAA), amino acid residues 256-976 of the IA-2 molecule (ICA512bdc), monosialoganglioside GM2-1 (GM2-1Abs) and disialoganglioside GD3 (GD3Abs) were investigated in 78 new onset type 1 diabetic sera (45 males, mean age 12.9±8.0; 33 females, mean age 11.3±8.2). ICA were measured by indirect immunofluorescence, CIAA by a competitive fluid-phase radioassay, GAD65Abs and ICA512bdc by radioassay using in vitro transcribed and translated recombinant human GAD65 or ICA512 bdc respectively, GM2-1Abs by an immuno-TLC method and GD3Abs by ELISA. ICA were detected in 56.4% (42/78), CIAA in 57.7% (45/78), GAD65Abs in 70.5% (55/78), ICA512bdc in 53.8% (42/78), GM2-1Abs in 61.5% (48/78), GD3Abs in 35.9% (28/78) type 1 diabetic sera respectively. Patient sera positive for at least one autoantibody were 97.4% (76/78). 9.0% of type 1 diabetic sera were positive for one, 19.2% for two, 19.2% for three, 26.9% for four, 15.4% for five and 7.7% for all the antibodies tested; it is of note that of the 7 patients with only one autoantibody positivity, 3 were GM2-1Abs positive and none ICA512bdc or GD3Abs positive. In conclusion, the combined study of a large panel of diabetes-related antibodies against protein and non protein antigens at disease onset restricts to less than 3% the percentage of type 1 diabetics apparently without humoral autoimmune phenomena.

280

CLASSICAL INSULIN DEPENDENT DIABETES VERSUS LATENT AUTOIMMUNE DIABETES IN ADULTS: TWO DIFFERENT ENTITIES?

I.Libman, D.Becker, M.Pietropaolo, J.Gay, J.MacGregor, R. Phillips, S.Pietropaolo, K.Riley, M.Smith, R.Vergona, A.Drash and R.LaPorte. University of Pittsburgh, Pittsburgh, USA

We evaluated conversion to diabetes in 53 individuals from a cohort of 5034 first degree relatives who have been followed for periods up to 17 years and who presented signs of B-cell autoimmunity, either islet cell antibody (ICA), antibodies to glutamic acid decarboxylase 65kd (GAD65) or to ICA512 (IA-2). We were struck by the fact that 14 appeared to be latent autoimmune diabetes in adults (LADA) and thus we prospectively investigated differences between the classical IDDM and the LADA group. The 53 converters were classified into two groups: group I (classical), who started insulin treatment immediately or within 1 year of diagnosis (n=39) and group II (LADA), who started insulin treatment 1 - 8 years after diabetes diagnosis (n=14). The mean age at start of insulin treatment was 23 years in group I and 43 years in group II. The frequency of antibodies in the first blood drawn prior to diabetes diagnosis was:

	Group I (n = 39)	Group II (n = 14)
ICA*	92.3% (36)	64.2% (9)
GAD*	87.2% (34)	50.0% (7)
IA-2	53.8% (21)	35.7% (5)
ICA + GAD*	84.6% (33)	42.9% (6)
ICA + IA-2	51.3% (20)	28.5% (4)
ICA + GAD + IA-2	46.1% (18)	28.5% (4)

* significant at 0.05 level, when comparing group I vs group II

We conclude that the characteristics of these two groups before the onset of diabetes are different in that the prevalence of ICA and GAD 65 autoantibodies is lower in LADA as compared to the classic converters. These results clearly suggest the existence of a slow progressing autoimmune form of diabetes which has been called LADA and which can occur in families of pediatric IDDM probands.

281

CORRELATION BETWEEN THE PRESENCE OF IAA, GAD-AB AND ICA AND AB-BSA IN CHILDREN WITH NEWLY DIAGNOSED IDDM.

D. Ciślak, A. Bąkowska, J. Drużyńska, B. Dorant, and C. Wójcikowski; Department of Endocrinology, Institute of Obstetrics and Gynecology, Medical University, Gdańsk, Poland.

It has been suggested that anti-bovine serum albumin (BSA) antibodies may participate in the autoimmune process leading to the destruction of pancreatic B-cells. The aim of the present study was to assess correlation between the frequency of anti-islet cell autoantibodies (ICA), anti-insulin autoantibodies (IAA), and anti-glutamic acid decarboxylase (GAD) autoantibodies with anti-BSA-antibodies in newly-diagnosed diabetic children.

We examined 67 children (age 4-16) during 1 month after diagnosis of IDDM. Anti-IAA and GAD autoantibodies were measured with RIA, and anti-ICA and BSA antibodies were measured with FIA.

Anti-IAA, GAD and BSA antibodies were found in 13%, 31% and 22%, respectively. Anti-BSA-positive subjects were anti-IAA and anti-GAD positive in 44% and 57%, respectively. In 5 cases all kinds of examined antibodies were found.

Our results confirm the possible role of BSA antibodies in the IDDM development.

282

DEFINING DIFFERENCES IN ANTIGEN-SPECIFIC ANTIBODIES ASSOCIATED WITH TYPE 1 AND TYPE 2 DIABETES

D.Fava[1,3], M.I.Hawa[1], A.L.Notkins[2], G.Sacchetti[3], G.De Mattia[3], R.D.G. Leslie[1], [1]London, UK, [2]Bethesda, Maryland, USA. [3]Roma, Italy.

Islet antigens associated with Type 1 insulin dependent diabetes (IDDM) include a protein tyrosine phosphatase-like molecule, IA-2 of 979 aminoacids containing an intracellular fragment from 603 to 979 (IA-2ic) and glutamic acid decarboxylase (GAD 65). The extent of the immune response, reflected by a combination of antibodies to these two antigens is highly predictive of IDDM. GAD 65 antibodies have also been found in patients with non-insulin dependent diabetes (NIDDM) who can progress to insulin dependency. To determine for the first time whether antibody responses to different antigens or different specificities of the same antigen distinguish NIDDM and IDDM patients we studied antibodies to IA-2, IA-2ic and GAD 65 in: a) 260 NIDDM subjects, b) 60 newly-diagnosed IDDM patients, c) 156 Controls. Of the 260 NIDDM patients antibodies to both IA-2 and IA-2ic were tested in 115. In NIDDM and IDDM, antibodies to GAD 65 were detected in 10% (26/260) and 77% (46/60) respectively, to IA-2ic in 5% (12/260) and 67% (40/60) respectively, and to either in fewer NIDDM 10% (26/260) than IDDM 87% (52/60) patients ($p<0.0001$); 1/156 controls had IA-2 but no other antibodies. Combinations of GAD 65 and IA-2ic antibodies were less prevalent in NIDDM 27% (7/26) than IDDM 63% (32/51) ; $p<0.002$). Of the NIDDM patients with antibodies to IA-2 or IA-2ic only 4/17 had antibodies to both, compared with 37/40 IDDM patients ($p<0.01$). In summary, antibodies to IA-2ic and GAD 65 in NIDDM compared to IDDM patients are less prevalent, less likely to occur in combination and, for IA-2, show a more restricted specificity. Thus, antibodies in NIDDM patients show restricted specificity both between antigens and within an antigen.

283

GLUTAMIC ACID DECARBOXYLASE AND ISLET CELL ANTIBODIES IN IDDM AND FIRST-DEGREE RELATIVES IN ANDALUSIAN

J. Ortego, F. Guerrero, C. Rodríguez, M. Aguilar, I. Gavilán, L. Escobar, MJ. Palomo, JM. Freire, M. Carrasco and JA. Brieva. Endocrinology and Immunology Units. H Puerta del Mar, Cádiz, Spain

The aim of this study was to evaluate the frequency of glutamic acid decarboxylase and islet cell antibodies (GADA and ICA) in IDDM and first-degree relatives (FDR). 136 subjects with IDDM, 280 FDR and 100 controls were analyzed as a part of the European nicotinamide diabetes intervention trial. GADA were measured by RIA, and ICA were determined by indirect immunofluorescence. Age, sex and IDDM duration were analyzed and related to both GADA and ICA. In IDDM group, GADA were positive in 38.5% (35/91; males: 16; age: 22 ± 10; IDDM duration: 3.3 ± 3.9), and ICA were positive in 20.5% (25/122; males: 12; age: 14.7 ± 6.1; IDDM duration: 1.7 ± 2.6), and both antibodies were positive in 13% (10/77). Age and sex were not related to the presence of these autoantibodies. However, IDDM duration was related inversely to ICA and GADA. In FDR group, GADA were positive in 5.6% (11/195; males: 6; age: 17.8 ± 9.5), and ICA were positive in 1.5% (4/271; males: 3; age: 19.2 ± 11.3), and both antibodies were positive in 1.1% (2/186). All controls were negative. The frequency of GADA and ICA in Andalusian affected IDDM and relatives is similar to other Caucasian population. Both autoantibodies could be useful for diagnosis of IDDM and screening of high risk subjects to prevention trials among first relatives.

284

DIAGNOSTIC SENSITIVITY OF AUTOANTIBODIES TO TYROSINE PHOSPHATASE-LIKE PROTEINS IA-2 AND IA-2ß IN IDDM AND NIDDM

J. Seissler, N. G. Morgenthaler, H. Steinbrenner, U.Y. Khoo-Morgenthaler, M.S. Lan[1], A.L. Notkins[1], W.A. Scherbaum. Department of Internal Medicine III, University of Leipzig, and [1]Laboratory of Oral Medicine, NIH, Bethesda, USA.

To evaluate the diagnostic sensitivity of antibodies to tyrosine phosphatase-like proteins IA-2 (anti-IA-2) and IA-2ß (anti-IA-2ß) for IDDM and latent insulin-dependent diabetes in adults (LADA) we tested sera from IDDM patients (age 0-40, median 17 years) and patients classified as non insulin-dependent diabetes (NIDDM, age 40-66, median 53 years) with diet failure 0.5-10 years after diagnosis who had preserved residual beta cell function (C-peptide >0.6 nmol/l). Autoantibodies were measured by radioligand assay using the recombinant intracytoplasmic IA-2 or IA-2ß and were compared to antibodies to glutamic acid decarboxylase (GADA) and cytoplasmic islet cell antibodies (ICA). Out of 200 patients with IDDM, 112 (56.0%) had anti-IA-2 and 76 (38.0%) were positive for anti-IA-2ß. The frequencies of anti-IA-2 and anti-IA-2ß were 70% and 49% in young children below age 10, 70% and 48% in patients aged 11-20 years but only 34% and 21% in patients above 20 years of age. Among subjects with anti-IA-2ß 73 of 76 (96.1%) were found positive for anti-IA-2. In all age groups both anti-IA-2 and anti-IA-2ß were significantly associated with the presence of ICA but not with GADA ($p<0.001$). Combined screening for anti-IA-2 and GADA identified 89% of all patients with IDDM and 94% of ICA positive subjects. In patients classified as NIDDM 19% (36 of 200) were found positive for one autoantibody specificity suggesting the presence of LADA. Only a few sera of LADA patients had anti-IA-2 (n = 3) or anti-IA-2ß (n = 1) whereas GADA were present in 18 and ICA in 27 patients. All sera positive for anti-IA-2 or anti-IA-2ß had ICA, 18 patients had ICA alone and 11were positive for GADA alone.

Our data indicate that antibodies to IA-2 are a sensitive marker for IDDM in childhood and adolescence but are of only limited value for IDDM in adults. The low prevalence of anti-IA-2 in NIDDM emphasizes the importance of both ICA and GADA to identify patients with LADA. Anti-IA-2ß may indicate a heterogeneous autoimmune response in a subgroup of anti-IA-2 positive individuals whose significance is still unknown.

285

MEASUREMENT OF GADA USING RADIOLIGAND BINDING ASSAY, RIA AND IRMA IN KOREAN PATIENTS WITH IDDM.

HW Lee, KC Won, IH Cho, Hy-W Lee and IK Lee*. Yeungnam University, Keimyung University* Taegu, Korea.

IDDM is an autoimmune disease in which serum antibodies against islet antigens have been recognized. These include insulin autoantibodies, cytoplasmic islet cell antibodies (ICA), ICA 512 and GAD antibodies(GADA). Recently, there is increasing interest in the use of GADA for identification of subjects at increased risk of developing IDDM. However, because the classic assays of GADA are still rather time-consuming, a more simple and reproducible radioligand binding assay is widely used recently. Also, RIA and IRMA for GADA using ^{125}I - labelled human GAD have been developed. To evaluate the prevalence of GADA (measured by radioligand binding assay, radioimmunoassay and IRMA) in Korean patients with IDDM and to observe the associations of GADA with ICA, we tested 26 IDDM sera (M:F=10:16, mean age 14±3) and 20 control sera (M:F=10:10, mean age 15±1) for GADA (using radioligand binding assay, RIA and IRMA) and ICA (using indirect immunofluorescence method). The results are follows : The overall prevalences of ICA and GADA in Korean patients with IDDM were 46% (12/26) and 31%(8/26)-38% (10/26) respectively. In a subset of these patients with recent onset IDDM (<1year), the prevalences of ICA and GADA were 50%(2/4)-75% (3/4). The frequency of GADA (by RBA, RIA and IRMA) increased as the JDF unit of ICA increased. There is significant correlation between ICA titer and GAD index (by RBA) & GAD concentration (by RIA and IRMA). There is significant correlation between GAD index (by RBA) and GAD concentration (by RIA and IRMA). These results suggest that GADA (by RIA, IRMA or Radioligand binding assay) test is useful for screening and diagnosis of Korean patients with IDDM.

286

LATENT AUTOIMMUNE DIABETES IN THAI NIDDM PATIENTS WITH SECONDARY ORAL HYPOGLYCEMIC AGENTS FAILURE.

C Rattarasarn,M Diosdado*and S Sunthornpun. Prince of Songkla University Songkhla,Thailand and * Hospital Universitario Puerta del Mar,Cadiz,Spain.

To study the clinical characteristics of and the prevalence of glutamic acid decarboxylase antibody (GAD-Ab) in Thai NIDDM patients who had secondary oral hypoglycemic agents (OHA) failure. Sera from 40 adult NIDDM patients who were followed at out-patient diabetic clinic of Songklanagarind University Hospital and had history of successful treatment, for at least a year, with and currently failed to respond to OHA were obtained for analysis of fasting c-peptide and GAD-Ab. Clinical characteristics of all patients were obtained by reviewing medical records and/or direct patient interview. Of 40 patients, 10(25.0%) were positive for GAD-Ab with a mean level of 59.9 U/ml (median 58.5, range 3.4-127). Patients with GAD-Ab(+) had a significantly lower fasting c-peptide levels than those with GAD-Ab(-) albeit shorter duration of diabetes (0.21± 0.19(SD) VS 0.52±0.33 nmol/L; p=0.003). Duration of treatment with OHA in patients with GAD-Ab(+) was also shorter (4.6±3.5 VS 10.4±5.5 years; p=0.001). Age of onset of diabetes did not differ between these two groups. Forty percent of patients had insulin deficiency (fasting c-peptide level <0.33 nmol/L); 50% of which had GAD-Ab(+). Patients with insulin deficiency had significantly lower BMI before insulin therapy regardless of their GAD-Ab status (18.6±2.8 VS 22.9±4.3 Kg/m^2;p=0.002). Among insulin-deficient patients, those with GAD-Ab(+) had significantly shorter duration of OHA treatment (3.3±2.3 VS 10.0±7.9 years;p=0.018). In conclusion, the prevalence of GAD-Ab in Thai NIDDM patients with secondary OHA failure was 25%. Almost all GAD-Ab(+) patients had insulin deficiency and most had been initially treated with OHA for a few years before depending on insulin. This group represents a slowly pregressive form of IDDM or latent autoimmune diabetes in adult diabetic population.

287

PREVALENCE OF GAD-ANTIBODIES IN A SELECTION-FREE DIABETIC POPULATION (JEVIN)

R. Schiel and U.A. Müller; University of Jena Medical School, Department of Internal Medicine II, Jena, Germany

Up to the present only a few data have been available concerning the prevalence of diabetes specific autoantibodies (anti-GAD, ICA, IAA, IA-2) in closed populations. Hence, the aim of the present trial is to determine the prevalence of anti-GAD in a selection-free population of diabetic patients (IDDM n=127, NIDDM n=117) aged 16 to 60 years and living in the city of Jena (100,247 inhabitants). In order to test sera for anti-GAD, serum samples were taken in 75% of IDDM (n=95) and in 80% of NIDDM (n=94) patients. **Results:** In the group of IDDM patients, according to a cut-off of 8 U/ml, 55% of all the patients tested positive for anti-GAD (102.9±141.5, range, 8.3-585.0 U/ml). In the group of NIDDM a total of 21% were positive (153.0±212.8, range, 9.2-626.0 U/ml). In IDDM patients anti-GAD titers were strongly correlated to diabetes duration (r=-0.23, p=0.024) and the duration of insulin therapy (r=-0.23, p=0.025), but not to HbA1c, BMI and insulin dose/kg body wt. In NIDDM patients there were no correlations. Also, no correlations were found between diabetes long-term complications (retino-, neuro- and nephropathy) and anti-GAD titers, neither in IDDM, nor in NIDDM. However, looking at the high number of anti-GAD positive NIDDM patients, although these patients showed no differences ($p<0.05$) in clinical parameters (HbA1c, age at diabetes onset or time up to initiation of insulin therapy), it must be suggested, that a part of them are patients with latent autoimmune diabetes mellitus in adults (LADA).

288

ANTIBODIES TO ICA512 AND GAD65 IN MALNUTRITION-RELATED DIABETES (MRDM) PATIENTS FROM EASTERN INDIA.

K.C. Samal, A. Shtauvere, A. Kanungo, B.B. Tripathy, Falorni and CB. Sanjeevi. Dept of Endocrinology, Cuttack; Dept of Molecular Medicine, Stockholm; Dept. of Internal Medicine and Endocrine and Metabolic Sciences, Perugia.. India, Sweden and Italy.

Antibodies to tyrosine pyrophosphatase (ICA512) and glutamate decarboxylase 65 (GAD65) are major markers for IDDM in Caucasians. The prevalence of ICA512 and GAD65 antibodies(Ab) in MRDM (n=128) and 123 healthy controls from Cuttack in Eastern India. was determined. MRDM was subdivided into Protein deficient diabetes (PDDM)(n=71) and Fibrocalculous pancreatic diabetes (FCPD)(n=47). MRDM patients are typically young at onset with low body mass index, require insulin treatment for glycemic control, have insulin resistance and do not develop ketosis on withdrawal of insulin. FCPD, but not PDDM, patients have abdominal pain and calculi in the pancreas. ICA512Ab and GAD65Ab were evaluated by RIA using *in vitro* translated recombinant human 35S-ICA512 and 35S-GAD65 respectively. None of the FCPD patients were positive for GAD65Ab suggesting that they have secondary form of diabetes. In controls, ICA512Ab were present in 3/123 (2%) and GAD65 Ab in 8/123 (7%). In PDDM, ICA512Ab were present in 17/71(24%) ($p<0.001$ vs controls) and GAD65Ab in 11/71 (16%)($p<0.001$ vs controls). In PDDM, the frequency of ICA512Ab and GAD65Ab was higher in patients with short-term (0-4 years) (12/46, 26% and 7/46, 15% respectively) than with long-term duration (>4 years) (5/25, 20% and 3/25, 12% respectively)(p=ns). ICA512Ab was higher in frequency in male (12/44, 27%) than female patients (2/27, 19%) while GAD65Ab was higher in frequency in female (5/27, 19%) than male patients (6/44, 14%). In PDDM patients, 53/71 (75%) were both ICA512Ab and GAD65Ab negative; 5/71 (7%) were both Abs positive; 23/71 (32%) were either ICA512Ab or GAD65Ab positive; 12/71 (17%) were ICA512Ab+/GAD65Ab-; and 6/71 (8%) were ICA512Ab-/GAD65Ab+. We conclude that PDDM patients from Cuttack in Eastern India, have ICA512Ab and GAD65Ab at a low but significant frequency compared to controls. ICA512 and GAD65 are important autoantigens in PDDM patients. ICA512Ab and GAD65Ab positivity suggest an autoimmune pathogenesis suggesting that protein deficiency may induce β-cell autoreactivity in susceptible individuals.

289

AN ELISA FOR ANTIBODIES TO GLUTAMIC ACID DECARBOXYLASE IN DIABETES MELLITUS PATIENTS

He Jungging.Cheng MingQing.Lin LiXiang
Fujian Provicial Hospital Fuzhou,P.R.China

Many data suggested that insulin-dependent diabetes mellitus (IDDM) is marked by circulating antibodies to a 64000-Mr islet cell antigen identified as glutamic acid decarboxylate(GAD),antibodies to GAD were measured by ELISA using recombinant GAD as antigen in 30 healthy subjects,30 autoimmune disease,37 IDDM and 30 NIDDM(non-insulin dependent diabetes mellites) patients.The prevalence of GAD antibodies was 83.8%(31/37) in IDDM patients and 16.7%(5/30) in NIDDM patients but the prevalence of GAD antibodies was in none of the other antoimmune disease patients and healthy subjects.islet-cell antibodies(ICA) were measured by immunofluorescence the results showed the prevalence of antibodies to GAD in IDDM patients was significantly higher than that of ICA($P<0.05$)the antibodies to GAD will be of clinical value in the diagnosis and indicate of diabetes mellitus patients.

Key words:Diabetes mellitus,Glutamic acid Decarboxylase. Islet-cell antibodies.

290

ISLET CELL AND GLUTAMIC ACID DECARBOXYLASE ANTIBODIES IN FIBROCALCULOUS PANCREATIC DIABETES

Mohan V, Deepa R, Bhatia E, Hitman G, Mackay IR and Zimmet PZ, Madras, Lucknow, London and Melbourne.

Fibrocalculous Pancreatic Diabetes (FCPD) is a type of diabetes secondary to tropical, chronic non-alcoholic pancreatitis. Little is known about etiopathogenesis of FCPD. We studied islet cell antibodies (ICA-b) and Glutamic Acid Decarboxylase antibodies (GAD-Ab) in healthy controls and patients with Fibrocalculous Pancreatic Diabetes, Insulin Dependent Diabetes Mellitus (IDDM) and Non Insulin Dependent Diabetes Mellitus (NIDDM) seen at our centre in southern India. Prevalence of ICA-b was 4.7% in controls, 0% in FCPD, 54% in IDDM and 9.9% in NIDDM. Prevalence of GAD-Ab was 0% in controls, 7% in FCPD, 47.5% in IDDM and 5.6% in NIDDM. Combined ICA-b and GAD-Ab positivity was seen in 0% of controls, 0% in FCPD, 40% of IDDM and 1.4% of NIDDM. The data suggests that in FCPD the frequency of auto-antibodies is low and its etiology is probably not linked to auto-immunity.

291

CLINICAL VERSUS LABORATORY CLASSIFICATION OF DIABETES TYPE IN YOUNG ADULTS

M.Landin-Olsson, H.Arnqvist, G.Blohmé, Å.Lernmark, F. Lithner, B.Littorin, L.Nyström, B.Scherstén, G.Sundkvist, L.Wibell and J.Östman, University Hospital, Lund and others, Sweden.

The classification of diabetes is based on descriptive clinical signs and the uncertainty in the classification increases with age of the patient. In this study a combination of clinical based criteria and laboratory tests for the classification of the type of diabetes are studied.

Methods: Blood samples from consequtively diagnosed patients with diabetes in the ages 15-34 years were collected during two years. A clinical classification of the diabetes was done at diagnosis by the doctor who treated the patient, without knowledge of the laboratory results. ICA (islet cell antibodies), GAD65-ab (glutamic acid decarboxylse antibodies) and C-peptide were analysed.

Results: Of 586 patients classified as Type 1 236 were negative for ICA and GAD65-ab (Type 1-), and these showed higher C-peptide (0.38±0.27 nmol/l) compared with autoantibody positive Type 1 patients (Type 1+) (0.30±0.21 nmol/l; $p<0.001$). Among Type 1- patients 20 (8%) were found to have C-peptide >0.50nmol/l and BMI>25. Of the 110 clinically classified Type 2 patients, 37 (34%) had ICA or GAD65-ab (Type 2+) and 51% were on insulin. C-peptide in Type 2+ were lower than in Type 2- (0.51±0.40 nmol/l vs 0.87±0.50; $p<0.001$), but higher than in Type 1+ patients (0.30±0.21; $p<0.001$).

Conclusion: The levels of C-peptide and BMI indicated that both Type 1 and Type 2 patients are misclassified. The estimated frequency of clinically classified Type 2 who are Type 1 is about 8%, and even higher, about 30%, are initially classified as Type 2 but should be in the Type 1 group. An identification of combined clinical and laboratory criteria are needed for an improved classification of diabetes in these ages.

292

PERSISTENT GAD 65 ANTIBODIES IN LONGSTANDING IDDM■ ARE NOT ASSOCIATED WITH RESIDUAL BETA CELL FUNCTION, NEUROPATHY OR A CERTAIN HLA-DR STATUS

C. Jaeger, J. Allendörfer, E. Hatziagelaki, T. Dyrberg*, K. Federlin and R.G. Bretzel. Medical Clinic III and Policlinic, Justus-Liebig University, Giessen, Germany.*Novo Nordisk, Bagsvaerd, Denmark.

Persistent humoral autoimmunity to the enzyme glutamic acid decarboxylase (GAD) has been described in a substantial proportion of patients with insulin-dependent diabetes mellitus (IDDM) of long duration. The source of the stimulus for this autoimmune reactivity is still unknown. Because the GAD 65 isoform is mainly expressed in pancreatic beta-cells and in the nervous system we investigated in 105 patients with longstanding IDDM (median duration: 21 years; range: 10-46 years) the presence of autoantibodies to GAD 65 (radioligand-binding-assay) and their relationship to a residual C-peptide response (Hendriksen's criteria) or peripheral and autonomic neuropathy. Additionally we studied the HLA-DR status relative to GAD 65 antibodies in 86 individuals. Autoantibodies to GAD 65 were present in 32% of the long-term diabetic patients, 82% of the recent onset IDDM patients and in 3% of the healthy control subjects. A preserved C-peptide response was observed in 23%, autonomic neuropathy was found in 67% and peripheral neuropathy in 79% of the patients. The HLA specificity DR 4/X was observed in 47% and HLA-DR 3/X in 22%. Patients who were heterozygous for DR3/DR4 were found in 23% of the cases. Diabetes duration showed a significant negative correlation with GAD 65 antibody index levels ($r=-0.22$; $p<0.01$). Interestingly, GAD 65 antibodies were not significantly correlated with residual beta cell function or neuropathy and no particular HLA-DR status was associated with persistent GAD 65 antibodies. In conclusion neither residual beta-cell function nor diabetic neuropathy or a certain HLA-DR specificity are exclusively associated with persistent autoimmunity directed to GAD 65 in longstanding IDDM. The stimulus for the persistent humoral immune response and its significance for the disease process and its complications remain to be established.

293

C-PEPTIDE LEVELS IN AUTOIMMUNE DIABETES DURING THE FIRST TWO YEARS AFTER DIAGNOSIS

C.Törn, M.Landin-Olsson, H.Arnqvist, G.Blohmé, Å.Lernmark, F. Lithner, B.Littorin, L.Nyström, B.Scherstén, G.Sundkvist, L.Wibell and J.Östman, Lund University Hospital, Lund, Sweden and DISS.

The aim of this study was to follow the C-peptide levels, the influence of autoimmune markers and other factors that may predict the course of C-peptide during the first two years after diagnosis of Typ 1 diabetes.

Method:In1992-93 all new onset diabetic patients aged 15-34 years, donated a blood sample.Only patients positive for either ICA (islet cell antibodies) or GAD65-ab (glutamic acid decarboxylase-antibodies) or both were included. 890 patients were registered of whom 607 were positive, 8,4% were classified as Type 2 and 7,5% unclassifiable. ICA were analysed with IF, GAD-ab and C-peptide with RIA. The reference range for the C-peptide was 0,25-1,0 nmol/l.

Results:At onset 57% had C-peptide values within the reference range, after one year it was 54% and after two years 39%. The mean value of the C-peptide levels was 0,33±0,25 nmol/l at diagnosis and unchanged after one year, 0,34±0,26. However, after two years the levels decreased with a mean of 0,05±0,28 to 0,28±0,26 nmol/l (p=0,003). The decline of the C-peptide during the first two years positively correlates to the initial level (rs=0,60;p<0,001), and also to age (rs=0,15;p=0,007). The initial levels of ICA or GAD65-ab and the decline of the C-peptide levels do not correlate.

Conclusion: Young adults with Type 1 diabetes have the same C-peptide levels after one year as at onset, but during the second year the levels decline. After two years 39% have C-peptide levels within the reference range. The decline of the C-peptide is larger if the initial level is high. The levels of ICA and GAD65-ab do not correlate to the decrease.

294

"The UK and Padua Polyendocrine Prospective Study". Association of antibodies to IA-2 and phogrin with progression to IDDM.

M Lai, M Christie*, C Betterle**, R Foxon, R Zanchetta**, A Spadaccino** and GF Bottazzo. Dept of Immunology, St Bartholomew's and the Royal London School of Medicine & Dentistry, London, UK; * Dept of Medicine, King's College Hospital, London, **Istituto di Semeiotica Medica, University of Padua, Padua.

Almost all ICA positive patients with polyendocrine (PE) autoimmunity have antibodies to GAD, but only a proportion (approximately 30%) develop IDDM. Previous studies have shown that antibodies to 40kD and 37kD fragments of islet antigens, now identified as tyrosine phosphatase (PTP)-like proteins IA-2 and phogrin respectively, can identify those PE patients with highest risk for IDDM. In this study, we have analysed antibodies to IA-2 and phogrin using assays with *in vitro* translated recombinant antigen in a larger population of PE patients to re-evaluate the value of these antibodies in prediction of IDDM. Of 154 ICA positive PE patients, 19 developed acute onset IDDM and a further 11 required insulin after a period of >1 year of non-IDDM. 37 of the PE patients, had antibodies to IA-2, of whom 10 developed acute onset and 7 slow onset IDDM, whereas 38 had antibodies to phogrin, 9 of whom developed acute onset and 5 slow onset IDDM. The sensitivity, specificity and positive predictive value for IDDM development within the PE population for IA-2 antibodies were 57%, 84% and 46% and for phogrin antibodies 47%, 80% and 36%. The majority (26/49) of PTP-antibody positive patients had antibodies to both IA-2 and phogrin, but a higher proportion of patients who developed acute onset IDDM (42%) were positive for antibodies to both IA-2 and phogrin than those who progressed to IDDM slowly (18%). However, 11 patients were positive for IA-2 antibodies in the absence of phogrin antibodies, and 12 patients were positive for phogrin antibodies alone; in spontaneous IDDM patients, individuals with phogrin antibodies alone are rare. Thus, antibodies to IA-2 and phogrin are markers for IDDM in PE patients and can develop independently, suggesting that autoimmunity to phogrin is not always the result of cross-reactivity between these two homologous proteins.

295

PANCREATIC RESERVE AND GAD ANTIBODIES IN MALAYSIAN YOUNG DIABETICS.

W.M. Wan Nazaimoon, B.A.K. Khalid, I. Faridah, I. Ikram Shah, W.B. Wan Mohamad, R. Letchuman, M. Singaraveloo and T.T. Tan. Institute for Medical Research, Universiti Kebangsaan Malaysia, Universiti Malaya, Universiti Sains Malaysia, Malaysia.

In Malaysia, it can be difficult to categorize and treat young diabetics. We investigated the pancreatic reserve and GAD antibodies in 320 diabetics, between the ages of 12 and 40 years and diagnosed within 5 years. Blood samples for GAD antibodies, C-peptides, insulin and IGF-I were taken at fasting and 6 minutes post-1mg glucagon, IV. Post-glucagon stimulated C-peptides of less than 600 pmol/L was used as the criteria of ß-cell deficiency. 93 (29%) were treated as IDDM and 227 as NIDDM. 60 patients (18.8%) were GAD positive, 29 in the IDDM (31%) and 31 in the 227 NIDDM (13.7%). 23/29 of the GAD positive IDDM had low C-peptides (79.3%), the other 6 (20.6%) had adequate reserve. Conversely, 38/61 (62.3%) IDDM with low C-peptides were GAD negatives. Of the 227 NIDDM, 59(26%) had low and 168 (74%) had high C-peptides. 16/59 (27.1%) of the NIDDM with low C-peptides and 15/168 (8.9%) with high C-peptides were GAD positive. The GAD-positive NIDDM were older and had significantly higher mean BMI, waist-hip ratio (WHR) and C-peptides than GAD positive IDDM. GAD antibodies had negative correlations with WHR and C-peptides only if the C-peptides were low. Using criterion of GAD positivity, 13.7% young NIDDM in Malaysia were latent autoimmune diabetes in adults. Conversely, 28% of young IDDM were GAD-negative and had adequate C-peptides, implying NIDDM.

296

METABOLIC, AUTO IMMUNE AND GENETIC MARKERS IN IDDM PATIENTS AND THEIR FAMILY

CE de Beaufort, R. Humbel, G. Michel, R. Wirion, EPIDID-CRP, Luxembourg.

In a prospective family study (over 3 years) we screened 45 families of IDDM patients (diabetics : 28M, 17F,age : 21 ± 2 yrs ; duration of IDDM : 7 ± 6 yrs ; siblings : 45M, 23F, age : 19 ± 2 yrs, parents : 40M, 41F) for the presence of metabolic, autoimmune and genetic markers. Despite higher sHbA1c levels (HPLC) in the diabetics (7.2 ± 0.2%, versus 4,6 ± 0,04%), cholesterol and triglyceride levels were slightly higher in the nondiabetic subjects (182 ± 5 vs 203 ± 5 mg/dl and 94 ± 7 mg/dl vs 114 ± 5 mg/dl).
IAA are present in most diabetics (84%) and in 3,3% of the control group. GAD Ab and ICA are still present in 40% of the IDDM patients compared to 6.7% and 2% respectively in the controls.
A high prevalence of auto Ab against colon (13% vs 21%), thyroïd (15% vs 24%), and ANF (17,8% vs 13,4%) are found as well in patients as in family members. No antibodies towards other endocrine glands have been demonstrated. In all diabetic patients at least 2 genetic high risk alleles (DQβ and DQα) are present. In family members only one has not at least one high risk allele. During the study period, the sib with ICA and GAD Ab developed IDDM. In two parents NIDDM was diagnosed. One patient with ANF developed SLE.
In conclusion : we observed a high prevalence of autoimmune markers in IDDM patients and their family members. Whether this is related to a higher prevalence of other autoimmune diseases remains to be evaluated. All subjects with positive antibody titers need further follow up.

297

EFFECTS OF ANTIBODIES TO GLUTAMIC ACID DECARBOXYLASE (ANTI-GAD) ON β-CELL FUNCTION IN DIABETIC PATIENTS.

Y. Maruyama[1], M. Morimura[1], Y. Kishitani[2], T. Saika[2], H. Hiramatsu[1] M. Imamura[2], Y. Ohno[2] and N. Aoki[2]. [1]Dept. of Medicine, Bell Land General Hospital, Sakai, Osaka, Japan. [2]Dept. of Medicine, Kinki University School of Medicine, Osaka-Sayama, Osaka, Japan.

To determine the effect of antibodies to glutamic decarboxylase (Anti-GAD) on β-cell function, we measured Anti-GAD and pancreatic β-cell secretory function in diabetic patients. Materials and Methods : Anti-GAD antibody titers in serum were measured using ELISA kits. The increment of serum C-peptide at 6 min after 1mg glucagon injection ($\triangle$CPR), 24 h urinary C-peptide excretion (UCPR), HbA_1c, the duration of DM, and daily insulin dosage were evaluated in insulin-dependent diabetes mellitus (IDDM) (11 males and 14 females) and in non-insulin dependent diabetes mellitus (NIDDM) (16 males and 15 females on insulin, 13 males and 20 females on SU agents). Results : The prevalence of Anti-GAD was 44% in patients with IDDM (11 GAD positive, 14 GAD negative) and 1.5% in patients with NIDDM. The values of $\triangle$CPR (ng/ml) in GAD positive and negative groups (IDDM groups) were 0.4 ± 0.1 and 0.3 ± 0.1, respectively, being significantly lower than those in NIDDM patients on insulin and on SU agents (2.3 ± 0.2, 2.8 ± 0.2). UCPR (μ g/day) levels in GAD positive and negative groups were 9.9 ± 2.3 and 4.8 ± 1.3, being significantly lower than those in NIDDM patients on insulin and SU agents (46.0 ± 1.9, 61.2 ± 3.2). The values of $\triangle$CPR and UCPR in GAD negative patients were significantly ($P<0.05$) lower than those in GAD positive patients. The duration (years) of DM in GAD negative group was significantly ($P<0.05$) greater than that in GAD positive group (10.3 ± 0.8 vs 4.2 ± 1.2). Daily insulin dosage (U/day) in GAD positive, GAD negative and NIDDM patients on insulin were 29 ± 1.5, 32 ± 2.6 and 17.9 ± 1.3, in which the level of the last was significantly lower ($P<0.01$) than the others. No significant differences in HbA_1c value were found between any groups except that the value in GAD positive group was significantly ($P<0.035$) higher than that in NIDDM patients on SU agents. Conclusion : The prevalence of Anti-GAD in IDDM patients decreases gradually with a progressive functional exhaustion of pancreatic β-cell.

298

GAD ANTIBODIES ARE ASSOCIATED WITH THYROID ANTIBODIES IN CHILDREN WITH IDDM AND IN THEIR SIBLINGS

P.Vähäsalo[1], A.Miettinen[2], P.Kulmala[1], E.Sabbah[1], H.K.Åkerblom[2], M.Knip[1] and the Childhood Diabetes in Finland (DiMe) Study Group. University of Oulu[1], Oulu and University of Helsinki[2], Helsinki, Finland

We have earlier reported no or only weak associations between ICA or IAA and other signs of humoral organ-specific or non-organ-specific autoimmunity. To explore the possible relationship between antibodies to glutamic acid decarboxylase (GADA) and other autoantibodies we analysed GADA and parietal cell (PCA), reticulin, adrenal, thyroid microsomal (TMsA) and thyroglobulin (TgA), smooth muscle, anti-nuclear and mitochondrial antibodies in 656 0-15-year-old children with IDDM and in their 588 3-19-year-old healthy siblings at the time of diagnosis of the index case. GADA were detected in 74.2% of the children with IDDM and in 6.5% of the siblings, TMsA in 11.1 and 7.9%, TgA in 5.3 and 3.3% and PCA in 6.7 and 4.6%, respectively. Diabetic children with TMsA tested more often positive for GADA than those without at the clinical manifestation (91.8 vs. 72.0%, p=0.0003) and they had higher GADA levels than those negative for TMsA (medians 46.2 vs. 22.0 RU, p<0.001). GADA positivity was also more often seen in TgA-positive index cases than in TgA-negative ones (88.6 vs. 73.4%, p=0.046). Siblings positive for TMsA were more often positive for GADA than those testing negative for TMsA (15.2 vs. 5.8%, p=0.012), but there was no significant difference in the GADA levels between TMsA-positive and negative siblings. A trend of association was also seen between GADA and PCA in siblings: 14.8% of PCA-positive tested positive for GADA, whereas only 6.1% of those negative for PCA (p=0.07). A similar trend was observed when comparing GADA levels in PCA-positive and negative siblings (medians 0.8 vs. 0.0 RU, p=0.075). No other associations were found between GADA and other autoantibodies. Our observations indicate that humoral autoimmunity against GAD may be determined by the same factors as those controlling susceptibility to thyroid autoimmunity, and GADA may predict susceptibility to thyroid disease in diabetic children and in their siblings who are at risk for IDDM.

299

COMPLEMENT DEPENDENT ANTIBODY MEDIATED CYTOTOXICITY IN TYPE 1 DIABETES: WHAT'S HAPPENING UNDER THE ICEBERG?

B.Kıran, N.Akış, İ.Yaylım, A.O.Gürol, A.O.Özdemir, Ş.Karadeniz, İ.Satman, and M.T.Yılmaz.
Institute for Exp. Med., Istanbul University, Istanbul-TURKEY.

In order to investigate the activation system of the classical and alternative pathway of complement, circulating immune complexes (cIC), human IgG and its subgroups, and ICA this study was conducted in 78 patients with Type 1 diabetes (mean age 28.4±12 yrs, duration of diabetes 2.1±1.1 yrs) and in 20 non-diabetic controls (mean age 27.1±11yrs). CH50 and AH50 were determined using immune haemolytic assay by microcomplement technique, cIC by microcomplement fixation test. The precipitation of cIC is accomplished by caprilic acid-ammonium sulphate method, purification of IgG by agarose gel filtration electrophoresis, fractioning of IgG using protein A sepharose column in HPLC, ICA by indirect immunofluorescence technique. Activation of classical pathway and cIC was significantly elevated in Type 1 diabetics compared to the controls (CH50 (ml) 271.2±122.1 vs 208.6±34, p<0.05; cIC (%) 21.5±11.1 vs 10.8±4, p<0.001), but the alternative way was not activated. In 86.2% of elevated CH50 group, cIC was found to be high (p<0.001). In the group with ICA>20JDF CH50 and cIC were significantly higher than in the ICA(-) group (CH50 (ml) 332.8±119 vs 226.9±104.5, p<0,001; cIC (%) 28.7±11.8 vs 16.2±7.1, p<0.001). In 77.4% of patients with ICA(+) cIC was high. Human IgG which is obtained by precipitation and purification of cIC was significantly higher in diabetics than in non-diabetics (3.9±1 vs 1.72±0.8mg/ml). IgG1κ had the highest peak (52.7%) in fractions of IgG. IgG1k was significantly elevated in Type1 diabetics compared to the non-diabetics (2.03±0.9 vs 1.03±0.23mg/dl, p<0.001). In conclusion, complement dependent antibody mediated cytotoxicity (C'AMC) which is activated by beta cell antibodies cIC play an important role in the destruction of beta cell. IgG1κ is a reliable indicator for the activation of C'AMC.

300

PREVALENCE OF SUBCLINICAL HYPOTHYROIDISM IN SIBLINGS OF PATIENTS WITH TYPE I DIABETES.

J. Libman, A. J. Muniagurria and A. M. Libman. University of Rosario. Rosario, Argentina

A higher prevalence of clinical hypo and hyperthyroidism as well of subclinical hypothyroidism (SCH) has been reported in IDDM. In order to evaluate the prevalence of SCH in siblings of patients with IDDM not previously suspected of having thyroid disease, TSH levels before and following the administration of TRH and thyroid microsomal (MCS -Ab) and thyroglobulin (TGB - Ab) antibodies were determined in 70 controls (C) (AGE 27±9, 41 F and 29 M), 42 patients with IDDM (AGE 24 ± 7, 25 F and 17 M) and 64 non-diabetic siblings (AGE 29 ± 10, 34 F and 30 M). TSH was measured by RIA, thyroid Ab by hemoaglutination. The prevalence of increased TSH concentrations (Basal≥ 5 uU/ml and/or post TRH≥ 25 uU/ml) was 2.8, 19.0 and 10.9 %, MCS-Ab were positive (≥ 1/100) in 4.2, 26.1 and 14%, and TGB-Ab in 2.8, 14.2 and 6.2% in C, patients with IDDM and their healthy siblings, respectively ($p<0.01$). Goiter was detected in 2.8, 14.2 and 7.8 % in the 3 groups. These results support the existence of a higher prevalence of SCH both in patients with IDDM and in their non-diabetic siblings, emphasizing the need to look for it in both groups.

301

THE DIABETES PREVENTION TRIAL-TYPE 1 DIABETES (DPT-1): DEMOGRAPHICS OF RELATIVES SCREENED AND ICA POSITIVE.

DPT-1 Study Group, Nationwide, USA

The DPT-1 is a nationwide study designed to determine whether insulin based therapies can delay or prevent the clinical onset of Type 1 diabetes in relatives of patients with established disease found to be at high risk of diabetes development. Parenteral insulin is used in relatives with >50% projected 5-year risk. Oral insulin is used in relatives with 26-50% projected 5-year risk. Screening for islet cell antibodies (ICA) began in February 1994. By November 30, 1996, there were 40,381 samples which had been received and analyzed for ICA. The age and gender distribution of subjects tested is as follows:

Age	Female	Male	Unknown	Total
0-9	5677	6268	3	11948
10-20	6455	6355		12810
21-45	10434	5189		15623
Total	22566	17812	3	40381

Rates of ICA positivity are:

Age	Female	Male	Total
0-9	3.3%	4.0%	3.7%
10-20	3.2%	4.5%	3.9%
21-45	2.6%	3.6%	2.9%
Total	3.0%	4.1%	3.4%

In terms of ethnicity, of subjects screened, 83.7% were non-Hispanic White, 8.2% were Hispanic, 2.5% were non-Hispanic Black, 0.8% were Asian or Pacific Islander, and 0.2% were native American Indian or Alaskan. Rates of ICA positivity were: 3.6% for non-Hispanic Whites, 2.3% for Hispanics, 3.4% for non-Hispanic Blacks, 2.2% for Asian or Pacific Islanders, and 1.0% for native American Indian/Alaskans. The rates of ICA positivity vary only slightly amongst different age, gender, and ethnic groups. Differences may be accounted for either by ascertainment bias or real biological variation.

302

GAD ANTIBODIES IN LONG TERM DIABETICS WITHOUT OVERT ENDOCRINOPATHY: A MARKER OF THYROID IMMUNITY AND DISEASE.

D Maugendre, C Massart, M Delamaire, JY Poirier, I Guilhem, H Allannic. Dep. of endocrinology, Lab. of hormonology and of humoral immunology. Rennes, France.

Persistent pancreatic antibodies have been described in diabetic patients with overt autoimmune thyroid disease. In diabetics without clinical thyroid disease, contradictory results have been reported about predictive value of persisting ICA in developpment of thyroid autommunity and disease . We have studied pancreatic markers (ICA and GAD antibodies), TPO antibodies and TSH values in 115 long standing (> 5 years) diabetic patients without known clinical and biological endocrinopathy Results: 16 of the 41 patients who were positive for ICA and/or GAD antibodies displayed also TPO antibodies (40%) versus only 5 of the 74 other subjects (7%, p<10-4).This result was also found when ICA positivity alone was analysed (p<0.05) but also for GAD antibodies with a greater significativity (p<10-4). ICA fluorescences in patients with ICA ≥20 units were restricted to ß cells and were totally or partially blocked after preincubation with brain GAD extracts. Eight patients, all with TPO antibodies, displayed abnormal TSH values, 6 of the 41 patients with persistent pancreatic autoimmunity (15%) versus only 2 of the 74 patients without ICA or GAD antibodies (3%, p=0.03). Among the 6 patients with persistent pancreatic immunity, 4 developped overt clinical thyroid disease (one hypothyroidism and 3 Graves'disease) in the next year. In conclusion, persistence of a humoral GAD reactivity is not only found in diabetic patients with overt clinical thyroid disease but is also associated with markers of thyroid autoimmunity and risk of further developpment of a thyroid dysfunction in diabetic patients without known clinical or biological autoimmune endocrine disease.

303

ADHERENCE OF FINNISH FAMILIES TO FREQUENT ISLET CELL ANTIBODY FOLLOW-UP OF CHILDREN AT GENETIC DIABETES RISK.

P. Muona, T. Simell, A. Kupila, M. Törmä, J. Hakalax, M. Knip, J. Ilonen and O. Simell. University of Turku, Turku, Finland, and University of Oulu, Oulu, Finland.

The Finnish Diabetes Prediction and Prevention (DIPP) project, which began in 1994, is a population-based, prospective trial aiming at 1) recognizing the newborn babies who are at genetic risk for IDDM, 2) determining the onset of autoimmune destruction of beta cells at an early stage, and 3) preventing/delaying the onset of clinical IDDM. Cord blood samples are examined for 2 susceptibility and 3 dominant protective HLA-DQB1 alleles associated with IDDM risk. Children with genotype associated with increased IDDM risk are invited for islet-cell antibody (ICA) follow-up. ICA titers are measured at 3-month intervals for 2 years, then every 6 months. The aim of this study was to evaluate 1) the parental acceptance of genetic screening of newborn babies for IDDM susceptibility, and 2) the adherence of Finnish families to immunological follow-up of the children at genetic IDDM risk. Altogether 6977 babies were born in the University Hospital of Turku between 11/94 and 11/96 (non-Caucasian babies excluded). Informed consent for the genetic screening was obtained from the parents of 6860 (98.3%) newborns. By 11/96, the genetic IDDM risk of 6438 babies has been determined. Of these, 811 (12.6%) carry an increased IDDM risk. In 11/96, 179/811 (22.1%) of the at-risk children have been lost from ICA follow-up. The majority (134/179 = 74.9%) of these families were unwilling to participate the follow-up either immediately after they had been informed about their child's increased IDDM risk by phone, or after the first counseling visit. When the children reach the age of 9 months, drop-outs become extremely rare; so far only two children have been lost from the follow-up after the 9-month visit, and none after the 15-month visit (to date, more than 500 children have visited at 15 months of age). In conclusion, the cord blood screening for genetic IDDM susceptibility is well accepted by Finnish families, and the adherence of families of the at-risk children to the rather laborous ICA follow-up is excellent, especially after the child has reached the age of 15 months.

304

HIGH PREVALENCE OF GAD65 ANTIBODIES IN JAPANESE IDDM PATIENTS BY A NEW IMMUNOPRECIPITATION ASSAY.

H. Akamine, I. Komiya, T. Shimabukuro, T. Asawa, N. Yagi, T. Taira, K. Nagata and N. Takasu. University of the Ryukyus, Okinawa, Japan.

Marked differences have been reported in the prevalence of glutamic acid decarboxylase (GAD) antibodies between Caucasian (63-84%) and Japanese (30-50%) or Asian (5-50%) IDDM patients. Using a new immunoprecipitation assay based on ^{125}I-labeled recombinant human GAD65, we reassessed prevalence of GAD65 antibodies in Japanese patients. GAD65 antibodies were detected in 83.3% of sera taken within 1 year of onset, comparable to the prevalence reported in Caucasian patients. Positivity decreased to 66.7% after 2 to 3 years and to 54.3% after 3 years from onset, still higher than previously reported Asian prevalence. Except in one patient, high antibody levels persisted chronically, up to 12 years. GAD65 antibodies were detected in 2.6% (1/38) of new-onset NIDDM sera, in 2.6% (1/38) of untreated Graves' disease sera, and in 1.5% (1/65) of normal subjects sera. GAD65 antibodies were not found in 18 Hashimoto's thyroiditis and 36 SLE patients sera. Even it positive, levels of GAD65 antibodies were very low. There was no difference in GAD65 antibodies between Japanese IDDM patients with and without autoimmune thyroid disease (AITD). The difference in positivity in Asian IDDM patients between present and previous reports arose from the sensitivity of our assay for GAD65 antibodies. Additionally, the patients we studied had classic IDDM with a well-defined onset. We conclude that prevalence of GAD65 antibodies in Japanese patients with IDDM is comparable to that in Western studies. There was no relationship of GAD65 antibody positivity to coexistence of AITD. Our results suggest that autoimmunity is the most significant cause of Japanese IDDM.

305

SEROCONVERSION TO AUTOANTIBODY POSITIVITY OF CHILDREN AT GENETIC RISK FOR INSULIN-DEPENDENT DIABETES.

O. Simell, T. Simell, P. Muona, A. Kupila, P. Arvilommi, M. Knip, J. Ilonen and H. Hyöty. University of Turku, Turku, Finland, and University of Oulu, Oulu, Finland.

The Diabetes Prediction and Prevention (DIPP) project aims at finding the newborns at genetic risk for IDDM development, recognizing early the appearance of autoimmune markers preceding clinical IDDM, and delaying the onset of the disease. In the population-based DIPP trial, which began in 1994, cord blood samples of all newborns are examined for 2 susceptibility and 3 dominant protective IDDM-associated HLA-DQB1 alleles. As 85-90% of new cases of IDDM occur in subjects with no family history of the disease, effective prevention has to be based on screening of genetic susceptibility and/or analysis of preclinical IDDM markers in the entire population. HLA-DQB1 allele combinations *0302/*0201 and *0302/*x (*x ≠ *0602, *0603 or *0301), which associate with ~7% and ~3% IDDM risk (risk of background population 0.66%), respectively, before the age of 15 years, define a population which in Finland includes 60-80% of those who develop IDDM in childhood. Children with these genotypes are followed for development of islet-cell antibodies (ICA) at 3 to 6 month intervals. By November 1996, the genetic IDDM risk of 6438 newborns has been determined in Turku. Of these, 811 (12.6%) carry an increased risk. Eight at-risk children have been ICA positive at 3 months; 3 of them have lost ICA by 6 months, 2 children by 9 months, 2 by 12 months, and 1 child by 15 months of age. Now that the oldest children are 24 months of age, 7 have seroconverted to ICA positivity at the age of ≥6 months; these titers often fluctuate. First rapidly-rising ICA titers appeared in 2 children between 9 and 12 months of age; these children have also antibodies against GAD or insulin. In conclusion, ICA detectable at birth are lost by 15 months of age in all children with increased genetic IDDM risk. Positive "own" ICA titers were first recognized between 3 and 6 months of age, but these titers often fluctuate. First aggressive-looking ICA titer curves appeared between 9 and 12 months of age.

306

ISLET CELL CYTOPLASMIC ANTIBODIES, GAD ANTIBODIES, AND ANTI-THYROID ANTIBODIES IN JAPANESE IDDM PATIENTS.

K. Takahashi, M. Fujita, T. Yokota, T. Kusumoto and Y. Miyake. Kurashiki Chuoh Hospital, Kurashiki, Japan

Onset of insulin-dependent diabetes mellitus(IDDM) is in consequence of autoimmune B-cell destruction. Islet cell cytoplasmic antibodies(ICA) and anti-GAD antibodies as immunological markers of the B-cell damage detected in sera from patients with IDDM in early stage were reported during the past decades. In Japan, it is well known that Hashimoto's thyroidis, an organ-specific autoimmune disease, is often co-existent with IDDM, so we investigated frequency of anti-thyroid antibodies in Japanese IDDM patients, and relations of the antibodies to anti-islet antibodies. In 46 IDDM patients, ICA, anti-GAD, thyroglobulin antibody, and TPO antiboby were determined in same serum samples, and inter-relationships of these antibodies were analysed in respect of antibody titer and positivity. In 50 non-diabetic patients with thyroid disease, these antibodies were also measured as control study. Of 46 IDDM, ICA were found in 36(78.3%), anti-GAD were in 28(60.9%), thyroglobulin antibody was in 23(50.0%), and TPO antibody was in 22(47.8%). Thyroglobulin antibody or TPO antibody were frequently positive in patients having high titer ICA(160≦) than in those having low titer or negative ICA(80≧)($P < 0.001$). Furthermore, these thyroid antibodies were also frequently positive in patients having high titer anti-GAD(700U/ml <) than in those having low titer or negative anti-GAD(700U/ml >)($P < 0.01$). In 50 non-diabetic controls, ICA and anti-GAD were detected in only one (2.0%) and two (4.0%) patients, respectively. The results that frequency of anti-thyroid antibodies in IDDM is associated with high titer of anti-islet antibodies indicate close relation of the two organ-specific autoimmune diseases in Japanese subjects. It should be resolved what is common immunological abnormality lying between two autoimmune diseases, IDDM and Hashimoto's thyroiditis.

307

DIRECT COSTS OF COMBINED GENETIC AND IMMUNOLOGICAL PREDICTION OF INSULIN-DEPENDENT DIABETES IN CHILDREN.

T. Simell, J. Hahl, P. Muona, J. Hakalax and O. Simell. University of Turku, Turku, Finland, and Economics Department, Turku School of Economics and Business Administration, Turku, Finland.

In the Diabetes Prediction and Prevention (DIPP) project two HLA-DQB1 alleles associated with IDDM risk and three dominant protective alleles of all newborns in Turku and Oulu (8,500 annual births) are analysed in cord blood. The screening finds 60-80% of those who will develop IDDM before the age of 15 years. Islet-cell antibody (ICA) titers of the at-risk children (12.6% of the newborns) are measured in cord serum, then at 3-month intervals for 2 years, and thereafter at 6-month intervals. The aims of this study were to analyse the direct costs of genetic screening for IDDM risk, to analyse the direct costs of repeated ICA follow-up, and to compare the direct costs of the approaches based on A) genetic screening with subsequent ICA follow-up of the at-risk children and B) repeated ICA screening of the entire population. The major part of the costs was caused by collection and handling of samples and by counseling of the families. The mean fixed (i.e., overhead costs 65%) and variable direct cost of one risk allele determination in our project is US$83. The direct cost of finding one child at genetic IDDM risk is US$653. If the at-risk child remains ICA negative, the direct costs of ICA follow-up are $239, $212 and $117 in the 1st, 2nd and 3rd year, respectively. If the child is ICA positive in all measurements, the costs increase to $478, $404 and $212, respectively. The 10-year costs of genetic screening and subsequent ICA follow-up of the at-risk children are in the mean $261/child; without genetic screening the mean costs of ICA follow-up are $680/child. Using 5% discount rate the present direct costs are $232 and $557 per child, respectively. At Finland's annual birth rate (65,000) the 10-year direct costs of extending the trial to all newborns and using the two approaches would be $15.0 million and $37.7 million, respectively. In conclusion, population-based genetic screening for IDDM risk is clearly cost-saving compared to the approach based on repeated ICA screening of the entire population.

308

IN NEW-ONSET IDDM PATIENTS THE PRESENCE OF IA2-ANTIBODIES IS NOT ASSOCIATED WITH INCREASED THYROID AUTOIMMUNITY

I. De Leeuw, C. Vandewalle and the Belgian Diabetes Registry, University of Antwerp, Antwerp, Belgium

In previous studies a strong association between the presence of anti-thyroid peroxidase antibodies (aTPO) and a positive level of islet-cell antibodies (ICA $\geq$ 12 JDFU) has been demonstrated in new-onset IDDM patients aged 10-39 yr but this observation could not be confirmed in patients with GAD 65 Ab positivity. Since recently a liquid phase radiobinding assay became available to measure autoantibodies against a transmembrane PTP-ase, IA2, a known antigen in IDDM, it seemed interesting to look after a possible relation with aTPO positivity. In 105 new-onset IDDM (71 men, 34 women, ages 10-39 yr) 49% showed an increased level of IA2-Ab ($\geq$0.51% of tracer binding). The median age of the IA2-Ab positive group was significantly lower (21 yr versus 26.5 yr, $p = 0.02$). The distribution between men and women was not different in the IA2-Ab+ and - groups. Positive thyroid autoimmunity (aTPO > 100 Uml^{-}) was equally distributed between both groups (10/51 IA2-Ab+ versus 11/54 IA2-Ab-). Although more women (35%) showed aTPO positivity as compared to men (12.8%, $p<0.01$) no sex differences could be disclosed for thyroid autoimmunity in the IA2-Ab+ group. When patients of this group were subdivided in a young (10-25 yr) and an older group at onset (26-39 yr) the equal distribution of aTPO positivity was maintained in contrast to previous observations where ICA and IAA positivity were significantly associated to aTPO+ in the older group. Finally in this limited number of patients Fisher Exact Test showed a significant relation ($p=0.02$) of the risk haplotype HLA-DQ DQA1*0301-DQB1*0302 with aTPO positivity but not with IA2-Ab positivity ($p=0.1246$). In conclusion it looks that IA2-Ab positivity at onset of IDDM does not permit a prognosis of future increased thyroid autoimmunity.

309

THE SARDINIAN SCHOOL CHILDREN - IDDM (SSI) STUDY. PREDICTIVE VALUE OF IDDM-RELATED AUTOANTIBODIES IN A COHORT OF HEALTHY SARDINIAN SCHOOL CHILDREN.

F Velluzzi, A Loviselli, P Mele, A Pilleri, A Pilo, S Serra, MA Calia, S Mariotti, M Shattock*, R Foxon*, V Sepe*, M Songini**, GF Bottazzo* and the SSI Study Group. *Dept of Internal Medicine, Cagliari University, Italy; *Dept of Immunology, St Bartholomew's & The Royal London School of Medicine & Dentistry, UK; ** Centre for Metabolic Diseases and Atherosclerosis, Cagliari, Italy.*

In order to define the predictive value of islet-related autoantibodies, as single or combined specificities, over 10,000 sera have been collected from school children living in the 4 provinces of Sardinia. To date, 3080 of them (from the 3 provinces of Cagliari, Oristano and Nuoro), have been followed-up for a period of 2 to 10 years. Their sera were tested for ICA, GADA and IA-2icA. 10 (M:F=1) developed IDDM between 2 and 60 months since they were recruited into the study. All but 1 were 'sporadic' cases of IDDM and none live in the province of Nuoro.

Test	Positive No (%)	Se %	Sp %	PPV %
ICA ≥5	255 (8.3)	100	92	4
ICA >20	64 (2.1)	80	98	13
GADA	37 (2.1)	40	98	11
IA-2icA	49 (2.8)	70	98	14
ICA >20 & GADA	19 (1 1)	30	99	16
ICA >20 & IA-2icA	22 (1.3)	70	99	32
GADA & IA-2icA	15 (0 9)	30	99	20
ICA >20 & GADA & IA-2icA	14 (0 8)	30	99	21

All were positive for ICA, 7 were positive for IA-2icA and 4 had also GADA. The overall results are summarized in the Table, which indicates that: 1) ICA alone, ≥5 JDFu (100%) or >20 JDFu (80%) showed the highest values of Se for pre-IDDM and 2) combination of ICA >20 JDFu and IA-2icA can still be regarded as a promising test for pre-IDDM (Se 70% & Sp 99%) also showing the highest PPV (32%). In summary, it is only by consistenly following these children, that prediction of IDDM among sc will be assessed in Sardinia.

Se sensitivity, Sp Specificity, PPV positive predictive value

310

INSULIN AUTOANTIBODIES BEFORE AND AFTER CARBIMAZOLE THERAPY IN ASIAN INDIAN PATIENTS WITH GRAVES' DISEASE.

R Goswami, A Jaleel, N Jayasurayan, N Tandon, and N Kochupillai. Dept. of Endocrinology, All India Institute of Medical Sciences, New Delhi, India

Spontaneous occurrence of Insulin autoantibodies(IAA) has been reported in patients with Graves' disease (GD). Also in Japanese patients with GD, IAA has been reported to be induced with carbimazole (CBZ) therapy. However CBZ has not been shown to cause induction of IAA in Caucasians. The HLA haplotypes associated with GD in Asian Indians have been reported to resemble Caucasians rather than Japanese. We assessed IAA levels in 114 north Indian patients with GD before and after CBZ therapy (mean duration 6.2 $\pm$ 3.9 months). We also evaluated the functional significance of IAA in them by assessing insulin response to intravenous glucose (IVGTT) and oral glucose tolerance test (OGTT). Thyroid hormones and insulin were measured by in-house radioimmunoassays. IAA was measured using radioligand assay and expressed in standard deviation scores (SDS) above healthy controls. On participation in the 5th IAA proficiency program (University of Florida, U.S.A.) our assay had 100% specificity and 90% sensitivity. Thyroid microsomal antibody (TMA) was measured by haemagglutination method. Pretreatment, 22 of 114 (19%) GD patients had positive IAA (mean$\pm$SD 5.5 $\pm$ 4.4 SDS). After CBZ therapy additional 11 (9.6%) showed IAA positivity (mean$\pm$SD, 3.5 $\pm$ 1.0 SDS). Of the 22 patients with IAA +ve before treatment, 12 became negative after CBZ therapy. The fasting insulin levels and area under insulin curve in IVGTT (mean$\pm$SD) were comparable in IAA+ve and -ve GD (43.7 $\pm$ 64 vs 56 $\pm$ 33 pmol/L and 3142 $\pm$ 215 vs 3458 $\pm$ 2195 pmol/10min respectively). OGTT results and %TMA positivity were also comparable in the IAA+ve and -ve groups. Thus, north Indian GD patients, though resembling Caucasians in HLA haplotypes, behave like Japanese in co-prevalence of IAA and their tendency to become IAA +ve on CBZ therapy.

311

THE SARDINIAN NEWBORN - IDDM (SNI) STUDY. EARLY ONSET OF IDDM CORRELATES WITH THE APPEARANCE OF ISLET-RELATED AUTOANTIBODIES IN A COHORT OF YOUNG CHILDREN FOLLOWED UP FROM BIRTH.

MF Mulas, G Guaita, I Pelligra, E Cossu, R Cirillo, M Shattock*, R Foxon*, V Sepe*, M Songini**, GF Bottazzo* & the SNI Study Group. *Dept of Internal Medicine, Cagliari University, Italy; * Dept of Immunology, St Bartholomew's & The Royal London School of Medicine & Dentistry, UK; **Centre for Metabolic Diseases and Atherosclerosis, Cagliari, Italy.*

In order to study the natural history of IDDM in reference to the appearance of islet-related autoantibodies, between Nov 1993 and Sep 96, 15,939 newborn were recruited and 12,858 cord blood sera were tested for ICA. Their prevalence was 2.4% (314) for titres ≥5 JDFu and 0.7% (86) for titres >20 JDFu, with a similar trend in the 3 provinces studied (Cagliari, Nuoro and Sassari). To date, of the 12,858 children initially recruited, 1897 blood samples have been collected at year 1 and 278 at year 2. The sera were tested for ICA (yr1=1853; yr2=238), GADA (yr1=1893; yr2=277) and IA-2icA (yr1=1894; yr2=275). The results are summarized in the Table.

AAbs	Year 1		Year 2	
	Pos	%	Pos	%
ICA	4	0.2	4	1.7*
GADA	8	0.4	4	1.4#
IA-2icA	3	0.2	2	0.7
ICA & GADA	2	0.1	3	1.5*
ICA & IA-2icA	1	0.1	2	1.0*
GADA & IA-2icA	0	0	2	0.7*
ICA & GADA & IA-2icA	0	0	2	1.0*

*p<0.001 vs Year 1, #p<0.05 vs Year 1

At year 1, 8 children were positive for GADA. At year 2, 4 of them did not attend the pre-IDDM Clinic, 4 were followed-up and confirmed GADA positivity, 3 showed ICA and 2 had also IA-2icA. To date 6 children (M:F=1) developed IDDM. They were between 11 and 29 months old and all but one were ICA negative at time of birth. At year 1, 2 out of 5 attended the pre-IDDM Clinic, and both were ICA positive, together with GADA or IA-2icA. At the time of onset, sera from 3 newly IDDM out of the 6 were available and all were positive for ICA and GADA, 1 was also positive for IA-2icA. In summary: 1) GADA developed before ICA and IA-2icA at year 1; 2) there is a significant increase in the appearance of islet-related autoantibodies at year 2, when compared with year 1; 3) children developing IDDM before the age of 3 years appeared to be ICA negative at birth, but islet-related autoantibody positive at the onset of the disease. In conclusion, a possible increase of incidence of IDDM under the age of 3 is presently monitored in Sardinia.

312

CO-APPEARANCE OF ANTINUCLEAR, MITOCHONDRIAL AND ISLET CELL ANTIBODIES IN HUMAN PANCREAS SECTIONS

S. Bilgiç, İ. Satman, G. Yıllar, G. Işıtmangil, Y. Tütüncü, and M.T. Yılmaz. Department of Immunology and Diabetes Research Unit, Institute of Experimental Medicine Research, Istanbul University, Istanbul - TURKEY.

In order to evaluate possible relationships between islet cell antibody (ICA) and antinuclear antibody (ANA) we screened totaly 1359 sera using I.F. technique in human pancreas sections. Sera were belonged to 378 non-diabetic (non-DM) first degree relatives of Type 1 DM cases and 491 Type 1 DM patients at different stages (177 early-clinical; < 3 months, 255 clinical; 3-12 months, and 59 late clinical period; ≥ 5 years). Specifically stained small clusters of islet cells (Askanazy cells; mitochondrial antibody, "MITO") were also investigated in the same sections. Results were compared with data of 305 non-DM first degree relatives of Type 2 DM cases, 146 Type 2 DM patients, and 38 healthy control subjects who have no diabetic relative. Antibody frequencies were shown as follows:

Type 1 DM	ICA≥10 JDF	ICA≥20 JDF	ANA	MITO
1°st non-DM relatives	15.1	4.0	2.6	0.003
Early clinical period	60.5	15.9	1.7	0.8
Clinical period	34.5	13.7	1.6	0.4
Late clinical period	20.3	1.7	-	-
Type 2 diabetes	6.8	3.4	-	-
1°st non-DM relatives	7.5	5.9	1.3	-
Control group	7.9	2.6	-	-

Both low and high titre ICA were most frequent in early period Type 1 DM patients, the frequency have shown a continuously decreased trend as expected from early to clinical, and to late periods ($p<0.005$ and $p<0.001$). ICA positivity among 1°st relatives of Type 1 DM were more prevalent than 1°st relatives of Type 2 DM, Type 2 DM patients and control subjects. Frequency of ANA was high both in 1°st relatives of and in early and clinical stages of Type 1 DM cases as compared to late period Type 1 DM, 1°st relatives, and clinical Type 2 DM and control subjects. MITO showed a similar trend to ANA. This antibody pattern might have suggest activaton of autoimmunity along with high titre ICA.

313

THE ULM SCHOOLCHILDREN STUDY: RISK ASSESSMENT FOR IDDM BY COMBINED ANALYSIS OF GAD65 AND IA2 ANTIBODIES.

W. Richter, U. Hartmann, K. Berling, R. Hartmann, U. Wiest, J. Seissler*, W.A. Scherbaum* and B.O. Boehm, University of Ulm, Ulm and University of Leipzig*, Leipzig, Germany

Risk assessment and prediction of insulin-dependent diabetes mellitus (IDDM) in the Ulm schoolchildren study of 1988 was based on islet cell autoantibodies (ICA) detected by the classical immunofluorescence test on human pancreatic tissue. We here developed a new strategy to replace the laborious and difficult to standardize histochemical ICA test in large scale screening programs for risk assessment of IDDM in the general population. We established radioimmunoassays for separate detection of autoantibodies to GAD65, the cytoplasmic part of IA2 ($IA2_c$) (one parameter tests) and for combined detection of GAD65-A and $IA2_c$-A in a single-step assay (two parameter test). Sera from 93 patients newly diagnosed with IDDM and 695 healthy controls were used to optimize the tests and to determine the optimal decision threshold levels for each assay by receiver operating characteristics (ROC) plot analysis. The cut-off value of the combined assay was selected in a way that no sera positive in the one parameter tests escaped detection in the two parameter test. This allowed to discriminate antibody-positive sera from antibody negative sera in one step. Only positive sera had then to be re-analysed in the GAD65- and $IA2_c$-A to determine their exact antibody specificity. By retrospective analysis, 4021 sera from the Ulm schoolchildren study sampled in 1988 were evaluated by our new tests. 31 sera (0.77%) were positive for GAD65-A and 7 sera (0.17%) were positive for IA2-A compared to 44 of 4287 sera (1,05%), which had been found ICA-positive. 5 sera were positive for ICA, GAD65-A and $IA2_c$-A; 4 sera showed 2 antibody specificities. 5 individuals developed IDDM during the follow up according to a questionaire sent out to all participants of the 1988 study. The data demonstrate that our strategy based on quantitative, reproducible and combined detection of GAD65-A and $IA2_c$-A allows cost-saving and most effective large scale screening of sera for prediciton of IDDM.

AUTOANTIBODIES TO THYROID PEROXIDASE AND THYROGLOBULIN MEASURED BY HIGHLY SENSITIVE RIA IN PATIENTS WITH JAPANESE DIABETES MELLITUS.

Y. Hayashi, M. Matsumura, R. Uchida, M. Okamoto, Y. Kokubun, N. Ogiwara, M. Kawakatsu, T. Murakami, A. Asaoka, and Y. Arakawa Nihon University, Tokyo, Japan

We studied frequency of autoantibodies to thyroid peroxidase (TPO-Ab) and thyroglobulin (Tg-Ab), and examined the relationship between these antibodies and antibodies to glutamic acid decarboxylase (GAD-Ab) in japanese patients with type 1 and type 2 diabetes mellitus. TPO-Ab and Tg-Ab were measured by highly sensitive radioimmunoassey (RIA), and GAD-Ab by Anti GAD RIA Kit of Hoechst Japan. The subjects of our study was 70 patients of type 1 diadetes and 138 patients of type 2 diabetes.

The frequency of GAD-Ab was observed in type 1 diabetes (47%) and in type 2 diabetes (11%). The frequency of TPO-Ab and Tg-Ab was observed in type 1 diabetes (48%, 24%) and in type 2 diabetes (19%, 23%). The frequency of GAD-Ab was observed in type 1 diabetes with Tg-Ab (negative 54%, positive 50%) and with TPO-Ab (negative 47%, positive 56%), but the frequency of GAD-Ab was observed in type 2 diabetes with Tg-Ab (negative 9%, positive 21%) and with TPO-Ab (negative 9%, positive 37%). We concluded that 48% of type 1 japanese diabetes has relationship with thyroid autoimmunity and, 20-30% of type 2 diabetes with GAD-Ab positive has relationship with thyroid autoimmunity.

315

Combined analysis of GADAs, IAAs, IA-2As and ICAs in a general population of schoolchildren

M. Strebelow, P. Augstein, U. Jacobi, B. Ziegler, M. Schlosser and M. Ziegler
Institute of Diabetes "Gerhardt Katsch" Karlsburg, University of Greifswald

Identification of subjects at risk for developing IDDM is based on detection of AAbs to ß-cell antigens. In order to identify high risk individuals for developing IDDM sera from 8,592 schoolchildren (6-17 years) were screened for GADA, IAA and IA-2A using 125I-labelled antigens and ICA measured by indirect immunofluorescence. 5% (433/8,592) exceeded the cut-offs of 99, 99 and 98 percentiles for GADA, IA-2A and IAA, respectively and 5 JDFU for ICA. Up to now 351 children initial positive for at least one AAb were re-examined after 8-12 weeks. For 69% (242/351) the AAb positivity was confirmed. We found 78% (189/242) to be positive for only 1 AAb, 13.2% (32/242) for only 2 AAbs, 6.1% (15/242) for 3 AAbs and 2.5% (6/242) positive for all 4 AAbs as follows:

1 AAb:	*prevalence*	*2 AAbs:*	*prevalence*	*3 AAbs:*	*prevalence*
GADA:	46.7%	GADA+IA-2A:	2.06%	GADA+IAA+IA-2A:	0%
IA-2A:	1.2%	GADA+IAA:	1.65%	GADA+IA-2A+ICA:	4.1%
IAA:	11.5%	GADA+ICA:	4.95%	GADA+IAA+ICA:	1.6%
ICA:	18.5%	IA-2A +ICA:	2.00%	IAA+ICA+IA-2A:	0.4%
		IA-2A+IAA:	0%		
		IAA+ICA:	2.47%		

64.8% (157/242) of the re-examined children were positive for GADA and/or IA-2A and only 27.2% (66/242) for IAA and/or IA-2A. 19.4% (47/242) were positive for at least 2 AAbs. Among these children the most frequent combination of AAbs measured by 125I-antigen binding assays was the combination GADA+IA-2A (8.7%) followed by GADA+IAA (5.7%) and IAA+IA-2A (2.9%). 45/242 were found to be of high risk for developing IDDM (defined by 1. positive for ≥3 AAbs; 2. ICA≥20 JDFU and GADA or IAA positive, or IA-2A and 1 further AAb is positive; 3. ICA≥40 JDFU, or GADA≥29xcut-off, or IA-2A≥2xcut-off). 76% (34/45) of them were positive for at least 2 AAbs, 53% (18/34) for GADA+IA-2A, 26% (9/34) for GADA+IAA and 20% (7/34) for IAA+IA-2A. From our preliminary results we conclude, for initial screening of large populations for risk for developing IDDM the easily measured AAbs GADA and IA-2A should be used, followed by the measurement of IAA and ICA in subjects positive for one or both of these.

316

LONGITUDINAL STUDY OF ANTICARDIOLIPIN AUTOANTIBODIES IN CHILDREN WITH INSULIN DEPENDENT DIABETES MELLITUS

P. Ciampalini, L. Giovannelli*, S. Corbi, D. Gianni, S. Spera and A. Crinò.
Dept. of Endocrinology and *Lab. of Immunology, "Bambino Gesù" Hospital, Rome, ITALY

Insulin dependent diabetes mellitus (IDDM), like other endocrinopathies, is characterized by an increased prevalence of organ and non-organ-specific autoantibodies. Recently, high levels of anticardiolipin antibodies (aCL) have been found in IDDM, but there are no reports on the follow-up of autoantibodies in these patients. We evaluated aCL-IgG and aCL-IgM (by ELISA assay) in 77 children and adolescents with IDDM (31 m, 46 f; age 9.6±4.6 yrs; duration of disease from onset up to 12 yrs; HbA1c 8.2±1.5%). In 51/77 diabetic patients aCL were periodically checked (every 3-4 months) for a period of 2.8±1.7 years. 102 age and sex-matched healthy subjects served as control group. ACL-IgG >20GPL and aCL-IgM >10MPL values were considered positive. ACL IgG or IgM were positive (at least once) in 28 patients (36%) ($p<0.0001$ vs control group), while aCL-IgG and IgM were positive respectively in 23 (30%) and 11 (14%) patients ($p<0.0001$ and $p<0.005$ vs control group). Only in 6 out of 77 (8%) IDDM patients aCL IgG and IgM were both positive. During the follow-up aCL-IgG were confirmed positive in 9/51 (18%) while aCL-IgM were positive in 4/51 (8%). The frequencies of aCL (IgG and IgM), in diabetic patients during the follow-up and in controls are reported in the table:

	n. 77	**n. 51** (follow-up 2.8±1.7 yrs)			*n.102*
aCL	once pos.	twice pos.	3 times pos.	>3 times pos.	*Controls*
IgG(>20GPL)	23 (30%)	4 (8%)	3 (6%)	2 (4%)	*8 (8%)*
IgM(>10MPL)	11 (14%)	2 (4%)	2 (4%)	0	*2 (2%)*

ACL (IgG and IgM), when positive, were always at lower levels and no correlation was found between aCL and sex, chronological age, metabolic control, and duration of the disease. Most of the patients had occasionally positive aCL (IgG or IgM), and in some of them they were fluctuating in time. Only 2 patients (males) had positive aCL-IgG during the whole follow-up tending to increase, but not significantly, with the duration of IDDM. In conclusion, aCL are significantly more frequent in young diabetic population fluctuating with time without clinical evidence of any specific autoimmune disorder.

317

SCREENING OF RISK FOR DEVELOPING IDDM IN SCHOOLCHILDREN BY AUTOANTIBODY ANALYSIS IN COMBINATION WITH GENOTYPING

M. Ziegler, M. Strebelow, R. Wassmuth*, M. Arnold*, M. Schlosser, and B. Ziegler
*Institute of Diabetes „Gerhardt Katsch" Karlsburg, University of Greifswald and *Institute for Clinical Immunology, University of Erlangen-Nürnberg, Germany*

Islet cell autoantibodies precede the onset of IDDM. The aim of our study is, to assess as an alternative to ICA the predictive diagnostic power of risk for developing type I diabetes of AAbs against the three ß-cell antigens, namely glutamic acid decarboxylase (GADA), protein tyrosine phosphatase (IA-2A) and insulin (IAA) by screening of a general schoolchildren population of an age range from 6 to 17 years. Up to now, sera from 8,592 children were screened for GADA, IA-2A and IAA by the use of 125I-antigen binding assays. The cut-offs used were 99, 99 and 98 percentiles, respectively. ICA (cut-off = 5JDFU) were detected by immunofluorescence technique. In the last AAb proficiency programs the sensitivity/specificity of these assays were 100%/100% for GADA and IAA and 100%/87% for ICA. The AAb screening of GADA, IA-2A, IAA and ICA revealed 5% (433/8592) AAb positive children. 397 (4.6%) were positive for only one AAb, 25 (0.29%) for two, 8 (0.09%) for three and 3 (0.03%) for four AAbs. By re-examination of primary positive children the AAb positivity was confirmed by 69%. By AAb determination, 0.52% (45/8592) of schoolchildren studied were found to be of high risk for developing IDDM. Four out of them - all positive for GADA and ICA, 3 additionally positive for IA-2A and 1 for IAA - followed already to IDDM. 9 out of the 45 (20%) high risk children are only positive for ICA (40 - 160 JDFU). 25 of 26 (96%) high risk individuals and 13 of 14 (93%) IA-2 antibody positive children bear the HLA DRQB1 genetic IDDM markers 0201 and 0302, and but not any child was positive for the protective genetic marker HLA DRQB1 0602. From our preliminary results we conclude, that the combined AAb detection by 125I-antigen binding assays is useful for initial screening of large populations and offers an alternative to the ICA screening assay. However, ICA is further needed to recognize individuals of risk for developing IDDM with highest diagnostic sensitivity. The predictive diagnostic power increases with the number of AAb species occurring and with their titres. The risk for developing IDDM is additionally increased by the absence of protective genetic markers and by the occurrence of HLA DRQB1 genetic markers of type 1 diabetes.

318

SELECTED MARKERS OF INFLAMMATORY RESPONSE IN NEWLY DIAGNOSED TYPE I DIABETES MELLITUS

D.Zozulińska, A.Majchrzak, M.Sobieska*, K.Wiktorowicz* and B. Wierusz-Wysocka. Poznań Diabetic Center, *Laboratory of Cellular Immunology. Academy of Medicine in Poznań, Poland

Evidence suggest that mediators of inflammatory response play an important role in pathology of diabetes and diabetic vascular complications. The aim of our study was to estimate some markers of the acute-phase reaction in newly diagnosed type I diabetes. The study was conducted in a group of 10 patients aged 31.3±8.5 years, with duration of diabetes 19.2±20.7 days. We estimated serum concentration of CRP, alpha-1 acid glycoprotein (AGP) and alpha-1 antychymotrypsin (ACT) and glycosylation profile of AGP and ACT (microheterogeneity). Microheterogeneity of AGP and ACT were studied by affinity electrophoresis with concanavalin A as the ligand. The results were expressed as reactivity coefficients (RC). CRP, AGP and ACT serum concentrations were similar to noticed in healthy subjects. We observed significantly lower values of AGP-RC and ACT-RC in patients with type 1 diabetes (1.08±0.10 and 2.99±0.71) in comparison with healthy individuals (1.27±0.08 and 4.12±0.89) ($p<0.05$) ($p<0.05$). In conclusion, the AGP and ACT glycosylation profile noticed in our study is characteristic for persistant inflammatory process.

319

LESSONS FROM ISTANBUL FAMILY STUDY: ARE RELATIVES OF YOUNGER ONSET DIABETES MORE RISKY?

G. Yıllar, İ. Satman, S. Bilgiç, Y.Tütüncü, G. Işıtmangil, S. Gedik, and M.T. Yılmaz. Department of Immunology and Diabetes Research Unit, Institute of Experimental Medicine Research, Istanbul University, Istanbul - TURKEY.

In this study we aimed to determine the prevalence of islet cell antibody (ICA) in first degree relatives of Type 1 diabetes patients. The study included 382 first degree relatives from 209 families (parenths; 134 -mother/father 86/48, siblings; 192 -female/male 100/92, and offsprings; 55 -female/male 27/28). Positive ICA was defined as ≥10 JDF u. and overall prevalence was 14.4% (55 relatives); however, only 15 subjects (3.9%) had a high titre ICA (20 JDF u.). Based on age at onset in the index case, family members were divided into two groups. 322 relatives of patients diagnosed ≤20 years of age composed group I, and 60 relatives of patients diagnosed > 20 years composed group II. Comparison of the two groups have shown that high titre ICA in group I was more frequent than in the group II (4.3% vs. 1.7%, $p<0.005$). Low titre ICA was also frequent in this group, but did not reach to a significant level. Although no difference was observed for ICA among parenths and siblings between two groups, frequency of ICA was found to be higher in offsprings of group I than in the group II (22.2% vs. 8.7%, $p<0.05$). Moreover, ICA was more prevalent among mothers, male siblings and female offsprings of group I (ICA in the same order; 16.7% vs. 0.0%, $p<0.001$, 13.6% vs. 0.0%, $p<0.001$, and 20.0% vs. 4.5%, $p<0.005$). In contrast, only fathers of group II were noticed to be more frequently ICA positive (33.3% vs. 11.1%, $p<0.001$). Our results have indicated that compared to relatives of older onset patients, ICA is more prevalent among first degree relatives of younger onset Type 1 diabetes patients. Particularly, mothers, male siblings, and female offsprings are seems to be utmost risk.

EVIDENCE FOR IMMUNOREGULATORY DEFECTS OF GLYCATED LYMPHOCYTES IN DIABETES

G. O. Ifere, J. Epoke and C. Odigwe. University of Calabar, Calabar, Nigeria.

Various *in vivo* and *in vitro* data indicate that, nonenzymatic glycosylation of membrane proteins may be implicated in the changes observed in intrinsic and exposed group properties in diabetic state. Similarly, glycosylation of lymphocyte membrane proteins may have far reaching immunological implications, considering the role of membrane receptors in immunological activity. To evaluate the role of glycation in the immunoregulatory defects of diabetic lymphocytes, we measured both humoral and cell-mediated immune responses in diabetic and nondiabetic subjects. For humoral response, Widal test was used to estimate somatic and flagellar antibody levels in 30 diabetic and 20 nondiabetic individuals. To evaluate cell-mediated immune response, tuberculin test was performed on 32 and 20 diabetic and nondiabetic subjects respectively. The role of glycosylation in the compromised immune response was ascertained by colorimetric assay of lymphocyte membrane protein glycosylation. The impaired humoral and cell-mediated immune responses with glycosylation was reflected in the significant ($P<0.01$) negative correlation coefficient ($r = -0.62$ and $r = -0.65$, respectively) but not in the control group. This glycosylation - induced immunoregulatory defects may bring to light reasons why lymphocytes of diabetic subjects were observed to exhibit decreased immunoregulatory factors like interleukin, HLA among others.

PS 4

Cellular Markers and Inflammatory Mediators in IDDM

321

PROLIFERATIVE T CELL RESPONSES TO PEPTIDES OF IA-2 BY IDENTICAL TWIN PAIRS DISCORDANT FOR IDDM

M.Hawa[2], R.M.Schulz[1], R.D.G.Leslie[2], F.Sinigaglia[3], N.Passini[3], L.Rogge[3] and M.Londei[1]. [1] Kennedy Institute for Rheumatology, Sunley Division, London, U.K. [2]St. Bartholomew's Hospital, London, U.K., [3] Roche Milano, Milan, Italy.

To define T lymphocyte reactivity to an islet antigen IA-2 associated with IDDM we tested identical twins discordant for IDDM. Ten peptides were selected from the IA-2 molecule due to their predicted ability to bind HLA-DR4. We demonstrate that 18 IDDM twins, their non-diabetic twins and 15 control subjects can respond to IA-2 peptides. Two peptides were of interest: peptide 11 and peptide 16. The majority (72%) of 51 subjects (both with and without IDDM) responded to peptide 11, unrelated to disease duration in IDDM twins. Responses to peptide 16 were detected in 81% of twins, both diabetic and non-diabetic, within 6 years of the onset in the index twin but after 12 or more years in only 15% of twins, both diabetic and non-diabetic ($p<0.001$). Magnitude of T cell responses correlated with disease duration in the index twin in both IDDM twins ($r^2= 0.34$; $p < 0.01$) and their non-diabetic twins ($r^2= 0.35$; $p< 0.05$) but not with age, HLA status or IA-2 antibodies. T cell reactivity to peptides 11 or 16 did not correlate between identical twins consistent with the changes being non-genetically determined. Thus, we demonstrate in IDDM patients an epitope-specific down-regulation of T cell responses to an autoantigen that is disease-related but not disease-dependent and associated in non-diabetic twins with low-disease risk. Identification for the first time that an altered T cell response to an epitope of a disease-related antigen, peptide 16 of IA-2, is associated with protection from developing IDDM raises the possibility of designing therapeutic agents to prevent IDDM.

322

BETA-CELL DIFFERENTIATION IS ASSOCIATED WITH AN INCREASED SENSITIVITY TO STREPTOZOTOCIN AND INTERLEUKIN 1-BETA

K.Nielsen, P.Serup, O.D.Madsen, T.M. Poulsen, J.Nerup & A.E. Karlsen. Steno Diabetes Center and Hagedorn Research Institute, Niels Steensensvej, 2820 Gentofte, Denmark.

Interleukin 1-beta (IL-1β) and streptozotocin (STZ) are toxic to the beta- cells, partly through the induction of the inducible nitric oxide synthase (iNOS). Increased sensitivity to STZ is caused by release of NO after uptake by GLUT-2. **AIM:** To determine the effect of STZ and IL-1β on the cytotoxicity and NO production in a pluripotent MSL-tumour cell-line, which express the GLUT-2, and a low GLUT-2 expressing MSL-AN cell-line transfected with Insulin Promotor Factor 1 (IPF-1). **METHODS:** Specific cytotoxicity was measured by the release of LDH (% of controls) and NO as accumulated nitrite (μM). The MSL-cell line obtain a pre-beta and a beta-cell phenotype dependent upon culture conditions. The glucagon producing MSL-AN cell-line was transfected with IPF-1, inducing insulin-secretion. **RESULTS:** Table 1: Dose dependent cytotoxicity to STZ in the beta-cells, and no effect on the pre-beta cells, despite PCR analysis shows GLUT-2 expression in both phenotypes. (N=3, in triplicates).

Table 1	1,0 mM STZ	2,5 mM STZ	5,0 mM STZ	7,5 mM STZ
MSL beta	16,98+/-6,03	20,56+/-8,74	35,86+/-4,63	57,14+/-11,73
MSL pre-beta	0,44+/-0,76	0,00+/-0,00	1,00+/-1,74	1,83+/-1,72
	p<0,02	p<0,03	p<0,01	p<0,01

In contrast after exposure of MSL-AN cells +/- IPF-1 expression to STZ, no significant differences were found. Table 2 shows increased cytotoxicity in the IPF-1+ cells, despite equal amounts of induced NO. (N=6, in triplicates).

Table 2	150 pg/ml IL-1	1500 pg/ml IL-1	3000 pg/ml IL-1
MSL-AN + IPF-1	5,06+/-1,23	37,38+/-1,19	39,24+/-5,04
MSL-AN - IPF-1	0,71+/-0,00	12,43+/-9,83	15,90+/-9,03
	p<0,02	p<0,02	p<0,01

CONCLUSION: Maturation from a pre-beta to a beta-cell phenotype is associated with acquired sensitivity to STZ, dependent upon the number of GLUT-2 receptors. The IPF-1 induced change from an alpha- to a beta-cell-like phenotype results in increased sensitivity to the toxic effect of IL-1.

323

RELATIONSHIP BETWEEN HUMORAL AND CELLULAR IMMUNITY TO IA-2 IN INSULIN DEPENDENT DIABETES

T.M. Ellis, D. Schatz, M.S. Lan, E. Ottendorfer, C. Wasserfall, A.L. Notkins, N.K. Maclaren and M.A. Atkinson. University of Florida, Gainesville, Florida, U.S.A.; The National Institutes of Health, Bethesda, Maryland, U.S.A.

Autoantibodies to the neuroendocrine molecule IA-2, a 105kD transmembrane protein of the tyrosine phosphatase family, have been observed in individuals with IDD. We determined the levels of humoral and cellular immune reactivity to this autoantigen in order to further define its role in the pathogenesis of IDD. Peripheral blood mononuclear cells (PBMC) from individuals with newly-diagnosed IDD and healthy controls were stimulated in vitro with recombinant IA-2, a series of control antigens (glutathionine-S-transferase, tetanus toxoid, *Candida albicans*, mumps, bovine serum albumin) and a mitogen (phytohemagglutinin). Whereas proliferation of PBMC to IA-2 was significantly higher (mean stimulation index; frequency of response) in newly-diagnosed IDD subjects (3.5 + 3.3 @ 10μg/ml ; 11 of 26 (42%)) compared to controls (1.5 + 1.1, $P = 0.02$; 1 of 12 (8%), $P = 0.03$), reactivities to all other antigens were remarkably similar (all P= not significant). Autoantibody frequencies in newly-diagnosed subjects (when sera were available) were 11 of 19 (58%) for IA-2, ICA 65% (13/20), IAA 20% (3/15), and GADA 50% (10/20); frequencies similar to the reported literature: Despite anecdotal cases suggesting an inverse association between humoral and cellular immune reactivities against IA-2, no such overall relationship was observed (r_s = 0.18, P = 0.39). These studies support the autoantigenic nature of IA-2 in IDD and suggest the inclusion of cellular immune responses as a marker for IDD.

324

More pronounced activation of mitogen activated protein kinases (MAPK) by IL-1 in β- than in pre-β-cell lines.

A. Jonsson*, C. M Larsen*, A. E. Karlsen*, K. Nielsen*, O. D. Madsen¤ and T. Mandrup-Poulsen*. *Steno Diabetes Center and ¤Hagedorn Research Institute, Gentofte, Denmark.

IL-1 causes destruction of rat β-cells partly by inducing expression of inducible nitric oxide (NO) synthase and NO synthesis in β-cells. Continous cytokine mediated activation of the JNK and p38 subgroups of MAPKs signals programmed cell-death in other cells. In rat β-cells IL-1 induces activation of the MAPKs. A subclone of the MSL islet stem-cell clone, AN #697C1, has two derived cell lines #2.9-AN (pre-β-cell phenotype) and after transfection with the transcription factor (TF) STF-1, #1.10AN/IN (β-cell phenotype). These cell lines produce similar amounts of NO in response to IL-1, but only 1.10 is susceptible to IL-1 toxicity. The aim of this study was to investigate if the two cell lines exhibited differential IL-1 induced MAPK activation with the hypothesis that MAPK activation is a necessary second signal for IL-1 induced cell-death in the β-cell phenotype. 150.000 cells of either cell line were incubated with 0-3500 pg/ml of recombinant human IL-1 for 20 minutes after which the cells were lysed. The lysates were investigated for the phosphorylation of the substrates Elk-1, ATF-2 and the heat shock protein HSP-25 by [^{32}P] incorporation in the substrate proteins. The TF Elk-1 is phosphorylated by the MAP Kinases ERK 1/2 and JNK, the TF ATF-2 by ERK 1/2, JNK 1 and p38 whereas HSP-25 is phosphorylated only by p38 via a down-stream kinase MAPKAP-2 The proteins were separated by SDS-PAGE and visualized by autoradiography. IL-1 caused a marked dose dependent biphasic phosphorylation of ATF-2 and HSP-25 in 1.10 cells starting at 50-150 pg/ml and peaking at 2500-3000pg/ml of IL-1 with a 12-14 fold increase. In contrast, IL-1 (150-3000pg/ml) only caused a 2-3 fold increase in ATF-2 and HSP-25 phosphorylation in 2.9 cells. These data suggest that IL-1 signalling in islet cells depends upon the differentiation stage and that JNK/p38 activation may provide a necessary second signal which together with NO causes IL-1 mediated β-cell apoptosis.

325

TYROSINE PHOSPHATASE IA-2 SPECIFIC CYTOTOXIC T CELLS FROM HIGH RISK IDDM RELATIVES

K. Takahashi, M. C. Honeyman and L. C. Harrison, The Walter and Eliza Hall Institute, Melbourne, Australia

Cytotoxic T lymphocytes (CTL) are proposed to play a key role in beta-cell destruction in insulin-dependent diabetes mellitus (IDDM). Beta-cell antigen-specific CTL activity could therefore reflect destructive islet autoimmunity and predict the development of IDDM. To facilitate the generation of human antigen-specific CTL, we derived dendritic cells (DC) from peripheral blood adherent cells from HLA-A2 positive high-risk IDDM relatives, in the presense of 600 U/ml GM-CSF and 400 U/ml IL-4. The DC were pulsed with a HLA-A2-restricted tyrosine phosphatase IA-2-peptide (MVWESGCTV) and cultured with autologous CD8 cells for 14 days. CTL specific for this peptide were generated in two out of six HLA-A2 positive at-risk IDDM first-degree relatives (Table, Subject 1: female, 11 y.o., HLA A2,2; DR4,4; DQ8,8. Subject2: female, 16 y.o., HLA A1,2; DR3,4; DQ2,8). In conclusion, this strategy may be a useful tool for investigating the diagnostic and predictive value of CTL in IDDM.

Table. Cytotoxic T lymphocyte activity against IA-2 peptide

INHIBITION OF NITRIC OXIDE PRODUCTION AFTER INDUCTION OF HEAT SHOCK PROTEINS PREVENTS DNA STRAND BREAKS

A. Dunger, S. Berg, B. Ziegler and U. Fischer*. Gerhardt Katsch Institute of Diabetes Karlsburg and * Inselklinik Heringsdorf, Germany

Nitric oxide (NO) is suggested to be a presumed mediator of interleukin 1ß (IL1)-induced ß-cell damage. Therefore it was the aim of this study (1) to prove whether the interruption of intracellular NO generation may prevent IL1-induced DNA damage, and (2) to elucidate the potential role of heat shock proteins (HSP) in protecting ß-cells from IL1-related injury. Study (1): RINm5F cells were treated for 18h either with human IL1 (25 U/ml) or N-nitro-L-arginine methylester (NAME, 1 mmol/l), a competitive inhibitor of NO synthase, alone or with a combination of both. Control cells remained untreated for the same period of time. Study (2): to attain maximal induction of HSP, RINm5F cells were maintained at 44°C for 30 min and transferred to 37°C for the following 5h. HSP expression was confirmed by means of autoradiography of SDS-PAGE separated [^{35}S]-labelled RINm5F proteins and Western blotting. After HSP induction, the cells were either incubated for 18h with IL1 (HS-IL1), or they were cultured without any treatment (HS-Controls). Results: IL1 exposure of RINm5F cells resulted in a more than 20-fold stimulation of NO generation measured by nitrite release into the culture medium (0.263±SEM0.016 vs. 0.012±0.002 μmol/10^5 cells in the controls, p<0.001). NO production was not altered by the addition of NAME or by the heat shock (HS) procedure alone. Both measures, however, totally prevented the IL1-stimulated NO generation. The abundance of cytoplasmic histone-associated DNA fragments (HADF) which were assessed by means of a sandwich ELISA was 2.5-fold increased in IL1-exposed cells as compared to controls (p<0.01). HADF were not influenced, neither by NAME alone nor by the HS procedure as such. Also, after these two treatments, no alteration of HADF was elicited by IL1. In conclusion, both the inhibition of IL1-stimulated NO production and the induction of HSP are effective in preventing IL1-induced DNA strand breaks. The mechanism underlying the protective effect of HSP seems to involve inhibition of intracellular NO generation.

T CELL RESPONSES TO THE NOVEL AUTOANTIGEN IA2 IN IDDM PATIENTS AND HEALTHY CONTROLS.

T. Lohmann, T. Halder[1], N.G. Morgenthaler, U.Y. Khoo-Morgenthaler, J. Seissler, J. Engler, K. Dähn, W.A. Scherbaum, and H. Kalbacher[1]. Dept. of Medicine III, University of Leipzig, Germany;[1]Medical Research Center, University of Tuebingen, Germany.

Insulin-dependent diabetes mellitus (IDDM) is probably mediated by T-lymphocytes recognizing critical β-cell autoantigens. Recently, a novel autoantigen in IDDM was described as the tyrosine phosphatase IA2. Antibodies to IA2 are detected at the peripheral blood of IDDM patients and prediabetic subjects. Nothing is known so far about epitope specific T cell reactivity to IA2. We studied T cell responses to the intracytoplasmatic domain of IA2 protein ($IA2_{ic}$) and predicted DR4- and DQ8-binding motifs (13mers) of the whole IA2-molecule in 12 IDDM patients less than 4 years from diagnosis and 5 HLA matched (DR4/ DQ8) healthy controls. Peripheral blood mononuclear cells of the probands were stimulated for 4 days by peptides and for 7 days by protein before measuring ^{3}H-Thymidine incorporation. Antibodies to $IA2_{ic}$ were measured by an immunoprecitation assay (sensitivity 72%). 10 out of 12 IDDM patients and 2/5 controls responded to $IA2_{ic}$ protein with stimulation indices (SI) >3. No correlation of T cell and antibody responses to $IA2_{ic}$ was seen. The HLA restriction (DR or DQ) of the T cell responses to $IA2_{ic}$ was investigated by antibody blocking experiments. 11 out of 12 IDDM patients and 3/5 controls responded to the selected IA2 peptides with SI>2. There were dominant responses to 2 DR4-motif and 1 DQ8-motif IA2 peptides. The DQ8-motiv peptide was recognised by 9/12 IDDM patients and 2/5 controls, one DR4-motiv peptide by 5/12 patients and 1/5 controls and the other DR4-motiv peptide by 2/12 patients and 0/5 controls. The binding of the peptides to either DR4 or DQ8 was confirmed by binding competition assays. Remarkable sequence homologies of all three IA2 peptides to a number of virus protein sequences were observed. The latter demonstration may be important for a molecular mimicry priming the immune response to IA2 following certain virus infections.

328

INHIBITION OF NITRIC OXIDE SYNTHASE, GUANYLYL CYCLASE OR PROTEIN KINASE G ATTENUATES INTERLEUKIN-1β-INDUCED APOPTOSIS IN HIT-T15 CELLS.

A. Loweth, G. Williams, J. Scarpello and N. Morgan. Keele University, Staffs., UK.

We have previously shown that the nitric oxide donor, GSNO, induces apoptosis in clonal pancreatic B-cells in a cGMP- and protein kinase G (PKG)-dependent manner. Since interleukin 1-β (IL-1β) is known to induce nitric oxide synthase in pancreatic B-cells we have now examined the possible dependence of interleukin-induced cytotoxicity on cGMP-signalling mechanisms. HIT-T15 cells were incubated for 24 hours in the absence or presence of 2pg/μl of human recombinant IL-1β. Attached cells were harvested, stained with acridine orange and scored as apoptotic or non-apoptotic, as judged by nuclear morphology, using fluorescence microscopy. IL-1β treatment resulted in a consistent increase in apoptosis in HIT-T15 cells and this effect was reversed by pre-incubation with the nitric oxide synthase inhibitor, L-NMMA (Number of apoptotic cells/ml: Control: 3032 ± 427; + 100μM L-NMMA: 1702 ± 146; + 2pg/μl IL-1β: 14245 ± 1661*; + IL-1β + L-NMMA: 4329 ± 780** (n=6).*=p<0.001, compared to controls,**=p<0.001, compared to IL-1β alone). Pre-treatment of HIT-T15 cells with the guanylyl cyclase inhibitor, ODQ, was also able to reverse IL-1β-induced apoptosis (Control: 2552 ± 245; + 10μM ODQ: 1237 ± 165; + 2pg/μl IL-1β: 10662 ± 1250*; + IL-1β + ODQ: 2046 ± 206** (n=6).*= p<0.001, compared to controls,**=p<0.001, compared to IL-1β alone). Furthermore, the specific PKG inhibitor, KT5823, significantly inhibited IL-1β-induced apoptosis (Control: 891 ± 116; + 0.5μM KT5823: 506 ± 64; + 2pg/μl IL-1β: 4949 ± 231*; + IL-1β + KT5823: 2225 ± 335** (n=6).*=p<0.001, compared to controls, **=p<0.001, compared to IL-1β alone). By contrast, the use of a protein kinase A-specific inhibitor, KT5720, had no effect on apoptosis (Control: 2593 ± 176; + 2μM KT5720: 2669 ± 218; + 2pg/μl IL-1β: 9696 ± 519*; + IL-1β + KT5720: 8295 ± 564** (n=6). *= p<0.001, compared to controls, **=p<0.001, compared to IL-1β alone). We conclude that interleukin-1β is able to induce apoptosis in HIT-T15 cells and that activation of the apoptotic mechanism is dependent on signalling pathways involving nitric oxide and cGMP generation and protein kinase G activation.

T-CELL REACTIVITY AGAINST IA-2 PROTEIN AT DIAGNOSIS OF TYPE 1 DIABETES

F. Dotta, V. Viglietta, S. Dionisi, B. Carabba, P. Cerrone, O. Diaz-Horta, MC. Matteoli, L. Lucentini and U. Di Mario. *University of Rome "La Sapienza", Rome; Ospedale Bambino Gesù, Palidoro; University of RC, Catanzaro, Italy.*

Several studies performed in animal models of autoimmune diabetes have indicated that the setective islet ß cell destruction is a T-lymphocyte mediated event. However, despite the importance of the T-cell response in the pathogenesis of type I diabetes, the target antigens of such a response remain largely uncharacterized. Among the diabetes-associated autoantigens identified so far starting from circulating autoantibodies, a specific T-cell reactivity has been reported against GAD65 and insulin, both in man and in the NOD mouse. In the present study we aimed to study the T cell response to the IA-2 islet tyrosine phosphatase autoantigen at the onset of type I diabetes. To this end, by participating to a T-cell workshop, we tested in blind a series of antigens (insulin, GAD65 and IA-2) for their reactivity with peripheral blood lymphocytes obtained from 8 newly diagnosed type I diabetic patients and from 9 age and sex-matched normal control individuals. A T-cell proliferation assay was performed in triplicate employing freshly isolated cells at a concentration of 150,000 cells/well, using RPMI containing 10% human autologous serum; after incubation for 72 h in presence or absence of the antigen to be tested, 3H-thymidine was added, left for 16h and plates were counted in a ß-counter. Among the antigens tested, a specific T-cell proliferation (defined as a Stimulation Index >3) was observed against IA-2 in 4/8 type I diabetic patients and in 0/9 control subjects ($p<0.01$ by Fisher extact test). A statistically significant difference ($p<0.01$ by Wileoxon test) was also found between the mean S.I. with IA-2 in patients (3.0±1.5) and that in controls (1.1±0.3). No difference was found between patients and controls in the T-cell proliferative response against insulin or GAD65. In conclusion these data show that a T-cell response against the IA-2 protein can be observed at type I diabetes diagnosis, suggesting that this islet molecule represents a target antigen not only at B-lymphocyte but also at T lymphocyte level.

330

IS PGE2 RELATED TO THE PANCREATIC β CELL DAMAGE?: THE POSSIBLE INTERRELATIONSHIP BETWEEN IL-1-β, PGE2 AND NO.

Mª A. Ortiz, J. Roselló*, C. Xaus*, E. Mato and J.Mª Pou. Institut de Recerca of HSCSP (UAB) and * CSIC, Barcelona, Spain.

The aim of this study was to evaluate the possible interrelationship of PGE2 (prostaglandin E2) and NO (nitric oxide) on the isolated neonatal rat islets incubated with IL-1-β (Interleukin-1-β). Neonatal rat islets were isolated by collagenase digestion and cultured for six days in RPMI 1640 with 10 % of FCS. Islets were incubated with IL-1-β at 20, 60 and 200 U/mL concentration for 24 h and the isletys incubated with 60 U/mL were also incubated with NAME 100 μM for 18 h.. β-cell damage was evaluated by measuring insulin secretion rate after incubation in KRB with 16,7 mM glucose. Insulin (pmol/mL), NO (pmol/islet) and PGE2 ($pg/mL(isletxh)^{-1}$) were determined by RIA, Greiss reaction and ELISA respectively. Insulin secretion rate (S.R.) was calculated as the percentage of secreted insulin versus total insulin .IL-1-β promoted a significant and dose dependent decrease in the insulin S.R. (C: 4.84 ± 0.31, 20 U/mL: 1.51 ± 0.15*, 60 U/mL: 1.17 ± 0.11* and 200 U/mL: 0.98 ± 0.07* * = p< 0.001). NO levels rose in incubated islets at 60 and 200 U/mL of IL-1-β (C: 4.51 ± 1.21, 60 U/mL: 9.13 ± 2.73* and 200 U/mL: 11.23 ± 2.23* * = p<0.01). The PGE2 production was also increased after IL-1-β incubation at 60 U/mL (c: 10.62 ± 0.83 and 60 U/mL: 44.40 ± 4.61. NAME partially normalized insulin S.R., PGE2 (12.93 ± 1.39) and NO. PGE2 and NO presented a good correlation with insulin S.R. (PGE2: r = -0.654, p < 0.001 and NO: r = -0.478 ± 0.01. In conclusion , the IL-1-β induced inhibition of the insulin secretion rate could be related not only to the increase of NO but also to the PGE2 increase.

331

ANALYSIS OF PEPTIDES ELUTED FROM IDDM-SUSCEPTIBILITY CLASS II MHC MOLECULES OF ANTIGEN PRESENTING CELLS PULSED WITH IA-2

M Peakman, EJ Stevens, M Trucco and JC Gorga. Children's Hospital of Pittsburgh, USA and King's College School of Medicine & Dentistry, London, UK

The nature of the mechanism by which class II MHC molecules such as DR4 and DQ8 confer susceptibility to IDDM is not known, but probably relates to presentation of key epitopes of autoantigens and/or microbes to T cells. In order to examine these events in detail, we have developed a system for the analysis of peptides eluted from antigen presenting cells (EBV-transformed B cells) pulsed with native autoantigen. EBV cells homozygous for DR4 and DQ8 grown *in vitro* were washed, resuspended in balanced salts and pulsed at 4^0C sequentially with lectin/avidin followed by recombinant biotinylated IA-2ic (intracellular domain). The lectin binds preferentially to disulphide-linked surface proteins with immunoglobulin-like domains (eg sIg, CR2). Cells were then incubated for 6 hours at 37^0C, by which time the complex was almost completely internalised, and harvested. HLA-DR4 was affinity purified from detergent extracts from approximately $2x10^{10}$ cells and α and β chains acid-dissociated. Peptides occupying the binding groove were separated from intact DR4 α and β chains by selective ultrafiltration and analysed by reverse-phase HPLC. IA-2 derived peptides were identified by comparing HPLC profiles of cells pulsed with lectin/avidin/IA-2 and lectin/avidin alone (control elution). In the control elution, six major discrete peptide peaks and numerous minor peaks were identified, spanning different degrees of peptide hydrophilicity and hydrophobicity. HPLC fractions were analysed by mass spectroscopy, and 85 novel peptide masses identified to high mass accuracy (0.01%) in the pulsed but not the control fractions. The 85 masses matched sequences in IA-2, often as "nested sets" of peptides around a core motif which was DR4 compatible. Our results suggest that it is possible to purify peptides naturally processed from IDDM-related autoantigens. The sequence analysis of these presented peptides will provide an insight into the role of HLA-DR and -DQ molecules in determining diabetes susceptibility and protection.

332

The effects of TNFα and IFNγ on activation of the mitogen activated protein kinases (MAPK) in rat islets of Langerhans.

N. Aa. Andersen*, C. M. Larsen*, T. Mandrup-Poulsen*. *Steno Diabetes Center, Gentofte, Denmark.

IL-1 causes destruction of rat ß-cells partly by inducing expression of inducible nitric oxide (NO) synthase (iNOS) and thereby production of toxic NO radicals in the ß-cells. IL-1 activates the MAPKs JNK 1 and p38 through generation of ceramide. As for IL-1 TNF signalling leads to generation of ceramide, activation of $NF_{\kappa}B$ and MAPKs. IFN signalling is dependent upon activation of the JAKs and a downstream phosphorylation of the STAT proteins. The aim of this study was to investigate if TNFα and IFNγ activates MAPKs in rat islets of Langerhans with the hypothesis that stimulation with TNFα but not with IFNγ would lead to an activation of the MAPKs. Rat islets of Langerhans from 4-8 days old Wistar rats isolated by collagenase digestion and handpicking were precultured in RPMI 1640 with 10 % fetal calf serum for 4-7 days. 150 islets were wasched in RPMI 1640 with 0.5 % human serum and incubated with 0.5-1000 U/ml of human recombinant TNFα or rat recombinant IFNγ for 20 minutes after which the cells were lysed. The lysates were investigated for the phosphorylation of the substrates Elk-1, ATF-2 and HSP-25 by ^{32}P incorporation in the substrate proteins. The transcription factors Elk-1 and ATF-2 are phosphorylated respectively by the MAP kinases ERK and JNK 1, and by ERK, JNK 1 and p38 wheras HSP-25 is phosphorylated by p38 via a downstream kinase MAPKAP-2. The phosphorylated proteins were separated by SDS-PAGE and visualized by autoradiography. TNFα caused a marked dose dependent increase in the phosphorylation of both ATF-2 and HSP-25. IFN caused a significant dose dependent decrease in the phosphorylation of Elk-1 and ATF-2, but did not have any significant effect on the phosphorylation of HSP-25. These data suggest that TNFα signalling in islets of Langerhans is dependent on activation of JNK/p38 MAPKs but not on activation of ERK and that IFNγ inhibits JNK and ERK but not p38 MAPKs via unknown mechanisms.

333

ENHANCED DETECTION OF T CELL PROLIFERATION TO IA-2 BY TARGETING ANTIGEN PRESENTING CELLS

E.J.Stevens[1], C.J.Hawkes[2], M.Christie[2] and M.Peakman[1]. Depts. of Immunology[1] and Medicine[2], King's College School of Medicine and Dentistry, London, UK.

The pivotal role of the T cell in the pathogenesis of IDDM has led to an increased interest in the detection of autoantigen-specific T cells. The First International Workshop on Autoreactive T Cells (Canberra, 1996) indicates that conventional proliferation assays remain hampered by poor sensitivity and specificity. Our aim was to examine whether targeting of test antigens directly onto the antigen presenting cell surface enhances the detection of T cell proliferation. We developed an antigen delivery system (ADS) comprised of biotinylated polyclonal goat anti-human IgG, streptavidin and biotinylated test antigen at a range of concentrations (recombinant human biotinylated IA-2ic at 0.4-200 µg/ml or biotinylated tetanus toxoid at 0.05-10 µg/ml). By FACS analysis, anti-IgG binds almost 100% of monocytes, presumably through occupied FcgammaR, and B cells via surface immunoglobulin. Freshly isolated PBMC were obtained from newly diagnosed IDDM patients and age- and sex-matched controls. Cells were pulsed on ice for 30 minutes sequentially with each ADS component prior to incubation at 37^0C, 5% CO_2 for 5 days. Assays with the ADS were performed in parallel with conventional T cell assays using antigen added directly to PBMC in culture medium. Peak proliferation to tetanus toxoid was at least doubled using the ADS (range of stimulation indices 5-56) compared with the conventional assay (15-235). In patients with IDDM (n=3 to date) peak proliferation responses to IA-2ic were increased 2.4 to 7 fold in the assays using the ADS (range of SIs 4-29) compared to conventional assays (1-10). In all subjects use of the ADS gave enhanced proliferation compared to the conventional assay. The increased responses via this system were specific as only minimal proliferation was detected with either the ADS alone or an irrelevant biotinylated antibody. These results suggest this novel ADS method offers a greatly enhanced sensitivity of detection of autoreactive T cell proliferation, which may be of value in the diagnostic use of these assays.

ISLET CELL CYTOTOXICITY AND DISEASE PROGRESSION IN THE BB RAT

A.J. Bone, P.R. Hitchcock and A. Dunger*. University of Brighton, Brighton, UK and * University of Greifswald, Karlsburg, Germany

β-cell response to autoimmune attack determines subsequent progression to diabetes in genetically susceptible individuals. The extent to which this response is genetically predetermined or directly modified by the disease process is not known. We have isolated neonatal islets from diabetes prone (DP- BB/OK/RT1u) and diabetes resistant (DR - Lewis/RT1a) rat strains and monitored islet function (nitrite production, insulin release, DNA synthesis) after 20 hr treatment with a combination of cytokines (IL-1β, TNF-α, IFN-γ). Control islets were cultured (20 hr) in the absence of cytokines. Media accumulation of nitrite, in the absence and presence of cytokines, was lower in DP vs DR islets (control, 2.5±0.61 vs. 3.9±0.09pmol/islet; treated, 7.5±0.9vs. 13.7±0.8pmol/islet: mean±SE) and islet DNA synthesis was similarly reduced in DP compared to DR rats (control 470.1±43.2 vs. 1460.3±194.9 DPM/µg DNA; treated, 374.2±50.0 vs. 997.5±157.4 DPM/µg DNA: mean±SE). Cytokine treatment stimulated nitrite production and inhibited insulin release and DNA synthesis to the same degree, relative to control values, in both DP and DR islets. Reg gene expression is upregulated during diabetogenesis in BB rats and NOD mice. We have determined Reg mRNA levels (RT-PCR) in untreated and cytokine-exposed neonatal DP and DR rat islets. No significant differences in Reg gene expression were observed between any of the DP or DR islet groups studied. Results suggest that islet functional state, response to cytotoxic attack and disease progression may depend both on genetic predisposition to IDDM and modification by an active insulitis process.

335

T CELL RESPONSES TO IDDM AUTOANTIGEN PEPTIDES SHARING HOMOLOGOUS REGIONS.

E. Sarugeri, N. Dozio, F. Meschi, M.R. Pastore, E. Bosi and E. Bonifacio. Scientific Institute H. San Raffaele, Milan, Italy.

Glutamic acid decarboxylase (GAD) is a major autoantigen in IDDM. Regions of homology exist between GAD (residues 250-273) and the Coxackie P2-C protein (residues 28-50) and between GAD (residues 506-518) and proinsulin (residues 24-36). The demonstration of T cell responses against these regions have substantiated postulates of molecular mimicry acting in the autoimmunity associated with IDDM. The aim of this study was to determine whether these homologous regions are shared targets of T lymphocyte reactivity in individual IDDM patients. Proliferative responses against two sets of peptides (50 μg/ml): $GAD_{254-276}$ and Coxackie P2-C_{32-54}, and $GAD_{506-518}$ and $proinsulin_{24-36}$ were measured in peripheral blood mononuclear cells from 17 newly diagnosed IDDM patients and 11 control subjects. Responses (SI>3) were found against each of the peptides in both patients and control subjects, and no differences were observed between groups. A strong positive correlation was found between responses to $GAD_{254-276}$ and Coxackie P2-C_{32-54} ($r^2 = 0.85$, $p<0.0001$), and between responses to $GAD_{506-518}$ and $proinsulin_{24-36}$ ($r^2 = 0.87$, $p<0.0001$), suggesting shared reactivity to the homologous regions in individual subjects. However, a similar correlation was also observed between responses to Coxackie P2-C_{32-54} and $proinsulin_{24-36}$, ($r^2 = 0.97$, $p<0.0001$) which do not share homology, suggesting that reactivity may not be due to mimicry. Examination of HLA DR and GAD antibody status in subjects showed responses in those with either DR3 or DR4, and in patients with and without GAD antibodies. These data suggest that 1. T cell responses to peptides containing putative autoreactive epitopes of GAD and proinsulin are not specific for IDDM, 2. correlation between T cell reactivity to peptides is not restricted to those containing homologous regions, and 3. non-antigen specific factors are important determinants of in vitro measurements of T cell reactivity.

336

DIFFERENTIAL CYTOKINE EFFECTS IN INS-1 AND RIN1046-38 INSULINOMA CELLS:

H.E.Hohmeier[1], A. Thigpen[2] and C.B.Newgard[1]. University of Texas Southwestern Medical Center[1] & BetaGene Inc. Dallas, Texas[2].

We are interested in engineering of cell lines that might serve as surrogates for islets in IDDM therapy. A possible problem for *in vivo* use is the well documented cytotoxic effect of cytokines such as IL-1b and γ-IFN on islet β-cells. We have therefore investigated the cytotoxic effects of these cytokines on two insulinoma cell lines, RIN1046-38 and INS-1. Whereas exposure of INS-1 cells to IL-1b for 48 h killed 50% of cells, no cytotoxic effect of this cytokine was observed on RIN1046-38 cells, even though both cell lines produced large quantities of nitrite (10 and 30 μM/mg protein/24 h, respectively). Northern blot analysis revealed that mRNA for inducible nitric oxide synthase (iNOS) was induced by IL-1b treatment in both lines within 4 h, but while expression faded quickly in RIN 1046-38 cells, it was sustained in INS-1 cells out to 18 h. Inhibition of iNOS by N-monomethyl-arginine (NMMA) blocked the cytotoxic effect of IL-1b on INS-1 cells. Opposite to its effects on iNOS expression, IL-1b treatment caused an induction of Mn superoxide dismutase (MnSOD) mRNA in RIN1046-38 cells that persisted for 18 h whereas in INS-1 cells MnSOD mRNA waned by 12 h. Rat γ-IFN had a cytotoxic effect on both insulinoma lines, but nitrite and iNOS mRNA could only be detected in the RIN1046-38 cells. NMMA did not block the cytotoxic effect of γ-IFN on the latter cell line. These data suggest that: 1) The higher MnSOD:iNOS ratio in RIN 1046-38 cells may explain their resistance to the cytotoxic effects of IL-1b; 2. The cytotoxic effect of γ-IFN is independent of iNOS induction and NO production in both cell lines.

337

HIGH T-CELL RESPONSES TO THE GLUTAMIC ACID DECARBOXYLASE (GAD) ISOFORM 67 REFLECT A HYPER-IMMUNE STATE THAT PRECEDES THE ONSET OF IDDM

M.C. Honeyman, N. Stone, H. DeAizpurua, P.G. Colman, M.J. Rowley*, L.C. Harrison, Walter and Eliza Hall Institute, Parkville; *Centre for Molecular Biology and Medicine, Monash University, Clayton, Australia

Pancreatic β-cell destruction leading to insulin-dependent diabetes mellitus (IDDM) is an autoimmune T cell-mediated process. Peripheral blood T cells which proliferate to islet antigens such as glutamic acid decarboxylase (GAD), (pro)insulin or tyrosine phosphatase IA-2, can be detected in at-risk, first-degree relatives of people with IDDM. However, cross-sectional studies cannot define the relationship between T-cell responses and progression to IDDM. Longitudinal studies were therefore undertaken on 50 at-risk, first-degree relatives tested at least yearly for up to four years, during which time five developed IDDM. Peripheral blood T-cell responses to GAD67(aa 208-404)-glutathione-S-transferase (GST) fusion protein, GST, insulin and tetanus toxoid were measured, together with antibodies to islet cells, GAD, insulin and IA-2. High levels of antibodies to GAD or insulin were generally associated with low T-cell responses to these antigens. Relatives who developed IDDM were characterised by high levels of antibodies to insulin and/or islet cells, and high T-cell responses to GAD67-GST and tetanus, but not insulin, in the 24 months before clinical diagnosis. Cross-sectionally, T-cell responses to GAD67(aa208-404)-GST and to full-length GAD65-GST were highly correlated ($R=0.75$, $p<0.002$). In conclusion, increased cellular immunity to the mid-region of GAD67 was a marker of late pre-clinical IDDM but appears to reflect a more general, transient state of cellular immune hyper-responsiveness.

338

INTERFERON-γ SIGNAL-TRANSDUCTION IN RINm5F CELLS AND HUMAN PANCREATIC ISLETS

M. Flodström[1] and Décio L. Eizirik[1,2]. [1]Department of Medical Cell Biology, Uppsala University, Uppsala, Sweden; [2]Department of Metabolism and Endocrinology, Vrije Universiteit Brussel, Brussels, Belgium.

The radical nitric oxide (NO) may be a mediator of β-cell damage in IDDM. The cytokines IFN-γ and IL-1β are required for expression of the enzyme nitric oxide synthase (iNOS) and NO production by human pancreatic islets. Possible mechanisms by which IFN-γ potentiates IL-1β-induced iNOS mRNA expression are: a. stabilization of iNOS mRNA; b. activation of the nuclear factor-κB (NF-κB); c. increased expression of interferon regulatory factor-1 (IRF-1). Addition of IFN-g (1000 U/ml), before or after arrest of IL-1β-induced iNOS gene transcription, did not prolong iNOS mRNA half life in the rat insulin-producing cell line RINm5F (50-60% decline in iNOS mRNA after 2-4 h, with or without the presence of IFN-g). IFN-g also failed to modify IL-1(25 U/ml)-induced NF-kB activation in RINm5F cells, as determined by electrophoretic mobility shift assay (optical density; n = 2-3): control, 82 ± 33; IFN-γ, 101 ± 50; IL-1β, 4531 489; IL-1β + IFN-γ, 4844 ± 633. However, IFN-γ induced a 19-fold ($P<0.01$ vs control) increase in nuclear IRF-1 protein content in RIN cells, an effect further potentiated by IL-1β (37-fold increase; $P<0.01$ vs control). The total cellular content of IRF-1 protein increased by 30-50-fold ($P<0.05$ vs control at 2h) in human islets exposed for 2, 4 or 8h to IFN-γ or IFN-γ + IL-1β. IL-1β alone induced a marginal and transient increase in IRF-1. It has been previously described that nicotinamide prevents IL-1β-induced IRF-1 expression in rat pancreatic islets. However, nicotinamide (20 mM) presently failed to prevent IL-1β + IFN-γ-induced IRF-1 protein expression in human pancreatic islets. In conclusion, the effects of IFN-γ on iNOS expression can neither be explained by iNOS mRNA stabilization nor increased NF-kB activation. However, IFN-γ induces an early increase in cellular IRF-1 content, and this may contribute to increased iNOS mRNA expression.

339

PROBABLE RECOGNITION OF HUMAN INSULIN IN THE CONTEXT OF HLA-DRB1*0406 MOLECULE BY Vβ8 T-CELLS

Y Uchigata, J Chino, H Katoh*, T Uchiyama*, K Tokunaga** and Y Omori. Diabetes Center, *Dept. of Microbiology and Immunology, Tokyo Women's Medical College and **Dept. of Human Genetics, Tokyo University, Tokyo, Japan

Insulin autoimmune syndrome (IAS, Hirata's disease) is thought to be an ideal model for investigating autoimmune mechanisms, especially human insulin autoantibody production. Glu74 in HLA-DRB1*0406 molecule revealed a crucial amino acid residue for the presentation of a human insulin epitope, and a posterior part of human insulin α chain after disulfide-bond cleavages were crucial for the T cell presentation. Here, we analyzed T-cell receptor (TCR) Vβ usages in cloned T cells which proliferated in autologous mixed lymphocytes reaction (MLR) of peripheral blood mononuclear cells (PBMC) with DRB1*0406 in the presence of human insulin. Human insulin-specific T cell clones by limiting dilution technique using PBMC from 2 donors with DRB1*0406 were established from blast cells in autologous MLR in the presence of 40 μM human insulin for the first week and 40 μM human insulin and 100 U/ml of rIL-2 for the following weeks. mRNA was isolated from the T cell clone and was analyzed by RT-PCR with 22 TCR Vβ specific primers. We found that there was a striking monoclonal increase in the amount of Vβ8 TCR gene product in the different T cell clones. It suggests that in this model, a limited number of T-cells cause the insulin autoantibody production.

IL-1 AND TGFβ_1 AFFECT THE EXPRESSION OF TYPE I AND II IL-1 RECEPTORS IN THE RAT INSULINOMA CELL LINE RIN-5AH.

P. Mitlianga[1], K. Vareli[1], and G.K. Papadopoulos[2]. Lab. of [1]Biol. Chemistry and [2]Immunology, Univ. of Ioannina Medical School, Ioannina, GREECE

Earlier studies from this laboratory had shown that the combination of IL-1β and TGFβ_1 was inhibitory to the logarithmic growth of RIN-5AH insulinoma cells, while either cytokine alone was without any effect. The aim of this study was first to document the presence of IL-1 receptor (types I and II) expression and then to investigate the effect of these cytokines on receptor expression at the mRNA level. RIN-5AH cells were grown logarithmically in high glucose-Dulbecco's MEM, with TGFβ_1 (80 pM) and IL-1 (5 nM) added, 2 or 26 hrs respectively after seeding of the cells (added in same order in combination experiments). Cells were harvested at given times and polyA+ cellular RNA was isolated. The effect on the mRNA IL-1 receptor levels was monitored by northern blotting of polyA+ RNA probed with specific probes. The RIN-5AH cells showed a gradual increase of RI mRNA with a doubling of the signal after 72 hrs of culture (near confluence). IL-1β showed a dramatic decrease in RI mRNA, that was evident at 6 hrs post-addition and maintained until 72 hrs of culture. TGFβ_1 showed a complex pattern of RI mRNA expression, with a substantial reduction in message by 8 hrs, an increase above controls at 24 hrs and a decrease well below background levels by 72 hrs. By contrast, the combination of the two cytokines leads to a very rapid (3 hrs) increase in RI mRNA. This is followed by severe down regulation of the message, making it undetectable by 72 hrs of culture. The cytokines, alone or in combination, have the same effect on RII mRNA for the first 24 hrs of incubation, yet by 72 hrs TGFβ and the combination of IL-1β and TGFβ_1 lead to an increase in RII message, compared to untreated cells. However, IL-1β incubation results in a severe downregulation of RII mRNA, making it undetectable at 72 hrs. In summary IL-1β causes severe down-regulation of RI and RII mRNA in RIN-5AH cells, while TGFβ_1 incubation leads to a more complex pattern that eventually results in down regulation of RI and upregulation of RII. The combination of the two cytokines leads to final down regulation of RI and upregulation of RII. We conclude that these two cytokines have quite complex pattern of interactive signal transduction that must be further investigated to determine the cause of the resulting inhibition of cellular growth.

CELLULAR IMMUNE REACTIVITIES AGAINST PROINSULIN IN INSULIN DEPENDENT DIABETES.

T.M. Ellis, D. Schatz, E. Ottendorfer, C. Wasserfall, N.K. Maclaren and M.A. Atkinson. University of Florida, Gainesville, U.S.A.

Investigations of animal models for insulin dependent diabetes (IDD) suggest that insulin may serve as a key autoantigen in the pathogenic events which culminate in this autoimmune disorder. In addition, recent studies of humans have suggested that proinsulin and/or a fragment from the region spanning C-peptide and the B-chain of insulin may serve as an autoantigen of IDD. Therefore, we analyzed cellular immune reactivities to proinsulin in order to clarify the role of this molecule in the pathogenesis of IDD. In vitro peripheral blood mononuclear cell (PBMC) responses (7 day, 10^5 PBMC/well) against proinsulin, insulin, control antigens (tetanus toxoid, *Candida albicans*, mumps, bovine serum albumin, and a mitogen (i.e., PHA) were determined in 32 individuals with newly-diagnosed IDD ($\leq$ one day from diagnosis) and 17 healthy non-diabetic individuals. Unlike previous reports by ourselves and others suggesting IDD associated elevations in cellular immunity to β cell antigens (e.g., glutamic acid decarboxylase, IA-2, etc.), we observed equivalent levels of PBMC proliferation against every antigen in this panel including proinsulin (all P = not significant). Specifically, the mean stimulation index ($\pm$ SD) and frequency of reactivity to proinsulin for controls and IDD patients (respectively) was: 1μg/ml (1.6 $\pm$ 1.1, 1/17(6%); 2.8 $\pm$ 3.2, 6/32 (18%)); 10μg/ml (1.7 $\pm$ 1.3, 1/17 (6%); 1.5 $\pm$ 0.8, 1/27 (4%)); and 50μg/ml (1.1 $\pm$ 0.7, 1/14 (7%); 1.4 $\pm$ 1.4, 1/25 (4%). Taken together with our previous studies reporting only rare occurrences of autoantibodies to proinsulin, the role of immunity to this molecule in the pathogenesis of IDD in humans is unclear.

342

CHARACTERIZATION OF DIABETOGENIC, GAD65-SPECIFIC T CELL CLONES ESTABLISHED FROM NOD MICE.

D. Wegmann, N. Schloot and P. Gottlieb, Barbara Davis Center for Childhood Diabetes, University of Colorado Health Sciences Center, Denver, Colorado, USA

The autoimmune destruction of beta cells which leads to insulin dependent diabetes in NOD mice and human subjects appears to be mediated primarily by T cells. Recent reports have implicated glutamic acid decarboxylase 65 (GAD65) as an important antigen in the pathogenic T cell response to beta cells in NOD mice. The goal of these investigations was to determine the role of GAD65-specific T cells in beta cell destruction in NOD mice. Beta cell destruction in human subjects and in NOD mice is preceded by lymphocytic infiltration of islets and it is presumably these infiltrating cells that are directly responsible for this destruction. Therefor, the approach taken was to establish panels of GAD65-specific T cell clones from the islet infiltrates of NOD mice. Isolated islets from prediabetic NOD mice were trypsin digested to release the infiltrating cells an these cells were used to establish GAD65 specific T cell lines and clones by in vitro stimulation with antigen and APCs. A mixture of three synthetic peptides of GAD 65 identified as dominant epitopes in this response by and designated 17 (residues 247-266), 34 (residues 427-446), and 35 (residues 435-456) was used as antigen. Thus far we have established GAD65-specific T cell lines from individual mice 7, 8, and 9 weeks old at the time of islet isolation, and have cloned the line from the 8 week mouse and analyzed the resultant clones. These clones responded to peptide 17, were predominantly of the TH1-like phenotype, and responded to islet cells in vitro. More importantly, the clones that have been analyzed thus far are capable of acceleration of diabetes in young NOD recipient mice in adoptive transfer experiments. These finding suggest that GAD65 specific T cells participate in beta cell destruction in the spontaneous disease process.

343

SULPHATIDE AND ITS PRECURSOR, GALACTOSYLCERAMIDE, INFLUENCE THE PRODUCTION OF CYTOKINES IN HUMAN MONONUCLEAR CELLS

K. Buschard, M. Diamant, L.F. Bovin, J.-E. Månsson, P. Fredman and K. Bendtzen. Bartholin Instituttet, Kommunehospitalet and Institute for Inflammation Research, National University Hospital, Copenhagen, Denmark; Department of Clinical Neuroscience, Section of Psychiatry and Neurochemistry, University of Göteborg, Mölndal, Sweden.

Sulphatide is expressed in the central and peripheral neural system, in islets of Langerhans, and in tissues affected by late diabetic complications. Autoantibodies to sulphatide are present in patients with insulin-dependent diabetes and the Guillain-Barré syndrome. Cytokines influence these disease processes, and we therefore studied whether sulphatide and its precursor galactosylceramide (gal-cer) influence the *in vitro* production of cytokines by blood mononuclear cells (MNC) originating from 15 healthy persons. Using lipopolysaccharide (LPS)-stimulated cells sulphatide increased the IL-2 production (163±17% of controls without sulphatide, p=0.02), and gal-cer increased the IL-1α production (145±13%, p=0.006), whereas neither gal-cer nor sulphatide had effect on the production of IL-6, IL-10 or TNFα. When stimulating cells with phytohemagglutinin (PHA), sulphatide decreased the production of IL-6 (88±5%, p=0.009), IL-10 (66±3%, p=0.000003), and TNFα (75±9%, p=0.02). Gal-cer, however, increased the production of IL-6 (188±13%, p=0.000006), and decreased the production of TNFβ (80±6%, p=0.007). Neither gal-cer nor sulphatide had effect on the production of IL-2 or IFNγ from PHA stimulated cells. Northern blot analysis using an IL-6 probe showed similarly an increased amount of IL-6 mRNA after gal-cer incubation (range 469%-150%, n=3, of PHA-stimulated control). Thus, sulphatide and gal-cer influence the production of several cytokines thought to be involved in immunoinflammatory disease processes.

344

A REDUCED *IN VITRO* GENERATION OF CD8$^+$ T CELLS BY SPLENIC DENDRITIC CELLS FROM THE BB RAT, BUT NOT FROM THE NOD MOUSE

H.A. Drexhage, F.G.A. Delemarre, K. Radosevic, Dept. of Immunolog, Erasmus University Rotterdam, the Netherlands

Development of type 1 diabetes results from an autoimmune attack of, primarily, effector T cells towards the β cells of the islets of Langerhans. Antigen presenting cells (APC), including dendritic cells (DC) and macrophages, play an important role in the regulation of T cell function. Intrinsic disturbances in DC function have been suggested in both human and animal (NOD mouse, BB rat) type 1 diabetes. Suboptimal activity of DC may lead to an insufficient activation of suppressor T cells whereas autoimmune T cells are fully activated.

In this study we investigated (1) the accessory cell function in syngeneic MLR (sMLR) of DCs from BB rats and NOD mice, (2) the *in vitro* generation of CD4$^+$ and CD8$^+$ T cell subsets, and (3) the expression of MHC class I, II and ICAM-1 on the DCs.

Splenic DCs (enriched by Nycodenz density gradient centrifugation) were cocultured with nylon wool-purified splenic T cells for 5 days at a radio 1:5. Proliferation of T cells was measured after adding tritiated thymidine for 16 hrs. Expression of surface markers on T cells and DCs were studied with FACS.

The stimulator capacity of DCs from control Wistar rats (age 307 wks) cocultured with either Wistar or BB T cells was 142029 ± 59091 resp. 9862 ± 4456 cpm. DCs from BB rats (age 3-7 wks) had a significant lower stimulatory capacity (35108 ± 57617 resp. 3333 ± 2330; n=6, p<0.05). DCs from the BB rat were unable to maintain particularly CD8$^+$ T cells in culture (n=6), resulting in an increased CD4/CD8 ratio. The expression of MHC class I, II and ICAM-1 on DCs from both rat strains did not differ. Regarding the NOD, DC from both spleen and lymph nodes, were as good stimulators of syngeneic MLR as control C57BL/10 DC. Moreover NOD DC as well as C57BL/10 DC stimulation of T cells induced a similar increase of the CD4/CD8 ratio in syngeneic MLR.

In conclusion, accessory cell function of splenic DCs from the BB rat is abnormal in young animals (before disease). This abnormality is not due to differences in MHC class I, class II and ICAM-1 expression on the DCs. Since DC function in the sMLR is related to the induction of regulatory or suppressive T cells, the reduction in the number of CD8$^+$ T cells in the MLR is suggestive for a defect in the generation of such T cell populations by DCs from the BB rat *in vivo*. The accessory cell function of DCs from the NOD mouse was normal, indicating that the immune disturbances in both models of spontaneous type 1 diabetes are dissimilar.

345

IN VITRO RELATIONSHIP OF LYMPHOCYTES FROM TYPE I DIABETIC CHILDREN AND RAT ISLET CELLS

N. Kvirkvelia, I. Vturina, M. Kiknavelidze, N. Porakishvili and R. Vasilov. Tbilisi State University, Tbilisi, Georgia, Institute of Biotechnology, Moscow, Russia

In order to investigate the cell mediated mechanisms of immune damage of beta cells we used a xenogeneic model of human peripheral blood lymphocytes (PBL) and rat islet cells. It is known that PBL form Type I diabetics inhibit the insulin secretion of cultured rat beta cells. Islet cell function was assessed by net insulin release in the presence of basal or stimulatory media and was expressed as the insulin release index-IR. After coculturing PBL from Type I diabetic children with rat islet cells, the islet cells lost their ability to repsond to stimulatory medium. The IR index in the group of diabetic children was 1.04±0.05, whilst the IR index for the nondiabetic control subjects was 1.8±0.05 (p<0.01). To elucidate the nature of the effector cells responsible for inhibition of in vitro insulin secretion PBL were treated with anti-CD3, anti-gamma-delta T, anti-CD25 or anti-LFA-1 antibodies. All suppressed the inhibition of insulin secretion by rat islet cells. However, treatment with antibodies to MHC Class I or II failed to suppress insulin secretion. The effects of anti-CD3 (IR index: 1.75±0.07), anti-gamma-delta T (IR index: 1.82±0.09), and anti-CD25 (IR index: 1.50±0.10), antibodies indicated a role for activated T cells expressing the CD3 associated gamma-delta receptor. In addition, the effect of anti-LFA-1 antibodies (IR index: 1.92±0.11), suggests that direct contact between PBL and rat cells is of importance. To examine this possibility we studied rosettes formed between PBL of diabetic children and rat islet cells (no rosettes form with PBL from control subjects and rat islet cells). Electron microscopy revealed a close association of PBL with the rat islet cells. In conclusion, our data suggest that at least one mechanism for the damage of beta cells is via their direct contract with non-MHC restricted activated gamma delta T lymphocytes.

SKIN TEST FOR DETECTION OF CELLULAR AUTOIMMUNITY TO GAD65 IN IDDM: A STUDY IN NOD MOUSE.

Y. Muto, S. Kure, Y. Sakata, T. Masuda, T. Shinka, Y. Matsubara, J. Satoh and K. Narisawa. Tohoku University, Sendai, Japan.

Cellular autoimmunity to GAD65 is closely associated with development of IDDM in human and NOD mouse. The cellular immunity has been detected by radioactive thymidine uptake into T-cells in presence of GAD65. To simply detect the cellular autoimmunity to GAD65, we devised a novel method by a skin test and examined its reliability and usefulness in NOD mouse. For an antigen of the skin test, a mouse GAD65 C-terminal peptide (86 amino acids) was expressed in E. coli and purified. Ten micrograms of the peptide was injected into the mouse footpad together with the crystal of alum potassium. The delayed type hypersensitivity reaction measured by footpad swelling was observed with peak at 48 h after the injection in NOD mice, but not in five normal mouse strains. Two recombinant peptides unrelated to the IDDM autoantigens, rat cyclophiline and bacterial carboxyl carrier protein, did not elicit the footpad reaction. Polymorphonuclear and mononuclear cell infiltrations were observed in the intradermal tissues injected with the GAD65 peptide, but not with the alum. Spleen cell proliferation to the GAD65 peptide measured by thymidine uptake was significantly higher in the NOD mouse than that in the other normal mouse strains. There was a significant correlation between the footpad swelling and thymidine incorporation (r=0.89, p<0.01). These results suggest the feasibility of detection of anti-GAD65 cellular immunity by the skin test and the potential clinical application of the GAD65 skin test for prediction and diagnosis of IDDM.

CD4$^+$ T LYMPHOCYTE SUBSETS DETERMINE DURATION OF CLINICAL REMISSION IN RECENT-ONSET INSULIN-DEPENDENT DIABETES

N.M.Lalić,*M.L.Lukić,**D.Kosec, M.Zamaklar, K.Lalić, A.Jotić and P.B.Đorđević
Institute for Endocrinology,*Institute for Microbiology and Immunology and **Center for Immunological Research, Belgrade, Yugoslavia

Previous studies have suggested that changes in CD4$^+$ T lymphocyte subsets might influence the clinical course of the disease in patients with recent-onset insulin-dependent diabetes mellitus (IDDM). The aim of this follow-up study was to compare changes in CD4$^+$ T cell subsets between two groups of recent-onset IDDM patients, exhibiting a long-term (> 6 months)(group A, N=16) or a short-term (< 6 months) clinical remission (CR) (optimal metabolic control without insulin lasting >30 days) (group B, N=18) and with those in age-matched healthy controls (group C, N=10). The percentage of CD4$^+$ T cell subsets was analysed in the peripheral blood by using two-color immunofluorescence staining with monoclonal antibodies defining helper-inducer (CD45R0$^+$) and suppressor-inducer (CD45RA$^+$) subsets of CD4$^+$ T cells and flowcytometry analysis. In each IDDM patient, the analysis was done sequentially (a) in initial insulin-requiring state (IRS I); (b) in CR and (c) in relapse of IRS after CR (IRS II). We found that percentage of CD4$^+$CD45R0$^+$ T cells in the state of CR was higher in group A than in group B (32.7$^+$/-2.2 vs 28.4$^+$/-2.0%, p<0.05), while simultaneously CD4$^+$CD45RA$^+$ T cells did not differ between the groups (25.8$^+$/-1.9 vs 24.2$^+$/-2.1%,p=NS). In both groups, the percentage of CD4$^+$CD45R0$^+$ T cells was lower in CR than in IRS I and IRS II (group A: IRS I: 35.7$^+$/-1.9, IRS II: 34.7$^+$/-2.2 %, p<0.05; group B: IRS I: 34.9$^+$/-1.8, IRS II: 35.3$^+$/-1.6 %, p<0.05; A vs B = NS) and it always remained higher than in controls (C:24.9$^+$/-1.4%;p<0.05). However, the percentage of CD4$^+$CD45RA$^+$ T cells was higher in CR than in IRS I and IRS II (group A: IRS I: 22.8$^+$/-1.6, IRS II: 23.1$^+$/-2.1 %, p<0.05; group B: IRS I: 23.2$^+$/-1.9, IRS II: 22.9$^+$/-1.9 %, p<0.05; A vs B = NS) and did not differ from controls. Our results signify that increased number of CD4$^+$CD45R0$^+$ T cells inversely correlates with shorter duration of CR, while the correlation between the number of CD4$^+$CD45RA$^+$ T cells and the duration of CR has not been found. The results imply that duration of CR could be modulated on the level of T helper-inducer activity.

348

DIABETOGENICITY OF INSULIN SPECIFIC, TH2 T CELL CLONES IN NOD MICE.

D. Wegmann and D. Daniel, Barbara Davis Center for Childhood Diabetes, University of Colorado Health Sciences Center, Denver, Colorado, USA

Insulin-specific T cells are a predominant component of the infiltrates that accumulate around pancreatic islets of NOD mice during the pathogenesis of insulin dependent diabetes. The great majority of nominally insulin specific T cell clones derived from these infiltrates (290/312, 93%) recognize epitopes contained on residues 9 - 23 of the B chain (B:9-23) of mouse insulin. Administration of B:9-23 to NOD mice by either subcutaneous or intranasal routes confers potent protection from diabetes. The aim of these investigations was to determine the mechanism by which B:9-23 protects NOD mice from diabetes. The cervical lymph nodes of NOD mice treated with intranasal B:9-23 were harvested and the resultant cell suspensions were cultured in vitro with B:9-23 to establish B:9-23 specific lines from four individual mice. All four lines produced the TH2 cytokines IL-4 and IL-10 upon stimulation with antigen and syngeneic splenic APCs. One of these lines was cloned and a panel of B:9-23 specific clones with TH2 cytokine production profiles was obtained. Many lines of evidence imply that TH2 cytokines protect NOD mice from diabetes, however, adoptive transfer experiments indicated that the TH2 clones were as potent as TH1 clones in transfer of diabetes to young NOD mice. In order to determine the fate of TH1 and TH2 clones in vivo, the cell tracking dye CFSE was used to label these clones. Mice were injected with CFSE labeled clones and total pancreatic infiltrating cells were isolated after the desired interval of time and analyzed by flow cytometry for various surface markers and cytokine production. The results of these experiments indicated that both TH1 and TH2 clones recruited large populations of other cells to the pancreas which outnumbered the injected clones by 10 to 200 fold. The recruited cells included: CD8 T cells, B cells, macrophages, and of interest, both TH1 and TH2 CD4 T cells. These results suggest beta cell destruction by TH2 cells is mediated by the recruited cells and that the recruited cells also contribute to pathogenicity when TH1 clones are injected.

349

INCREASED CD69 AND HLA-DR EXPRESSION IN IDDM OF LONG STANDING

A. Gessl and W. Waldhäusl. Department of Medicine III, Division of Endocrinology and Metabolism, University of Vienna, Austria.

To better define activation of circulating T-cell subsets in IDDM of recent onset (N=30) and of long standing (N=27; duration of disease >36 months), CD4$^+$ and CD8$^+$ T-cells were differentiated as to naive and memory cells, and expression of HLA-DR, interleukin-2 receptor (IL-2R, CD25) and CD69 was analyzed by three-color flow cytometry. Twenty-six healthy subjects of similar age and sex served as controls. No significant deviation was seen in IDDM vs. controls in CD25 expression on CD4$^+$ or CD8$^+$ cells, nor in their CD45RA$^+$ or CD45RA$^-$ subsets. CD8$^+$ cells, however, showed significantly increased amounts of HLA-DR molecules in newly manifested IDDM, both on CD45RA$^+$ CD8$^+$ cells (+ 45%) and the total population (+ 39%), but not on CD45RA$^-$ CD8$^+$ cells (+ 34%, NS). The same observation could be made in IDDM of long standing (CD45RA$^+$, + 76%; total CD8$^+$ cells, + 57%), where also CD45RA$^+$ CD8$^+$ cells exhibited increased HLA-DR expression (+ 40%, p<0.04). These patients also expressed increased amounts of HLA-DR molecules on CD4$^+$ cells (+ 29%), with CD45RA$^-$ cells being largely responsible for that elevation (+ 32%). CD69 expression in IDDM was not different from controls, but was higher in IDDM of long standing (p<0.05) for CD69 expression on CD4$^+$ (+ 48%), CD8$^+$ (+ 40%), and CD45RA$^-$ CD4$^+$ (+ 50%) cells than in IDDM of recent onset. Enhanced HLA-DR expression on T-cells was mainly due to their expression on naive CD8$^+$ T lymphocytes and was similar in both longstanding and newly manifested IDDM, whereas CD69 was slightly decreased at disease manifestation, but increased in longstanding disease. The observed peripheral T cell activation suggests an ongoing immune process in IDDM both at the time of its clinical manifestation and after 136 $\pm$ 109 months of duration.

350

MADCAM-1 IS REQUIRED FOR THE DEVELOPMENT OF DIABETES IN NONOBESE DIABETIC MICE

A. Hänninen, I. Jaakkola and S. Jalkanen. MediCity Research Laboratory, University of Turku, and National Public Health Institute, Turku, Finland

Environmental antigens may trigger the activation of self-destructive T cells in insulin-dependent diabetes via molecular mimicry. Many of the proposed antigens enter the body via gastrointestinal tract and are therefore presented to T cells in the gut-associated lymphoid tissue (GALT) wherein lymphocytes enter by interacting with the mucosal vascular addressin MAdCAM-1. The aim of this study was to investigate if the development of diabetes in nonobese diabetic (NOD) mice can be prevented by blocking lymphocyte homing to GALT. We show that an early blockade of MAdCAM-1 function prevents diabetes. While ineffective if started later, blockade started at 3 weeks age resulted in a near-complete reduction in diabetes incidence ($p < 0.01$). The blockade affected GALT by depleting Peyer's patches of naive (CD44^{low},CD45RB^{high}) T cells, inhibited the development of diabetogenic cells and also selectively diminished pancreatic homing of lymphocytes derived from GALT of young donors. These results show that MAdCAM-1 is required at two distinct steps of diabetes pathogenesis in the NOD mouse: for the development of diabetogenic lymphocytes and for the homing of the early-developing effector cells to the pancreas. Thus, MAdCAM-1-mediated homing of lymphocytes to, and activation in the GALT is critical for the development of early diabetogenic lymphocytes which use MAdCAM-1 also for their homing to the pancreas.

351

EXPRESSION OF SURFACE CD8 AND CD23 AND PRODUCTION OF SOLUBLE FORMS IN IDDM PATIENTS WITH ANTIBODIES TO GAD

M.Itoh, K.Shimazaki, N.Hayakawa, R.Kato, Y.Ito, S.Kato, T. Mokuno, and A.Nagasaka. Fujita Health University, Toyoake, Japan.

Autoreactive T cells and anti-GAD antibodies may participate in the autoimmune-mediated process in IDDM. T cell activation markers are increased in IDDM, but B cell activation remains uncertain. To investigate the roles of B cell activation the production of soluble (s)CD8 and B cell-derived autocrine growth factor, sCD23, and expression of surface T and B cell antigens were examined. Peripheral mononuclear cells were obtained from 5 patients with anti-GAD antibody(+) IDDM, 8 patients with Graves' disease, and 12 normal controls. The cells were incubated with or without anti-CD40 monoclonal antibody and IL-4 for 7 days. The sCD8 and sCD23 in the supernatant were measured by enzyme immunoassay and cell surface antigens were measured by FACS using monoclonal antibodies. Anti-GAD antibodies were measured by radioimmunoassay. The production of sCD 8 and sCD23 were increased after 7 days of incubation with anti-CD40 and IL-4 in IDDM (sCD8:95±38→142±49U/ml; sCD23:2.4±0.4→12.5±2.1ng/ml) as well as in other groups. The percentages of CD8(+) cells were significantly decreased in patients with Graves' disease(21.6±2.4→12.0±2.7%), and slightly decreased in the normal controls (23.7±1.6→20.0±1.5%), but was not changed in anti-GAD(+)IDDM (24.7±3.6→24.9±4.3%). The percentages of CD4(+) and CD23(+)cells remained unchanged during the incubation. Anti-GAD antibodies were not detected in the supernatant after the incubation. Thus, B cell activation mediated by CD40 and IL-4 is involved in the increase of soluble forms of CD antigens in autoimmune endocrine disease but differently in IDDM and Graves' disease.

352

ROLE OF MACROPHAGE-DERIVED CYTOKINES IN THE PATHOGENESIS OF KRV-INDUCED AUTOIMMUNE DIABETES IN DR-BB RATS.

Y.H. Chung, H.S. Jun, Y. Kang, K. Hirasawa, B.R. Lee, N. Rooijen, and J.W. Yoon. University of Calgary, Calgary, Alberta, Canada; Ajou University, Suwon, Korea; Free University, Amsterdam, The Netherlands.

The diabetes-resistant BioBreeding (DR-BB) rat, derived from DP-BB forebears, does not normally develop spontaneous insulitis or diabetes, but when infected with Kilham rat virus (KRV) this animal develops autoimmune diabetes similar to the DP-BB rat. In this study, we attempted to determine whether macrophages and macrophage-derived cytokines play any role in the development of KRV-induced diabetes in DR-BB rats. 78% of DR-BB rats treated with KRV and Poly I:C developed diabetes; whereas, depletion of macrophages with liposome- encapsulated dichloromethylene diphosphonate (Cl_2-MDP) in KRV and Poly I:C-treated DR-BB rats resulted in the near complete prevention of insulitis and diabetes. Measurement of the macrophage-derived cytokines IL-12, TNF-α, and IL-1β revealed a selective increase of expression, after KRV infection, in the splenic lymphocytes and the pancreatic islets. Measurement of CD4+ T cell-derived cytokines revealed that IL-2 and IFN-γ cytokine gene expression closely correlates with an elevation of IL-12, but IL-4 and IL-10 did not change. Inactivation of CD8+ T cells using anti-CD8 antibody resulted in a significant decrease in the incidence of diabetes and severity of insulitis. Depletion of macrophages before the isolation of splenic lymphocytes from DR-BB rats treated with KRV and Poly I:C resulted in the loss of ability to transfer diabetes to young DP-BB rats. On the basis of these observations, we conclude that macrophages and macrophage-derived cytokines play a critical role in the cascade of events leading to the destruction of pancreatic β-cells, culminating in the development of IDDM.

353

GAD-PEPTIDE STIMULATES TH1 LYMPHOCYTES IN DIABETIC CHILDREN, WHILE ABBOS STIMULATES BOTH TH1 AND TH2.

M. Karlsson and J. Ludvigsson, Department of Pediatrics, Faculty of Health Sciences, Linköping University, Linköping, Sweden

Background: The insulitis at the clinical onset of IDDM involves CD4+ lymphocytes or Th-lymphocytes with at least two subpopulations: Th1-lymphocytes which produce e.g. IFN-γ and Th2-lymphocytes which produce e.g. IL-4. Glutamic Acid Decarboxylase (GAD), and especially a peptide with similar amino acid sequence as the Coxsackie B virus, may trigger the autoimmune process. Other studies have suggested the ABBOS-peptide from bovine serum albumin (BSA) in cow´s milk.

Aim: To identify if Th1 and/or Th2-lymphocytes are activated by the Coxsackie-virus associated GAD-peptide or by the ABBOS-peptide in children with recent onset of IDDM.

Patients and Methods: Human peripheral blood mononuclear cells (PBMC) from 20 children with recent onset of IDDM and from ten healthy HLA-matched children and adults (DR3, DR4 or DR3/4) were isolated by Ficoll Paque and stimulated with the specific GAD-peptide a.s. 247-279 or the ABBOS-peptide a.s. 152-169. The first-strand cDNA, achieved by reversed transcription, was diluted in different concentrations. Reversed transcriptase coupled to the polymerase chain reaction (RT-PCR) was used to give a semi-quantitative mRNA expression of IL-4 and IFN-γ. C-peptide was determined by radioimmunoassay (RIA).

Results: No increased mRNA for GAD and only weak IL-4 mRNA for ABBOS could be seen in healthy controls, while the GAD-peptide caused mRNA for IFN-γ in 8/20 patients ($p<0.05$); of whom 5/10 at diagnoses and 3/10 after 3-15 months duration. No mRNA for IL-4 was noticed except in 2/4 after 9-15 months duration. A high C-peptide at three months of duration seems to be correlated to a low IFN−γ mRNA response ($p=0.07$). The ABBOS-peptide produced IFN-γ mRNA alone in 4 patients, IL-4 mRNA alone in 2 patients and both in 7 patients.

Conclusion: The specific GAD-peptide causes a Th1 response which may damage the β-cells, while the ABBOS-peptide causes a mixed Th1/Th2 response which may just reflect either intolerance to cow´s milk or an activated immunesystem.

354

ACTIVATION OF Syk TYROSINE KINASE PLAYS A KEY ROLE IN THE EXPRESSION OF THE IL-1β GENE IN CY-TREATED NOD MICE.

M. Imamura, N. Aoki, H.S. Jun, H.S. Han, K. Hirasawa, and J.W. Yoon. Kinki University School of Medicine, Osaka, Japan; Ajou University, Suwon, Korea; University of Calgary, Calgary, Alberta, Canada.

We and others have previously shown that activation of macrophages with cyclophosphamide (CY) resulted in the upregulation of IL-1β gene expression, which mediates inducible nitric oxide synthase (iNOS) and nitric oxide (NO) production. iNOS and NO are known to be associated with the destruction of β-cells and the inhibition of β-cell function, leading to the acceleration of diabetes in NOD mice. This investigation was initiated to determine whether the enhanced expression of the IL-1β gene by CY is a result of the activation of Syk tyrosine kinase in NOD mice. First, we examined the cytokine gene expression (IL-1β, IL-12, IFN-γ, IL-4 and IL-10) of the splenocytes, peritoneal macrophages and pancreatic islets containing immunocytes. We found that IL-1β was significantly increased in the splenocytes, peritoneal macrophages, and pancreatic islets containing immunocytes in CY-treated NOD mice. In addition, IL-12 and IFN-γ , but not IL-4 or IL-10, increased in the pancreatic islets containing immunocytes. Second, we examined whether Syk tyrosine kinase is increased in Mac1+ cells in CY-treated NOD mice. We found that Syk tyrosine kinase clearly increased in Mac1+ cells prepared from splenocytes and peritoneal macrophages of CY-treated NOD mice. On the basis of these observations, we conclude that CY may activate macrophages, resulting in an increase of IL-1β gene expression due to the activation of Syk tyrosine kinase.

355

DECREASED IN VITRO IL-4 AND IL-10 PRODUCTION BY PERIPHERAL BLOOD IN FIRST DEGREE RELATIVES AT HIGH RISK OF IDDM

A.Krętowski, M.Szelachowska and I.Kinalska, Department of Endocrinology, Medical School, Białystok, Poland

There is an accumulating evidence that the imbalance between Th1 and Th2 lymphocyte subsets plays a key role in the development of autoimmune diabetes in NOD mice, but it is possible also in humans. The aim of the present study was the estimation of in vitro production of Th1-(INF-γ, IL-2) and Th2-derived (Il-4, IL-10) cytokines by peripheral blood in high risk of insulin-dependent diabetes subjects (preclinical stage), since alterations in their secretion could represent early events in the immune-mediated islets destruction. The study was performed in 25 first degree relatives of type 1 diabetes patients with high (>20JDF), persistent ICA titres and 21 age and sex-matched healthy controls. Cytokines concentrations in supernatants of whole blood cultures with PHA (10ug/ml) were quantified by ELISA. We observed a lower concentrations of IL-4 in culture supernatants in ICA positive relatives as compared with the control group, both at 48h ($p<0.05$) and 72h of incubation ($p<0.05$). Similary in the prediabetic group lower IL-10 levels at 48 and 72h of culture ($p<0.05$) was found. We did not observe statistical differences in *in vitro* production of IL-2 and INF-γ by peripheral blood in high risk diabetes mellitus subjects and healthy controls. In subjects at increased risk of type 1 diabetes levels IL-4 positively correlated with IL-10 ($R=0.342$, $p<0.03$). There were negative correlation between IL-10 concentrations after 48 h of incubation and levels of HbA1c ($R=-0.437$, $p<0,05$). In conclusion our study has shown decreased IL-4 and IL-10 production, but normal secretion of Th1-derived cytokines by peripheral blood of prediabetic humans. It could suggest that the early stage of autoimmune process in type 1 diabetes in humans is associated with decreased function of Th1-cells rather than overactivation of Th2 subset in the peripheral blood.

356

SPECIFIC REG II GENE OVEREXPRESSION IN THE NOD MOUSE PANCREAS DURING ACTIVE DIABETOGENESIS.

N. Baeza, D. Sanchez, B. Vialettes and C. Figarella: University of Marseille, FRANCE

The reg genes, normally expressed by acinar cells, have been shown to be associated with beta cell regeneration. We have described an overexpression of reg genes in the Non Obese Diabetic (NOD) female mice pancreas suggesting that the regenerative process may be involved in autoimmune aggressed beta cells (Diabetes, 1996, 45, 67-70). Since two reg genes have been characterized in the mouse genome, we have quantified the respective pancreatic reg I and reg II mRNA using specific probes and the Dot blot method. We firstly found a significant higher level of both reg genes before 130 days of age in non diabetic NOD mice compared to older animals. In addition reg II expression was prevalent to reg I (females: 4.97 ± 1.34 A.U. vs 2.39 ± 0.4 A.U., $p<0.05$, $n=11$; males: 3.41 ± 0.79 A.U. vs 1.55 ± 0.27 A.U., $p<0.05$, $n=11$) which is the opposite pattern to that found in OF1 control mice of the same age (reg II/reg I= 0.24). Secondly a much higher expression of reg II gene, but not of reg I, was observed in other animals at high risk of diabetes (cyclophosphamide injected males, n=6, reg II : 21.6 ± 6.86 A.I., reg I : 1.38 ± 0.47 A.U. or overtly diabetic females, n=13, reg II : 8.44 ± 2.4 A.U., reg I : 2.07 ± 0.43 A.U.). In diabetic animals, reg II overexpression was present despite undetectable insulin mRNA suggesting that this phenomenom does not depend on the persistance of beta cells. In conclusion, this observation confirms that autoimmune diabetogenesis is associated with reg gene overexpression in the exocrine pancreas and also demonstrates that the two reg genes are modulated by different regulations.

357

DECREASED CD3-MEDIATED PROLIFERATION IN TYPE 1 DIABETES COULD BE DUE TO A CONSTITUTIVE DEFECT OF THE TRANSDUCTION SIGNALING PATHWAY

S. Nervi, C. Gepner, L. Hermite, J. Nunez, C. Mattei and B. Vialettes. Laboratoire de Diabétologie, Hôpital Sainte Marguerite, Marseille, France.

CD3- mediated proliferative response of PBMC of IDDM adults patients (newly diagnosed patients n= 25, long-standing patients n= 19) was studied and compared to healthy control subjects (n= 36) , type II diabetic patients (n= 12) and non diabetic first degree relatives of IDD patients (n= 19). The effect of addition of costimulative signals (i-e PMA and exogenous cytokines IL-2 or IL-4) was evaluated. Proliferative response to anti-CD3 mAb was significantly lower in IDDM patients (mean SI 4.21± 2.55 in newly-diagnosed IDDM and 2.75± 3.03 in long-standing IDDM) compared to other groups (mean SI 5.85± 3.51 in control subjects, 5.96± 5.80 in type II diabetic patients, 5.26± 4.47 in first degree relatives). Addition of either PMA or exogenous cytokines was unable to overcome the defective proliferative response. Production of IL-2, IFNγ and IL-4 of CD3- stimulated PBMC was not different in IDDM patients and controls. Furthermore, there was no correlation between the stimulation index and degree of metabolic control (HbA_1C), genetic background (MHC class II DR or DQ), persistence of autoantigenic stimulation (C-peptide, ICA, GADA, IA2A).
In conclusion, because this low proliferative response was found whatever duration of symptoms, a constitutive defect of the CD3-TcR signaling pathway is suspected and is currently studying.

BETA-CELL REPLICATION IN INSULIN-INDUCED REMISSION OF IDDM IN BB/WOR//TKY RATS

C. Ishii[1], S. Kawazu[2], K. Negishi[1], S. Katayama[1], J. Ishii[1], T. Ohno[2], T. Utsugi[2], N. Kato[2], Y. Ito[2], S. Tomono[2] and K. Komeda[3]
[1]4th Dept. of Int. Med., Saitama Med. Sch. [2]2nd Dept of Int. Med., Gunma Univ. Sch. of Med. [3]Animal Research Center, Tokyo Med. Col. JPN

In this study, we investigated the biochemical and histological characteristics of remission in diabetic BB/Wor//Tky rats. Plasma glucose levels (PG), pancreatic insulin content (PIC), histological severity of insulitis (i.e. area of islet occupied by mononuclear cells; score 0: 0%, 1: 1-24%, 2: 25-49%, 3: 50-100%, 4:atrophied), and islet beta-cell volume (%/pancreas) were determined in non-diabetic rats (aged 7-10 weeks), newly diabetic rats (onset day; aged 11-12 weeks), rats in remission (aged 12-15 weeks), and non-remission diabetic rats (> 7 days after the onset; aged 11-12 weeks). Beta-cell replication was also estimated using the 5-bromo-2'-deoxyuridine (BrdU) pulse labeling method. In rats in remission, PIC were higher than in newly diabetic rats, as evidenced by the near normalization of PG. Mean insulitis scores were significantly lower and beta-cell volume was significantly higher in rats in remission than in newly diabetic rats (mean insulitis score: 0.93 ± 0.64 vs. 3.02 ± 0.39, beta-cell volume: 0.46 ± 0.12 vs. 0.12 ± 0.08 %/pancreas, respectively). In newly diabetic rats, both the mean insulitis score and beta-cell volume were heterogeneous (insulitis score range: 2.38-3.87; beta-cell volume: 0.02-0.36 %/pancreas). BrdU labeling index significantly increased 3- to 4- fold in newly diabetic rats and also in rats in remission, compared with young adult non-diabetic rats (aged 9-10 weeks). Beta-cells may therefore still be present even in newly diabetic animals, and at the very early stage of insulitis the suppression of insulitis by insulin treatment and the compensatory replication of beta-cells might possibly contribute to IDDM remission in BB/Wor//Tky rats.

359

INCREASED IN VITRO INTERLEUKIN-12 PRODUCTION BY PERIPHERAL BLOOD IN HIGH RISK IDDM FIRST DEGREE RELATIVES

M.Szelachowska, A.Krętowski and I.Kinalska, Department of Endocrinology, Medical School,Białystok, Poland

Cytokines secreted by antigen presenting cells, lymphocytes T and pancreatic β cells are considered as the major mediators in pathogenesis of IDDM. It is suggested that cytokines released by macrophages/monocytes could have initial role in β-cell damage. The aim of the present study was the estimation of in vitro production of macrophage-derived cytokines:IL-1β, TNF-α, IL-12 by peripheral blood in high risk IDDM first degree relatives, since it could reflect early events leading to the development of type 1 diabetes in humans. The study was performed in 25 high risk IDDM subjects and 21 age and sex-matched healthy controls.IL-1β, TNF-α and IL-12 concentrations in supernatants of whole blood cultures with PHA(10ug/ml) were quantified by ELISA. In the ICA positive relatives of IDDM subjects levels of IL-12 were significantly higher as compared with the control group, both at 48h ($p<0.02$) and 72h ($p<0.05$) of incubation and positively correlated with TNF-α and IL-1β ($R=0.46$, $p<0.002$ and $R=0.32$, $p<0.05$). We did not observe statisitcal differences in *in vitro* production of TNF-α and IL-1β between the study groups. In conclusion we suggest that our finding support the hypothesis, that IL-12 is involved in the pathogenesis of human IDDM. If the involvement of Th1 cells is confirmed in the destruction of islet β-cells, it is possible that IL-12 antagonists will have a role in the future prevention of insulin dependent diabetes mellitus.

360

RESTORATION IN VITRO OF INSULIN SECRETION FROM NOD MOUSE ISLETS WITH SEVERE INSULITIS

J. Sternesjö and S. Sandler, Department of Medical Cell Biology, Uppsala University, Uppsala, Sweden.

Pancreatic islets isolated from 12 wk old prediabetic NOD mice have a suppressed glucose stimulated insulin release. This can be be reversed by culture of the islets. In this study we have examined whether islets isolated from much older animals with advanced insulitis also can recover. We also studied whether supplementing the culture medium whith the cytokine IL-12 (10 ng/ml), which accelerates diabetes development in vivo in NOD mice, alone or in combination with the T-cell stimulating cytokine IL-2 (4 ng/ml) affected this recovery. Islets were isolated from 5, 12, 20 and 26 wk old female NOD mice. Some islets were used immediately after the isolation process for insulin release determination while others were cultured for 7 days with or without cytokines. Medium was changed on day 2, 4 and 6. In the age groups above 5 wk the glucose stimulated insulin release (ng/10 islets x 1 h) was lower in freshly isolated compared to cultured islets (5wk:4.1±0.9 vs 7.3±1.2, NS; 12wk:6.9±1.6 vs 14.3±3.6, p=0.014; 20wk:9.3±1.6 vs 17.0±3.4, p=0.045; 26wk:5.0±1.1 vs 14.9±1.1, p=0.003). Culture with IL-2 + IL-12 induced a minor decrease in glucose stimulated insulin release in islets from 12 wk old animals (10.9±3.2 vs control 16.4±5.6, p=0.025 paired t-test). With increasing age islet DNA content in freshly isolated islets increased due to immune cell infiltration. Islet DNA content in cultured islets was decreased by 40-60% ($p<0.01$) compared to freshly isolated islets in the age groups over 5 wk. This study shows that islets from NOD mice, as old as 26 wk, have an ability to recover from suppressed islet function when removed from the autoimmune in vivo environment.

361

Is the assumed TH1/TH2 imbalance at diabetes onset reflected by serum total and specific IgE-levels?

O. Kordonouri, M. Schmitt, T. Danne, B. Niggemann, U. Wahn, and B. Weber. Kinderklinik, Charité-Virchow Klinikum, Humboldt Universität, Berlin, Germany

Introduction The development of type I diabetes mellitus (IDDM) has been assumed to be mediated by T helper 1 (TH1) cells, while TH2 cells have been considered to possess some protective potency. In contrast, atopic diseases are TH2 mediated, and IgE-production is regulated by TH2 cytokines. Therefore, a relative TH2 deficit, as assumed in IDDM, could well be reflected by low serum IgE-levels at the time of IDDM onset. ***Material and Methods*** Total IgE and specific IgE to seven frequent inhalative allergens (Phadiatop®, Pharmacia, Uppsala, Sweden) were measured in sera of 59 children [26 boys, 33 girls; median age 9.6 years (1.8-14.6)] at IDDM onset by the Pharmacia CAP system. Furthermore, glutamic acid decarboxylase-antibodies (GADA) and insulin-auto-antibodies (IAA) were simultaneously determined by radioimmuno-assays (Brahms Diagnostica GmbH, Berlin, Germany). ***Results*** Total IgE was elevated in 11 patients (19%). Specific IgE was found to be elevated in 25% of the children (see table), which is not markedly different from its prevalence in the age-related general population. Moreover, GADA- and IAA-positivity was as frequent in patients with normal and elevated specific IgE-levels.

Age group (years)	Total IgE(kU/l) mean±SD	Upper normal values	Elevated total IgE	Elevated specific IgE
< 4.0	75.9 ± 85.7	66 kU/l	2 / 5 (40%)	0 / 5 (0%)
4.0-6.9	94.7 ± 77.6	118 kU/l	4 / 15 (26.6%)	4 / 15 (26.6%)
7.0-10.9	137.4 ± 313.8	330 kU/l	1 / 18 (5%)	3 / 18 (16.6%)
≥ 11.0	115 ± 135.3	240 kU/l	4 / 21 (19%)	8 / 21 (38%)

Message We conclude that patients at IDDM onset have the potency to produce specific IgE-antibodies indicating appropriate TH2 mediated immunity.

362

A REDUCTION IN THYMIC B-LYMPHOCYTE NUMBER IS ASSOCIATED WITH AUTOIMMUNITY IN THE RAT.

L. Hornum, P. Farris, S. Tullin and H. Markholst, Hagedorn Research Institute, Gentofte, Denmark.

A thymic B-cell deficiency (TBD) was originally found in the diabetes-prone BB-rat (DP) by differential screening using thymic cDNA libraries from DP and NEDH rats. TBD is inherited in a recessive mode, and the gene responsible for the trait, *Tbd*, was found to be tightly linked to the diabetes susceptibility gene *Lyp*. To investigate whether *Tbd* is identical to *Lyp*, we have analyzed several rat strains for presence of TBD using immunolabelling of single cell suspensions followed by FCM and immunohistochemistry. Brown Norway (BN) and NEDH rats was used as control strains. Four rat strains, diabetes-resistant BB, Lewis, PVG and Wistar Furth rats showed thymic B-cell numbers significantly lower than the control strains ($p < 0.05$ for all strains) - although higher than DP rats. The first three of these are known to be susceptible to induction of autoimmune diseases such as type I diabetes. This is in agreement with the role of thymic B-cells in negative selection. We speculate that *Tbd* may be a new diabetes (or autoimmune) susceptibility gene of the rat, since none of the four strains carries the DP allele of the *Lyp* gene, indicating that *Tbd* is not identical to *Lyp*.

363

TROGLITAZONE ALTERS THE CYTOKINE PRODUCTION OF ACTIVATED LYMPHOCYTES FROM HUMAN DONORS.

A.Giorgini, *D.Scott, R.Liddi, P.Beales and P.Pozzilli. Dept Diabetes & Metabolism, St Bartholomew's Hospital, London UK. and *NIBSC, South Mimms, Potters Bar, UK.

Troglitazone (TGL) is a thiazolidinedione compound which increases sensitivity to insulin and is used to treat insulin resistance in NIDDM. This compound also has anti-inflammatory properties which make it of interest as an immunomodulator. In vivo experiments have shown that the compound reduces diabetes incidence in NOD mice, an animal model of IDDM. This study aimed to investigate the ability of TGL to interfere with pathological processes mediated by cytokines which play a critical role in TH1/TH2 switching (IL-4, IFNγ and GM-CSF). Lymphocytes were collected from healthy human donors and cultured with different concentrations of TGL (0-62500 ng/ml). The cells were then stimulated with PHA and the resulting culture supernatant assayed by determining its ability to support the growth of a GM-CSF/IL-4 dependent cell line (TF-1). The presence of IFNγ was determined by ELISA technique. The results indicate that IL-4 levels were unchanged when lymphocytes were cultured in presence of different TGL concentrations. However IFNγ and GM-CSF levels were reduced in the presence of high TGL concentrations (12500-62500 ng/ml). IFNγ and GM-CSF are secreted by TH1 lymphocytes, therefore we suggest that TGL could reduce diabetes incidence in vivo by reducing TH1 cytokine production.

364

ANTI-CD38 AUTOANTIBODY: A NEW MARKER FOR POTENTIAL IDDM - A STUDY WITH NON-OBESE DIABETIC(NOD) MOUSE.

T.Taminato,T.Itoh,H.Natsume,H.Katoh and T.Yoshimi.

Hamamatsu University School of Medicine, Japan.

We have shown that pretreatment of pancreatic B cell with anti-CD38 antibody inhibited D-glucose-induced insulin release and $[Ca^{2+}]i$ rise, indicating the involvement of CD38 antigen, an ecto-enzyme ADP-ribosyl cyclase, in insulin secretion. The present study was aimed to know the possible existence of autoantibody against CD38 in diabetics.

A method to detect CD38 antibody(CD38-AB) was developed in which two fragment peptides(287-297;Ag-1), 241-255;Ag-2) as antigen and a biotin-avidin method using ABTS as detection system were employed. NOD mice aged 5-12 weeks were sacrificed to obtain sera and pancreases. Higher values of OD than mean +2SD of control samples(sera from B6 mice) was judged as "positive".

Sera of 5-week old mice, whose pancreatic islets were normal, were CD38-AB negative. After 7 weeks, varying degree of lymphocytic infiltration around the islets were observed in all subjects tested, and 84 % of mice were shown to be positive for CD38-AB. A majority of CD38-AB exhibited stronger binding to Ag-1 than to Ag-2. Most of mice older than 11 weeks became diabetic, and remained CD38-AB positive.

These results clearly indicate a diagnostic value of CD38 autoantibody to predict the onset of IDDM.

PLASMA INSULIN AND PROINSULIN CONCENTRATIONS IN IGT AND NIDDM

K. Suzuki and Y. Goto. Tohoku Kosei-nenkin Hospital, Sendai, Japan

Disproportionate hyperproinsulinemia was observed in non-insulin-dependent diabetes mellitus (NIDDM). Diminished proinsulin (PI) and insulin (IRI) responses to a glucose load (75 g OGTT) are also predictive of worsening to diabetes. In the present study, we performed a study in 72 subjects with varying degrees of glucose tolerance to clarify β-cell dysfunction. Proinsulin and insulin were measured by a radioimmunoassay. The antibody against proinsulin was cross-reactive with 65-66 split proinsulin. At baseline, NIDDM (12) subjects had disproportionate hyperproinsulinemia (PI:IRI ratio; $16.2 \pm 1.3\%$) as compared to that in subjects with normal glucose tolerance NGT ($13; 9.0 \pm 1.1\%$) and with IGT ($45; 9.7 \pm 0.9\%$). Proinsulin and insulin index (Δ IPI:Δ BS30; Δ IRI:Δ BS30) in NIDDM ($4.7 \pm 1.2; 12.5 \pm 3.4$) were significantly lower than those who have NGT ($8.2 \pm 1.6, p<0.05; 56.0 \pm 10.8, p<0.01$) and IGT ($10.8 \pm 3.4$; $66.5 \pm 17.2, p<0.01$) in OGTT. Although OGTT in NIDDM showed a significant correlation between both Δ IPI:Δ BS30 ($r=-0.6, p<0.05$) and Δ IRI:Δ BS30 ($r=-0.7, p<0.01$) and 120-min glucose levels, this not the case in NGT nor in IGT. Both proinsulin and insulin responses to OGTT revealed a gradual decrease according to the degrees of glucose tolerance. The present findings suggest that an intracellular abnormality of pancreatic B-cell function, which reduces the conversion of PI to insulin and the release of disproportionately large amounts of PI relative to insulin.

366

HEPATIC INSULIN CLEARANCE AND B CELL SECRETION DURING THE PROCESS OF AGING IN MAN.

K. Dębe, W. Karnafel, P. Pacuła and A. Czyżyk. University School of Medicine, Warsaw, Poland.

The aim of the study was to evaluate the secretory activity of pancreatic beta cell and the hepatic clearance of insulin in healthy subjects during aging. In 100 subjects (males and females) in age range 17 to 92 years with BMI <27 kg/m^2, divided in four groups according to age: (I: 18 aged 17 - 59 years, II: 23 aged 60 -69 years, III: 33 aged 70 - 79 years, IV: 26 aged from 80 to 92 years) oral glucose tolerance test (75g) and the i.v. glucagon test (1 mg) were carried out, and the blood glucose, serum insulin (IRI) and serum C-peptide (CP) were measured in fasting state and over 2 h after oral glucose and after glucagon. The hepatic insulin clearance was calculated from CP/IRI ratio. With advanced age the increase in fasting blood glucose and in blood glucose area under the curve after both stimuli, a decrease in fasting and stimulated serum CP, with no differences in fasting and stimulated serum IRI concentrations was observed. Consequently, the serum CP/IRI ratio decreased from 10±3.8 (SD) in group I to 5.4±1.7 in group IV, $p<0.05$. These results indicate that process of aging is associated with reduced hepatic clearance of insulin probably expressing a compensatory adaptation to the age-dependent decrease in pancreatic beta cell secretory activity.

367

PLASMA PROINSULIN RESPONSE IN OBESE INDIVIDUALS WITH VARYING DEGREES OF GLUCOSE TOLERANCE IN KOREA.

YS. Kim, MS Nam, MR Kim, and YJ Kim. Inha University, Incheon, Korea.

Controversy continues as to the role of β-cell function in the etiology of noninsulin-dependent diabetes mellitus(NIDDM). The β-cell function of NIDDM includes alterations in proinsulin levels, an observation made in several ethnic groups. We have performed a cross-sectional study evaluating proinsulin response after 75g oral glucose tolerance test(OGTT) in obese individuals(>27 kg/m^2 in body mass index, BMI). ALL 37 subjects were classified as 3 groups(obesity with normal glucose tolerance;12, obesity with IGT;10, obese NIDDM;15 cases). The patients were all new-onset diabetics. We measured proinsulin, specifc insulin, and c-peptide by radioimmunometric assay. The age and BMI were similar between groups but NIDDM group had lesser in basal c-peptide and insulinogenic index(p=0.01). The basal proinsulin level did not have difference (0.14, 0.13, 0.19 pM)between 3 groups, but the plasma proinsulin response in NIDDM group at 30 minutes after OGTT had greater than in other groups(p=0.05). And the ratio of proinsulin/(proinsulin+insulin) in NIDDM group at 30 minutes after OGTT also had greater than of other groups(0.07±0.03, 0.08±0.01, 0.15±0.06, p=0.01). These results show that the β-cell dysfunction of new-onset obese NIDDM includes increased proinsulin response after OGTT. And the proinsulin response at 30 minute after OGTT may be an indicator of early onset NIDDM.

368

DIABETES MELLITUS IN THE ELDERLY: CLINICAL ASPECTS, BETA CELL FUNCTION AND IMMUNOLOGY PROFILE. Nasri, F.; Sá, J.R.; Pimenta,W.; Russo, E.K and Dib, S.A. UNIFESP-EPM São Paulo Brazil

The prevalence of Diabetes Mellitus (DM) are high in the elderly. Although the NIDDM is the most common type of DM in this population 30-40% of these patients are non obese and 5-1% are IDDM. Also in this group we have a less family history of DM and chronic complications. The aim of this study its to promote a better characterization of DM with diagnostic after 65 y.o. We studied 2 groups: Group I- normal elderly (10 (9 F/1M) - 76.1±5.7 y.o) Group 2- Elderly patients with 1 year or less of clinical DM, without retinopathy (15(11F/ 4 M) - 72.0 ± 4.9 y.o). In these 2 groups we studied: HbA1c, Anti-Islet cell (ICA-protein A) antibody, C-peptide(RIA) before and 60' (In 8 diabetic patients and 8 normal we measured the C pep at 90' and 120') after Sustacal^R (360Kcal/dose), also we used the C-peptide index (C-Pep/glucose). We stopped the oral hypoglycemic agents 3 months before the Sustacal^R Test. We used the non-parametric tests: Mann-Whitney and Wilcoxon and values of $p < 0,05$ were considered to statistic significance. Results: There were not difference between age, family history of diabetes (I:40%;II:53.3%),BMI (I:27.2±3.3; II:29.3±4.5Kg/m^2), HbA1c(I:5.8±0.3; II:6.43±1.7%), ICA (positive I:20% ;II:26.6%),were similar in the 2 groups. The C-peptide levels also were similar between the 2 groups in the basal condition and after Sustacal^R : basal - I: 0.21 ± 0.15 and II: 0.23 ± 0.24 pmol/ml and high value- I: 0.47 ± 0.39 and II: 0.41 ± 0.49 Before x after : $p < 0.05$ in I and II. The C-peptide index increased in 1.64 (90') fold in the control group and in 2.84 (90') in the diabetic group, after Sustacal^R . After 3 months on diet treatment we observed a group(IIA) of diabetic patients that answered to diet with glucose levels ≤ 7 mmol/l (8 patients: HbA1c: 5.6±1.8) and another group (IIB) with no answer to diet (gluc.>7.0),(7 patients: HbA1c: 7.1 ± 1.8). The basal (IIA: 0.32±0.24; IIB: 0.19± 0.22 pmol/ml) and highest value (IIA: 0.45±0.47 and 0.37±0.38 pmol/ml) were similar but the increase in C-peptide index after SustacalR was higher in the group that answered to diet (IIA: 3.2 fold and IIB: 2.2 fold). Our data did not shown differences between clinical, HbA1c and C peptide secretion between normal control and elderly diabetic patients. Also a high prevalence of ICA in this age group. So others studies are need to verify the difference pathogeneses of hyperglycemia and the real significance of autoantibodies in the elderly.

369

INTACT PROINSULIN CONVERSION IN PATIENTS WITH INSULINOMA.

M E. Røder, B. Dinesen , P. Houssa*, F. Sodoyez-Goffaux*, and M Nauck+. Steno Diabetes Center, Gentofte, Denmark; *Centre Hospitalier Universitaire, Liège, Belgium; and +Medizinische Universitätsklinik, Bochum-Langendreer, Germany.

The nature of proinsulin processing and secretion in insulinoma patients is incompletely understood. Levels of intact proinsulin (IPI) and total proinsulin immunoreactivity (PIM)(intact proinsulin and conversion intermediates) were measured by specific ELISA methods in the fasting state and under exogenous hyperinsulinaemia with and without hypoglycaemia. Nine insulinoma patients were compared with 10 healthy control subjects matched for body adiposity (BMI 26.7±3.9 vs. 25.5±4.8 kg/m^2). In the fasting state plasma (P) glucose levels were lower in insulinoma patients: 3.2±0.9 vs. 5 4±0.3 mmol/l in controls, p<0.001. However, both IPI and PIM were increased 20-30-fold in insulinoma patients: 76±47 vs. 2.4±0.3 pmol/l and 168±102 vs. 7.8±0.8 pmol/l in controls, respectively, p<0.001. The fasting ratio of IPI/PIM was also significantly elevated in insulinoma: 45±3 vs. 31±2% in controls, p<0.001. During a 180-min hyperinsulinaemic euglycaemic clamp (P-glucose 4.4-5.0 mmol/l) levels of both IPI and PIM were remarkably constant in the insulinoma patients. Thus, at the end of the clamp (180 min) IPI/PIM was unchanged 44±4%. In contrast in the controls both IPI and PIM decreased as expected: 180-min: 1.3±0.2 and 4.0±0.7 pmol/l, respectively, p<0.01, IPI/PIM 35±3%. Hypoglycaemia (P-glucose 2.2-2.5 mmol/l) was then introduced and kept constant for 60 min (210-270-min). During this part both IPI and PIM were still unchanged in insulinoma, thus IPI/PIM at 270 min was 47±5%. In controls there was a further suppression of IPI and PIM levels: 0.6±0.1 and 1.5±0.2 pmol/l, IPI/PIM was 42±7%.

We conclude, that since intact proinsulin is disproportionately increased in insulinoma patients, conversion of intact proinsulin is impaired. However a significantly proportion is further converted to proinsulin conversion intermediates. The study support the autonomous nature of intact proinsulin secretion in insulinoma.

370

HOW MUCH IS POSSIBLE RECOVERY OF INSULIN SECRETION IN INSULIN DEPENDENT DIABETICS AT TIME OF CLINICAL REMISSION?

M.Zamaklar,N.Lalić,A.Jotić,K.Lalić,S.Popović ,M.Bogić,Lj.Lukić,N.Rajković and P.Djordjević. Institute for Endocrinology and diabetes ,Belgrade,Yugoslavia

It was known that lost of first phase of Insulin secretion precede onset of IDDM.At time of clinical remission patients have not got recovery of this phase.The aim of this study was to estimate how much we can expect recovery of beta cells secretors capacity at time of remission.IVGTT was performed to estimate Acute Insulin Response-AIR. Glucose 0,5g/kg BW as 30% solution was fast infused and blood samples were drawn at 0,1,3,6,10, 15,30 and 60 minutes.We measured C-peptide in daily profile also.Investigations were performed in 21 newly diagnosed IDDM patients(group A), treated by intensified insulin Pen therapy. In 11 patients IVGTT was repeated at time of clinical remission (group B).Results were compared with10 patients who did not have clinical remission (Group C),one month after IDDM diagnosis(8h after last regular insulin doses).At time of IDDM onset,first phase was impaired, as at time of remission.No significant improve of both phases of insulin secretion at time of remission(differences for all values were no significant (p>0,05).Patients without remission had very similar insulin levels also.Values of Insulin(mIU/l) are on table:

Groups	0'	1'	3'	6'	10'	15'	30'	60'
A	16,2+ 2,2	18,4+3,5	20,6+5,4	15,9+4,4	14,8+3,2	23,3+4,5	18,6+5,6	7,6+4,2
B	16,8+ 3,3	19,2+2,3	21,2+4,4	18,3+4,7	10,4+2,2	20,4+4,5	20,5+3,5	18,5+2,5
C	17,2+3,4	17,4+3,5	17,4+2,7	13,4+3,5	14,2+3,5	19,6+3,7	19,6+2,9	19,3+4,3

We found significant differences in C-peptide(nmol/l) values during daily profile at time of IDDM onset and at time of remission($p<0,01$),except for values at 13h.

Time	8h	10h	13h	15h	18h	20h	24h
Onset	0,43+0,02	0,69+0,03	0,42+0,02	0,59+0,04	0,61+0,05	0,71+0,10	0.59+0,1
Remiss.	0,17+0,03	0,36+0,02	0,48+0,10	0,29+0,01	0,24+0,03	0,33+0,02	0,22+0,1

Our results suggest that AIR during clinical remission is very weak and satisfied metabolic control at that time probably dependent of beta cells stimulation with other stimulators such as maybe amino acids.

371

LEVELS OF DES 64, 65 PROINSULIN IN SUBJECTS WITH HISTOLOGICALLY PROVEN INSULINOMAS

V.Mohamed-Ali[1], J.Thornton[1], P.Sawicki[2] and J.S.Yudkin[1]. [1]University College London Medical School, London, UK; [2]Medizinische Klinik and Poliklinik, Dusseldorf, Germany

We investigated the relative contribution of the proinsulin-like molecules, intact, des 31, 32 proinsulin and des 64, 65 proinsulin, to the hyperinsulinaemia in 20 subjects with histologically proven insulinomas (male:female, 4:16; age median (range) 58.0(32 - 82)yrs; and BMI 25.5(20.1 - 38.4)kg.m^{-2}). Insulin, intact and des 31, 32 proinsulin were determined by in-house immunometric assays. Des 64, 65 proinsulin was assayed with a novel in-house two-site immunoradiometric assay based on a guinea-pig polyclonal antibody against des 64, 65 proinsulin and an anti-proinsulin monoclonal antibody. The assay showed less than 5% cross reaction with intact proinsulin (at 250pmol.l^{-1}), and no cross-reaction with insulin (up to 2500pmol.l^{-1}) or des 31, 32 proinsulin (up to 250pmol.l^{-1}). The sensitivity of the assay was 0.12 to 0.06pmol.l^{-1}. Recovery of the des 64, 65 proinsulin added to human plasma or 5% BSA/Tris buffer at 2.5pmol.l^{-1} was 98.4% range 92 -105%, at 7.6pmol.l^{-1} was 89.0 range 84 - 95% and at 16.0pmol.l^{-1} was 102.8 range 98 to 104%. The inter and intra-assay CVs at 3.0pmol.l^{-1} were 12.3 and 9.3%, at 8.5pmol.l^{-1} were 7.4 and 8.2% and at 15.6pmol.l^{-1} were 6.9 and 11.0% respectively. The proinsulin-like molecules as a proportion of total immunoreactive insulin ranged from 7.5 to 89.8%. Intact proinsulin was the predominant insulin precursor in 9 of the subjects and in 11 of the subjects the des 31, 32 species was predominant. While des 64, 65 proinsulin was detected in all the samples assayed it was not the predominant precursor in any of them. Des 64,65 proinsulin only comprised 4% (range 1 -11%) of immunoreactive insulin in these subjects.These results support the findings that 1) proinsulin to insulin conversion occurs primarily via the des 31,32 branch , 2) the des 64,65 proinsulin form may be of little physiological significance and 3) assays for insulin that show only cross-reaction with the des 64,65 species may be considered largely specific for insulin.

372

LESSONS SHOULD BE TAKEN FROM 60 COMPLETE REMISSION PATIENTS WITH TYPE 1 DIABETES

M.T.Yılmaz , İ. Satman, K. Karşıdağ, N. Dinççağ, Ç. Karaca , M. Sargın, A.M. Şengül, Ş. Karadeniz. Diabetes Division, Istanbul Faculty of Medicine, and Institute for Experimental Medicine, Diabetes Research Unit, Istanbul University, Istanbul-TURKEY

In this study we aimed to define clinical and laboratory characteristics of 60 complete remission cases with Type I diabetes (F/M 13/46, age 17.4±6.1 yrs, BMI 19.5±2.6 kg.m^{-2} and ICA +/- ; 36/18). Remission was induced by multiple subcutaneous insulin injections (MSCII) and defined as no insulin requirement with daytime normoglyceamia for at least 15 days. Results were compared with data of 10 incomplete remission [ICR: ≤0.25 IU.kg^{-1}.day^{-1} insulin requirement, (F/M 6/4, age 18.0±5.6 yrs, and BMI 19.1±2.2 kg.m^{-2} , ICA +/- 4/6) and 19 non-remitted (F/M 13/6, age 15.4±5.0 yrs, and BMI 18.3±2.0 kg.m^{-2}, ICA +/- 12/7)] cases. Compared to florid period, mean fasting blood glucose (FBG) and HbA_{1c} levels were decreased (p=0.000), while basal C-peptide (BCP) and insulin autoantibody (IAA) levels were increased significantly at clinical remission (p=0.000). Stimulated C-peptide (SCP) was also increased but did not reached to a significant level. Mean time to starting of remission was 53±29 days. Compared to remission values, mean FBG, HbAıc, and BCP did not change at 3rd month, and no change was observed in HbAıc and BCP at 6th month (p=0.007). However, at 12th month mean FBG increased (p=0.036) and BCP decreased (p=0.04), HbAıc did not changed from remission values. Insulin requirement in IU.kg^{-1}.day^{-1} have shown a slow trend from 0.6±0.3 at entry to 0.1±0.1 at 3rd month and 0.3±0.2 at 6th and 12th month (p=0.000 , p=0.007, and p=0.03 respectively). Results of insulin induced CR patients were also compared to 25 spontaneously occured CR patients while under conventional insulin therapy (F/M 4/21, age 21.1± 7.6 year, BMI 21.0 ±3.7 kg.m^{-2}, ICA+/-17/3 and time to remission; 211.4± 128.1 days, florid and remission BCP/SCP in ng.ml^{-1} were respectively 0.5±0.4 /1.7±0.3 and 1.3±0.5/2.3±0.7). Both BCP and SCP in spontaneous CR were increased more remarkably at remission. Trends in decreasing insulin requirement was slower than insulin induced CR patients. We conclude that male gender , older age at onset, normal BMI, lesser insulin requirement at onset are predictors of CR. Moreover, there is at least another form of CR occured spontaneously, the parameters mentioned above are even more remarkable along with better beta cell reserve than insulin induced CR.

373

FIRST-DEGREE RELATIVES OF NIDDM SUBJECTS HAVE REDUCED INSULIN SECRETION.

TW van Haeften, S Dubbeldam, ML Zonderland, and DW Erkelens. Utrecht University Hospital, Utrecht, The Netherlands.

We aimed to study insulin release in first degree relatives of NIDDM patients. Twenty-one normo-glucose tolerant relatives (mean± SEM age 45.4±1.3 yr, BMI 26.4±0.8kg/M^2, waist-hip ratio 0.803±0.015, aerobic capacity ($\dot{V}O_2$Max) 29.1±1.4 ml/kg/min) of NIDDM patients, and 21 normo-glucose tolerant controls matched individually for gender, age, BMI, waist-hip ratio and $\dot{V}O_2$Max underwent a hyperglycemic clamp (10 mMol/L, 180 min). First phase insulin release (0-10 min) was not significantly lower (logarithmic transformation, MANOVA, p=0.11). Second phase insulin release was lower in relatives (MANOVA, F=4.18, p=0.047). ANOVA showed lower plasma insulin levels from 120 minutes onwards in the relatives (all p<0.05); at 180 min geometric mean (95 %CI) plasma insulin levels were 55 (45 to 67) and 77 (61 to 97) mU/L. Insulin action assessed as Glucose Infusion Rate (GIR) divided by mean plasma insulin (I) during 2nd and 3rd hour of the clamp (GIR/I) was not different (both p>0.20); GIR/I_3 was 0.17-±0.01 vs 0.18±0.02 mg/kg/min/mU/L.

Conclusion: Normo-glucose tolerant first-degree relatives of NIDDM subjects have a decreased second phase insulin release. Insulin action is not markedly decreased.

374

INSULIN SECRETION AND RESISTANCE IN URBAN SOUTH INDIANS: ASSESSMENT BY HOMEOSTASIS MODEL ASSESSMENT (HOMA)

Mohan V, Premalatha G, Revathi S, Padma A, Deepa R, M.V.Diabetes Specialities Centre and Madras Diabetes Research Foundation, Madras, India.

A house to house survey was done in 3 areas in Madras city. A total of 613 subjects were studied. Investigations included fasting and post glucose (2 Hr) plasma glucose estimations and fasting and 2Hr plasma insulin levels. Insulin resistance and insulin sensitivity were derived by HOMA model. Fasting insulin levels were highest in those with Impaired Glucose Tolerance (IGT) (n = 98) 11.2 ± 20 Uu/ml followed by diabetics (n = 144) 7.0 ± 5.6 Uu/ml and those with Normal Glucose Tolerance (NGT) (n = 371) 6.7 ± 6.6 Uu/ml. However insulin secretion as assessed by HOMA was lower in diabetics compared to subjects with NGT 0.06 ± 0.05 vs 0.09 ± 0.08 but IGT subjects had higher values 0.14 ± 0.25. Insulin resistance was significantly higher in diabetic and IGT subjects 46.1 ± 45.6 and 47.5 ± 87.4 respectively compared to NGT subjects 26.1 ± 27.8 (P <0.001). Use of HOMA model provides reliable estimates of insulin secretion and resistance in epidemiological studies.

375

INSULIN SENSITIVITY, INSULIN SECRETION AND GLUCOSE EFFECTIVENESS IN SUBJECTS WITH NIDDM IN KOREA: A MINIMAL MODEL ANALYSIS

Yoon, KH., Jang, YJ., Ahn, YB., Han, JH., Lee, JM., Son, HS., Kang, MI., Cha, BY., Lee, KW., Son, HY., and Kang, SK., Catholic University Medical College, Seoul, Korea

The clinical characteristics of patients with non-onsulin dependent diabetes mellitus(NIDDM) in Korea are different from that of western countries and most of them are non-obese. Obesity is well known cause of insulin resistance. So insulin secretory defect would be more important role for the developement of diabetes in Korean NIDDM patients. Twenty subjects with NIDDM(8 male, 12 female: mean age 38.4 yr) were performed the 75 gram oral glucose tolerance test(oGTT) and insulin administration-modified frequently sampled intravenous glucose tolerance test (FSIGT). The insulin and glucose dynamics were analyzed by MINMOD computer program. The peak insulin levels after i.v. glucose load(PI) were significantly decreased in diabetic patients(98±77 pmol/L vs 361±290 pmol/L, $p<0.05$). S_I and S_G of diabetic patients were significantly lower than those of control subjects(SI : 1.84±1.13 vs 6.51±4.24 x 10^{-4} min^{-1}/ (uU/ml), $p<0.05$, S_G: 0.0191±0.0066 vs 0.0445 ± 0.0136 per min., p=0.0002) There was significant inverse correlation between S_I and waist/hip ratio($p<0.05$, r=-0.4). These results suggest that insulin resistance may be an important risk factor for obese old age onset NIDDM, while impairment of insulin secretion could be a major risk factor for non-obese young age onset NIDDM in Korea. Exogenous insulin administration-modified FSIGT is a useful tools for the assessment of insulin secretory capacity and resistance in normal and NIDDM patents with well controlled blood glucose levels.

376

QUANTIFICATION OF PANCREATIC RESPONSIVENESS DURING A STANDARDISED MEAL TOLERANCE TEST

R. Hovorka, L. Chassin, S.D. Luzio, D.R. Owens, City University, London, University of Cardiff College of Medicine, Cardiff, UK

We have quantified pancreatic responsiveness employing a novel model of C-peptide secretion during a standardised meal tolerance test (MTT). The model relates C-peptide secretion in a linear fashion to glucose concentration during MTT and defines (i) pancreatic sensitivity M_1 as an increase in C-peptide secretion per unit increment in plasma glucose concentration and (ii) basal pancreatic sensitivity M_0 as C-peptide secretion per unit plasma glucose concentration at fasting plasma glucose level. A population (standard) was used to derive values of transfer rate constants of a two compartmental model of C-peptide kinetics. MTT (75g CHO, 500kcal) was performed after overnight fast in 60 normal subjects (M:F: 27:33; age: 50±10 yrs; BMI: 26.4±5.0 kg/m^2; fasting plasma glucose: 5.2±0.5 mmol/L; mean±SD) and 26 subjects with newly diagnosed NIDDM (M:F: 20:6; age: 49±10 yrs; BMI: 31.0±4.0 kg/m^2; FPG: 11.9±3.0 mmol/L). Plasma C-peptide and glucose were measured every 10 to 30min over 180 min and employed to estimate indices M_1 and M_0. Subjects with newly diagnosed NIDDM showed reduced pancreatic sensitivity M_1 (21.8 ± 12.9 vs 87.2 ± 37.0 x 10^{-9}/min; NIDDM vs normal; $p < 0.001$) and basal pancreatic sensitivity M_0 (6.6 ± 3.1 vs 10.7± 4.0 x 10^{-9}/min, $p < 0.001$). M_1 and M_0 were estimated with excellent precision (CV < 15%) and were significantly correlated (r=0.50, p<0.001). Additional model-independent calculations confirmed that C-peptide secretion is linearly related to glucose concentration during MTT. We conclude that pancreatic responsiveness can be quantified with *precision* during MTT in both normal subjects and subjects with newly diagnosed NIDDM.

377

LEUCINE IS A BETTER PRIMING AGENT THAN ARGININE FOR INSULIN SECRETION IN GLICLAZIDE TREATED NIDDM

D R Matthews & O Boland - Oxford Diabetes Centre, Radcliffe Infirmary, Oxford OX2 6HE

Both branch chain amino acids and charged ionic amino acids stimulate insulin scretion from the beta-cell, but the mechanisms are different: we wished to examine synergistic effects with sulphonylurea therapy. Eight gliclazide-treated non-insulin-dependent diabetic patients were studied on two occasions with a protocol of basal observation for 30min, 60 min infusion of randomised leucine or arginine and a further 90 min hyperglycaemic clamp. Basal glucose concentration was the same on both occasions (mean 7.82mmol/l leucine study vs 7.79 mmol/l arginine study; p=ns.) and the glucose declined to 7.50 mmol/l and 7.25mmol/l respectively by 30min. After leucine infusion the declination of glucose continued, but levelled out or reversed with arginine, such that by the end of the infusions, glucose levels were 6.63±0.69mmol/l (leucine) and 7.62±0.67mmol/l (arginine);$p<0.02$. Arginine caused a sharp rise in insulin secretion (17.8.mU/l to 43.8mU/l in six minutes) at the onset of the infusion and thereafter insulin secretion was not significantly different throughout either the amino acid or hyperglycaemic clamp periods (mean 42.1 mU/l, vs. 44.7 mU/l respectively; p=ns). By contrast the leucine infusion caused little acute change in secretion but augmented with time from basal 17.2 mU/l to end of infusion 29.4mU/l.. During the hyperglycaemic clamp period there was significant further augmentation of insulin secretion rising to 81.6±16mU/l at the end of the study. Leucine significantly augmented insulin secretion compared to arginine (81.6±16 vs. 54.0±8.4 mU/l respectively $p<0.002$). These data suggest that leucine is a better priming agent for sulphonylurea than arginine. Additive effects on insulin secretion may allow one to use combinations of branch chain amino acids and sulphonylureas to augment insulin secretion in the presence of hyperglycaemia.

378

INTERIM REPORT FROM AN INTERNATIONAL WORKSHOP FOR THE COMPARISON OF AMYLIN ASSAYS

S.E. Manley and C.N. Hales on behalf of the participating laboratories, Oxford UK and Cambridge, UK

Amylin is a 37 amino acid peptide that is cosecreted with insulin by pancreatic β-cells in response to nutrients. Since amylin's discovery in 1987 many researchers have initiated studies to investigate its potential biological functions and physiological roles. Several laboratories have reported plasma amylin concentrations using different immunoassay techniques. We therefore established a workshop to compare the amylin assays since it is important to know to what extent they produce comparable results. A total of 10 amylin assays were compared from 8 separate participating laboratories. The represented methodologies included both ELISA and RIA with either solid phase, liquid phase, or no pre-assay extraction requirement. Six different primary antibodies or antibody pairs were represented. Blinded plasma samples including pools from Type I diabetic, fasting non-diabetic (F), glucose stimulated non-diabetic (S) and glucose stimulated IGT subjects were analyzed by each laboratory using both the individual laboratory's standard curve and a supplied common standard (F and S were each submitted as 3 blinded individual samples in order to assess intra-lab imprecision). The median (interquartile range) intra-lab %C.V was 11.1% (4.6%-38.3%) and 8.4% (4.2%-16.6%) for F and S respectively when the common standard was used. Results between labs, however, had several fold differences in values for samples in the quantitative range of the assays (see table below).

Sample	Median (pM)	Interquartile Range (pM)	Min - Max (pM)
Type I	1.6	0.3 - 3.6	0.1 - 5.4
F (mean of 3)	4.4	2.1 - 6.9	1.4 - 14.3
S (mean of 3)	8.9	5.6 - 11.8	4.1 - 18.5
IGT	13.3	8.6 - 25.3	3.5 - 33.3

We conclude that variation between individual laboratories makes it currently difficult tc compare plasma amylin results between labs. Since it has been reported that circulating amylin is heterogeneous, it is possible that the variation seen in this comparison is due, at least in part, to differences in assay specificity. Further investigation, including additional sample comparisons, will be completed before recommendations are made.

379

THE EFFECT OF ONE MONTH CORTICOTHERAPY ON GLUCOSE TOLERANCE AND INSULIN SECRETION

J.Krassowski,M.Godziejewska,P.Soszyński,H.Jastrzębska,M.Gietka-Czernel and T.Górowski. Dept. of Endocrinology, Medical Centre of Postgraduate Education,Warsaw,Poland.

Chronic corticotherapy deteriorates glucose tolerance and induces insulin resistance. Earlier reports suggested that chronic effects of corticotherapy may be less pronounced than the acute ones. The aim of the sudy was to compare the acute (one week) and chronic (one month) effects of corticotherapy on glucose tolerance and insulin secretion. Three glucose tolerance tests were done in a group of 12 euthyroid patients with Graves' ophthalmopathy: before therapy, after one week and after one month of prednisone administration in a daily dose of 60mg. Basal glucose levels did not change during therapy. Glucose levels at 60 and 120 min were higher than pretreatment values but the differences were not significant. Glucose levels at one week and at one month were not different. In 5 patients glucose tolerance was unchanged during therapy, in 5 patients it deteriorated, in one patient glucose tolerance improved after prednisone and in one patient diabetic curve was noted. Basal insulin (IRI) levels increased from 24.3 μU/ml to 42.2 μU/ml ($p<0.001$) after a week and to 35.8 μU/ml ($p<0.01$) after a month. IRI levels at 60 and 120 min were significantly higher during treatment when compared to pretreatment IRI levels but again there was no difference in IRI levels at one week and at one month. The analysis of variance (ANOVA) showed significant difference in insulin response during treatment ($F=17.62481, p<0.00001$),while this cannot be demonstrated for glucose levels. It is concluded that 1) the administration of prednisone 60 mg/d for one month markedly increases insulin response while only slightly deteriorating glucose tolerance and 2) glucose tolerance and insulin response at one week and at one month are not different.

380

MEASURING INSULIN SECRETION: ACCURACY AND EFFECT OF SAMPLING SCHEDULE

R Hovorka, E Koukkou, D Southerden, JK Powrie, and MA Young, City University, London, St Thomas' Hospital, London, Glaxo Wellcome plc, Greenford, UK

We have evaluated the accuracy of calculations of pre-hepatic insulin secretion during a simulated meal tolerance test (MTT) using the standard population model of C-peptide kinetics (POP-MOD). Five normal male subjects (N) (age: 36±2 yrs; BMI: 22.7±0.8 kg/m^2; mean±SE) and five male diet-treated patients with NIDDM (D) (age: 49±4 yrs; BMI: 26.8±2.1 kg/m^2) received a variable infusion of biosynthetic human C-peptide (I-BHCP) mimicking pre-hepatic insulin secretion during MTT while endogenous C-peptide secretion was suppressed. Plasma C-peptide was measured every 5 min for 240 min. POP-MOD and a deconvolution method were used to reconstruct I-BHCP from the measurements. Total infusion rate was estimated with clinically acceptable bias (N: 13±9; D: 19±4%; mean±SE) which was not significantly different from zero. Similar bias (p=NS, ANOVA) was observed when calculations were based on samples taken at 15 min intervals (N: 8±8; D: 20±4%) and 30 min intervals (N: 13±9; D: 21±4%). Root mean square error measuring the average deviation between the infused and calculated BHCP was also independent of the sampling frequency (N: 1.2±0.2; D: 1.3±0.2 pmol/kg/min). We conclude that this methodology can accurately estimate post-prandial total C-peptide secretion both in normal subjects and subjects with NIDDM thus obviating the need for individual estimates of C-peptide kinetics. Plasma C-peptide samples need only be drawn at 30 minute intervals.

381

INSULIN SECRETORY CAPACITY AND EXOCRINE PANCREATIC FUNCTION IN PATIENTS WITH MALNUTRITION-RELATED DIABETES MELLITUS

L. Rossi[1,2], S. Parvin[2], L. Ali[2], Z. Hassan[2], A.K. Azad Khan[2] and K Gyr[1]. University Hospital, Basel[1], Switzerland, and Bangladesh Institute of Research and Rehabilitation in Diabetes, Endocrine and Metabolic Disorders (BIRDEM)[2], Dhaka, Bangladesh.

The relationship between endocrine and exocrine pancreatic functions in patients with Protein Deficient Diabetes Mellitus (PDDM) and Fibrocalculus Pancreatic Diabetes (FCPD), the two subtypes of Malnutrition-Related Diabetes Mellitus (MRDM), is still unclear. Recent ERCP data of cases with FCPD and TCP (non-alcoholic Tropical Calcific Pancreatitis without diabetes) suggest that the severity of pancreatic damage does not follow a straightline relationship with the development of diabetes. The present study was undertaken to explore this relationship in greater detail using arginine stimulation test as a measure of insulin secretory capacity and secretin stimulation test as an indicator of exocrine pancreatic function. Six patients with PDDM (5male/1female; BMI 17±1 (M±SD); HbA1c 15.6±3.1%) and 3 patients with FCPD (3m; 16±3; 15.2±3.9%) along with 6 nondiabetic controls (6m; 18±1; 5.1±0.4%) and 3 patients with TCP (2m/1f; 20±3; 5.4±0.5%) were studied. Arginine HCl (1.4 mval/kg/30 min) was infused i.v. and blood taken at 15 min. intervals to assess plasma C-peptide (EIA) and glucose. Secretin (1 CU/kg/60 min) was infused i.v. and duodenal juice collected at 15 min. intervals via a duodenal tube using marker perfusion technique. Bicarbonate output was measured and is presented as area under the curve. The results (M±SD) are as follows:

	BIC (AUC)	C-PEPTIDE pmol/l		GLUCOSE mmol/l	
	mmol/60min	0 min	30 min	0 min	30 min
Control (n=6)	248 ± 79	636 ± 113	1173 ± 257†	4.5 ± 1.2	5.1 ± 0.7
PDDM (n=6)	180 ± 129	301 ± 138	604 ± 315‡	15.2 ± 2.1	16.3 ± 3.4
FCPD (n=3)	37 ± 17*	361 ± 104	607 ± 203	12.3 ± 4.5	13.6 ± 3.5
TCP (n=3)	28 ± 16*	753 ± 351	1754 ± 829	4.5 ± 0.5	5.2 ± 0.1

* $P < 0.01$ vs. Control. † $P < 0.01$ vs. 0 min. ‡ $P < 0.05$ vs. 0 min.

The data shows that exocrine pancreatic function is fairly well-preserved in PDDM cases, and insulin secretory capacity may be highly dissimilar in FCPD and TCP groups inspite of similar levels of exocrine dysfunction. Although the patient numbers are very low the present data reinforces the earlier impression that factors other than generalized pancreatic damage are also involved in the development of diabetes in FCPD.

382

INTERFERENCE BY ANTI-MURINE ANTIBODIES IN C-PEPTIDE ASSAY KITS

T.Shimizu, F.Sasakuma, K.Hasegawa and A.Sasaki. Osaka Medical Center for Cancer and Cardiovascular Diseases, Osaka, Japan.

Anti-murine antibodies (HAMA) are known to interfere immunoassay using mouse monoclonal antibodies (mmab). We have studied the interference by HAMA in three commercial C-peptide assay kits sold in Japan: Daiichi C-peptide kit III(method 1), Tosoh IIC-peptide (method 2) and Shionogi C-peptide RIA (method 3). Method 1 is a two antibody competitive RIA and uses mmab for the second antibody. Method 2 is a two-site immunometric assay and uses mmab for detection antibody. Method 3 is a one antibody competitive RIA and uses rabbit polyclonal antibody. Serum HAMA level was assayed using Immunostrip HAMA IgG(Immunomedics, USA). Case 1 was a 3-year-old DM and case 2 was a 74-year-old DM. Both cases were HAMA (+). Interference was noticed in method 1. In case 2, peak of the interference came 16 months after that of HAMA. No interference was observed in method 2. Treatment of serum by polyethyleneglycol or protein A eliminated interference in method 1. When the second antibody of method 1 was changed to rabbit polyclonal antibody, CPR values were close to those by method 3. Addition of mouse immunoglobulin (mIg, ~2000 μg/ml) to assay buffer decreased interference, although weak interference still remained. Pretreatment of serum with magnetic particle bound mIg (150μg/ml) completely eliminated interference, showing that all interference was due to HAMA. We conclude that method 1 is vulnerable to interference by HAMA.

	[case 1]	[case 2] 0	5	21	29	42 Months
R1	4.1	1.0	4.2	14	8.0	2.7
R2	0.91	-	-	0.94	0.94	0.97
HAMA	45	3	460	287	65	12 (ng/ml)

R1 and R2 denote the ratio of CPR values by method 1 and by method 2 to those by method 3, respectively.

383

ALTERED ANTIOXIDANT/PRO-OXIDANT HOMEOSTASIS AND INSULIN SECRETORY RESPONSE IN DEVELOPMENT OF DIABETES FROM OBESITY

G. Kocić, D. Pavlović, R. Kocić, T. Cvetković, M. Milenović, S. Živić, S. Radenković and D. Mikić. University of Niš, Niš, Yugoslavia.

The study was performed with the aim: to obtain the evidence whether decreased antioxidative defence mechanism, accompained with increased oxidative stress, can reflect an evolution of diabetes from obesity; to establish the possible relationship between insulin secretory response and antioxidant/pro-oxidant homeostasis, as well as the extent of changes in their responsivity during glucagon stimulation. The study included 24 obese healthy subjects(BMI=35.81±4.33) and 12 obese patients considered as diabetics (BMI=33.66±5.67), as well as 20 control normal-weight, age-matched subjects (BMI=20.03±3.12). Total plasma antioxidative capacity (TPAC) progressivelly decreased from obesity toward diabetes (66.05±5.21% $p<0.001$ in obese diabetics vs 72.3±2.45% $p<0.05$ in obese and 84.8±5.09% in control subjects), together with plasma GSH (4.08±0.81 $p<0.05$ in obese diabetics vs 4.96±2.07 in obese and 6.3±1.12 nmol/l in control) and marked decrease of Er GSH (0.72±0.12 $p<0.001$ in obese diabetics vs 1.05±0.03 $p<0.05$ in obese and 1.25±µmol/mlRBC in controls).The increase of plasma MDA was significant in obese diabetics (6.28±1.56 $p<0.001$) compared with obese (4.12±0.76) or controls (3.67±1.02µmol/l). The increase of Er lipid peroxidation was shown to occur in basal state (3.53±0.28 $p<0.05$ in obese diabetics vs 3.23±0.36 $p<0.05$ in obese and 2.75±0.34nmolMDA/ml in control) and increased susceptibility to oxidative stress (7.92±0.44 $p<0.05$ in obese diabetics vs 7.66±0.28 in obese and 7.12±0.83nmolMDA/ml RBC). All parameters were measured simultaneously in basal state and after glucagon stimulation. Glucagon-stimulated insulin release was accompained with the increase of plasma GSH (29.64±7.05% $p<0.05$ in obese vs 6.13±1.95% in obese diabetics) and decrease of plasma and Er MDA (-13.26±-7.93 in obese vs -7.94±5.33% in obese diabetics). Positive correlation was found between the percent of rise of C-peptide and plasma GSH ($r=0.58$ $p<0.05$). Obtained results suggest that the insulin-secretory potential could be functionaly dependent on the plasma and Er redox state. The progressive deterioration of TPAC, plasma GSH and Er GSH from obese subjects to obese diabetics, could point to evolution of diabetes from obesity and progressive loss of insulin secretory reserve due to increased oxidative stress.

FASTING GLUCOSE CONCENTRATION HAS A GREATER EFFECT THAN BMI ON INSULIN PULSATILITY IN NORMAL SUBJECTS

S. Ahmed and D.R. Matthews. Oxford Diabetes Centre, Radcliffe Infirmary, Oxford, England.

Basal insulin pulsatility, which is found in normal individuals, is known to be reversibly diminished in both mild hyperglycaemia and obesity. To address the question of the importance of obesity or glucose concentration on this effect we have studied 23 normoglycaemic subjects (11F,12M) for 120 minutes in the basal state taking 1-min samples assayed for glucose and insulin. Data were analysed by mean concentration and by Fourier Transform analysis to examine for insulin pulsatility. Overall insulin pulsatility could be detected with a peak oscillatory periodicity between 9 and 15 min. When split by mean fasting glucose level of 5.1mmol/l (range 4.51 to 5.87mmol/l; group size 11 and 12 subjects) there was less oscillatory activity in those with the higher basal glucose concentration which was significantly different (ANOVA 3-20 mins: $p=0.037$) and most significant at 15min oscillatory period $p<0.025$ (paired t). This was reproduced by sub-group analysis where the changes were more apparent in a best-six v worst-six comparison. By contrast, when the data were divided by median Body Mass index 25 (BMI range 19.3 to 37.53kg/m^2; group size n=11 & 12) there was no differences in the FT profile (p NS). Thus we conclude that even within the normal range, those with a higher fasting plasma glucose have less oscillatory insulin activity. It is not possible from these data to decide whether the reduction of oscillations is the cause or the effect of the elevated glucose concentration.

Insulin Secretion in Vitro: Ion Channels and Oscillations

386

ß-CELL DYSFUNCTION IN THE 'FINNISH TYPE' OF NEONATAL HYPERINSULINISM WITH NO IDENTIFIED MUTATIONS IN K_{ATP} CHANNEL GENES.

K. Cosgrove, T. Otonkoski, J.C. Chapman, M.N. Hashmi, C. Ämmälä, R.M. Shepherd, J. Komulainen, H. Huopio, P. Thomas, and M.J. Dunne. Children's Hospital, Helsinki University, Finland, Pediatrics Departments, Kuopio University, Finland, Michigan University at Ann Arbor, USA and Biomedical Science, Sheffield University, UK.

Mutations in the genes encoding subunits of the ß-cell K_{ATP} channel (i.e. SUR1 and $K_{IR}6.2$) cause familial persistent hyperinsulinaemic hypoglycaemia of infancy (PHHI). In Finland, the phenotype of the disease is generally severe, necessitating pancreatectomy in the affected infants. Other unique clinical features include high frequency of premature birth (47%) and gestational diabetes (28%). The majority of the known cases (n=19 since 1983) originate from a limited area in central Finland, suggesting a common recessive gene. Two cases were analysed by direct sequence analysis of the SUR1 and $K_{IR}6.2$ genes. None of the known mutations were found, and 19 (of 39) SUR1 exons and the entire coding sequence of $K_{IR}6.2$ revealed wild-type sequence. We have now examined the function of insulin-secreting cells in a familial Finnish patient with a severe form of PHHI. The patient did not respond to treatment with diazoxide, and responded poorly to octreotide. Near-total pancreatectomy was performed, and islet-like cell clusters (containing ~15% ß-cells) isolated for in vitro studies of ion channels and intracellular Ca^{2+} homeostasis. In situ patch-clamp recordings, whole-cells and inside-out patch studies consistently revealed the absence of functional K_{ATP} channels in the presence of the channel agonists diazoxide (0.5mM, n=10), and somatostatin (100nM, n=8) and under 'ATP-free' conditions (n=8). The loss of K_{ATP} channel function was associated with the appearance of action potentials in intact cells, consistent with an inability of PHHI ß-cells to maintain a normal resting membrane potential. $[Ca^{2+}]_i$ responses to glucose (15mM), KCl (40mM), tolbutamide (0.1mM), and diazoxide (0.5mM), all of which affect ß-cells through depolarization-response coupling, were not seen in PHHI ß-cells. Islets were, however, responsive to agonists that are not strictly dependent upon voltage-gated Ca^{2+} influx, such as acetylcholine. In summary, isolated ß-cells from patients with the 'Finnish' PHHI phenotype lack functional K_{ATP} channels and this is associated with generation of Ca^{2+} action potentials.

DEMONSTRATION OF TETRODOTOXIN-INSENSITIVE Na^+ OSCILLATIONS IN GLUCOSE-STIMULATED β-CELLS

E. Grapengiesser. Department of Medical Cell Biology, Biomedicum, Box 571, S-751 23 Uppsala, Sweden.

Glucose promotes the turnover of Na^+ in β-cells both by enhancing the entry of the ion and providing the ATP required for the extrusion by the Na/K pump. Recent studies have demonstrated glucose-induced oscillations of the cytoplasmic Na^+ concentration ($[Na^+]_i$), which were amplified by opening of the voltage-dependent Na^+ channels by veratridine. In the present study it was analyzed if glucose-induced $[Na^+]_i$ oscillations are affected by cyclic AMP, which has been proposed to facilitate entry of Na^+ through an unspecific cation channel. $[Na^+]_i$ was measured in individual mouse β-cells with dual wave-length fluorometry using the indicator SBFI. Small oscillations of $[Na^+]_i$ (amplitude 1-4 mmol/l; frequency 0.2-0.5/min) were observed in the presence of 11 mmol/l glucose during perifusion with media containing either 1.3 mmol/l Ca^{2+} or 5 mmol/l Sr^{2+}. The amplitudes of the oscillations increased to 5-15 mmol/l after introduction of 10 nmol/l glucagon or 1 mmol/l 8-Br cAMP. These oscillations remained unaffected by 3 µmol/l tetrodotoxin. However, the oscillations disappeared when lowering glucose to 3 mmol/l or adding 10 µmol/l methoxyverapamil, 400 µmol/l diazoxide or 0.1 µmol/l clonidine. It is concluded that glucose-stimulated pancreatic β-cells exhibit oscillations of $[Na^+]_i$ also in the presence of tetrodotoxin and that this rhythmicity will be particularly pronounced after raising cyclic AMP.

REGULATION OF PHOSPHOLIPASE C - LINKED CA^{2+}-SIGNALING AND INSULIN SECRETION BY K_{ATP}-CHANNELS IN CLONAL BETA CELLS

C. Schöfl, T. Mader, J. Börger, A. von zur Mühlen, and G. Brabant. Abteilung Klinische Endokrinologie, Medizinische Hochschule Hannover, Germany.

Modulation of the ATP-sensitive K^+ current (I_{KATP}) is central to glucose-induced Ca^{2+} signaling and insulin secretion. Agonists coupled to phospholipase C (PLC), like arginine-vasopressin (AVP) and bombesin, cause frequency-modulated Ca^{2+} transients and enhance insulin release under conditions where glucose is elevated. Thus, modulation of I_{KATP} activity by glucose may interact with PLC-linked Ca^{2+} signaling and insulin secretion. To test this hypothesis we investigated the effects of I_{KATP} modulation on AVP or bombesin-induced Ca^{2+} signals and insulin secretion. Intracellular free Ca^{2+} ($[Ca^{2+}]_i$) was measured in single fura-2 loaded HIT cells and insulin secretion was determined from cell populations. In the presence of glucose (10 mM) tolbutamide (3-300 μM) which inhibits I_{KATP} by binding to the sulfonylurea receptor increased the frequency and sometimes the amplitude of the AVP- and bombesin-induced Ca^{2+} transients, or switched the Ca^{2+} transients to a plateau-like rise in $[Ca^{2+}]_i$. Diazoxide (10-100 μM), which activates I_{KATP}, lowered $[Ca^{2+}]_i$ in the presence of glucose (10 mM), reduced the frequency and sometimes the amplitude of the Ca^{2+} transients, or stopped them in a subset of cells. Glucose deprivation decreased the frequency and amplitude of AVP-induced Ca^{2+} transients and lead to their complete cessation, which was partly antagonized by tolbutamide. In the presence of glucose (10 mM) AVP or bombesin-induced insulin secretion from populations of HIT cells was potentiated by tolbutamide and inhibited by diazoxide. In glucose-free medium, AVP or bombesin-stimulated insulin release was reduced, but was potentiated by tolbutamide. Thus, modulation of I_{KATP} by glucose or pharmacological interventions critically regulates PLC-linked Ca^{2+} signaling and insulin secretion from HIT cells presumably by modulating voltage-gated Ca^{2+} influx. (Supported by DFG Scho 466/1-3)

GLUCOSE-INDUCED PULSATILE RELEASE OF INSULIN INDEPENDENT OF ATP-SENSITIVE K^+ CHANNELS

J. Westerlund, H. Ortsäter, F. Palm, T. Sundsten and P. Bergsten; Department of Medical Cell Biology, University of Uppsala, Uppsala, Sweden

Glucose-induced cyclic variations in the permeability of the ATP-sensitive K^+ channel in pancreatic β-cells result in periodic depolarization and entry of Ca^{2+} and oscillations in the cytoplasmic Ca^{2+} concentration ($[Ca^{2+}]_i$). These oscillations occur in parallel with the pulsatile release of insulin and have been suggested to regulate the secretory pulses. However, pulsatile release of insulin has also been observed under conditions with a stable $[Ca^{2+}]_i$ such as at non-stimulatory glucose concentrations or after depolarization with tolbutamide or K^+. We have now investigated whether variations in the ATP-sensitive K^+ channel activity are required for the generation of glucose-induced pulsatile insulin release from individual islets of Langerhans using a sensitive ELISA for determination of insulin. When the islet β-cells were depolarized by 30.9 mM K^+ and their ATP-sensitive K^+ channels were continously opened by 400 µM diazoxide, insulin release was oscillatory with a frequency of 0.41 ± 0.04 per min whereas $[Ca^{2+}]_i$ was stable and elevated in the presence of 3 mM glucose. When the glucose concentration was increased to 11 or 20 mM glucose, the amplitude of these insulin oscillations increased whereas their frequency was unaffected. The results show that glucose-induced pulsatile release of insulin can occur independently of variations in the ATP-sensitive K^+ channel activity or $[Ca^{2+}]_i$ of islet β-cells and indicate that other factors, possibly an oscillatory metabolism, are important for the generation of pulsatile release of insulin.

PROPERTIES OF ION CHANNELS AND THE REGULATION OF INSULIN SECRETION IN THE NOVEL GLUCOSE-RESPONSIVE β-CELL LINE, BRIN-BD11.

J.C. Chapman, K. Cosgrove, N.H. McClenaghan, C. Ämmälä, P.R. Flatt and M.J. Dunne. Biomedical Science, Sheffield University, Sheffield, UK, and School of Biomedical Science, Ulster University, Coleraine, N. Ireland, UK.

We recently cloned a β-cell line by the electrofusion of normal rodent β-cells and the immortal RINm5F insulin-secreting cells. These cells - BRIN-BD11, display a normal concentration-related glucose-responsiveness. In this study we have extensively investigated the properties of K^+ channels in BRIN-BD11 cells using patch-clamp techniques, and also characterised the effects of pharmacological regulators of ion channels on insulin release. At sub-stimulatory concentration of glucose (2mM), openings from K_{ATP} channels were routinely observed in the intact cell-attached patch configuration (n=40). These channels were inhibited by the presence of higher glucose concentrations (15mM) and by tolbutamide (TOL, 0.2mM) and the imidazolines efaroxan (EF, 0.2mM) and phentolamine (PHE, 0.2mM). At equivalent concentrations TOL, EF and PHE were all able to initiate insulin secretion from BRIN-BD11 cells (2mM glucose) and potentiate the actions of higher glucose concentrations (n=6). This is consistent with the inhibition of K_{ATP} channels. In addition, K_{ATP} channels were activated by both diazoxide and pinacidil (0.2-0.4mM), and both compounds inhibited glucose-, TOL-, EF- and PHE-induced insulin secretion in parallel experiments (n=6 replicates each). Whole-cell studies revealed the presence of inward currents (carried by Ca^{2+} and/or Na^+) and outward K^+ currents resulting from voltage-gated K_{Ca} and delayed rectifier K^+ channels; these currents were sensitive to TEA^+ and quinine (n=6). Finally, inside-out patches (n=42) were used to assess the biophysical properties and nucleotide-dependent regulation of K_{ATP} channels. Current-voltage relationship plots revealed an inward rectification to the I-V profile with a linear inward conductance of approximately 60pS. In isolated patches K_{ATP} channels underwent 'run-down', they were inhibited by ATP (10μM-1mM; IC_{50}=~30μM), and were sensitive to ADP (0.01-1mM) added alone and in combination with ATP. In summary, BRIN-BD11 cells show many features of ion channel function that resemble native β-cells indicating that they are an important model cell for *in vitro* studies of the regulation of insulin secretion.

391

VOLTAGE–INDEPENDENT Ca^{2+} CHANNELS DO NOT MEDIATE THE SLOW Ca^{2+} OSCILLATIONS IN β-CELLS

S. Dryselius, E. Gylfe and B. Hellman. Department of Medical Cell Biology, Uppsala University, Sweden

Single pancreatic β-cells respond to stimulating concentrations of glucose with 2-5 min oscillations of the cytoplasmic Ca^{2+} concentration. It is generally believed that these oscillations reflect periodic entry of Ca^{2+} into the β-cells. There is extensive evidence that repetitive depolarization with opening of voltage-dependent Ca^{2+} channels (VDCCs) is the underlying phenomenon. However, it has also been claimed that the oscillations are mediated by specific voltage-independent channels (VICCs). The latter conclusion was based on lack of effect of the L-type VDCC blocker nifedipine and the observation that Mn^{2+}, which supposedly does not enter VDCCs, permeates into glucose-stimulated β-cells. We have now used these tools to evaluate the possible involvement of VICCs in the generation of glucose–induced slow Ca^{2+} oscillations. It is demonstrated that rapid influx of Mn^{2+} into mouse β-cells requires depolarization and is blocked by 5 μmol/l nifedipine. This concentration also abolished the glucose–induced Ca^{2+} oscillations. Moreover, parallel measurements of cytoplasmic Ca^{2+} and electrical activity demonstrated that the oscillations occur in synchrony with bursts of action potentials. We conclude that the slow oscillations of Ca^{2+} in glucose–stimulated β–cells reflect periodic openings of VDCCs.

392

HIGH EXPRESSION OF *TRP*, A PUTATIVE CALCIUM-RELEASE ACTIVATED CHANNEL IN MOUSE INSULINOMA CELLS

H. Sakura and F.M. Ashcroft. University Laboratory of Physiology, Oxford, UK

Insulin secretion is stimulated by glucose, hormones and neurotransmitters. Both activation of a non-selective cation current and activation of a Ca^{2+} current in response to depletion of intracellular Ca^{2+} stores have been suggested to play a role in this stimulation. The properties of these currents resemble those reported for the Drosophila gene *trp*. The aim of this study was to determine whether *trp*-related genes are expressed in pancreatic β-cells. We used RT-PCR and Northern blot analysis to examine expression of *trp* genes in the mouse insulinoma cell line (MIN6) and in pancreatic islets. Of the six known mammalian *trp*-related genes (*trp*1-6), only *trp*1 was expressed at high levels in MIN6 cells. We cloned the murine *trp*1 cDNA from a MIN6 cDNA library and identified four variants (α, β, γ and δ), generated by alternative splicing near the N-terminus. In vitro translation showed that only the α and β splicing variants are efficiently expressed. The β variant is the dominant form in MIN6 cells and mouse pancreatic islets, whereas the α variant is the major type in the mouse brain. Functional studies suggest that the human *trp*1 β-variant encodes a non-selective cation channel, activated by depletion of intenal Ca^{2+} stores. This suggests that murine *trp*1 may also encode a non-selective cation channel in β-cells.

393

POTENTIATION OF SULPHONYLUREA-INDUCED INSULIN SECRETION BY EFAROXAN INVOLVES BLOCKADE OF α2-ADRENOCEPTORS.

M. Mourtada, C.A. Brown, S.L.F. Chan, S.A. Smith*, V. Piercy* and N.G. Morgan. Dept. of Biol. Sci., Keele University, Staffs ST5 5BG.*Dept. of Vascular Biology, SmithKline Beecham Pharmaceuticals, Welwyn, Herts.

Imidazoline compounds and sulphonylurea drugs each stimulate insulin secretion from the pancreatic B-cell and can also interact functionally to generate an enhanced secretory response *in vivo* and *in vitro*. In the present study we have used the two enantiomers of the imidazoline efaroxan (efx) to investigate whether potentiation of the secretory response to glibenclamide (glib) reflects binding to the islet imidazoline receptor or whether α2-adrenoceptor antagonism is more important. (+)Efx is a potent α2-antagonist and when administered to Wistar rats (3.5mg/kg) together with glib (2.5mg/kg), it caused a marked increase in circulating insulin beyond that in response to glibenclamide alone. (-)Efx (the more potent imidazoline ligand) failed to potentiate the insulin response to glib. Equivalent data were obtained with isolated rat islets incubated *in* vitro where (+)efx did not alter insulin secretion itself at concentrations up to 50μM but dose-dependently enhanced the response to 1μM glib ((+)Efx: 0.7±0.06 ng/islet/h; glib: 1.2±0.15; (+)Efx&glib: 2.3±0.2; P<0.001) . By contrast, (-)efaroxan (25μM) provoked an insulin secretory response but did not further enhance the response to glibenclamide ((-)Efx: 1.4±0.15 ng/islet/h; glib: 1.25±0.15; (-)Efx&glib: 1.5±0.18). When isolated islets were treated with 1μM phenoxybenzamine to block the α2-adrenoceptors, (+)efaroxan failed to potentiate the secretory response to glibenclamide ((+)Efx: 1.3±0.10 ng/islet/h; glib: 2.3±0.2; (+)Efx&glib: 2.1±0.2). Similar results were obtained when the α2-adrenoceptors were down-regulated by exposure to the agonist UK14304 (10μM) or when they were uncoupled by treatment with 200ng/ml pertussis toxin. None of these treatments prevented the stimulation of insulin secretion by (-)efaroxan or glibenclamide, alone. Thus, the results indicate that the ability of efaroxan to enhance the insulin secretory response to glibenclamide does not result from interaction with imidazoline receptors but suggest that it occurs as a consequence of the blockade of islet α2-adrenoceptors.

EXPRESSION OF CALCIUM CHANNEL SUBUNITS IN PANCREATIC β-CELLS OF OLD RATS

J. Hildenbrand, M. Rönfeldt-Büttel and H.P.T. Ammon. Department of Pharmacology, Institute of Pharmaceutical Sciences, University of Tübingen, Federal Republic of Germany.

Age in men is often associated with the development of NIDDM (non insulin dependent diabetes mellitus). One of the major pathological effects in NIDDM is a reduction in the ability of pancreatic β-cells to respond appropriately to an increase in the blood glucose. Ca^{2+} influx through voltage dependent L-type calcium channels and consequent increase in cytosolic calcium are accepted as crucial steps in insulin secretion. Islets of old rats have been shown to exhibit decreased Ca^{2+} influx and impaired insulin secretion. The aim of our study is to investigate the influence of age per se on the subunit expression of the L-type calcium channel. We characterized in islets of 2 year old rats the α_{1C}, α_{1D}, β_3 and $\alpha_2\delta$ subunit messages of the L-type calcium channel representing the subtypes which have been shown to be mainly expressed in the pancreas. Oligonucleotide primers were designed to amplify by RT-PCR regions specific to the subunits. The amplification products were verified by southern blotting and non-radioactive hybridization. Compared to young rats the cardiac isoform α_{1C} message was found in islets of old rats at much lower levels. The expression of the neuroendocrine subtype α_{1D} was in age also significantly reduced. The levels of the $\alpha_2\delta$-complex detected in old rats were slightly different compared to young rats. But the expression was also reduced. In contrast to the other subunits we observed for the β_3 in both tissues equal expression. This down-regulation of L-type calcium channel subunits suggests that the changed expression may contribute to the impaired insulin secretion associated with age. Our results indicate that this defect may be caused by decreased transcription of genes encoding β-cell L-type calcium channel subunits. These alterations in the stimulus secretions coupling process during aging could therefore have important implications for the development of NIDDM.

395

IMPAIRED EFFECT OF SULFONYLUREA ON ATP SENSITIVE K^+ CHANNEL BY INHIBITION OF METABOLISM IN β CELLS

E Mukai, H Ishida, Y Tsuura, N Yasuda, S Ueda, K Tsuda and Y Seino, Kyoto University Faculty of Medicine, Kyoto, Japan.

Sulfonylureas becomes less potent to reduce blood glucose levels according to the severity of NIDDM. We have reported that glucose metabolism in pancreatic β cells is impaired under NIDDM. Using dinitrophenol (DNP) which inhibits mitochondrial metabolism, we examined insulin secretory capacity, K_{ATP} channel activity and binding for sulfonylurea receptor (SUR) or K_{ATP} channel protein (BIR) using glibenclamide and cibenzoline. The augmentation of insulin secretion by glibenclamide was disappeard under 100μM DNP, but that by cibenzoline was intact. In experiments using patch-clamp techniques, the dose dependency of glibenclamide for K_{ATP} channel inhibition was observed to shift the right from IC_{50} of 3.04nM to 51.3nM under 100μM DNP in cell-attached mode. In inside-out mode, dose-dependent inhibition of K_{ATP} channel was observed under 10μM ATP, but under 0.1μM ATP K_{ATP} channels were not closed even at high concentration of glibenclamide (1μM). On the other hand, cibenzoline also inhibited K_{ATP} channels dose-dependently in cell-attached mode, but IC_{50} was not changed under 100μM DNP (41.5μM vs 40.7μM). The binding of [^{3}H]-glibenclamide to β cells was equally displaced by unlabelled glibenclamide with and without 100μM DNP. In bindng experiment using expressed protein of SUR or BIR, glibenclamide bound to SUR only, but cibenzoline also bound to BIR. These data indicate that uncoupling between SUR and BIR is involved in impaired inhibition of K_{ATP} channels and dissappearance of insulin secretory augmentation by glibenclamide under inhibiton of metabolism in pancreatic β cells.

NA^+ ENTRY THROUGH VOLTAGE-GATED CHANNELS IS ESSENTIAL FOR SULFONYLUREA-INDUCED INSULIN RELEASE FROM PANCREATIC B CELL.

S. Saha, H. Ishida, Y.Tsuura, Y. Seino. Kyoto University, Japan.

Freshly isolated pancreatic islets from Wister rats (male,2-3 mo) were batch-incubated to assess the role of Na^+ in insulin secretion by estimating IRI (μU/islet/30 min) using RIA.Glucose stimulated insulin secretion at all concentrations beyond the basal supply of 5.5 mM (G5.5).Neither TTX(4μM), the Na^+ channel blocker, nor its activator veratridine (VT, 100μM), altered the glucose effect on insulin secretion (G16.7=40±12, G16.7+TTX=60±11, G16.7+VT=43±8; p= ns). However, when Na^+ was removed from outside of islets (Na^+0), the glucose effect disappeared by about 80%: the residual 20% stimulatory effect (4.7± 0.5 at basal vs 11±2 at G16.7;p=0.002) could be ascribed to stimulation of Ca^{2+} entry through reversely operated Na^+/Ca^{2+} exchanger that occurs under Na^+0 conditions. In the absence of TTX , both glibenclamide (10μM) and gliclazide (100μM) stimulated insulin release (for glibenclamide IRI being 6±0.7, for gliclazide 7±0.4 at p=0.02 and 0.01 respectively vs IRI 3.4±0.5 at G 5.5).When the toxin was added in presence of the hypoglycemic agents, the latter became completely ineffective (glibenclamide + TTX=4.3±0.7, gliclazide+TTX =2.88 ±0.4; p=ns both vs G5.5 as well as G5.5+TTX). Na^+0 mimicked the effect of TTX on glibenclamide but unlike glucose it had no residual effect. Moreover, a dose-reponse experiment revealed a concentration-dependent decrease in insulin release by glibenclamide (at 100 nM 10±0.5, at 1 μM 7.5±0.8 and at 10 μM 6.7±0.6: a significant decrease between 100 nM and 10 μM at p=0.006 was observed). Vt not only counteracted this fall but also showed a tendency to significantly increase the effect of glibenclamide at 1 μM (7.5±0.9 to 10±0.9 at p=0.06).We conclude that Na^+ entry through voltage-dependent channels are essential for sulfonylurea-induced insulin release.

398

INTRA-ISLET GLUCAGON IS A DETERMINANT FOR THE ELECTRICAL ACTIVITY OF PANCREATIC β-CELLS

E. Gylfe, Y.J. Liu, A. Tengholm, S. Dryselius, E. Grapengiesser and B. Hellman. Dept. of Medical Cell Biology, Uppsala University, Sweden

Pancreatic islets exposed to 11 mM glucose exhibit complex variations of the cytoplasmic Ca^{2+} concentration ($[Ca^{2+}]_i$) with slow (0.3-0.9 min^{-1}) or fast (2-7 min^{-1}) oscillations or with a mixed pattern. It is well established that the regular fast oscillations correspond to the electrical burst activity in islets, and we now show that the slow oscillations are explained by very long bursts of action potentials. Using confocal microscopy it is demonstrated that the mixed pattern with slow and superimposed fast oscillations is due to simultaneous presence of cell populations with the respective responses. In islets with mixed $[Ca^{2+}]_i$ oscillations, exposure to the intracellular Ca^{2+}-ATPase inhibitors thapsigargin or DTBHQ resulted in selective disappearance of the fast pattern and amplification of the slow one. Islets exhibiting only the slow oscillations reacted to low concentrations of glucagon with induction of the fast pattern and sometimes the typical mixed one. Also the glucagon-induced fast oscillations were counteracted by DTBHQ. In the absence of added glucagon the fast oscillations decreased with the duration of islet culture and were more common in large islets. Since glucagon-releasing α-cells are more abundant in large islets, the fast oscillations seem to require the presence of this cAMP-elevating hormone. We have recently demonstrated that cAMP amplifies intracellular Ca^{2+} mobilization evoked by inositol 1,4,5-trisphosphate. The data indicate that glucagon-facilitated mobilization of intracellular Ca^{2+}, with or without capacitative Ca^{2+} influx, is a determinant for the glucose-induced electrical activity of β-cells located within pancreatic islets.

399

THE MECHANISM BY WHICH NALIDIXIC ACID INHIBITS INSULIN RELEASE FROM RAT PANCREATIC ISLETS.

T.Tamagawa, N.Maeda, K.Uemura, S.Yoshioka and N.Hotta. Department of Internal Medicine, Nagoya University, Nagoya, Japan.

We previously reported that the hypoglycemic effects of new quinolone antibiotics might be ascribed to an increase in Ca influx. In the present study, we studied possible effects on insulin release of the oldest quinolone, nalidixic acid (NA), which was reported to induce hyperglycemia. Rat pancreatic islets were isolated by collagenase digestion and incubated for 1 h. When the effects of NA (1-1000 uM) on insulin release induced by 10 mM glucose was examined, the maximal inhibition (ca. 50 % of the control, $p<0.01$) was observed at 0.1 mM. Either an increase in glucose concentration from 10 to 20 mM or addition of forskolin (5 uM) or TPA (100 nM) completely antagonized the inhibitory effect of NA. At 3 mM glucose, TPA (100 nM) induced insulin release, which was not affected by 0.1 or 1 mM NA. In conrast, high K (25 mM) induced insulin release, which was augmented by NA (0.25-1 mM) dose-dependently. The oxidation of D-[U-^{14}C] glucose was not affected by 0.1 mM NA at 3 or 10 mM glucose. At 10 mM glucose, cyclic AMP accumulation was inhibited by 17 % ($p<0.01$) with 0.1 mM NA. This inhibition was disappeared when glucose concentration was increased to 20 mM. In the presence of 0.25 mM diazoxide and 25 mM K, insulin release induced by 10 mM glucose was doubled compared to that observed in the usual KRB buffer. The release was not affected with 0.1 mM NA but inhibited by 20% with 1 mM NA. These data suggest that NA inhibits insulin release at the step(s) distal to an increase in cytosolic Ca concentration and that it may be due to inhibition of adenylate cyclase and protein kinase C.

SPECIFICITY OF CAPACITATIVE Ca^{2+} ENTRY INTO β-CELLS

Y.J. Liu and E. Gylfe. Department of Medical Cell Biology, Uppsala University, Sweden

Capacitative influx of Ca^{2+} is believed to be important in the signal transduction of pancreatic β-cells. We have now used the fluorescent indicator fura–2 to characterize the specificity of this capacitative Ca^{2+} entry pathway. To avoid interference with voltage-dependent Ca^{2+} entry the cells were hyperpolarized with 400 μmol/l diazoxide and the channel blocker methoxyverapamil was also present in some experiments. The cytoplasmic Ca^{2+} concentration ($[Ca^{2+}]_i$) of the hyperpolarized mouse β-cells was strikingly resistant to changes in external Ca^{2+}. In cells exposed to 20 mM glucose, stimulation with 100 μmol/l carbachol induced an initial $[Ca^{2+}]_i$ peak followed by a sustained increase due to capacitative influx of the cation. Capacitative influx was also permanently induced by the intracellular Ca^{2+}-ATPase inhibitor thapsigargin. In the presence of capacitative influx $[Ca^{2+}]_i$ became markedly sensitive to variations in external Ca^{2+}, but this sensitivity was blocked by La^{3+}. In β-cells exposed to both Ca^{2+} and Mn^{2+} there was slow Mn^{2+} quenching of the fura–2 fluorescence, which was accelerated upon stimulation of capacitative influx. In β-cells equilibrated in 5 mmol/l Sr^{2+}, carbachol exposure resulted in a pronounced $[Sr^{2+}]_i$ peak due to intracellular mobilization but little or no sustained elevation. Moreover, after activation of the capacitative pathway by exposure to thapsigargin, variations in extracellular Sr^{2+} in the 0–20 mM range had only marginal effects on $[Sr^{2+}]_i$. β-cells equilibrated with Sr^{2+} exhibit almost normal signaling due to influx through voltage-dependent channels and release from internal stores. However, since there are some intriguing differences compared to Ca^{2+}, Sr^{2+} may become an important experimental tool for elucidating the role of the capacitative pathway in β-cell signal transduction.

401

THE ANTIMALARIAL DRUGS MEFLOQUINE AND HALOFANTRINE INHIBIT ATP-SENSITIVE POTASSIUM CHANNELS

FM Gribble, C Higham, A Clarke, FM Ashcroft and TME Davis. University Laboratory of Physiology and Diabetes Research Laboratories, Oxford, and University Department of Medicine, Fremantle Hospital, Western Australia.

The cinchona alkaloids quinine and quinidine are known to cause hyperinsulinaemic hypoglycaemia. In a recently-published placebo-controlled volunteer study, the commonly-used quinoline methanol antimalarial drug mefloquine also reduced plasma glucose and increased serum insulin significantly (Davis TME *et al.*, B J Clin Pharm 1996;42:415-421). The aim of the present study was to investigate whether the cellular mechanism of action of mefloquine and the chemically related phenanthrene methanol drug halofantrine on pancreatic beta cells is through closure of ATP-sensitive potassium (K-ATP) channels. Experiments were carried out using the cloned beta cell K-ATP channel which comprises two subunits (Kir6.2 and the sulphonylurea receptor SUR1). Both subunits were co-expressed in *Xenopus* oocytes and K-ATP currents examined in giant inside out patches. The intracellular membrane surface was exposed to a range of drug concentrations and the vehicle alone. Mefloquine at 10 μM inhibited K-ATP channel currents by a mean ± SEM of 80 ± 4% (n=9). Halofantrine (10 μM) inhibited activity by 34 ± 2% (n=5). The chemically unrelated sequiterpene lactone antimalarial artesunate had little inhibitory effect at 10 μM (7 ± 2%, n=5). The drug vehicle was without effect. These data show that, consistent with the effects of cinchona alkaloids, mefloquine and halofantrine close pancreatic beta cell K-ATP channels. In certain clinical situations, this may predispose to hypoglycaemia through enhanced insulin secretion.

402

INSULIN SECRETION IS DOMINATED BY COMPOUND EXOCYTOSIS IN MOUSE β-CELLS.

K. Bokvist and M. Holmqvist*. Islet Cell Physiology, Novo Nordisk, Copenhagen, Denmark and *Brandeis University, Waltham, USA.

The aim of this study was to correlate changes in cell capacitance with amperometric detection of secretion in mouse pancreatic β-cells. We used amperometry to detect 5-hydroxytryptamine (5-HT) which is taken up by the β-cell granules and co-secreted with insulin. Glucose induced electrical activity which was accompanied by spikes of 5-HT release. Voltage-clamp pulses initiated 5-HT release within 100-400 ms of the onset the depolarisation. Peak 5-HT levels were attained ≈200 ms after the commencement of the response although secretory events could be observed several seconds after the end of the stimulation. Capacitance increases occurred simultaneously with and were proportional to the 5-HT responses. The basic secretory event seen in conjunction with 5-HT release was a step increase followed by an mono-exponential decline. There was an easily detectable minimum size of these events which compares favourably to what can be estimated for the release of a single vesicle. A typical 5-HT transient had a jagged appearance resulting from the summation of several basic secretory events of various size and latency time. Both single and aggregates of vesicles appear to participate in the secretory response. The vesicle aggregates contributed with >90% to the response. In ≈25% of the cells, 5-HT release occurred without any simultaneous increase in cell capacitance thus indicating that endocytosis and exocytosis occur simultaneously. Regions of the cell which were rich in granules (as indicated by quinacrine fluorescence) exhibited, on average, a 40% larger 5-HT response than regions poor in granules. Our data suggests that amperometric detection of secretion, when combined with capacitance measurements, provides useful additional information on the processes involved in insulin secretion.

Direct stimulation of insulin release from the MIN6 ß cell line by a new imidazoline compound, S-21663, via an original site

L. Le Brigand, A. Virsolvy*, K. Peyrollier*, D. Manechez**, J.J. Godfroid***, B. Guardiola-Lemaître**, and D. Bataille*. Inserm U376, Montpellier. **Institut International de Recherches SERVIER, Courbevoie.. *** Laboratoire de Pharmacologie Moléculaire, Paris, France.*

The MIN6 cell line derived from *in vivo* immortalized insulin-secreting pancreatic ß cells was used to study the insulin-releasing capacity and the mode of action of S-21663, a newly synthesized imidazoline compound known for its hypoglycemic effect *in vivo* and its ability to release insulin from perfused pancreas. S-21663 (10^{-5} M to 10^{-3} M) released insulin from the MIN6 cells with a maximal effect observed at 10^{-4} M; a drop in the stimulation factor was noted between 10^{-4} and 10^{-3} M. Its efficacy, which did not differ whatever the glucose concentration (stimulatory or not), was higher than that of the other secretagogues tested (glucose, sulfonylureas or the peptide tGLP-1). In contrast to tGLP-1, S-21663 did not modify the cyclic AMP content. On the other hand, it increased Ca^{2+} influx *via* verapamil- and nifedipine-sensitive voltage-dependent calcium channels, the insulin release being a direct consequence of this Ca^{2+} entry. The S-21663-induced Ca^{2+} influx appears to be the consequence of a closure of potassium channels distinct from the K-ATP channels, as determined by measurement of ^{86}Rb efflux and use of a K-ATP channel opener. Considering the actions of S-21663 on insulin release and ion fluxes as compared to that of other secretagogues, including efaroxan (an imidazoline compound which was shown to act on insulin release in a glucose-dependent manner *via* a binding site distinct from the imidazoline I_1 and I_2 sites), we conclude that S-21663 acts through a novel site linked to an original intracellular pathway. The unique features displayed by S-21663 (an efficient secretagogue acting through a novel site linked to non-K-ATP K^+ channels) indicate that this compound, or new drugs derived from it, might be the basis for a new type of pharmacological management of NIDDM.

OSCILLATORY SIGNALLING FOR INSULIN RELEASE IN MAN

B. Hellman, E. Gylfe, P. Bergsten, E. Grapengiesser, A. Berts, Y-J. Liu, A. Tengholm and J. Westerlund. Department of Medical Cell Biology, University of Uppsala, Sweden.

Single human islets are known to respond to glucose with oscillations of cytoplasmic Ca^{2+} and insulin release. So far there is no evidence for a corresponding rhythmicity in unequivocally identified human β-cells. In the attempts to characterize signalling of importance for pulsatile release of insulin in man advantage was taken of the Ca^{2+} analogue Sr^{2+}, which is particularly useful for demonstrating oscillatory activities in islet cells. Dual wavelength fluorometry with the indicator fura-2 was used for measuring cytoplasmic Sr^{2+} in β-cells taken from cadaveric organ donors and identified by immunostaining for insulin at the end of the experiments. Glucose-induced slow oscillations (frequency 0.1-0.5/min) were sometimes seen in individual β-cells already at a concentration of 3 mmol/l of the sugar. Addition of 10 nmol/l glucagon resulted in a broadening of the oscillations and sometimes in their transformation into sustained increase. Moreover, the presence of glucagon resulted in the appearance of short transients of Sr^{2+}, which disappeared after exposure to the intracellular Ca^{2+}-ATPase inhibitor thapsigargin. Digital image analyses indicated that the slow oscillations are synchronized among cells in small aggregates and entire islets. Measuring insulin in the perifusate from single islets with a sensitive ELISA technique the slow oscillations were found to correspond to pulsatile release of the hormone. It is concluded that the human β-cell has similar type of oscillatory signalling for insulin release as observed in experimental animals.

THE SIGMA RECEPTOR LIGAND (+)-3PPP EXHIBITS IMIDAZOLINE-LIKE INSULIN SECRETAGOGUE ACTIVITY IN RAT ISLETS OF LANGERHANS

S.L.F. Chan & N.G. Morgan. Cellular Pharmacology Group, Dept. of Biological Sciences, University of Keele, Staffs., ST5 5BG, UK.

The insulin secretagogue activity of imidazoline compounds is mediated by an imidazoline receptor, that is functionally associated with K-ATP channels. This receptor has eluded complete characterisation but recently, it has been suggested that it may be similar to the sigma-2 site found in brain. Thus, we have studied the effects of sigma receptor ligands on insulin secretion to investigate the involvement of sigma receptors in the insulin secretagogue activity of imidazolines. In contrast to imidazoline secretagogues, the potent sigma ligands haloperidol and ifenprodil markedly inhibited glucose-stimulated insulin release. Three other compounds, ketamine, phencyclidine and (+)-MK801, partially reversed the inhibitory action of diazoxide on glucose-induced insulin release (a characteristic of imidazoline agonists acting at the islet imidazoline receptor), despite exerting slight inhibitory effects on secretion alone. However, one compound, (+)-3PPP ((R)-3-(3-hydroxyphenyl)-N-propylpiperidine hydrochloride), reported to be a sigma receptor agonist, did not inhibit glucose-induced insulin release, but rather, it potentiated the insulin secretory response of islets incubated at 6mM glucose, in a dose-dependent manner. (+)-3PPP was also able to reverse the effects of diazoxide on insulin release. Significantly, both the direct stimulatory effect on secretion (6mM glucose: 2.38 ± 0.29 ng/islet/h; + 100μM (+)-3PPP: 5.46 ± 0.57; + (+)-3PPP + 50μM KU14R: 3.55 ± 0.37* (7); * P<0.01 relative to (+)-3PPP alone) and the reversal of diazoxide (20mM glucose plus 200μM diazoxide: 0.65 ± 0.07; + 100μM (+)-3PPP: 3.41 ± 0.35; + (+)-3PPP + 50μM KU14R: 2.33 ± 0.19* (12): *P<0.01 relative to (+)-3PPP alone) by (+)-3PPP were antagonised by the specific imidazoline secretagogue antagonist KU14R. Thus, (+)-3PPP appears to behave like an imidazoline secretagogue in isolated rat islets. The results with (+)-3PPP suggest that the islet imidazoline receptor may share certain pharmacological characteristics with the sigma receptor found in brain.

406

UNMASKING OF GLUCOSE-REGULATED Ca^{2+} TRANSIENTS IN PANCREATIC β-CELLS BY REPLACING K^+ WITH Cs^+

M. Eberhardson and E. Grapengiesser. Dept. of Medical Cell Biology, Uppsala University, Sweden

The glucose-induced movements of Ca^{2+} resulting in insulin release are known to depend on the K^+ permeability of the pancreatic β-cell. We have examined how equimolar replacement of 5.9 mmol/l K^+ with its less permeable analogue Cs^+ affects the cytoplasmic Ca^{2+} concentration ($[Ca^{2+}]_i$) in isolated mouse β-cells loaded with the fluorescent indicator fura-2. Whereas the presence of Cs^+ did not affect $[Ca^{2+}]_i$ in resting β-cells, it transformed the slow $[Ca^{2+}]_i$ oscillations seen at 11 mmol/l glucose into sustained elevation. When Cs^+ was allowed to equilibrate with the β-cells during 40 min in the presence of 3 mmol/l glucose, a subsequent rise of the sugar to 5-7 mmol/l resulted in sustained elevation of cytoplasmic Ca^{2+} with initial 5-10 min periods of superimposed transients (frequencies 3.4 ±0.4/min). These pronounced transients persisted after depletion of intracellular Ca^{2+} stores by thapsigargin. However, after elevation of glucose from 3 to 20 mmol/l there was sustained elevation of $[Ca^{2+}]_i$ without transients. Both the sustained elevation and the transients were immediately eliminated by blocking the L-type Ca^{2+} channels with 50 µmol/l methoxyverapamil. It is suggested that the short transients reflect the depolarisation-dependent entry of Ca^{2+} in response to the reduction of K^+ permeability obtained by Cs^+ and glucose. When sufficiently pronounced the depolarisation will counteract the Cs^+ blockage, explaining the gradual disappearance of the Ca^{2+} transients and their absence at 20 mmol/l glucose.

407

THE IMIDAZOLINE RX871024 AND THE SECRETIN GLP-1 INDUCE GLUCOSE DEPENDENT INSULIN SECRETION IN βTC-6 CELLS

J. Schloos, B. Steckel, A. Raap, M.R. Jirousek*, G. Gold* and H.-J. Mest. Beiersdorf-Lilly, Hamburg, Germany and *Lilly, Indianapolis, USA.

The βTC-6 cell is a glucose sensitive insulin secreting clonal line of pancreatic islet ß-cells derived from transgenic mice. Modulators of insulin secretion like the imidazolines phentolamine and RX871024 (RX) as well as the glucagon-like peptide-1 (GLP-1) were studied with respect to their glucose dependent insulin secreting properties. In the absence of glucose 100 µM RX induced a 1.9-fold insulin secretion in βTC-6 cells ($p<0.05$). However, in the presence of 10 mM glucose the secretion of insulin was concentration-dependently enhanced by RX (EC_{50} = 14.2 µM) which was 2.8-fold ($p<0.05$) at 100 µM RX. This RX induced insulin secretion could be attenuated by the addition of α_2-adrenergic agonists like epinephrine and UK 14,304 ($p<0.05$). In the presence of 150 µM diazoxide the RX stimulated insulin secretion in the absence of glucose was reduced about 50% ($p<0.05$). In the presence of stimulatory concentrations of glucose, however, the RX induced insulin secretion was not influenced by diazoxide. GLP-1 (7-37) was more potent (EC_{50} = 0.9 nM) compared to RX with respect to insulin secretion in βTC-6 cells. In the presence of 10 mM glucose 30 nM GLP-1 increased the insulin secretion about 1.9-fold ($p<0.05$). Thus, the maximal stimulation obtained with GLP-1 was about 2-fold lower compared with the maximal effect obtained with the imidazolines phentolamine and RX ($p<0.05$). Insulin secretion stimulated by glucose, RX and GLP-1 was markedly increased in the presence of 25 µM of the PDE inhibitor IBMX. Thus, cAMP may be a common intracellular mediator in the process of insulin secretion of βTC-6 cells. In conclusion, the insulin secretion stimulated by RX is dependent on the glucose concentration used and shows striking similarities to GLP-1 induced insulin secretion. This indicates a second mechanism of action of RX despite blockade of ATP-sensitive K^+-channels. The data presented may provide further insight into the mechanism of the insulinotropic effect of RX and other imidazolines.

408

OSCILLATIONS IN CYTOSOLIC CA^{2+} BY GASTRIN RELEASING PEPTIDE IN SINGLE INSULIN PRODUCING HIT-T15 CELLS

S. Karlsson and B. Ahrén, Dept Med, Lund Univ, Malmö, Sweden.

Gastrin releasing peptide (GRP) occurs in islet nerves and stimulates insulin secretion by a phospholipase C-dependent mechanism. The effect of the neuropeptide on cytosolic Ca^{2+} ($[Ca^{2+}]_{cyt}$) is, however, not established. We therefore investigated the effect of GRP on $[Ca^{2+}]_{cyt}$ in FURA-2-loaded, superifused, single insulin-producing HIT-T15 cells at 3.3 mM glucose. GRP (100 pM) induced an initial peak in $[Ca^{2+}]_{cyt}$ followed by either a sustained increase (44% of cells) or a variable pattern of oscillations (56% of cells). GRP-induced oscillations had a frequency of 1.1±0.1 per min (range 0.63-1.9) and an amplitude of 113±11 nM (range 33-250 nM; n=31). When extracellular Ca^{2+} was chelated by EGTA (2 mM) during GRP-induced oscillations, one transient of $[Ca^{2+}]_{cyt}$ still appeared, whereafter oscillations stopped but reappeared promptly when extracellular Ca^{2+} was normalized. EGTA added to cells exhibiting a GRP-induced sustained increase in $[Ca^{2+}]_{cyt}$ reversibly lowered the $[Ca^{2+}]_{cyt}$. Depletion of intracellular Ca^{2+} stores by the Ca^{2+} ATPase-inhibitor thapsigargin (1 µM) stopped GRP-induced oscillations. Similarly, the protein kinase C activator 12-O-tetradecanoyl-phorbol-13-acetat (TPA; 20 nM) markedly reduced the frequency of GRP-induced oscillations (0.14±0.1 per min during TPA+GRP compared to 1.05±0.3 per min during GRP alone, $P<0.05$). It is concluded that **1)** GRP induces oscillations in $[Ca^{2+}]_{cyt}$ in a majority of HIT-T15-cells, whereas other cells respond with a sustained increase in $[Ca^{2+}]_{cyt}$ **2)** the oscillations are caused by repetitive mobilization of Ca^{2+} from intracellular stores but extracellular Ca^{2+} is required to maintain oscillations **3)** the GRP-induced sustained increase in $[Ca^{2+}]_{cyt}$ is dependent on Ca^{2+}-uptake **4)** the frequency of GRP-induced oscillations is negatively modulated by direct protein kinase C activation. Hence, two major separate actions are exerted by GRP on $[Ca^{2+}]_{cyt}$ in insulin producing cells, the nature of which is determined by the individual cell.

Insulin Secretion in Vitro: Secretagogue Recognition and Signal Transduction

409

INSULIN RELEASE AND GENE EXPRESSIONS OF INSULIN II AND GLUT2 ARE DIFFERENTLY MODULATED BY GLUCOSE EXPOSURE IN INS1 CELLS

B Brock and K Hermansen, Dept. of Endocrinology and Metabolism, Aarhus County Hospital, Aarhus University Hospital, Aarhus, Denmark.

We have previously shown that long term exposure to high glucose down regulates the gene expressions of GLUT2 and insulin as well as the glucose stimulated insulin secretion in the glucose sensitive β cell-line INS-1. The aim of the present study was to detect if there was a differential impact on the gene expression of GLUT2 and insulin II as compared to insulin release of 1 and 4 days exposure to a graded range of glucose levels between 1.0 and 26.6 mM. Cells were cultured in a modified RPMI 1640 medium containing the different glucose levels. Total RNA was analysed by northern blotting and insulin release analysed by RIA. Students unpaired one-tailed t-test was used to test the degree of significance. After 1 day we found no difference in the GLUT2 gene expression in cells cultured at this broad range of glucose. The amount of insulin II mRNA was equally high at glucose levels between 1.0 and 13.3 mM whereas higher glucose caused a down regulation of insulin II gene expression.This contrasted to the uniform high insulin release at glucose concentrations at or above 6.6 mM and the reduced insulin release found in cells cultured at 3.3 mM glucose or less ($p<0.0002$). After 4 days GLUT2 gene expression was down regulated in cells cultured at 13.3 mM glucose or more. The amount of insulin II mRNA was lower at glucose levels below 6.6 mM or above 13.3 mM than to the expression found at concentrations in between. This is in agreement with the pattern of insulin release. Thus the maximal insulin release appeared at 6.6 mM glucose being reduced at lower ($p=0.0000$) as well as at 10 mM ($p<0.02$) or higher glucose concentrations ($p=0.0000$). **In conclusion:** The insulin release surprisingly correlates better to the amount of GLUT2 mRNA than to the amount of insulin II mRNA at glucose levels higher than 6.6 mM. In contrast, the insulin release corresponds better to the level of insulin II mRNA than to the GLUT2 mRNA level at low glucose concentrations as expected. This points to a putative importent role for GLUT2 in the development of glucose desensitization.

410

FUNCTIONAL AND IMMUNOHISTOLOGICAL SPECIES SPECIFICITY OF $G\alpha_{olf}$ AND $G\alpha_i$ EXPRESSION IN PANCREAS, ISLETS AND ß-CELLS

H. Phan, M. Pessah, C. Boissard, N. Ferrand, A. Astesano, S. Emami, W.J.Malaisse*, N. Yanaihara# and G. Rosselin INSERM U55, Paris, France. *Lab. of Exp. Med., Brussels, Belgium. #Res. and Dev. Yanaihara Inst. Fujinomiya-Shi Japan

Proteins Gα are part of trimeric G proteins which transduce the regulatory signals of the pancreatic islet B cell function. Our aim was to evidence in different rodent species and B cell lines, the presence of $G\alpha_{olf}$ and of $G\alpha_i$ isotypes likely to be coupled to adenylate cyclase stimulation and inhibition. Immunodetection studies were coupled to western blot analysis and ADP-ribosylation by cholera toxin (CTX) or pertussis toxin (PTX). The presence of $G\alpha_{olf}$ was doubly checked by antibodies raised against 23-38 (Y27) or 100-118 (SC) sequences, and that of $G\alpha_{i3}$ by antibodies against 345-354 (SC) or 105-127 (Y45) sequences. Specific immunofluorescence of α_{olf} was localized in the B cell lines HIT-T15 and RINm5F and almost exclusively in B cells of rat, mice, hamster and human and in endothelial cells of small vessels. Some α-cells are slightly labeled. By western blot only one or two bands in the 43-48 kD zone were detected in islets and B cell lines, with differences according to the species of the animals or the passages of the cell lines. The same band was detectable in neonatal rat pancreatic membranes due to the abundance of islets. $G\alpha_s$ was present in both exocrine and endocrine pancreas. Specific bands were detected in hamster islets and rat islets at the expected place at 52 and 46 kD, with additional bands in the 28-30 and 18-20kD zones. After CTX the [^{32}P]-labeled bands corresponded to the major immunoexpression of $G\alpha_{olf}$ and α_s with some additional labeling above 80 Kd or around 28kD. Gαi was almost exclusively present in B cells and the $G\alpha_{i3}$ isotype was found in normal B cells and HIT cells. This study indicates that the diversity of the functional α subunits present in normal ß-cells is shared by different mammal species and that, their specific role in the answer of B cells remaining unknown.

411

THE CALCIUM SIGNAL TRANSDUCTION PATHWAY REGULATES CRE-BP1 TRANS-ACTIVITY.

Y.Yamada, N.Ban, Y.Someya and Y.Seino, Kyoto University, Kyoto, Japan

We have previously shown that transcription factor CRE-BP1 activates insulin gene expression. In this study we investigate the regulatory mechanism of CRE-BP1 trans-activity. Fusion proteins of the GAL4 DNA-binding domain and the CRE-BP1 activation domain (amino acids 1-345) were introduced with expression plasmids encoding the catalytic domains of protein kinase A (PKA), calmodulin-dependent protein kinase II (CaMKII), or calmodulin-dependent protein kinase IV (CAMKIV). The 5xGAL4-luc reporter plasmid contains tandem repeats of the GAL4-binding site and the coding sequence of luciferase. CaMKIV alone activated CRE-BP1 trans-activity 4.7-fold. CRE-BP1 seems to be phosphorylated by CaMKIV on two closely spaced threonine residues (Thr-71 and Thr-73), since replacement with alanine inhibited the trans-activity of CRE-BP1. Moreover, co-transfection of CBP or p300 co-activator increased the transcriptional activity of CRE-BP1 further. These results suggest that the increased intracellular calcium ion concentration elicited by glucose might activate CaMKIV and CRE-BP1, which in turn increase insulin gene expression through their association with CBP and p300 co-activator.

412

FUNCTIONAL AND MOLECULAR CHARACTERIZATION OF B-CELL $G\alpha_{olf}$ GENE USING OLIGO ANTISENSE

S. Emami, A. Astesano, F. Shimizu*, N. Ferrand, M. Bendayan#, N. Yanaihara*, and G. Rosselin, *Japan, #Montreal, INSERM U-55 Saint Antoine Hospital, Paris, France.

We have undertaken molecular characterization and functional studies of $G\alpha_s$ and $G\alpha_{olf}$ in various B cell lines and pancreatic tissues. Antisense (-36-1, upstream of ATG) for in situ hybridization (ISH) were used in combination with specific antibodies raised against the 100-118 sequence for western blot to comprehend the $G\alpha_{olf}$ topology from mRNA to functional protein. The validity of the probes was attested by its specific expression in adult rat striatum. Here, we show that $G\alpha_{olf}$ mRNA was expressed in rat pancreatic B cells by ISH using the digoxigenin-labeled antisense probe. This further extend our previous results demonstrating the presence of the $G\alpha_{olf}$ protein in pancreatic B cell obtained by optical and ultrastructural studies. We next assessed the effectiveness of the antisense using HIT-T15 cells in which $G\alpha_{olf}$ protein was expressed. Fifteen bases of the phosphothioate specific 5' noncoding region covering the ATG translation initiation codon of $G\alpha_{olf}$ as antisense templates were selected. Antisense RNA blocks the expression of the targeted protein by hybridizing $G\alpha_{olf}$ mRNA, preventing translation. Antisense and sense oligonucleotides were transfected into HIT-T15 cells for 72 hours by simple diffusion or lipofection and tested for $G\alpha_{olf}$ expression by immunoblotting. Cells containing antisense $G\alpha_{olf}$ showed a decrease in the expression of $G\alpha_{olf}$ when compared to either the control cells or cells containing sense oligonucleotides. Staining of immunoblot with specific antibody to $G\alpha_s$ demonstrated that this inhibition was specific to $G\alpha_{olf}$ in HIT-T15 cells. Immunofluorescence of $G\alpha_{olf}$ antibody was also shown to be much lower in antisense-transfected cells. Further studies are undertaken to elucidate the role of $G\alpha_{olf}$ protein in the control of the pancreatic B cells development and in the regulation of insulin secretion with the prospect to obtain a B-cell line where the $G\alpha_{olf}$ antisense will be permanently expressed.

413

β CELL DYSFUNCTION IN THE MOUSE WITH THE β CELL-SPECIFIC GLUCOKINASE GENE DISRUPTION.

T.Aizawa,[1] N.Asanuma,[1] Y.Terauchi,[2] T.Kadowaki,[2] K. Yamauchi,[1] and K.Hashizume[1]. [1]Shinshu University, Matsumoto, and [2]University of Tokyo, Tokyo, Japan.

The role of glucokinase (GK) in the pancreatic β cell was systematically examined in the heterozygous mouse with targeted disruption of the β cell-specific GK gene at the age of 20-40 weeks. The heterozygotes were with significant hyperglycaemia (the mean random sample plasma glucose, 13.3 mM) with normoinsulinaemia and with normal body weight; the microscopic appearance and insulin content of the islets were unchanged. In the heterozygotes' islets, both the first and second phases of insulin release was reduced upon stimulation with 16.7 mM glucose; when the concentration-dependency was examined with 3-40 mM glucose, the EC50 was elevated with the maximum response being unaltered. The K^+ATP channel-independent glucose action was exaggerated, if any, in the heterozygotes' islets, however, the EC50 was elevated in this branch too. Discrimination of α and β glucose was impaired in the heterozygotes' islets. A daily sc insulin injection for 2 weeks resulted in modest but significant lowering of plasma glucose in the heterozygotes, which was accompanied by a dramatic depression of glucose-stimulated insulin release by the islets. The data is compatible with the GK glucose sensor concept inasmuch as glucose sensitivity is reduced in the heterozygotes' β cell. Preservation of K^+ATP channel-independent glucose action and anomeric malaise in the heterozygotes' β cell are likely due to chronic hyperglycaemia.

414

EFFECT OF ISLET CATECHOLAMINE RELEASE ON INSULIN SECRETION

M.I. Borelli, I. Armando, M. Barontini and J.J. Gagliardino. CENEXA (UNLP-CONICET), La Plata and CEDIE, Buenos Aires Argentina.

The presence of catecholamines (CAs) as well as the enzymes involved in their synthesis (tyrosine - hydroxylase [TH] and dihydroxyphenyl- alanine [DOPA]-decarboxylase) suggest that CAs can be synthesized by insular cells. Furthermore, we have previously shown that normal adult rats fed for a week only with carbohydrates increased the TH activity and decreased the norepinephrine (NE) content in their pancreatic islets, together with a significant reduction in the release of insulin in response to glucose. The aim of this work was to study the role of endogenous CAs on the control of insulin secretion. Thus, we studied the release of DOPA, dopamine (D), and NE (measured by HPLC) as well as of insulin (measured by radioimmunoassay) in response to glucose (3 or 16 mM) in islets isolated from normal rats. Insulin secretion was also studied in islets incubated with 3 or 16 mM glucose in the absence or presence of α_2 (yohimbine [Y], 0.01 to 1 μM), and α_1 (Prazocin [P], 0.01 to 0.5 μM) adrenergic receptor antagonists. Medium DOPA concentration was lower in islets incubated at a high glucose concentration (313 vs 1.0 pg/ml), whereas D and NE concentrations were higher at 16 mM glucose than in those islets incubated at a low glucose concentration (D: 70.4 vs. 133.2 pg/ml; EN: 28.6 vs. 75.0 pg/ml). Islets incubated in the presence of Y significantly enhanced the insulin response to high glucose (Y = 0.1 μM: 14.31 ± 2.71; 1 μM: 21.32 ± 2.19 vs. control : 7.85 ± 1.21 ng/islet/h, $p < 0.05$);conversely, the addition of P in the incubation media significantly diminished insulin secretion in the presence of 16 mM glucose (P= 0.1 μM: 3.98 ± 0.63; 0.5 μM:3.41 ± 0.34 vs. control: 7.37 ± 0.87 ng/islet/h, $p<0.025$).These results suggest that endogenous CAs can be synthesized and released by insular cells in response to glucose, contributing to the paracrine regulation of insulin secretion.

415

EXPRESSION OF GLUCOKINASE IN GLUCOSE-UNRESPONSIVE HUMAN FETAL ISLET-LIKE CELL CLUSTERS

J. TU and B. E. TUCH, The Prince of Wales Hospital, Sydney, Australia

Glucokinase (GK) is the glucose sensor in the adult β cell resulting in fuel for insulin synthesis and secretion. Defects in this enzyme in the β cell are responsible for the genetic disorder maturity-onset diabetes of the young (MODY) with the β cell being unable to secrete insulin appropriately when challenged with glucose. The human fetal β cell is also unable to secrete insulin when exposed to glucose but whether GK is present and functional in this developing cell is unknown. To determine the expression of GK in human fetal pancreatic tissue, cytosolic protein was extracted from human fetal islet-like cell clusters (ICCs) at 17-19 week gestation and examined for protein content and enzyme activity. On Western blots a single band corresponding to GK was seen at 52-kDa, and this was similar in amount to that obtained from human adult islets. GK was measured fluorometrically, the Vmax being less in fetal ICCs than adult islets: 8.7 vs 20.7 nmol/mg protein/h; similar Km values were found in both ICCs and islets. No attempt was made to determine which cells in an ICC contained GK. Glucose utilization was determined radiometrically, the Vmax of the high Km component being less in ICCs than islets: 31.3 pmol/ICC/h vs 101.4 pmol/islet/h. Culturing of ICCs for 3-7 days in medium containing 11.2 mmol/l glucose resulted in a 3.7-fold increase in the Vmax of GK and a 1.8-fold increase in glucose utilization. These enhanced activities of glucose phosphorylation and glycolysis, however, did not lead to the β cell being able to secrete insulin when exposed to glucose. In conclusion, glucokinase is present and functional in human fetal ICCs but the inability of the human fetal β cell to secrete insulin in response to an acute glucose challenge is not due to immaturity of this enzyme.

416

Effect of Neuroendocrinological and Second Messenger Signals on Insulin Secretion in ßTC Cells.

VALERIE K. WILLIAMS, CECILE M. GONZALEZ, GERALD GOLD, LAWRENCE E. STRAMM, JUERGEN SCHLOOS AND MICHAEL R. JIROUSEK, Indianapolis, IN, USA and Hamburg, GERMANY

Clonal beta cell lines, such as ßTC6-f7 cells, that maintain glucose sensitive insulin secretion allow a greater understanding of the cellular mechanisms that induce glucose potentiated insulin release (GPIR). We have characterized the effect of selective agonists and antagonists at the histamine, serotonin, dopamine, acetylcholine, CCK, GLP-1, ß-adrenergic, and α-adrenergic receptors, in addition to intracellular second messenger activity such as arachidonic acid metabolites on GPIR. Insulin secretion (IS) from cultured βTC6-f7 cells (passage 48-52) was quantified using a scintillation proximity assay (SPA). Conditions that simulate low (0 mM glucose 25 μM IBMX) and high (10 mM glucose and 25 μM IBMX) glucose were used to obtain dose response relationships for each agent and compared in each assay with the IS induced by the imidazoline RX871024 (RX). Some of the most interesting responses were: chlorpheniramine, an H-1 antagonist, induced a GPIR (EC50 = 23 μM, 2.5 fold increase in IS at the maximal dose 100 μM) comparable to RX (EC50 = 21 μM, 2.5 fold increase in IS at the maximal dose 100 μM). Additional H agonists and antagonists will be discussed. 3-PPP, a dopamine agonist, induced a lower maximal GPIR (2 fold) and higher EC50 (40 μM) than RX, 6-7 ADTN, a dopamine agonist inhibited IS. Muscarinic agonist, APE, had a five fold lower EC50 (4 μM) and was glucose sensitive. Atropine blocked this effect and by itself did not have an agonistic or antagonistic effect on IS. Alprenolol, a ß-adrenergic antagonist, induced GPIR similar to RX. GLP-1 has a nM activity (EC50=5 nM) although a small fold induction (1X) of IS in this cell line. Sulfonylureas. CCK. prostaglandins have also been examined and dose response GPIR for these agents will be discussed.

417

DISSOCIATED EFFECTS OF 3-O-METHYL-D-GLUCOSE UPON D-GLUCOSE UPTAKE, METABOLISM AND INSULINOTROPIC ACTION IN RAT PANCREATIC ISLETS

A. Sener, O. Scruel, K. Louchami, H. Jijakli and W.J. Malaisse. Laboratory of Experimental Medicine, Brussels Free University, Brussels, Belgium.

The transport of D-glucose across the B-cell plasma membrane is currently considered not to represent a rate-limiting factor in the metabolism and, hence, insulinotropic action of the hexose. In the present study, however, 80 mM 3-O-methyl-D-glucose (3OMG) was found to inhibit insulin release evoked, over 90 min incubation, by D-glucose. This effect, which was concentration-related in the 30 to 80 mM range, was not reproduced by 80 mM D-fructose or D-galactose. Moreover, 3OMG failed to affect insulin release evoked by 2-ketoisocaproate (10 mM) or the association of L-leucine and L-glutamine (10 mM each). In islets exposed for 90 min to 16.7 mM D-glucose, 3OMG also decreased both D-[5-^{3}H]glucose utilization and D-[U-^{14}C]glucose oxidation. The fractional inhibition of insulin release, relative to that of glucose metabolism, was comparable in islets exposed to either 3OMG or D-mannoheptulose (1 mM). In perifused islets exposed to a sudden rise in D-glucose concentration, 3OMG delayed the early secretory response, which was more markedly affected than the second phase of insulin release. Yet, whether over 5 or 20 min incubation, 3OMG failed to decrease, and even slightly increased, the radioactive intracellular content of islets exposed to 16.7 mM D-[U-^{14}C]glucose. Likewise, D-glucose (16.7 mM) tended to augment the radioactive intracellular content of islets exposed to 80 mM 3-O-[^{14}C-methyl]-D-glucose. The phosphorylation of D-[U-^{14}C]glucose by islet homogenates was slightly but significantly decreased, however, by 3OMG. These findings suggest that, except during the early secretory phase, the inhibition by 3OMG of glucose-stimulated insulin release is not merely attributable to an impaired hexose transport into the B-cell.

418

1,25-DIHYDROXYVITAMIN D_3 INFLUENCE ON ISLETS INSULIN RELEASE AND PKC PATHWAY IN VITAMIN D_3 DEFICIENT RATS.

Sutter, B.Ch.J., Dussert-Faure, A., and Billaudel, B. Laboratoire d'Endocrinologie, Université Bordeaux I, Avenue des Facultés, F-33405 Talence Cedex, France.

As previous works with islets from normal (N) rats and 4 week-vitamin D_3 deficient rats (-D) showed a more rapid stimulatory influence of 1,25-dihydroxyvitamin D_3 [1,25$(OH)_2D_3$] on insulin response to acetylcholine (Ach) than to glucose stimulus, we studied the in vitro insulin release (RIA assay) in similar conditions, taking into account the Ach-induced activation of the PKC pathway. A 45 min induction time of 10^{-8} M 1,25$(OH)_2D_3$ induction was not sufficient to improve the insulin response over basal release to 16.7 mM glucose of 50 perifused islets from -D (+0,69±0,15 vs N rats: +2,88±0,25 ng/min ; n=7; p<0.001), whereas the insulin response to glucose could be restored when same groups of islets were first submitted to both influences of 1,25$(OH)_2D_3$ and 10 µM Ach before glucose stimulation whatever it concentration was: 16.7, 11.1 or 8.3 mM. When -D islets were pre-exposed to 10^{-8} M 1,25$(OH)_2D_3$ and 8.3 mM glucose before a stimulation by Ach, their insulin release increased, especially during the PKC-dependent 2nd phase of Ach stimulation. This potentiating effects could be suppressed by the addition of H_7, a PKC inhibitor (+0,60±0.06 vs +1.44±0.19 ng/min without H_7; n=7; p<0.001). Prior exposure of -D islets to 8.3 mM glucose, 10 µM Ach and 50 µM MOG (a diacylglycerol kinase inhibitor) rendered glucose much more efficient on insulin release from islets preexposed to 10^{-8} M 1,25$(OH)_2D_3$ (+0,38±0.07 ng/min; n=8) versus control islets (+0.13±0.04 ng/min; n=8 ; p<0.01) with 10^{-12} M inactive concentration of the steroid. These results sustained the hypothesis that the beneficial influence on insulin release of prior exposure to 1,25$(OH)_2D_3$ and Ach was mediated via the activation of PKC pathway.

419

EVALUATION OF THE ROLE OF GTP IN GLUCOSE STIMULATION OF INSULIN SECRETION

P. Detimary and J.C. Henquin. Unité d'Endocrinologie et Métabolisme, University of Louvain, Brussels, Belgium.

Glucose metabolism in pancreatic β cells leads to an increase in the ATP/ADP ratio which may participate in the regulation of insulin secretion. We have reported recently that good correlations also exist between guanine nucleotide levels in islets and insulin secretion. However, to determine whether variations in GTP concentration play a specific role in stimulus-secretion coupling, this concentration should be modified selectively. This was attempted by culturing mouse islets overnight in the presence of mycophenolic acid (MPA), an inhibitor of GMP synthesis at the level of IMP-dehydrogenase. The drug (25-50 µg/ml) did not affect the insulin content, but decreased the GTP content of the islets (by 65 %, P< 0.001). During subsequent incubation, glucose (15 mmol/l)-induced insulin secretion was inhibited (by 50 %, P< 0.001), while basal secretion (3 mmol/l glucose) was unaffected. However, MPA also lowered the ATP/ADP ratio in the islets. Addition of guanine to the culture medium (to stimulate the salvage pathway of GTP synthesis) restored normal GTP levels corrected the ATP/ADP ratio, and partially prevented the inhibition of insulin release. In contrast, attempts to stimulate ATP synthesis specifically (by provision of adenine or adenosine) failed to reverse any of the effects of MPA. It is concluded that guanine and adenine nucleotide pools are tightly linked in islet cells and cannot be specifically affected by MPA probably because of the activity of the nucleoside diphosphate kinase and of the role of GTP in several reactions leading to adenine nucleotide generation. MPA is not an adequate tool to support or exclude a specific role of guanine nucleotides in the control of insulin release.

AUTOANTIBODIES AGAINST CD38 (ADP-RIBOSYL CYCLASE /CYCLIC ADP-RIBOSE HYDROLASE) IN DIABETIC PATIENTS.

H. Okamoto, F. Ikehata, J. Satoh, S. Takasawa, A. Tohgo, K. Nata, I. Kato and T. Toyota. Tohoku University School of Medicine, Sendai, Japan.

Glucose is the primary stimulus of insulin secretion. We have proposed a model for insulin secretion by glucose via cyclic ADP-ribose (cADPR)-mediated Ca^{2+} mobilization in pancreatic B-cells: In the process of glucose metabolism, millimolar concentrations of ATP are generated, inducing cADPR accumulation by inhibiting the cADPR hydrolase activity of CD38, and cADPR acts as a second messenger for intracellular Ca^{2+} mobilization from the endoplasmic reticulum for insulin secretion. In the present study, we expressed human CD38 (amino acid residues 45-300) in *E. coli* and purified it to homogeneity. Using the purified CD38, we examined the presence of autoantibodies against CD38 in the sera of 466 Japanese diabetic patients and 75 controls by immunoblot. In the diabetes group, 19% of IDDM patients and 15% of NIDDM patients had autoantibodies against CD38, while only 1 in 75 (1.3%) in the control group exhibited a extremely low level of autoantibody. When sera of patients with autoantibodies against CD38 were added at 10% to the enzyme assay, the cADPR metabolizing enzyme activity of CD38 was inhibited (43-84% of control). Some sera with the anti-human CD38 antibodies reacted with recombinant rat CD38 and inhibited glucose-induced insulin secretion from rat isolated islets (44-86% of control). Therefore, it is quite possible that autoantibodies against CD38 in diabetic patients suppress the cADPR metabolizing enzyme activity of CD38 in pancreatic islets and inhibit insulin secretion to develop and exacerbate diabetes.

421

MODULATION OF GLUCOSE-INDUCED INSULIN SECRETION BY CYTOSOLIC REDOX STATE IN BRIN-BD11 CELLS

A.P. Salgado[1], A.P. Fernandes[1], F.C. Pereira[1], R.M. Seiça[1,5] P.R. Flatt[3], R.M. Santos[1,2], L.M. Rosário[1,2] and R. Ramasamy[4]. [1]Centre for Neurociences of Coimbra, Portugal; [2]Dept. Biochemistry, Fac. Sciences and Technology, University of Coimbra, Portugal; [3]School Biomed. Sci.,Univ. Ulster, Northern Ireland, UK; [4]Division of Cardiovascular Medicine, University of California at Davis, USA; [5]School of Medicine, University of Coimbra, Portugal.

Stimulation of β-cell metabolism plays a crucial role in glucose-induced insulin secretion, but some of the underlying mechanisms remain unresolved. Previous studies either did not detect measurable effects of glucose on cytosolic NADH/NAD^+ or did detect them, albeit with a discrepant time course in relation to insulin secretion. We have now assessed the role played by cytosolic redox state in glucose-induced insulin secretion, using the novel glucose-sensitive cell line BRIN-BD11. Exposing the cells to glucose (2-16 mM) for 45min caused a dose-dependent increase in insulin release rate and lactate/pyruvate (L/P) ratio (ie. a measure of cytosolic NADH/NAD^+ ratio). Glyceraldehyde (10 mM) mimicked the stimulatory effect of 16 mM glucose on both insulin release and L/P ratio. Pre-incubating the cells with the NAD^+ precurssor niacin (100 μM) for 45 min supressed the glucose-evoked rise in the L/P ratio and inhibited (40%) the concomitant increase in insulin release. Niacin nearly suppressed the rises in cytosolic free Ca^{2+} concentration ($[Ca^{2+}]_i$, assessed from single cells by fura-2 microfluorometry) evoked by acute (5 min) exposure to 16 mM glucose. Niacin had no effect on tolbutamide (100 μM) - or high K^+ (30 mM)- evoked $[Ca^{2+}]_i$ rises and insulin release. Thus, the drug did not interfere with either voltage-sensitive Ca^{2+}channels, intracellular Ca^{2+} buffering or more distal events in the stimulus-secretion coupling cascade. The data indicate that changes in cytosolic redox state of the pancreatic β-cell account for a significant part of the insulinotropic capacity of glucose, by a mechanism that may involve direct shuttling of reducing equivalents into the mitochondria.

422

ANTI-CD38 ANTIBODY MODULATES INSULIN SECRETION THROUGH SOME MECHANISM OTHER THAN K-ATP CHANNEL.

T. Itoh, T. Taminato, Y. Kato, H. Natsume, Y. Suzuki, G. Sarwar, T. Yoshimi, *A. Hazama and *Y. Okada. Hamamatsu University School of Medicine, Hamamatsu,Japan. *:Cellular and Molecular Physiology, National Institute.

【Aim】 We made sure that cyclic ADP-ribose (cADPR; cADPR synthetase is nearly equal CD38 antigen), which recently drew the public attention as a newly second messenger of intracellular calcium regulation, had might act against the membrane potential (K-ATP channel) in the early phase of insulin secretion with patch-clamp technique. 【Method】 We practiced a patch-clamp technique (on-cell configuration) to pancreatic beta cells isolated from Wister Rat. In on-cell experiments extracellular solution (PBS: phosphate buffer solution) with or without each loaded substance (D-glucose 20mM, diazoxaide 0.3mM, glibenclamide 0.1 μ M) was applied. Two types of anti-CD38 antibodies, both anti-T10 monoclonal antibody and anti-CD38-fragment (287-297: N-CVKNPEDSSCT-C) polyclonal antibody, were preloaded for 1 hour before patch-clamp experiments. The activity of K-ATP channel was compared each open-provability value (Po value). 【Result】 The Po values were 0.057 ±0.076, 0.020±0.022, 0.070±0.072 and 0.001±0.005 in control group and 0.133±0.109, 0.011±0.017, 0.111±0.062 and 0.001±0.003 in anti-CD38 antibody preloaded group, for PBS, high glucose, diazoxaide and glibenclamide, respectively. The Po value for each loaded substance (D-glucose, diazoxaide, glibenclamide) was not distinguishable between the control group and anti-CD38 antibody preloaded group. 【Conclusion】 The effect of anti-CD38 antibody preloading on insulin secretion is not present directly against K-ATP channel. So, we guess that that effect may be present against another step of insulin secretion, for example, voltage-dependent calcium channel or mobilization of intracellular calcium or the other.

423

POSSIBLE MECHANISMS OF THE K-ATP CHANNEL-INDEPENDENT STIMULATION OF INSULIN SECRETION BY GLUCOSE

Y. Sato, Y. Miura, P. Detimary, M. Nenquin and J.C. Henquin. Unité d'Endocrinologie et Métabolisme, University of Louvain, Brussels, Belgium.

Glucose controls insulin secretion by regulating Ca^{2+} influx in B cells through changes in K^+-ATP channel activity and membrane potential, and by modulating the effectiveness of cytoplasmic Ca^{2+} on exocytosis. The second mechanism is still poorly understood and was investigated in the present study. Insulin release from mouse islets stimulated by 30 mmol/l K^+ (and 250 μmol/l diazoxide) was sustained in the presence of high glucose, but only transient in its absence in spite of a sustained rise of $[Ca^{2+}]_i$ in B cells. This progressive decline of the secretory response might suggest that the releasable pool rapidly empties unless it is refilled by glucose. However, stimulation of microtubule polymerization (taxol) or depolymerization (nocodazole) similarly decreased the secretory response to low or high glucose, without changing the pattern. Contrary to previous suggestions, the effect of glucose could not be ascribed to activation of PKC because it was resistant to three inhibitors which antagonized the effect of a phorbol ester. No evidence could be found for the intervention of a recently described ATP-sensitive phospholipase A_2, for a signal originating from the endoplasmic reticulum, or for a role of the nitric oxide pathway. In contrast, the effect of glucose was decreased by okadaic acid and calyculin A, two inhibitors of protein phosphatases which did not influence the ATP/ADP ratio. In conclusion, numerous possible mechanisms of this second effect of glucose have now been ruled out. The best correlations remain with the changes in adenine nucleotide levels. This study further indicates that phosphatases might be involved at a stage that has yet to be identified.

424

NITRIC OXIDE MODULATES INSULIN AND GLUCAGON SECRETION INDUCED BY CHOLINERGIC STIMULATION

B. Åkesson and I. Lundquist, Department of Pharmacology, University of Lund, Lund, Sweden

Immunohistochemical evidence has been obtained for the occurrence of a constitutive nitric oxide synthase (cNOS) in both endocrine cells and nerves in the pancreatic islets. By a combined in vivo and in vitro approach we have studied the role, if any, played by nitric oxide (NO) in insulin and glucagon secretion induced by cholinergic stimulation. Carbachol-induced insulin release from isolated islets in the presence of basal glucose (7mmol/l) was greatly enhanced by the NOS inhibitors N^G-nitro-L-arginine methyl ester (L-NAME) and N^G-monomethyl-L-arginine (L-NMMA). In contrast, carbachol-induced glucagon release was suppressed by the NOS-inhibitors. A similar effect by L-NAME on insulin release induced by the protein kinase C activator TPA was observed. Glucagon release was not affected. Carbachol-induced hormone release was not influenced by the enantiomer D-NAME, which is devoid of NOS inhibitory properties. Carbachol-induced insulin release from islets depolarized by 30 mmol/l K^+ in the presence of 250 μmol/l diazoxide was still increased by L-NAME, although the response was less pronounced. The intracellular NO donor hydroxylamine suppressed insulin release and enhanced glucagon release. Moreover, in vivo studies showed that the insulin secretory response to an i.v. injection of carbachol was greatly enhanced by pretreatment with L-NAME. In contrast, carbachol-induced glucagon response was suppressed by a previous injection of L-NAME. The data strongly suggest that NO is an important regulator of cholinergically stimulated insulin and glucagon secretion, being a negative modulator of insulin and a positive modulator of glucagon release. The effect on insulin release is, at least partly, independent of membrane depolarization events.

425

EFFECTS OF PROTEIN KINASE ON INSULIN SECRETION VIA ATP-SENSITIVE K^+ CHANNEL-INDEPENDENT PATHWAY.

M Nishimura, H Ishida, S Kato, Y Tsuura, N Mizuno, S Fujimoto and Y Seino, Kyoto University Faculty of Medicine, Kyoto, JAPAN.

We examined the possibility that glucose-induced insulin secretion can be elicited by protein kinase activations by a pathway independent of ATP-sensitive K^+ channels (K_{ATP} channels), using 100 μM diazoxide-hyperpolarized islets. No detectable $[Ca^{2+}]_i$ changes were observed by Fura-2 fluorometry under these conditions. Protein kinase C (PKC) activation was found to augment K_{ATP} channel-independent insulin release even at a lower glucose concentration (1.6 mM or 3.3 mM ; $p<0.01$). On the other hand, protein kinase A (PKA) activation augmented K_{ATP} channel-independent insulin release at higher glucose concentrations ($\geq$ 11.1 mM; $p<0.01$). Meanwhile, protein kinase G activation did not involve the mechanism. These facts indicate that the two mechanisms depend on phosphorylation of functionally distinct target proteins. Because mannoheptulose depressed PKC or PKA related insulin release, some intracellular metabolic signals derived from the sugar should be necessary for these pathways. This study clearly shows the existence of a novel regulatory system in pancreatic ß cell: glucose augments insulin release in a dose-dependent manner within a range of physiological concentration through a pathway independent of K_{ATP} channel closure under protein kinase activations without detectable $[Ca^{2+}]_i$ elevation.

426

A ROLE FOR PARACRINE NITRIC OXIDE IN THE EARLY PHASE OF GLUCOSE-STIMULATED INSULIN SECRETION

R. Laffranchi[1], M. Reinecke[2], I. David[2], C. Richter[3] and G. A. Spinas[1]. [1]University Hospital Zürich, [2]University of Zürich, [3]ETH Zürich, Switzerland.

Nitric oxide (nitrogen monoxide, NO) acts as a signal transducer in a variety of cells. There is substantial evidence to suggest that NO could also be involved in the insulin secretory pathway of pancreatic β-cells. In this study the effect of NO on acute glucose-stimulated insulin secretion from isolated islets of Langerhans and the localization of constitutive NO-synthase were investigated. Newborn rat islets were precultured in RPMI-1640 for 5-6 days and perifused with Krebs-Ringer buffer (KRHB) at a flow rate of 600µl/min in a 300µl perifusion chamber. After an equilibration period of 45min in KRHB + 1.6mM glucose, 0.5mM L-methylarginine (L-NMMA), or 10µM carboxy-PTIO, respectively, was added to the buffer. Glucose concentration in the perifusion medium was kept at 1.6mM for another 10min, was then raised to 16mM for 40min and was finally reduced to 1.6mM for 15min. For light- and electron-microscopic studies semithin and ultrathin sections, respectively, were analyzed with anti-NO-synthase antibody and antibodies against the classical islet hormones. Perifusion in the presence of the NO synthase inhibitor, L-NMMA, resulted in an inhibition of the early phase of glucose-stimulated insulin secretion by 66%: area under the curve (AUC) 12.2±3.2pg/islet x min vs. 35.4±3.8pg/islet x min in control islets ($p<0.001$). The second phase was not influenced by L-NMMA: AUC 34.6±3.8pg/islet x min and 36.1±9.2pg/islet x min in control and L-NMMA-exposed islets, respectively. Addition of 10µM carboxy-PTIO, a NO scavenger, to the perifusion medium resulted in an inhibition by 49% of the first phase of insulin secretion. The AUC was 34.4±7.3pg/islet x min and 17.5±5.3pg/islet x min in controls and carboxy-PTIO-exposed islets, respectively ($p<0.05$). The second phase was not affected, the AUC being 38.7±17.2pg/islet x min and 34.0±15.2pg/islet x min in controls and carboxy-PTIO-exposed islets, respectively. Light- and electron-microscopic studies revealed that pancreatic islets constitutively express NO-synthase in α- and δ-cells, where it is confined to the secretory granules. These data, thus, indicate that NO is important in the signal transduction pathway of the early phase of glucose-stimulated insulin secretion and that NO is likely to act in a paracrine and not in an autocrine manner.

427

PARTICIPATION OF CREATINE KINASE IN CONTROL OF INSULIN SECRETION

K. Gempel[1], D. Brdiczka[2], R. Kaddurah-Daouk[3], T. Wallimann[4], P. Kaufhold[1] and K.D. Gerbitz[1]; *[1]Institutes of Clinical Chemistry and Diabetes Research, Munich, Germany; [2]University of Konstanz, Germany; [3]Avicena Group Inc., Cambridge, USA; [4]ETH Zürich, Switzerland*

We have shown that the rat insulinoma cell line INS-1 contains brain type-creatine kinase (CK) as well as the mitochondrial CK isoform. The aim of this study was to elucidate whether the CK system takes part in the control of energy flow from the mitochondrium to energy-dependent sites of insulin secretion. To this end, INS-1 cells were loaded with the creatine analogue cylcocreatine (cCr) which is readily phosphorylated by CK and can serve as an energy donor at ATP-consuming sites, but at a severely lower rate compared to creatine phosphate. After loading cells for 24 hours with cCr ATP content of perchloric acid extracts of whole cells was measured by the firefly luciferase/luciferin method. Insulin secretion and insulin content were determined in parallel. Results: Incubation of INS-1 cells with cCr leads to dose-dependent intracellular accumulation of cCr. Percentage of phosphorylated cCr was generally greater than 90 %. With 5 mM extracellular cCr, cCr phosphate accumulated to 20 mmol/l cell water. ATP in these cells was 0.9 mmol/l cell water which was not significantly different from non-treated cells. However, insulin secretion in cCr-loaded cells was enhanced 3-fold ($p<0.05$), while insulin content was unchanged. Enhanced insulin secretion and cCr content were almost fully reversible after 24 hours of incubation in cCr-free medium. In conclusion these results suggest that in clonal beta cells CK participates in mitochondrium-plasma membrane energy transfer believed to be necessary for glucose-stimulated insulin secretion. Energy transfer cannot be demonstrated on the sole basis of ATP measurements and may be better explained by kinetic analysis as has been recently shown for adenylate kinase-catalyzed phosphotransfer (JBC 271:16544-52, 1996).

428

ISLET ACID GLUCAN-1,4-α-GLUCOSIDASE IN RELATION TO NITRIC OXIDE AND INSULIN SECRETION

H. Mosén, A. Salehi and I. Lundquist, Department of Pharmacology, University of Lund, Sweden

We have previously shown that activation of the islet lysosomal enzyme acid glucan-1,4-α-glucosidase increases, whereas nitric oxide (NO) inhibits, glucose-induced insulin release. Isoforms of α-glucosidehydrolases contain several cystein-residues being possible targets for NO-induced thiol inactivation processes. We therefore investigated, in isolated islets, the influence of NO on insulin release and islet acid α-glucosidehydrolase activities. It was observed that the intracellular NO donor hydroxylamine (300 µmol/l) markedly inhibited glucose-induced (16.7 mmol/l) insulin release. At the same time hydroxylamine strongly suppressed the activities of acid glucan-1,4-α-glucosidase, acid α-glucosidase and N-acetyl-β-D-glucosaminidase. The activities of acid phosphatase as well as neutral α-glucosidase were unaffected by the NO donor. Islet homogenates exposed to the spontaneous NO donor sodium nitroprusside (SNP) lost approximately 20-50% of their acid α-glucosidehydrolase activities during a 60 min incubation period. Acid phosphatase decreased by 25%, whereas N-acetyl-β-D-glucosaminidase was unaffected. When isolated islets were incubated at 16.7 mmol/l glucose in the presence of the specific NO synthase inhibitor N^G-nitro-L-arginine methyl ester (L-NAME; 5 mmol/l) the activities of the acid α-glucosidehydrolases were markedly increased, compared with the 16.7 mmol/l controls. Concomitantly there was a large increase in insulin release. Other lysosomal enzyme activities and the neutral α-glucosidase were not influenced. The data suggest that a possible mechanism for NO-induced inhibition of glucose-stimulated insulin release is exerted through an NO mediated inactivation of the acid glucan-1,4-α-glucosidase activity.

STIMULATION OF INSULIN RELEASE BY MICROMOLAR CONCENTRATIONS OF A NOVEL SUCCINIC ACID ESTER

W.J. Malaisse, L. Ladrière, J.A. Garcia-Martinez*, C. Viñambres*, M.L. Villanueva-Peñacarrillo*, I. Valverde* and F. Björkling**. Laboratory of Experimental Medicine, Brussels Free University, Brussels, Belgium, *Fundación Jiménez Diaz, Madrid, Spain and **Leo Pharmaceutical Products, Ballerup, Denmark.

Esters of succinic acid are currently under investigation as possible tools for stimulation of insulin release in NIDDM. They are indeed well suited to bypass site specific defects of D-glucose metabolism in diseased B-cells. In recent studies, two potential limitations of this therapeutic approach were already dealt with. Thus, it was first shown that several esters of succinic acid not susceptible to lead to the undesirable generation of methanol by intracellular hydrolysis are, like the methyl esters, potent insulin secretagogues. Second, some esters of succinic acid remain able to stimulate insulin release after enteral administration. The present work deals with two other objections to the use of succinate esters in NIDDM, namely the necessity of administering high amounts of these esters and, hence, their utilization as gluconeogenic precursor. In isolated rat pancreatic islets, 1,2,3-tri(methylsuccinyl)glycerol ester (3SMG) stimulated both biosynthetic and secretory activities. The release of insulin was increased by 3SMG both in the absence and presence of D-glucose. At a close-to-physiological hexose level (7 mM), as little as 10 μM 3SMG significantly augmented insulin output. Likewise, in anaesthetized rats, the plasma insulin concentration was increased by 2.72 ± 0.26 ng/ml (n = 6) two min after the intravenous injection of only 0.07 μmol of 3SMG per g body wt. With such a low amount, the risk of an untoward increase in gluconeogenesis is probably negligible. In conclusion, therefore, the present work provides essential support to the proposal that suitable esters of succinic acid could be used as insulinotropic agents in the treatment of NIDDM.

430

CITRULLINE-ARGININOSUCCINATE-ARGININE CYCLE IN β-CELLS COUPLED TO Ca^{2+}-SIGNALING AND INSULIN RELEASE VIA NITRIC OXIDE

M. Nakata[1,2], I. Maruyama[1], and T. Yada[2,3]. Departments of [1]Laboratory Medicine and [2]Physiology, Faculty of Medicine, Kagoshima University, Kagoshima, [3]Cellular Metabolism, National Institute for Physiological Sciences, Okazaki, Japan.

In the presence of stimulatory glucose (8.3 mmol/l), L-citrulline at physiological concentrations (0.1-1 mmol/l) under arginine-deficient conditions increased the cytoplasmic Ca^{2+} concentration ($[Ca^{2+}]_i$) in rat pancreatic β-cells and HIT cells, an insulinoma cell line, as demonstrated by ratiometric fura-2 microfluorometry. The enzymes involved in citrulline metabolism, argininosuccinate synthetase (ASS) which metabolizes L-citrulline to L-argininosuccinate, and argininosuccinate lyase (ASL) which metabolizes L-argininosuccinate to L-arginine, as well as the cerebellar-type NOS, were immunohistochemically localized in rat islets. The mRNAs of all three enzymes were also expressed in rat islets. Argininosuccinate and arginine at 0.1-1 mmol/l also increased $[Ca^{2+}]_i$ in rat β-cells. An NO-donor increased $[Ca^{2+}]_i$ in rat β-cells. Furthermore, citrulline also increased insulin release from rat islets in 8.3 mmol/l glucose. The citrulline-induced $[Ca^{2+}]_i$ increase and insulin release were inhibited by NMMA, an inhibitor of NOS. We propose that citrulline and arginine at physiological concentrations are recycled through ASS-ASL-NOS circuit, thereby activating a NO-mediated Ca^{2+} signalling pathway, which appears to be linked to potentiation of glucose-induced insulin release.

431

FAILURE OF D-FRUCTOSE TO STIMULATE PROTEIN BIOSYNTHESIS IN RAT PANCREATIC ISLETS

C. Viñambres, M.L. Villanueva-Peñacarrillo, I. Valverde and W.J. Malaisse*. Fundación Jiménez Díaz, Madrid, Spain and *Laboratory of Experimental Medicine, Brussels Free University, Brussels, Belgium.

Under suitable experimental conditions, D-fructose displays a modest but sizeable insulinotropic action. For instance, it was recently documented that, even in the absence of any other exogenous nutrient, D-fructose stimulates insulin release from rat pancreatic islets provided that the ketohexose is present in the incubation medium at a 240 mM concentration. Some doubt was expressed, however, on the view that the insulinotropic action of D-fructose would involve the same coupling factors as those currently incriminated in the process of glucose-induced insulin release. For instance, an apparent dissociation was observed between the secretory and metabolic effects of D-fructose in islets prepared from normal rats. These findings led us to investigate, in the present study, whether D-fructose, tested in high concentrations, mimics the stimulant action of D-glucose on biosynthetic activity in rat pancreatic islets. The islets were incubated in the presence of L-[4-^{3}H]phenylalanine (3.7 μM) and, as required, D-glucose (16.7 mM) or D-fructose (80 and 240 mM). After 90 min incubation, the islet content in tritiated TCA-soluble material was not significantly different in islets deprived of exogenous nutrient or exposed to either D-glucose or D-fructose. The amount of tritiated TCA-precipitable material found in the islets after incubation in the presence of 16.7 mM D-glucose was much higher ($P < 0.001$) than the basal value. D-fructose, however, whether tested at a concentration of 80 mM, which is close to the threshold value for the insulinotropic action of the ketohexose, or at 240 mM failed to stimulate the labelling of islet peptides. These findings reinforce the view that the stimulation of insulin release by D-fructose does not entail the same metabolic determinants as those operative in glucose-stimulated islets.

432

BIOCHEMICAL AND FUNCTIONAL ASPECTS ON ISLET HAEM OXYGENASE ACTIVITY AND CARBON MONOXIDE FORMATION.

R. Henningsson and I. Lundquist. Department of Pharmacology, University of Lund,Sweden.

Nitric oxide has been the molecule of the last decade, and its role as an endocrine modulator in the pancreatic islets is still controversial. The last few years yet another two-atomic gas, carbon monoxide produced from heme under the influence of the heme oxygenase (HO) enzyme, has been postulated also to function as a neuroendocrine modulator. In the present study we have detected and quantified CO production in mouse islet homogenate using a sensitive gas chromatographic method. Islet hormone release studies using the CO precursor hemin and the HO inhibitor zincprotoporphyrin IX indicate that CO is a positive modulator of both insulin and glucagon secretion. Exogenously applied CO also stimulates islet hormone secretion, in contrast to exogenously applied NO, which inhibits insulin secretion. The effects of CO seem mainly to be mediated through an elevation of intracellular cGMP levels. Further, hemin has been shown to potentiate L-arginine stimulated insulin secretion, an observation which could reveal a possible connection between the heme-CO and L-arginine-NO pathways. CO produced from heme might inhibit the nitric oxide enzyme activity and thereby L-arginine derived NO formation. We have previously shown NO to be a negative modulator of insulin release. In conclusion, mouse pancreatic islets contain a constitutive heme oxygenase enzyme producing detectable amounts of CO, which stimulates both insulin and glucagon secretion. There seems to be an important connection between the CO - system and the NO - system in islet tissue.

433

DO TOLBUTAMIDE AND DIAZOXIDE INFLUENCE INSULIN SECRETION BY MODULATING Ca^{2+} EFFICACY IN B CELLS ?

P. Gilon, M. Nenquin and J.C. Henquin. Unité d'Endocrinologie et Métabolisme, University of Louvain, Brussels, Belgium.

Sulfonylureas trigger insulin secretion by blocking K-ATP channels of the B cell membrane, thereby causing depolarization, Ca^{2+} influx and rise in cytoplasmic Ca^{2+} ($[Ca^{2+}]_i$). It has recently been suggested that they also potentiate the action of Ca^{2+} on exocytosis. We have already challenged this hypothesis, but further tested it here with normal mouse islets cultured overnight in RPMI medium containing 10 mM glucose. Depolarizing islet cells by raising extracellular K from 4.8 to 15, 30 and 60 mM, abolished $[Ca^{2+}]_i$ oscillations induced by 15 mM glucose and progressively raised $[Ca^{2+}]_i$. The effect of 100 µM tolbutamide on $[Ca^{2+}]_i$ was marked in 4.8 mM K, smaller in 15 mM K, minor in 30 mM K and absent in 60 mM K. The effect on insulin secretion paralleled that on $[Ca^{2+}]_i$. Tolbutamide was also ineffective in islets depolarized with 60 mM K in the presence of only 0.5 mM $CaCl_2$ (instead of 2.5 mM), without or with dibutyryl cAMP, or in the presence of low (3 mM) instead of high (15 mM) glucose. Repaglinide is a non-sulfonylurea drug that blocks K-ATP channels but does not potentiate the action of Ca^{2+} on exocytosis. In the presence of meglitinide, a parent compound, tolbutamide did not affect $[Ca^{2+}]_i$ (expected from the common action on K-ATP channels) and did not increase insulin release further (unexpected if tolbutamide also increases the efficacy of Ca^{2+}). In contrast to sulfonylureas, diazoxide has been reported to decrease the effectiveness of Ca^{2+}. However, 250 µM diazoxide was without effect on $[Ca^{2+}]_i$ and insulin release in islets depolarized by 60 mM K in 0.5 or 2.5 mM external $CaCl_2$. In conclusion, no evidence for a modulation of the Ca^{2+} action on exocytosis by tolbutamide or diazoxide could be found in normal mouse B cells.

434

PACAP AS AN INTRA-ISLET AMPLIFIER OF GLUCOSE-INDUCED INSULIN SECRETION.

T. Yada[1,6], M. Sakurada[4], H. Ishihara[4], M. Nakata[1,2], K. Yaekura[1,3], M. Kikuchi[4] and Y. Oka[5]. [1]Physiology, [2]Laboratory Med. and [3]Internal Med. I, Kagoshima Univ. Sch. of Med., Kagoshima, [4]The Institute for Adult Diseases, Asahi Life Foundation, Tokyo, [5]Internal Med. III, Yamaguchi Univ. Sch. of Med., Ube, [6]Cellular Metabolism, National Institute for Physiological Sciences, Okazaki, Japan.

It has been shown that pituitary adenylate cyclase activating polypeptide (PACAP) is localized in the pancreas and potently augments glucose-induced insulin release by increasing cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) in islet β-cells. We examined whether PACAP is involved in the regulation of glucose-induced insulin secretion by islets. High glucose (8.3-20 mM)-stimulated insulin release from isolated rat islets was attenuated by a specific anti-PACAP antiserum. The islet incubation medium with high glucose possessed a capacity, which was neutralized by PACAP antiserum, to increase $[Ca^{2+}]_i$ in rat β-cells, as measured by fura-2 microfluorometry. PACAP-immunoreactivity was localized in the entire region of rat islets. Furthermore, PACAP mRNA expression and PACAP biosynthesis were detected in islets and a β-cell line, MIN6. The (type-I) PACAP receptor was immunohistochemically observed in islets. $[Ca^{2+}]_i$ measurements revealed a substantial population of glucose-unresponsive β-cells, many of which were recruited by 10^{-13} M PACAP into $[Ca^{2+}]_i$ responses. These results indicate that PACAP is a novel islet hormone, which is synthesized and released by islets and then, in an autocrine manner, arouses and potentiates β-cell responses to glucose, thereby amplifying glucose-induced insulin secretion in islets.

435

CALCIUM SIGNALLING IS INVOLVED IN THE INSULIN-RELEASING EFFECT OF 4-HYDROXYISOLEUCINE

P. Petit[1], YJ Liu[3], C. Broca[1], Y. Sauvaire[2], G. Ribes[1] and E. Gylfe[3]. [1]Lab. Pharmacol., Fac. Medicine (UPRES 1677 & UMR 9921 CNRS); [2]Lab. Rech. Subst. Nat. Végétales (UPRES 1677), Université Montpellier II, Montpellier, France and [3]Depart. Med. Cell Biology, Biomed. Center, Uppsala University, Sweden.

The novel amino acid 4-hydroxyisoleucine (4-OH-Ile), extracted from *Trigonella foenum graecum L* seeds, stimulates insulin release from pancreatic islets; it also increases insulin secretion from isolated rat pancreas, in a glucose-dependent manner. This study was aimed at evaluating more precisely the influence of glucose in the insulinotropic effect of 4-OH-Ile, and investigating the role of calcium signalling in this effect. Insulin secretion was studied using the perfused rat isolated pancreas and cytoplasmic Ca^{2+} ($[Ca^{2+}]_i$) was measured in mouse β-cells loaded with the indicator fura-2. In the presence of 5 mmol/l glucose, 4-OH-Ile (200 µmol/l) did not modify insulin secretion. The difference in the area under the curve for insulin secretion compared to controls (Δ $AUC_{10\text{-}min}$) was 0.5 ± 0.4 ng. In the presence of 6.6, 7.4, 8.3 and 10 mmol/l glucose, the Δ $AUC_{10\text{-}min}$ were 5.6 ± 2.4, 57.5 ± 12.1, 77.1 ± 20.0 and 186.1 ± 14.4 ng, respectively. At concentrations of 0.5-1.0 mmol/l, 4-OH-Ile was ineffective on the cytoplasmic Ca^{2+} concentration of β-cells exposed to 3 mmol/l glucose. Elevation of glucose to 11 mmol/l resulted in large amplitude oscillations of $[Ca^{2+}]_i$, which were unaffected by the presence of 0.5 mmol/l 4-OH-Ile. In contrast at 7-8 mmol/l glucose, 0.5 mmol/l 4-OH-Ile induced large amplitude oscillations of $[Ca^{2+}]_i$. Reduction of glucose from 11 to 7 mmol/l inhibited the large amplitude $[Ca^{2+}]_i$ oscillations in most β-cells but they could be restored by 0.5 mmol/l 4-OH-Ile. In conclusion, the results show clear glucose dependence of the insulin-releasing effect of 4-OH-Ile. Moreover, the $[Ca^{2+}]_i$ data indicate that the amino acid potentiates the effect of intermediary glucose concentrations on Ca^{2+} signalling.

436

CALCIUM AND SODIUM DEPENDENCY OF THE INSULINOTROPIC EFFECT OF PACAP38 IN HIT-T15 CELLS

K. af Klinteberg and B. Ahrén. Dept. of Medicine, Lund Univ., Malmö, Sweden.

Pituitary adenylate cyclase-activating polypeptide (PACAP) is a pancreatic neuropeptide, which stimulates insulin secretion. Although the mechanism of its insulinotropic action is far from clear, the peptide raises cellular cAMP, increases cytosolic Ca^{2+} and induces formation of inositol phosphates (IPs) in insulin producing HIT-T15 cells. Earlier studies have shown that the mechanism of the insulinotropic effect of glucagon-like peptide-1 (GLP-1) not only involves cAMP, but is also Na^+ and Ca^{2+} dependent. Therefore, in this study, we examined the dependency of Na^+ and Ca^{2+} for the increases in insulin, cAMP and IPs after activation by PACAP38 in insulin producing HIT-T15 cells. IPs were measured from cells prelabeled with [2-^{3}H]-myoinositol, and eluted by anion chromatography. Removal of extracellular Ca^{2+} at 10 mM glucose abolished the insulinotropic effect of PACAP38 completely, without affecting the increase in cellular cAMP (44±8.9% in controls vs. 64±20% in the absence of Ca^{2+}, n=5, n.s.). PACAP38 increased IPs formation in the presence of Ca^{2+} (60±25%, n=3), but not in the absence of Ca^{2+} (-1±5.3%, n=3). Furthermore, removal of Na^+ from the medium and replacing it with N-methyl-D-glucamine reduced the insulinotropic effect of PACAP38 (430±48% in controls vs. 150±17% in the absence of Na^+, n=12, $P<0.001$) and the increase of cellular cAMP (100±13% vs. 24±7.9%, n=5, $P<0.01$), but the formation of IPs was not affected (81±8.9% vs. 95±23%, n=3, n.s.). In contrast, the markedly stimulated IPs formation induced by gastrin releasing peptide at 100 nM was diminished in the Na^+ free medium (980±150% vs. 213±39%, n=3, $P<0.01$). We conclude that the insulinotropic effect of PACAP38 in HIT-T15 cells, like that of GLP-1, is both Ca^{2+} and Na^+ dependent, whereas the PACAP38 induced formation of cAMP is dependent of Na^+ but is independent of Ca^{2+}. The results therefore suggest that after stimulation by PACAP38, Na^+ is required for the formation of cAMP whereas Ca^{2+} is required for the distal events of exocytosis in insulin producing HIT-T15 cells. Finally, we also suggest that formation of IPs is not of mechanistic importance for the insulinotropic action of PACAP38 in these cells.

437

INSULIN RELEASE DEPENDS ON GLUCOSE CONCENTRATION, INCUBATION TIME, TEMPERATURE, AND PH TESTED IN MOUSE AND RAT ISLETS

K.Wahls and H.-J.Mest. Beiersdorf-Lilly, Hamburg, Germany.

The purpose of the present study was to investigate the differences in insulin response of isolated mouse and rat islets under different conditions.The islets of both species were isolated and tested under the same conditions.Insulin was measured by means of RIA.The statistic was made by means of SIGMASTAT package. The numbers of experiments were between 16 and 24 for each point of different series. Insulin secretion was strongly dependent on glucose concentration for both species:3.3mM glucose did not induce insulin release (about 1ng/ml/islet) whereas 16.7mM glucose induced the same insulin release as 30mM glucose secreted insulin after 2 hours was 2-fold higher, $p<0.05$ in isolated mouse islets (about 6ng/ml/islet) than in rat islets (3ng/ml/islet).Insulin release was also dependent on incubation time:a longer incubation time elicited insulin secretion constantly, after 6h at 16.7mM glucose the insulin secretion of mouse islets was nearly 4-fold higher (30 ng/ml/islet), $p<0.05$ than of rat islets (8ng/ml/islet).Insulin release was enhanced in isolated pancreatic mouse and rat islets at higher temperatures. At 40°C the insulin release was 1.5-fold, $p<0.05$ increased compared to the insulin response at 37°C. The insulin content released by mouse islets was about 10 ng/ml/islet compared to 6 ng/ml/islets, $p<0.05$ whereas the rat islets released 7 ng/ml/islet at 40°C and 4 ng/ml/islet. $p<0.05$ at 37°C. We also demonstrated that alkaline pH reduced insulin secretion. In the range of pH7.2 to pH7.6 insulin release was almost the same for mouse and rat islets.At a pH of 8.0 there was a dramatic increase of insulin release in mouse islets (6.1 to 11.9 ng/ml/islet,$p<0.05$) whereas the rat islets (3.7 to 4.1 ng/ml/islet,$p<0.05$) did not release as much insulin as mouse islets. In conclusion, both mouse and rat islets released insulin in a time- and glucose concentration-dependent manner, insulin secretion was enhanced at higher temperatures and alkaline pH, but the released insulin content was much higher in mouse islets than in rat islets. The present data have demonstrated that the mouse islets seem to be more sensitive compared to rat islets under different conditions.

438

SPECIFICITY OF ADENYLYL CYCLASE ISOFORMS EXPRESSION IN PANCREATIC ISLETS AND ACINI

N. Ferrand, T. Demongot, G. Rosselin, S. Emami. INSERM U-55, Saint Antoine Hospital, Paris, France.

Eight adenylyl cyclase (AC) isoforms were described specifically in mammalian tissues, from broadly distributed types II and IV, to brain specific types I and VIII, but not in pancreas. In the present study we have investigated the presence and the distribution of six different isoforms, AC-I, II, III, IV and V/VI in neonate and adult mouse, rat, and hamster pancreas using antibodies raised against the C-terminal h817-836, rh1071-1090, r1125-1144, r1045-1064, hm1149-1165 sequences, respectively. Localization of AC in pancreatic endocrine cells, was performed using double labeling with either insulin or glucagon. The specific AC protein band was evaluated by western blotting in RINm5F cell line. AC-II was: (1) the most prominant protein expressed in rat and mouse pancreas, (2) strong expression was restricted to A and B cells of rat and mouse and (3) exclusively seen in A cells of adult hamster pancreas. In adult rat, ultrastructural study revealed the abundancy of AC-II isoform with a more pronounced labeling in the secretory granules and the plasma membrane of A and B cells. A marked fluorescence was observed with AC-III in A and B cells of 3-day-old mouse pancreas, with a lower intensity in 3-day-old rats and not detected in adult rats. Isoforms IV and V/VI were also expressed in B and A cells of 3-day-old mouse and with a lower intensity in 3-day and adult rats. Furthermore, scattered labelings were detected in exocrine area. AC-I was faintly, if any, expressed both in rat and mouse islets. This isoform as well as AC-III and IV was not detected in adult hamster. Western blots show 120, 100, 155, 110-135 and 105-140 kD bands corresponding to the AC-I, II, III, IV and V/VI isoforms, respectively. Coexistence of AC-III with G_{olf}, and of AC-II with G_s, G_i, Gq in the B cells suggest a possible association of these molecules into complexes required for the transduction of signal in B cells.

439

ROLE OF THE CYSTEINE STRING PROTEIN CSP IN INSULIN SECRETION FROM PANCREATIC β-CELLS

H. Zhang, W. Kelly*, L. H. Chamberlain[&], R. Bourgoyne[&], C.B. Wollheim and J. Lang

*Div. of Clinical Biochemistry and * Dep. of Medical Biochemistry, CMU, U. of Geneva, Switzerland; [&] Physiological Laboratory, U. of Liverpool, U.K.*

We investigated the putative function of CSP in insulin sceretion as this protein has previously been implicated in the regulation of neurotransmission. In addition, two splice variants have been cloned recently from chromaffin cells, localized to exocytotic vesicles and proposed to function via their DnaJ-domains as chaperones in the folding of proteins required to induce secretion by membrane fusion of secretory granules with the plasma membrane. Western blot analysis demonstrates the presence of a 36 kDa CSP in HIT-T15, INS-1, RINm5F and MIN6 cells. Subcellular fractionation and immuno-cytochemistry using confocal microscopy localizes CSP mainly on secretory granules and on synaptic-like microvesicles in INS-1 and primary β-cells. Despite its known high degree of palmitoylation in its cysteine string domain CSP was removed from membranes only by detergent (Triton-X100) but not by ethanolamine and, therefore, behaves as an integral membrane protein. Upon transient coexpression of human insulin gene and myc-tagged CSP splice variants, both CSP forms are localized to vesicular structures in hamster HIT-T15 cells. Furthermore both splice variants inhibit insulin release evoked by Ca^{2+}-influx as measured by the release of human C-peptide used as a reporter gene. In contrast, a point mutation in CSP (G91V) abolished its inhibitory effect although its subcellular distribution was comparable to the wild-type. Transient overexpression of antisense CSP in HIT-T15 cells largely reduced stimulated insulin release. We are currently investigating the effect of highly conserved residues in the DnaJ-domain by the use of different point mutations. In conclusion, CSP is a secretory granule protein in insulin-secreting cells and the functional observations are compatible with a chaperone function of CSP on the secretory machinery required for insulin secretion.

440

GLUCOSE DEPENDENT INSULIN SECRETION BY THE ADENYLATE CYCLASE (AC) / cAMP-SYSTEM IN THE INSULINOMA CELL LINE ßTC6,F7.

M. Hamann, B. Steckel and H.-J. Mest, Beiersdorf-Lilly GmbH, Hamburg, Germany

It is well known, that compounds that enhance intracellular cyclic adenosinmonophosphate (cAMP) are able to stimulate insulin secretion of beta cells only in the presence of high glucose concentrations (glucose dependent). However the mechanisms underlying this effect are remain controversal. The aim of the present study was to investigate the glucose dependent insulin secretion by the AC/cAMP-system on the recently developed insulinoma cell line ßTC6,F7 (passages 54-85). All experiments were carried out by static incubations of the cells in the absence and in the presence of 10 mM glucose. In contrast to glucose, that had no effect on insulin secretion itself, the phosphodiesterase inhibitor IBMX (25 µM) stimulated insulin secretion in the presence of glucose by 1.5-fold ($p<0.001$). The AC-stimulator forskolin enhanced insulin release in the presence of glucose dose dependently with an EC_{50} of 1 µM and its maximal stimulation at 3 µM (2.2-fold, $p<0.001$). In the absence of glucose, IBMX and forskolin had only a slight effect on insulin release. GLP-1 (7-36) as a physiological insulin secretagogue was also able to potentiate insulin release only in the presence of glucose and IBMX (1.5-fold, $p<0.001$). In contrast GLP-1 had no effect on insulin release with or without IBMX in the abscence of glucose. 8-bromo-cAMP the stable analogue of cAMP stimulated insulin release in the presence of glucose at higher concentrations by 1.5-fold (100µM, $p<0.001$). Surprisingly, all glucose dependent insulin secretions by the above-mentioned secretagouges were completly blocked by 200 µM Diazoxid. 9-(tetrahydro-2-furyl)adenin (SQ22536) an AC-inhibitor was able to inhibit the forskolin induced but not the IBMX induced insulin release. The glucose dependent insulin releasing effects of forskolin and IBMX were not inhibited by 100 nM of the proteinkinase A inhibitor H89. We conclude that at first the glucose dependent insulin secreting AC/cAMP system in ßTC6,F7 insulinoma cells is functional and secondly cAMP exerts its effect on insulin secretion in a glucose dependent mechanism at the beta cell membrane that does not include proteinkinase A.

441

THE 55 kDa CA^{2+}/CALMODULIN KINASE II δ_2 (CaMkin II) COMIGRATES WITH INSULIN SECRETION GRANULES IN INS-1 CELLS

M. Möhlig, S. Wolter, J. Lang*, M. Osterhoff, H. Schatz and A. Pfeiffer, Dept. Int. Medicine, Univ. clinic Bergmannsheil, Bochum, Germany and *Div. Clin. Biochemistry, Univ. Geneva, Switzerland

CaMkin II phosphorylates insulin secretion granule proteins including synapsin in ß-cells and is activated by glucose. The mRNAs of CaMkin II δ_2, δ_6, $ß_3$ and γ were found in insulinoma cells. We investigated the intracellular distribution of CaMkin II to assess its role in insulin secretion. **Methods:** Antibodies were generated in rabbits against the bacterially expressed C-terminal 200 amino acids of CaMkin II δ_2 which crossreact with bacterially expressed CaMkin γ. INS-1 cells were fractionated on 5 to 20 % sucrose gradients or on metrizamide step gradients. Insulin, synaptophysin (synaptic-like vesicles), Na/K-ATPase, 78 kDa heat shock protein (ER), arylsulfatase (lysosomes) were determined as marker enzymes. **Results:** A 55 kDa CaMkin II immunoreactivity corresponding in size to the recombinant δ_2 variant was present predominantly in the detergent insoluble compartment and fainter in cytosol. Fractionation of postnuclear supernatant on sucrose gradients showed close comigration with insulin granules and no comigration with synaptic-like vesicles, plasma membrane, ER or lysosomal markers. On metrizamide step gradients the 55 kDa CaMkin II also apperard in the insulin granule fraction. **Conclusion:** The comigration of CaMkin II δ2 with insulin secretion granules suggests a role in insulin secretion. The poor detergent solubility may indicate cytoskeletal components which may localize CaMkin II in granule recruitment. Other isoforms of CaMkin II should be larger (γ, $ß_3$) or smaller (δ_6) but were not detectable with our antibody. Remarkably, CaMkin II δ_2 was not present on synaptic-like vesicles containing GABA in contrast to its association with synaptic vesicles in brain.

B-CELL INSENSITIVITY LINKS TO Ca^{2+}-INDEPENDENT DECREASE IN cAMP GENERATION AND RIGHT-SHIFT IN cAMP-INDUCED INSULIN RELEASE

A Björklund, V Grill Dept Endocrinology, Karolinska Hospital, Stockholm, Sweden

Diazoxide (D) blocks glucose-induced insulin secretion and thereby protects against excessive stimulation, which is a major cause of hyperglycemia-induced B-cell insensitivity. D was used to explore the role of the adenylatecyclase-cAMP system for insensitivity. Rat pancreatic islets were cultured for 22 h in RPMI with 27 mM glucose (G) and with or without 325 µM D. In the presence of 3.3 mM G previous D increased forskolin-induced islet cAMP from 18.3±2.2 to 23.0±2.1, from 46.2±10.6 to 68.1±15.5 and from 163±21 to 231±37 fmol/islet for forskolin concentrations 0.1, 1 and 25 µM respectively, $p<0.05$ or less. These effects were not due to D per se since co-culture with D and 6 mM G failed to influence cAMP levels. In islets cultured at 27 mM G, co-culture with D enhanced insulin secretion only at 0.1 µM and not at higher concentrations of forskolin. Omission of Ca^{2+} to preincubation (30 min) and final incubation media did not diminish the cAMP response to 25 µM forskolin and did not reduce the enhancing effect of previous D. Insulin responses to the cAMP analogue (Sp)5,6-dichloro-1-β-D-ribofuranosyl-benzimidazole-3',5-cyclic monophosphorothioate (BIMPS) were tested in 60 min final incubations together with 6 mM G. At concentrations 0.01, 0.025 and 0.05 mM previous D increased insulin responses by 73, 217 and 69% respectively, $p<0.025$ or less. However, previous D failed to affect insulin responses to 0.1 mM BIMPS. Omission of calcium reduced the insulin response to 0.05 mM BIMPS comparatively more after previous D than in islets cultured without D. Conclusions: Averting excessive stimulation by D moderately increases forskolin-induced cAMP responses. This effect is not secondary to perturbations in calcium inflow. Furthermore, previous D left-shifts insulin release in dose-response to elevations of cAMP but does not alter maximal responses.

443

Effect Of Protein Kinase Cβ Selective Inhibitors On Insulin Secretion and Beta cell activty.

CECILE M. GONZALEZ, VALERIE K. WILLIAMS, GERALD GOLD,* LAWRENCE E. STRAMM,* AND MICHAEL R. JIROUSEK*, Indianapolis, IN, USA

Phorbol esters such as 4-β-phorbol-12-myristate-13-acetate (PMA) have been shown to stimulate insulin secretion under high glucose conditions from pancreatic islets presumably by activation of protein kinase C (PKC). Staurosporine has been shown to inhibit high glucose/PMA induced insulin secretion in pancreatic islets. Likewise, we have found potentiated insulin secretion to occur under high glucose conditions on phorbol ester, 4-β-phorbol-12,13-dibutyrate (PDBu), challenge (ED50=10 nM) in transformed beta cells (BTC6-f7). Staurosporine was able to inhibit insulin secretion on PDBu challenge in BTC6-f7 cells (IC50=30 nM). However staurosporine is a more potent inhibitor of both calcium calmodulin (IC50=4 nM) and src tyrosine kinase (IC50=1 nM) than most PKC isozymes (PKCβII IC50=19 nM). We tested the effect of several of the PKCβ isozyme selective antagonists we have developed, such as LY333531, on insulin secretion under basal, high glucose, and on phorbol challenge in BTC6-f7 cells. Cells were treated with PDBu, staurosporine, and various PKC inhibitors for one hour. Activity of the compound was assessed by measuring insulin secretion via insulin RIA. Cell viability was assessed by testing the compound in low glucose. LY333531 as well as other analogues from the series inhibit PKC activity but were unable to inhibit PDBu stimulated insulin secretion. In the absence of PDBu these PKCβ selective inhibitors stimulated insulin secretion under high glucose concentration in βTC6-f7 cells. The above results indicate that a PKCβ selective antagonist does not inhibit insulin secretion and is capable of stimulating insulin secretion only under high glucose conditions, from transformed βTC6-f7 cells.

444

ABNORMAL cAMP CONTENT AND INSULIN RELEASE IN ISLETS OF SPONTANEOUSLY DIABETIC GK RATS.

N. Dachicourt, P. Serradas, D. Bailbé and B. Portha
Lab. Physiopathol. Nutr. CNRS-URA 307 - Paris, France.

We have tested the possibility that a defect in the islet cAMP production could be involved in the failure of the glucose-induced insulin release in the diabetic GK rats, a recognized model of NIDDM. Exposure to increasing glucose concentrations induced a rise of the cAMP content in the control islets. In the GK islets, cAMP content was 1.6-fold higher as compared to controls at 2.8mM glucose and increasing glucose concentrations elicited no further increase. This coincided with a very low glucose-induced insulin release by the same GK islets. Forskolin markedly enhanced both cAMP and insulin release at 16.7mM glucose in GK islets and to a lesser extent in control islets. IBMX increased the cAMP content to the same extent in both type of islets. Nevertheless, insulin release was significantly higher in the GK islets as compared to control islets. GLP-1 amplified the cAMP content and insulin release to the same extent in both type of islets. Somatostatin decreased cAMP content and insulin release more efficiently in GK islets that in control islets. Kinetics of insulin release in vitro by islets were tested using perifusion procedure. Following exposure to 16.7mM glucose a biphasic pattern of insulin release was observed in the control islets whereas it induced only a modest increase in insulin output in GK islets. Accordingly, the incremental insulin response to 16.7mM glucose was 4-fold decreased in GK as compared to control rats. IBMX and GLP-1 enhanced the secretory response to 16.7mM glucose respectively by 5-fold and 4-fold in control rats and by 12-fold and 5-fold in GK rats. Under these conditions a clear biphasic pattern of the insulin release was regained in GK islets. In summary, ß-cell of diabetic GK rats showed 1) an increased cAMP content already at 2.8mM glucose 2) a defective glucose-stimulated cAMP generation. However it is possible to regain competence of the GK ß-cells to glucose with agents that artificially rise their intracellular cAMP.

445

INDUCIBLE OVEREXPRESSION OF CA^{2+}/CALMODULIN KINASE II δ_2 IN INSULINOMA CELLS BY MEANS OF RETROVIRAL INFECTION

P.A. Horn, M. Möhlig, C. Stocking, J. Hofmann, H. Schatz and A. Pfeiffer, Medizinische Universitätsklinik Bergmannsheil, Bochum, and Heinrich-Pette-Institut für Exp. Virologie und Immunologie, Hamburg, Germany

Ca^{2+}/calmodulin-dependent kinase II (CaM kinase II) participates in stimulated insulin secretion. A promising approach to elucidate its exact role is overexpression in insulin secreting cells. Retroviral vectors allow clean and stable insertion of single copies of foreign genes. Inducible gene expression permits to investigate effects of inserted genes without variations introduced by clonal differences. **Methods:** Retroviral producer cell lines of a replication deficient retroviral vector with an estrogen responsive 5' LTR driving a neomycin resistance and the CaM kinase II δ_2 cDNA were generated and used to infect the RINm5F insulinoma which was previously infected with estrogen receptors (ER). CaM kinase expression levels were quantified by immunoblotting with antibodies generated in rabbits and kinase activity was measured by ^{32}P-transfer. **Results:** After infection and selection of RIN cells expressing ERs, the E_2 response was tested by transient transfection with an E_2 responsive luciferase reporter plasmid yielding an up to 20-fold increase in luciferase counts, while no stimulation was detected in normal RIN cells. ER positive cells were subsequently infected with the E_2 responsive CaM kinase II δ_2 vector and selected. CaM kinase II immunoreactivity in transduced but unstimulated cells was almost twice that of untransduced RIN cells. Stimulation with 10 nM E_2 led to a 5- to 6-fold increase. CaM kinase phosphotransfer activity increased 6-fold upon stimulating with E_2 over normal RIN cells. **Conclusion:** Stable insulinoma cell lines with E_2 inducible overexpression of CaM kinase II δ_2 can be generated using a novel E_2 inducible retroviral vector. This inducible overexpression will allow detailed studies on the physiological role of CaM kinase II in insulin secretion. Supported by DFG.

POTENTIATION BY FORSKOLIN OF GLIQUIDONE INSULINOTROPIC ACTION IN THE PERFUSED PANCREAS OF NORMAL AND GK RATS

V. Leclercq-Meyer and W.J. Malaisse. Laboratory of Experimental Medicine, Brussels Free University, Brussels, Belgium.

The insulinotropic action of hypoglycemic sulfonylureas is modulated by the metabolism of nutrients in the B-cell, and could thus be altered in NIDDM because of an impaired sensitivity of the B-cell to glucose. The present study deals with a possible modality for potentiation of the B-cell response to the hypoglycemic agents in NIDDM. It indeed explores the influence of forskolin upon gliquidone-induced insulin release in the perfused pancreas of normal and GK rats. The effect of gliquidone (1 μM) upon insulin and glucagon output was examined, at a low concentration of glucose (2.8 mM), in the absence or presence of forskolin (1.3 μM). In normal rats, the diterpene exerted little effect upon basal insulin release but markedly augmented gliquidone insulinotropic action. Such a potentiation was observed whether the response to the sulfonylurea was examined first in the absence and then in the presence of forskolin, or in the reverse sequence. In GK rats, forskolin dramatically augmented both basal and gliquidone-stimulated insulin output. In relative terms, forskolin increased to a much greater extent the response to gliquidone in GK rats than in control animals. Forskolin enhanced basal glucagon output, especially in normal rats, and unmasked the glucagonotropic potential of gliquidone in GK rats. These findings suggest a dual mechanism -metabolic and energy-independent- for the response of islet cells to the forskolin-induced generation of cyclic AMP. They also draw attention to the improvement by endogenous cyclic AMP of the B-cell secretory response to hypoglycemic sulfonylureas.

INSULIN SECRETION FROM PANCREATIC β-CELLS: CONTRADICTORY EFFECTS OF PROTEIN KINASE C INHIBITORS

T.E. Harris, S.J. Persaud and P.M. Jones. Biomedical Sciences Division, King's College London, London, U.K.

Previous studies that have used chemical inhibitors of protein kinase C (PKC) in β-cells have yielded conflicting evidence as to the importance of PKC in nutrient-stimulated insulin release (IR). There are many types of chemical PKC inhibitors available, which interact with various regions within the enzyme structure. We have investigated the effect of three PKC inhibitors on IR from intact rat islets. Two of the inhibitors target the ATP-binding site of PKC: Ro 31-8220 (Ro), which is selective for PKC but not for individual isoforms; and Gö 6976 (Gö), which preferentially inhibits Ca^{2+}-dependent PKCs. The third inhibitor safingol (S) competitively interacts with the phorbol ester binding site of PKC. Ro (10 μM) inhibited phorbol ester (PMA)-induced IR (20 mM G, 100±6.5%; 20 mM G + 500 nM PMA, 142.5±5.7%; + Ro, 101.4±3.6%, $p<0.001$, $n=9$) and partially inhibited glucose (G)-stimulated IR by 38.5±2.2% ($p<0.001$, $n=9$). Similarly, Gö also inhibited PMA-induced IR (10 mM G + 500 nM PMA, 292.1±21.9% of G-stimulated response; + 1 μM Gö, 130.7±21.4%; $p<0.01$, $n=7$) but unlike Ro, did not compromise G-induced IR (10 mM G, 2.12±0.36 ng/islet/h; + 1 μM Gö, 2.21±0.38; $p>0.2$, $n=8$). In some experiments, S (1-100 μM) inhibited PMA- and G-induced IR in a concentration-dependent manner (10 mM G + 500 nM PMA, 183.7±26.3% of G-induced response, + 100 μM S, 94.1±5.4%, $p<0.01$, $n=7$; 10 mM G, 100±13.4%, + 100 μM S, 25.5±4.6%, $p<0.001$, $n=6$). However, unlike Ro and Gö, the effects of S tended to be irreproducible between experiments and on some occasions these concentrations of S were without effect on either PMA- or G-induced IR. These apparently contradictory results using different PKC inhibitors presumably reflect non-selectivity of some or all of the inhibitors and reinforce the conclusion that caution should be applied when using chemical inhibitors of PKC in pancreatic β-cells.

DISSOCIATION BETWEEN CYTOSOLIC Ca^{2+} AND INSULIN RESPONSES IN GLUCOSE-STIMULATED ISLETS FROM DIABETIC GK RATS

R.M. Santos[1,2], R.M. Seiça[1,3], A.P. Salgado[1], F.C. Pereira[1], C.M. Antunes[1], K. Suzuki[4], and L.M. Rosário[1,2]. [1]Centre for Neurociences of Coimbra; [2]Dept. Biochemistry, Fac. of Sciences and Technology, University of Coimbra; [3]School of Medicine, University of Coimbra; [4]Dept. of Medicine, Tohoku Kosei-Nenkin Hospital, Sendai, Japan.

Goto-Kakizaki (GK) rats have been extensively used as an animal model to study defective insulin release in NIDDM. Since impaired β-cell metabolism appears to be a major contributing factor to the GK diabetic syndrome, it has often been assumed that intracellular Ca^{2+} signalling might also be compromised in β-cells from GK rats. We have assessed this hypothesis by undertaking a comparative study of cytosolic free Ca^{2+} concentration ($[Ca^{2+}]_i$, *via* fura-2 microfluorometry) and insulin secretion in glucose-stimulated isolated islets from normal Wistar and GK rats. GK rats from the Coimbra colony (11-14 weeks) were overtly hyperglycemic in the fasting state and displayed pronounced glucose intolerance. Raising glucose concentration from 2 to 11 mM evoked a biphasic insulin response from normal islets (10-fold stimulation over basal at 20 min) and a feeble monophasic response from GK islets (0.2- and 2-fold stimulation over basal at 20 and 50 min, respectively). In contrast, the depolarizing aminoacid arginine (20 mM) and the K_{ATP} channel blocker tolbutamide (500 μM) stimulated insulin release and $[Ca^{2+}]_i$ to about the same extent in normal and GK islets. Glucose raised the $[Ca^{2+}]_i$ to the same final extent in normal and GK rats, albeit with a different time course (notably slower for GK islets). In contrast to normal rat islets, GK islets often displayed fast $[Ca^{2+}]_i$ oscillations. We conclude that long term stimulation of glucose metabolism in β-cells from diabetic GK rats is sufficient to elicit an appropriate Ca^{2+} signal while being insufficient to provide full support to the Ca^{2+}-dependent reactions leading to exocytosis (for example, in the form of adequate cytoplasmic ATP levels).

449

Effects of PD098059, an inhibitor of the MAPK cascade, on insulin secretion from pancreatic β-cells.

C.J. Burns, E. Hogan, S.L. Howell, P.M. Jones and S.J. Persaud
Biomedical Sciences Division, King's College London, London, UK

We have investigated the expression of members of the MAPK cascade in a glucose-responsive pancreatic β-cell line (MIN6) and examined the effects of modulation of signalling through the cascade on insulin secretion in response to nutrients and an activator of protein kinase C (PKC). Western blotting studies using specific antisera demonstrated that MIN6 cells express MAPK (42 and 44kDa isoforms), MEK (45 and 46kDa isoforms), the activator of MAPK, as well as raf-1 (~70kDa) and MEK kinase (~76kDa), which activate MEK in the cascade. The MAPK cascade is blocked by PD 98059 (PD), a highly selective inhibitor of the phosphorylation and activation of MEK. MIN6 cells showed a dose-dependent increase in insulin secretion in response to glucose (2mM: 2.2±0.2ng/5000 cells/h; 8mM: 2.9±0.2; 14mM: 5.0±0.5; 20mM: 5.7±0.7; n=9; P<0.001 by ANOVA) and also responded significantly to 10mM ketoisocaproate (KIC; 162±7% basal; n=9; P<0.001). Pre-treatment of MIN6 cells with 50μM PD for 1-2 hours did not significantly affect insulin secretion in response to 20mM glucose(G) (20mM G: 5.2±0.31ng/15,000 cells/h; 20mM G+PD: 6.1±0.39; n=7; P>0.1) nor to 10mM KIC (10mM KIC: 5.78±0.39ng/15,000 cells/h; 10mM KIC+PD: 5.7±0.22; n=6; P>0.8). Similarly, pre-exposure of islets to a range of PD concentrations (0.16-50μM) had no effect on glucose-stimulated insulin secretion from normal rat islets (2mM G: 0.44±0.10ng/islet/h; 20mM G: 2.21±0.30; +1.6μM PD: 1.96±0.10; +50μM PD: 2.54±0.32; n=8-9; P>0.7 by ANOVA). Activation of PKC with 500nM PMA potentiated glucose-stimulated insulin secretion from both MIN6 β-cells and islets, and this was not significantly affected by inhibition of the MAPK cascade with 50μM PD (MIN6: 20mM G+PMA: 7.85±0.62ng/15,000 cells/h; 20mM G+PMA+PD: 6.66±0.77; n=8, P>0.1; Islets: 20mM G+PMA: 3.27±0.45ng/islet/h; 20mM G+PMA+PD: 2.61±0.50; n=8, P>0.3). These results suggest that β-cells express components of the MAPK cascade, but that signalling through this pathway is not essential for secretion in response to nutrients, nor to activators of PKC.

450

GLUCOSE TOXICITY ON PANCREATIC β-CELLS IS NOT DUE TO INSULIN ACTION OR HYPEROSMOLARITY AND IS COUNTERACTED BY PACAP.

K. Yanagida[1,2], T. Arima[2] and T. Yada[1,3]. Departments of [1]Physiology and [2]2nd Internal Medicine, Faculty of Medicine, Kagoshima University, Kagoshima, [3]Cellular Metabolism, National Institute for Physiological Sciences, Okazaki, Japan.

Whether the glucose toxicity on pancreatic β-cells is produced directly by hyperglycemia or via high levels of insulin or hyperosmolarity induced secondary by hyperglycemia was examined. Isolated single β-cells from Wistar rats were cultured in a normal condition (5.6 mM glucose) and in conditions with high glucose (22-33 mM), insulin (10^{-5} M) or mannitol (27.4 mM). After culture for 2-3 days, the β-cell response to glucose (8.3 mM), tolbutamide (300 μM) and arginine (10 mM) was assessed by measurement of the cytoplasmic Ca^{2+} concentration ($[Ca^{2+}]_i$) by fura-2 microfluorometry. Percentage of β-cells responding to glucose with an increase in $[Ca^{2+}]_i$ was significantly lower (40%) in the high glucose culture group than in control group (70%), whereas no difference was observed between the insulin, mannitol and control groups. The responsiveness to tolbutamide and arginine was not different between all the control and test groups. When pituitary adenylate cyclase activating polypeptide (PACAP) was added in high glucose culture, the responsiveness to glucose was partially restored (50%) and $[Ca^{2+}]_i$ oscillations were frequently superimposed on the $[Ca^{2+}]_i$ increase in response to glucose. In conclusion, the glucose toxicity is not due to the action of high levels of insulin or hyperosmolarity but primarily to the hyperglycemia itself. PACAP has an ability to protect β-cells against hyperglycemia.

451

REGULATABLE CARBOXYL METHYLATION OF THE CATALYTIC SUBUNIT OF PROTEIN PHOSPHATASE 2A IN THE PANCREATIC β CELL

A. Kowluru and S. Metz, University of Wisconsin-Madison, USA

Recently, we identified that the 36 kDa catalytic subunit of protein phosphatase 2A (PP2Ac) undergoes carboxyl methylation (CM) in normal rat islets and INS-1 cells, an effect accompanied by increased PP2A activity. Recent studies have described adenine and guanine nucleotides, or glycolytic intermediates, as modulators of PP2A activity in the pancreatic β cell. Therefore, we examined whether these molecules regulate the CM of PP2Ac in β cells. ATP (-82%), ADP (-81%), GTP (-83%), or GDP (-88%) all inhibited PP2Ac CM. Moreover, the latter was also inhibited by mM concentrations of glucose-6-P (-64%), glucose-1,6 P_2 (-44%), fructose-6-P (-18%) or fructose-1,6-P_2 (-53%), compatible with described inhibitory effects of these modulators on the phosphatase activity. Additionally, however, the CM of PP2Ac was significantly stimulated by divalent metal ions (Mn^{2+} >Mg^{2+} > Ca^{2+} > control); furthermore, the nucleotide phosphate-mediated inhibition of CM of PP2Ac was completely reversed by Mn^{2+} or Mg^{2+}, suggesting that the effects of phosphorylated molecules are generalized and non-specific. In most cells, acetyl CoA carboxylase (ACC) is regulated by phosphorylation (inactive)-dephosphorylation (active) and indeed, recent studies have implicated PP2A in the regulation of hepatic ACC activity by dicarboxylic acids and Mg^{2+}. Therefore, we investigated whether dicarboxylic acids and metal ions regulate the CM of PP2Ac (and its activity) and ACC in β cells. Glutamate or succinate stimulated (+ 42-84%) the CM of PP2Ac and increased ACC activity (+ 150%) in β cell homogenates. Okadaic acid (50 nM), a specific inhibitor of PP2A, abrogated the CM of PP2Ac as well as Mg^{2+}- or glutamate-stimulated ACC activity in β cell homogenates. These data imply that CM -derived changes in PP2A activity may contribute to regulation of key enzymes (e.g., ACC) of β cell intermediary metabolism.

452

GOTO-KAKIZAKI RAT, A MODEL OF GLUCOSE PRIMING RATHER THAN GLUCOSE TOXICITY?

N.Suzuki, T.Aizawa, N.Asanuma, M.Komatsu and K.Hashizume. Shinshu University, Matsumoto, Japan.

This study was designed to delineate the nature of β cell dysfunction in a model of genetically determined non-obese diabetes, the Goto-Kakizaki (GK) rat. Pancreatic β cell function was analyzed immediately after weaning and 5 weeks thereafter, comparing animals with or without insulin treatment during the interval. In 3.5 week-old GK rats, fasting plasma glucose was significantly elevated with normoinsulinaemia, and the islet insulin content was reduced by 33%. When incubated with 3-30 mM glucose *in vitro*, the islets from 3.5 week-old GK rats showed reduced glucose sensitivity, i.e., the EC50 values were 19.5 and 15.9 mM, and the Hill constants for the positive cooperativity 2.1 and 4.2, in the islets of GK and the control rats, respectively. On the other hand, the maximum response to glucose was not attenuated when reduced islet insulin content was considered. In 8.5 week-old GK rats, hyperglycaemia worsened and glucose-stimulated insulin release by the islets more severely impaired. A daily sc insulin (Novolin U®) injection from the age of 3.5 to 8.5 weeks significantly prevented worsening of hyperglycaemia, which was accompanied by a near-total obliteration of glucose (6-30 mM) -stimulated insulin release by the islets: An acceleration of β cell dysfunction by insulin treatment in the GK rat implies the β cell dysfunction is not due to glucose toxicity in this model. On the contrary, the rat may well be a model of β cell glucose priming.

453

G-PROTEIN-mRNA REGULATION: A MECHANISM FOR HETEROLOGOUS DESENSITIZATION OF INSULIN SECRETION IN INS-1 CELLS

E. J. Verspohl, S. Kesper, Dept. Pharmacol., Inst. Pharm. Chem., Münster, Germany

Prolonged exposure of cells to an agonist usually results in an attenuation of the cellular response. We investigated the regulation of mRNA levels of G-protein α_S- and α_{i2}-subunits in an insulin-secreting cell line (INS-1) and its influence on insulin secretion by northern blot analysis using specific DIG-labeled DNA probes and by RIA. Exposure to epinephrine (50 µM) for 8 h decreases α_S- and α_{i2}-mRNA levels to 58% and 72%, resp. After 24 h exposure α_{i2}-mRNA levels are increased to 150%, whereas α_S-mRNA levels reach control levels. Isoprenaline (10 µM) does not influence either mRNA level. Treatment with the specific α_2-agonist UK 14.304 (1 µM) (5-bromo-6-[2-imidazolin-2-ylamino]-quinoxaline) shows the same effects as epinephrine indicating that epinephrine actions are mediated via α_2-adrenoceptors. Exposure to either incretin hormone glucagon-like peptide I (GLP-1) (10 nM) and gastric inhibitory polypeptide (GIP) (10 nM) increases α_S- and α_{i2}-mRNA levels (GLP-1: 129% and 137%; GIP: 131% and 182%). The Ca^{2+}-channel blocker verapamil causes a reduction of α_{i2}-mRNA (85%). Incubation with either GIP or GLP-1 together with verapamil decreases α_{i2}-mRNA levels (54% and 77%) showing that the increase of α_{i2}-mRNA depends on Ca^{2+}-influx into the cell. This regulation of mRNA levels is accompanied by reciprocal changes in insulin secretion. Looking at heterologous desensitization an 8 h preincubation with UK 14.304 leads to an increased insulin secretion due to stimulation with GLP-1 (227%) or 8.3 mM glucose (137%) compared to non-pretreated cells (143%, 100%).The GIP effect on insulin release is decreased by pretreatment with GLP-1 (239% to 123%), the UK 14.304 effect from 37% to 27% and the glucose effect from 100% to 47%. Similar results were obtained for GIP-preincubation. The modulation of insulin secretion parallels the regulation of α_{i2}-mRNA levels. We, therefore, conclude that α_{i2}-mRNA regulation plays an important role in heterologous desensitization of insulin secretion.

454

B-CELL GLUCOTOXICITY AND HEXOSAMINE BIOSYNTHESIS PATHWAY

Y. Sako, K. Iwashige, Y. Yoshikawa, T. Shimoike, T. Sano, T. Kuroki, Y. Ono, T. Hashimoto, F. Umeda and H. Nawata: The Third Department of Internal Medicine, Kyushu University, Fukuoka, Japan

We tested the hypothesis that glucosamine, a putative activator of glucotoxicity in vitro through acceleration of the hexosamine biosynthesis pathway, may also play a role in glucose-induced impairment of B-cell function. Pancreatic islets were isolated by collagenase digestion from 220-280g male Wistar rats. After 48h islets culture with DMEM containing 5.5 or 22mM glucose, 16.7mM glucose-induced insulin secretion from the islets was estimated by static incubation. 16.7 mM glucose-induced insulin secretion of islets cultured with 22mM glucose was significantly decreased compaired with that of islets cultured with 5.5mM glucose(50.8±10.8 vs. 89.5±7.9, µU/islet/h, $p<0.01$). This impairment of insulin secretion by high glucose culture was partially improved by co-culture with 10µM azaserine, a specific inhibitor of the rate-limiting enzyme(glutamine:fructose 6-phoshate amidotransferase) of hexosamine pathway(68.2±6.7 vs. 50.8±10.8, $p<0.05$). 16.7mM glucose-induced insulin secretion of islets cultured with 5.5mM glucose was significantly inhibited by co-culture with 5 or 20mM glucosamine in a dose-dependent manner(106.8 ±9.6 vs. 63.7±8.8, 33.4±5.6, $p<0.05$), whereas 20mM arginine-induced insulin secretion was unaffected by co-culture with glucosamine. On the other hand, 5mM mannosamine or 5mM galactosamine, added to the same protocol, had no significant effects on 16.7mM glucose-induced insulin secretion. These results indicate that an increase of glucosamine in B-cell hexosamine biosynthesis may play an important role in B-cell glucotoxicity.

455

ACTIVATION BY GLUCOSE OF THE CARBOXYL METHYLATION OF γ SUBUNITS OF TRIMERIC G-PROTEINS IN PANCREATIC β CELLS

A. Kowluru, G. Li, and S. Metz, University of Wisconsin -Madison, USA

Like most low molecular mass G-proteins, γ subunits of trimeric G-proteins undergo post-translational modifications (e.g., carboxyl methylation; CM) at their C-terminii. Herein, we examined whether CM of Gγ is regulatable in isolated β (HIT-T15) cells. Using selective antisera, we localized γ_1,γ_2,γ_5, and γ_7 isoforms in β cells. Of these, GTP[S] significantly stimulated the CM of γ_2 and γ_5 in broken cells. Acetyl farnesyl cysteine (100 µM), a competitive inhibitor of prenyl cysteine methyl transferases, completely inhibited the CM of these proteins. Exposure of intact HIT cells to either glucose (11.1 mM) or KCl (40 mM) resulted in a rapid (within 30 sec) and sustained (at least up to 60 min) stimulation of γ subunit CM. Immunoprecipitation studies indicated that glucose and KCl differentially modulated the carboxyl methylation of each of the four isoforms. Either removal of extracellular calcium (via EGTA) or depletion of intracellular GTP (via the synthesis inhibitor, mycophenolic acid) markedly attenuated the ability of glucose or KCl to stimulate the CM of these proteins. Pretreatment of intact HIT cells with pertussis toxin (PTx; 100 ng/ml overnight), which selectively inactivates G_i and G_o, markedly attenuated the stimulatory effects of glucose or potassium without altering the concomitant rises in $[Ca^{2+}]_i$. Glucose-induced CM of isoforms γ_2 and γ_5 was abrogated by coprovision of (2 µM) indomethacin. Conversely, PGE_2 (10 µM), which is known to activate G_i and G_o in HIT cells and thereby would dissociate α from βγ, stimulated the CM of isoforms γ_2 and γ_5 in intact and broken HIT cells. These data indicate that the CM of γ subunits of trimeric G-proteins in insulin-secreting cells may be facilitated by dissociation of the trimer into α and βγ. Regulation of such a cascade by glucose, an effect dependent on calcium influx and the consequent activation of phospholipases releasing arachidonic acid, implies a role for the CM of γ subunits in β cell function.

456

DIFFERENTIAL IMPACT OF PALMITATE AND GLUCOSE ON INSULIN RELEASE FROM INS-1 CELLS.

K.K Alstrup, B.Brock and K.Hermansen, Department of Endocrinology and Metabolism, Aarhus University Hospital, Tage-Hansen gade 2, DK-8000 Aarhus C, Denmark.

Studies in β-cell lines and islets have demonstrated that elevated glucose concentrations have a detrimental effect on the ability of the β-cell to secrete insulin. In vivo and in vitro studies have furthermore revealed that elevated levels of free fatty acids induce impaired β-cell function corresponding to the abnormalities being present in NIDDM. Since increased glucose and lipid levels often operate concomitantly in diabetes, it is important to clarify how the combination of elevated glucose and fatty acids influence insulin secretion from β-cells. The aim of the present study was to elucidate how the exposure to high palmitate and glucose in combination influences the insulin release from INS-1 cells. Firstly, we focussed on insulin output after culturing for 4 days at either 3.3, 6.6, 11.0, or 16.7 mM glucose with concomitant addition of 0, 0.05, 0.1 or 0.2 mM palmitate respectively. Subsequently, we tested the responsivness of the INS-1 cells to 3.3 mM (basal secretion) and 16.7 mM glucose (stimulated secretion). Cells were cultured in a modified RPMI 1640 medium containing different glucose and palmitate concentrations. Insulin secretion was measured by RIA. Mann-Whitneys nonparametric test was used for comparisons. At all glucose concentrations applied (3.3-16.7 mM) the addition of 0.05 mM palmitate for 4 days caused an increase in insulin output ($p<0.05$), whereas the exposure to higher palmitate concentrations (0.2 mM) resulted in decreased insulin output ($p<0.05$) compaired to culturing without palmitate. After 4 days culture in the prescence of 3.3 mM glucose and 0.1 mM palmitate basal insulin secretion was increased compaired to culturing without palmitate ($p<0.05$), whereas the addition of 0.2 mM palmitate had no influence on basal insulin secretion. In contrast in the prescence of higher glucose levels (6.6-16.7 mM) palmitate (0.1-0.2 mM) caused an inhibition of basal insulin release ($p<0.05$). When culturing the INS-1 cells in increasing glucose levels (from 3.3 to 16.7 mM) the glucose stimulated insulin secretion declined. The simultanous addition of an increasing amount of palmitate resulted in a more pronounced suppression of glucose stimulated insulin secretion. **In conclusion** We have demonstrated, that the inter-relationship between glucose and palmitate plays a crucial role for the INS-1 cell function.

ROLE OF MAP KINASE IN THE FORMATION OF INSULIN-PRODUCING CELLS FROM PANCREATIC AR42J CELLS

M.Furukawa, H.Mashima and I.Kojima. Institute for Molecular & Cellular Regulation, Gunma University, Maebashi 371, Japan.

Rat pancreatic AR42J cells are derived from an acinar cell tumor and possess properties characteristic of both exocrine and neuroendocrine cells. When AR42J-B13 cells, a subclone of AR42J, are exposed to a combination of activin A and hepatocyte growth factor (HGF), they stop growing and convert into insulin-secreting cells within three days. The present study was conducted to identify the signal transduction pathway involved in the differentiation of AR42J cells induced by activin A and HGF. AR42J cells were incubated for three days with activin A and HGF in the presence or absence of wortmannin, rapamycin or PD098059. Then insulin-producing cells were determined by immunocytochemistry. Wortmannin, an inhibitor of phosphatidylinositol 3-kinase did not affect the formation of insulin-positive cells induced by activin A and HGF. Likewise, rapamycin, an inhibitor of activation of p70 S6 kinase, did not affect the effect of activin A and HGF. In cotrast, PD098059, an inhibitor of activation of MAP kinase kinase, inhibited the formation of insulin-positive cells in a concentration-dependent manner. In AR42J-B13 cells, HGF but not activin A induced a sustained activation of MAP kinase, which was blocked by PD098059. These results suggest that the MAP kinase pathway is involved in the formation of insulin-secreting cells from amylase-secreting AR42J cells.

REDUCED INSULIN RELEASE FROM MICROENCAPSULATED PANCREATIC ISLETS AFTER TRANSPLANTATION.

J. Drużyńska, M. Cybal and C. Wójcikowski. Department of Endocrinology, Institute of Obstetrics and Gynecology, Medical University, Gdańsk, Poland

The application of a semipermeable membrane as a mechanical barrier is an attractive approach to the protection of transplanted tissue from the host's immune system. The present study was undertaken to assess the function of islets microencapsulated in alginate-poly-L-lysine-alginate (APA) membranes after their transplantation into streptozotocin-diabetic and normal, non-diabetic recipients. Isolated rat pancreatic islets were microencapsulated in APA-membranes and transplanted intraperitoneally into recipients. Islet containing microcapsules were recovered by peritoneal lavage 14 days after transplantation into diabetic mice and after 1, 7 and 14 days after implantation to normal recipients. Recovered microencapsulated islets were subjected to determination of the in vitro insulin release during incubation.

Microencapsulated islet transplantation restored normoglycemia in diabetic recipients. In contrast, the freshly-prepared free islet grafts were rapidly rejected.

The microencapsulated islet implants removed from diabetic recipients showed a significant response to 20 mM glucose plus 1 μM forskolin challenge during incubation in vitro, although the amount of insulin released to the incubation media was significantly reduced as compared to freshly-microencapsulated islets.

Reduction of insulin secretion was also found during incubation of microencapsulated islets retrieved from normal recipients 1, 7 and 14 days after transplantation. The insulin secretion from islet explants from diabetic mice did not differ from that of normal controls (0.68±0.2 vs. 0.93±0.2 ng/45 min/islet; $p>0.05$).

Our results suggest that islet transplantation into peritoneal cavity may impair islet function. This finding may explain why the relatively large number of islets is required to achieve normal or near-normal blood glucose control in diabetic recipients.

Properties of Human Pancreatic β-Cell-Lines Developed Using Retroviral Vectors Expressing SV40 T-Antigen and H-ras^{val12}.

F. Levine, S. Wang, G.M. Beattie, M.I. Mally, V. Cirulli, A.D. Lopez, and A. Hayek. University of California, San Diego, La Jolla, USA

Our goal is to develop cell lines from human β-cells for diabetes therapy and for research on pancreatic endocrine cell biology. We have created human pancreatic endocrine cell lines, HAP-5, TRM-1, and TRM-6, from 18 week ICCs and 24-week fetal islets, respectively. They were isolated using a retroviral vector expressing SV40 T-antigen and H-ras^{val12}. This vector, LoTPRRNLo, contains a *lac* repressor binding site in the LTR for inducible oncogene expression. The cell lines express markers consistent with their origin from endocrine cells and endocrine cell precursors, including low levels of insulin in early passages. However, insulin expression was lost over time. Interestingly, later passages of the adult β-cell line HAP-5 expresses glucagon and somatostatin, but not insulin, by both RT-PCR and radioimmunoassay. The fact that cell lines from mature endocrine cells produce only low levels of pancreatic hormones suggests that oncogene expression is causing dedifferentiation. We have found that primary pancreatic endocrine cells undergo similar changes in differentiation state when grown in monolayer culture on extracellular matrix in the presence of hepatocyte growth factor, suggesting that the signal transduction pathways that are being stimulated in the primary cells and in the cell lines are overlapping. Expression of the lac repressor gene in the cell lines results in growth arrest due to oncogene downregulation. Current efforts are focused on inducing differentiation in the cell lines as well as developing new cell lines using oncogenes that may permit retention of differentiated function. In summary, we have developed an efficient system for creating human pancreatic β-cell lines, but more work needs to be done on maintaining differentiated characteristics.

SUCCESSFUL ISLET TRANSPLANTATION USING PLANAR TYPE DIFFUSION MEMBRANE DEVICES

K. Suzuki[1], S. Bonner-Weir[1], N. Trivedi[1], K-H Yoon[1], J. Hollister-Lock[1], C. K. Colton[2] and G. C. Weir[1].
Joslin Diabetes Center, Harvard Medical School[1], Boston and Massachusetts Institute of Technology[2], Cambridge, USA.

Immunobarrier devices may protect transplanted islets from immune destruction in diabetic recipients, but there are questions about the number of islets that be supported within these devices. Alginate (1%) solution was used to form a gel to prevent clumping of islets in the devices (two laminated PTFE membranes held together by titanium rings, Baxter Healthcare). Varying numbers of syngeneic mouse islets (1000, 750, 500, 250) were loaded into each device, which were implanted into epididymal fat pads of streptozocin diabetic B6AF1 mice. Some mice received two devices containing 500 islels each. After transplantation random blood glucose levels and body weight were measured for 4 weeks. The percentage of mice achieving glucose levels <200mg/dl were 34.2%(1000), 29.6%(750), 43.8%(500), 18.8%(250) and 59.3%(500×2). The mean insulin content of these devices for these groups ranged from 2.5 to 12.9 μg, with there being no correlation with the initial number of islets. Many mice maintained euglycemia for 12 weeks. These results provide new information about optimal packing density for these devices. With this approach 500 islets appears to be the optimal number with no benefit being obtained from adding larger numbers. Limitation of oxygen supply is likely to be responsible for this limitation in packing density. These results provide information about the sizes (surface area) of diffusion devices that are required for successful transplantation.

Ex vivo expansion of human pancreatic endocrine cells on HTB-9 matrix.

G M Beattie, V Cirulli, A D Lopez and A Hayek, The Whittier Institute, UCSD, la Jolla CA USA

Cell transplantation, as a therapy for diabetes, will be facilitated by ex vivo expansion of cells without loss of differentiative characteristics. The aim of this study was to determine the optimal conditions for in vitro growth of functional human pancreatic endocrine tissue. We examined the mitogenicity of matrices from a variety of cell lines. Proliferation was more pronounced in cells growing on matrices from bladder carcinoma cell lines and significantly higher in monolayers grown on matrix from the human cell line HTB-9 ($p>0.05$). After 14 days there was a >100 fold proliferative increase, augmented to >200 fold when hepatocyte growth factor/ scatter factor was added. However, hepatocyte growth factor/ scatter factor induced a rapid decrease in insulin content. Without the growth factor, fetal cell monolayers increased 4 fold without insulin loss and 12 fold with insulin levels still at 40% of unexpanded cells. Adult islet cells increased 3 fold without insulin loss and 5 fold with insulin levels still at 75%, while retaining a normal response to secretagogues. Together, these results show that HTB-9 matrix provides the best stimulatory effects on replication of human endocrine cells with little loss of in vitro function.

462

A BIO-ARTIFICIAL ENDOCRINE PANCREAS (BIO-AEP) FOR THE TREATMENT OF DIABETES.

H.Ohgawara, S.Hirotani and S.Karibe. Tokyo Women's Medical College, Tokyo, Japan.

Immunoisolation is a potentially important approach to transplanting islets without any immunosuppressive therapy. Immunoisolation systems have been conceived in which the transplanted tissue is separated from the immune system of the host by an artificial barrier

A diffusion chamber for a bioartificial endocreine pancreas (Bio-AEP) was constructed by placing pancreatic B-cells trapped in a mixed matrix containing agarose and collagen-gel, supplemented with nicotinamide, in the center of a ring holder sandwiched between nuclepore membranes , which were shielded by silicone.

In vivo experiment, we studied nucleopore membranes of different pore size (0.6, 0.4, 0.2, 0.1 and 0.05um) employed as the semipermeable membrane providing a mechanical barrier between the endocrine pancreatic graft and the host's immune system. In a twenty-week experiment, a return to normoglycemia was observed in STZ-diabetic rats implanted with Bio-AEPs fitted with membranes of pore size 0.1 um. However, in other rats implanted with Bio-AEPs with membranes of differeant pore sizes, normoglycemia continued for only a very short period.

The experiment was evaluated a suitable pore size for the nuclepore membrane for immunoisolation during xenoimplantation of the Bio-AEP. The protective effect of the Bio-AEP from humoral immunity was determined in vitro, using sensitized sheep erythrocytes (EAs). A compliment protein could not destroy the cell membranes of EAs in the diffusion chamber with 0.1um pore size.

The results indicated that the Bio-AEP with a 0.1 um pore size membrane should be useful for the implantation of xenograft pancreatic endocrine cells in diabetic animals and may open a new field in the therapy of human IDDM.

LONG-TERM INCUBATION OF HUMAN FETAL ISLETS WITH GROWTH HORMONE: A DOSE DEPENDENT EFFECT ON INSULIN SECRETION

P.B.Đorđević, N.M.Lalić, A.Jotić, K.Lalić, I.Paunović, M.Zamaklar, V.Dimitrijević, Lj.Lukić and N.Rajković, Institute for Endocrinology, Belgrade, Yugoslavia

In our previous studies we have shown that a long-term in vitro incubation with growth hormone (GH) preserves the insulin secretion capacity of isolated human fetal islets in the pretransplantation period, but the dose dependency of this effect has not yet been clarified. The aim of this study was to analyse the effect of a long-term (15 days) incubation with 250 μg/l (protocol A) , 500 μg/l (protocol B), 1000 μg/l (protocol C) and 2000 μg/l GH (Genotropin, Kabi Pharmacia) (protocol D) on glucose+theophyllin-stimulated insulin response of isolated human fetal islets. The islets were obtained from pancreata originating from 16 - 24 old fetuses by collagenase digestion, and cultured in the media containing 10% fetal calf serum at 37^0C, 5%CO2. The insulin secretion capacity was evaluated by determining insulin levels in the culture media after one hour incubation with 1.67 and 16.7 mmol/l glucose+5mmol/l theophyllin sequentially and expressed as the percentage of the increase in insulin levels after stimulation. We found that in protocols A and B the glucose+theophyllin-stimulated insulin response declined significantly, showing similar patterns of the decline in the islets incubated with GH and in those without GH (A: GH+: day 0: 736.5+/-61.6%, day 15:478.9+/-39.4%, $p<0.05$; GH-: day 0: 342.6+/-31.6%, day 15: 235.7+/-29.7%, $p<0.05$; B: GH+: day 0: 747.5+/-72.6%, day 15: 513.8+/-45.8%, $p<0.05$; GH-: day 0: 331.2+/-29.5%, day 15: 219.8+/-34.6%, $p<0.05$). However, in protocols C and D, the insulin response did not decline in the GH-incubated islets (C:day 0: 731.7+/-69.5%, day 15: 735.5+/-64.8%; D: day 0: 737.8+/-67.8%, day 15: 734.+/-72.8%; p=NS respectively). Simultaneously, the secretory response remarkably declined in the control islets incubated without GH (C: day 0: 357.6+/-37.9%, day 15: 232.8+/-27.8%; D: day 0: 332.6+/-39.3%, day 15: 253.2+/-28.4%, $p<0.05$ respectively). Our results have demonstrated that the long-term incubation with GH was efficient in preventing the decline of the in vitro insulin secretory capacity of isolated human fetal islets, but this beneficial effect was dose dependent and it could not be achieved with very low GH concentrations.

464

A COMPARATIVE STUDY OF ALLOXAN TOXICITY IN ISLET GRAFTS PREPARED FROM DIFFERENT SPECIES

B. Tyrberg and A. Andersson. Department of Medical Cell Biology, Uppsala University, Uppsala, Sweden.

Alloxan has for long been known as a diabetogenic substance in experimental animals, but we recently showed that human islets are resistant to alloxan. There are, at present, no systematic comparative studies with regard to the alloxan sensitivity of β-cells in different species. Therefore, we compared the alloxan sensitivity of grafts prepared from adult human, mouse, rat, dog, guinea pig and fetal pig islets.

For this purpose the islets were transplanted under the kidney capsule of nude mice. Two weeks later (eight weeks in case of fetal pig islets) alloxan (85 mg/kg) or saline (controls) was injected i.v. One week thereafter the mice were killed and the islet grafts and pancreata fixed for immunohistochemistry. The number of β-cells was then evaluated with a semi quantitative method in sections immunostained for insulin. As expected the endogenous pancreata showed total β-cell destruction in all alloxan injected recipients. The morfology of the human islet grafts did not differ from that seen in the saline controls. The same hold true for the β-cells of the guinea pig and pig islet grafts. Quite in contrast, the β-cells of the islet grafts from mouse ($p<0.001$ vs control, non-parametric Mann-Whitney test), rat ($p<0.001$) and dog ($p<0.05$) were almost totally destroyed. Preliminary data suggest that in alloxan-exposed guinea pig islets there was a high proliferative activity evidenced by auto-radiographical examinations.

This study shows that there are distinct species differences with regard to the β-cell sensitivity to the classical diabetogenic substance alloxan. The mechanisms involved have so far not been possible to identify, but it is obvious that the present experimental protocol lends itself very suitable for such studies. The finding that, in relation to man, both close (pig) and more distant (guinea pig) species have alloxan-resistant β-cells might implicate that different mechanisms, evolved separately, underly this resistance.

465

DISTRIBUTION AND DEVELOPMENTAL CHANGE OF ANNEXIN V IN RAT PANCREATIC ISLETS

R. Miyoshi, M. Tokuda, M. Ohnishi, N. Uemura, Y. Hosokawa, H. Hosokawa, K. Kawanishi, O. Hatase, T. Ishida, and J. Takahara. Kagawa Medical University, Kagawa, Japan

Annexins are a family of structurally related proteins which bind to phospholipids in a Ca^{2+}-dependent manner. Annexin V is a member of the annexin family and it has recently been reported to form Ca^{2+}-channels and may act as a regulator of protein kinase C. Thus, annexin V may play a role for hormone secretion and differentiation in endocrine tissues. In this study, we investigated the expression patterns and the dynamic changes of annexin V in the rat pancreatic islets during postnatal development by both Western blot analysis and immunohistochemistry using polyclonal anti-annexin V antibody. We performed the isolation of pancreatic islets from 3 weeks-old (w.o.) to 15 w.o. of male Sprague-Dawley rats for Western blot analysis. Also rat pancreas from 1 w.o.to 15 w.o. were fixed with 4% paraformaldehide in PBS and embedded in paraffin for immunohistochemistry. Pancreatic islets were exclusively shown to express annexin V, while exocrine tissues were not. Capillary endotherial cells in pancreas were also stained. Annexin V was present in both α and β cells in islets. Strong staining was detected on the cell membrane and in peri-membranous area of islet cells. The expression level of annexin V in pancreatic islets gradually increased with postnatal development, but it became constant after 12 weeks-old. The present study suggested that annexin V may be related to the maturation of the function of pancreatic islets.

466

NORMAn PANREATIC ISLETS TRANSPLANTATION IMPROVES DIABETIC PROGRESSION OF NIDDM MODEL(OLETF) RATS

I.Katsuragi, T.Okeda, H.Sakino, N.Noda, K.Tsuda, T.Seguchi, T.Noguchi, K.Ina and T.Sakata, Oita Medical University, Oita, JAPAN

To investigate the effect of normal islets transplantation on NIDDM, we employed Otsuka Long Evans Tokushima Fatty (OLETF) rats which manifest obesity, degeneration of pancreatic islets, proliferation of mesangial matrix and nodular lesion of renal glomeruli as a NIDDM model rat. Normal islets from Wister King A rats were implanted into the portal vein of OLETF rats at their age of 12 weeks before onset of diabetes (n=7). Normal 1500 islets were cultured at 24℃ for 7 days and transplanted into the liver. Fasting plasma glucose and insulin, body weight, and histopathological changes in the pancreas and kidneys were evaluated 33 weeks after transplantation. Body weight gain in the transplanted group rats was started to be suppressed 6 weeks after transplantation ($p<0.05$). Islets transplantation lowered fasting plasma glucose level 20 weeks after grafting ($p<0.05$), but leaving fasting insulin levels unaffected. Hyperplastic and fibrotic changes in pancreatic islets of the transplanted group were suppressed 33 weeks after grafting. The proliferation of the mesangial matrix in gromeruli of the transplanted group was suppressed in comparison to those of controls (normal gromeruli 10.9% vs 24.6%, proliferation of the mesangial matrix: mild 44.2% vs 52.7%, moderate 24.6% vs 14.5%, diffuse 20.2% vs 6.9%; control vs transplanted group, respectively). These results indicate that transplantation of normal pancreatic islets into the portal vein of OLETF rats improves progression of the NIDDM model.

467

β-CELL MASS DYNAMICS DURING GLUCOSE INFUSION

D.T. Finegood, D. Tzur, W.E. Fieldus, M.D. McArthur, N. Dhatt and A. Dunichand-Hoedel. Simon Fraser University, Burnaby, British Columbia, Canada.

Bonner-Weir and colleagues previously demonstrated that infusion of 50% dextrose for 4 days resulted in a 60% increase in β-cell mass, a 5 fold increase in β-cell replication rate and a 60% increase in individual cell size. Although no morphologic evidence of apoptosis was found, calculation of cell numbers after 4 days of glucose or saline infusion suggests that the increase in mass was not due to an increase in the number of cells and that the 5 fold increase in replication must be balanced by a 5 fold increase in cell death. Presently, we have re-examined this paradigm in an effort to elucidate the dynamic changes in β-cell mass. 50% dextrose was infused at 2 ml/min. Cohorts of glucose infused rats were killed on days 0 (n=3), 1 (n=4), 2 (n=3), 3 (n=4), 4 (n=4), 5 (n=2) and 6 (n=2) and compared to similar cohorts of control animals. During glucose infusion, tail vein plasma glucose levels rose from 6.9 ± 0.1 mM to 25.4 ± 0.8 mM after 1 day. Plasma glucose remained elevated after 2 days of infusion (24.4 ± 1.7 mM) but was reduced by day 3 (11.6 ± 1.1 mM) and persisted at this level for the remainder of the infusion period. There was no significant effect of glucose infusion on plasma free fatty acid levels ($P > 0.05$). β-cell mass was increased in response to the glucose infusion ($P < 0.05$). β-cell mass dynamics were complex, giving the best fit to a 3rd order polynomial of β-cell mass versus time. There was an initial increase in β-cell mass in the first day (6.1 ± 0.8 versus 4.2 ± 1.0 mg), a plateau between days 2 and 5, and a further increase to 9.9 ± 0.4 mg on day 6. These data suggest that β-cell mass dynamics during glucose infusion do not mirror changes in plasma glucose. The presence of hyperglycemia may restrain the growth in the β-cell mass until sufficient adaptation has occurred. (Supported by Medical Research Council of Canada).

468

Inefficacy in prolonging pancreatic islets allograft survival after multiple oral administrations of low doses of highly purified islets.

B.Senesi, V. Curiale, L. Lione, A. Puddu, A. Pedemonte, A. Pastorino* and G.L. Viviani. D.I.M.I., Dipartimento di Medicina Interna, *Istituto di Anatomia Patologica, Università di Genova, Italy.

Oral antigen administration has been shown to prolong allograft survival. The aim of this study was to investigate the implications of the effects which repeated administrations of purified antigenic material in inducing immunologic tolerance of islets transplantation. We used genetically and antigenically distant strains of inbred rats such as Lewis and PVGs. Streptozotocin-induced diabetic PVG rats received daily an intragastric administration of purified islets from donors Lewis rats. These injections were performed from 7 days before TX until rejection occurred. No immunosuppressive agents were administred. Rats were injected with 3000 fresh Lewis islets into an affluent of their superior mesenteric vein..We did not find any significant difference between islet survival rates in the tolerized and control groups: mean graft survival was 3 days (range 0-4) for the tolerized group and 2 days (range 0-7) for the control group. Histological analysis from the animals with the shortest survival of the graft shows the presence of endothelitis in association with large infiltration of monocytes in the liver. On the other hand, animals with a longer survival of the graft did not have the endothelites. These results suggest that multiple oral administrations of low doses of highly purified islets is not as effective in achieving islets survival rate as those reported for single dose administration of low purified pancreatic tissue. The results obtained make us believe that at this moment in time this experiment is not apt to induce allograft immunologic tolerance.

469

LIMITED REPLICATION OF PANCREATIC ß-CELLS CHRONICALLY EXPOSED TO HIGH GLUCOSE.

M.Raurell, V.Nacher, M.Biarnés, JF.Merino, O.Aranda, J.Soler and E.Montanya. Laboratori de Diabetis i Endocrinologia Experimental. CSUB-Hospital de Bellvitge. Barcelona. Spain.

To study the effects of chronic exposure to high glucose on pancreatic ß-cell replication, rat islets were cultured at 11.1 and 22.2 mM glucose for 7 or 14 days with or without human growth hormone (hGH) (1µg/ml). BrdU was added for the final 24 hours of culture; ß-cell replication was expressed as percentage of BrdU positive ß-cells. Insulin secretion was measured by RIA. ß-cell replication was increased after 7 days of culture at 22.2 mM glucose (11.1 mM: 1.01±0.19%; 22.2 mM: 1.64±0.19%, $p<0.05$), but not after 14 days (11.1 mM: 0.21±0.04%; 22.2 mM: 0.33±0.09%). However, islets cultured at 22.2 mM glucose for 14 days maintained a higher insulin secretion (11.1mM: 1.98±0.18 ng/h/islet; 22.2mM: 3.03±0.41 ng/h/islet, $p<0.05$). hGH increased ß-cell replication both in islets cultured at 11.1 mM glucose (7 days: 4.24±0.48%, $p<0.001$; 14 days: 1.99±0.18%, $p<0.001$) and 22.2 mM glucose (7 days: 2.64±0.23%, $p<0.01$; 14 days: 1.89±0.10%, $p<0.001$) compared to islets cultured with no hGH. In summary, when ß-cells were chronically exposed to high glucose the capacity to increase replication in response to glucose became limited, but islets were able to respond to other mitogenic factors, suggesting that the limited ß-cell replication was specific for glucose.

470

EFFECT OF VASOACTIVE INTESTINAL POLYPEPTIDE ON INSULIN SECRETION FROM ISLETS AFTER TRANSPLANTATION OR PROLONGED CULTURE

C.-L.Shi[1], S.Person-Sjögren[1], I.-B.Täljedal[1], S.Forsgren[2] and U.Kjörell[2]. Department of Histology and Cell Biology[1] and Department of Anatomy[2], Umeå University, Umeå, Sweden.

Transplanted mouse islets loose their responses to cholinergic and adrenergic stimulation. To test whether the peptidergic response is also modified by prolonged denervation, we studied the effect of vasoactive intestinal polypeptide (VIP) on glucose-induced insulin release from islets kept in culture or transplanted under the kidney capsule of syngeneic BALB/c mice. Insulin secretion induced by 16.7 mmol/l D-glucose was potentiated by VIP (10 nmol/l) by 56±10% (mean±SEM; $p<0.05$) in fresh islets hand-picked directly after collagenase digestion. When islets were purified by dextran density centrifugation (dextran islets) and cultured overnight, the VIP potentiating effect was lost (12±9%). When dextran islets were transplanted to the kidney for 4 days, removed, and perifused in vitro, the VIP potentiating effect was partially recovered (31±9%, $p<0.05$). The VIP effect was eventually lost 21-day after transplantation (-2±10%). When islets were hand-picked without dextran (hand-picked islets) the potentiating effect of VIP was not affected by overnight culture (56±16%, $p<0.02$). Four days of culture abolished the potentiating effect of VIP in both dextran and hand-picked islets (-19±22%, and -7±16%). When VIP (10 nmol/l) was added to culture medium, the VIP potentiating effect was diminished in both overnight cultured dextran and hand-picked islets (-14±11%, and -13±24%). However, a marked potentiating effect of VIP was observed in 4-day cultured dextran or hand-picked islets (440±170%, and 249±49%). The content of VIP extracted from 4-day islet transplants (423±123 pg/mg wet) was larger than that from 12-week transplants (2.3±0.1) or fresh islets (64±16). In conclusion, the effect of VIP on glucose-induced insulin secretion from islets was diminished by transplantation, dextran and prolonged-in-vitro-culture. The improved response to VIP in 4-day transplants might be related to the high VIP content in the grafts. This concept is supported by the fact that an enhanced VIP response was achieved in 4-day cultured islets by exogenous VIP. We suggest that local neurocrine release of VIP is important for the secretory function of transplanted islets.

471

LATE FETAL AND EARLY POST-NATAL MALNUTRITION IMPAIRS RAT ß-CELL DEVELOPMENT

B. Bréant, A. Garofano and P. Czernichow, INSERM U457, Paris, France

A rat model of perinatal malnutrition was developped to study the role of nutrition on the development of the endocrine pancreas. Severe caloric restriction (50% of control intake) beginning on day 15 of pregnancy, was applied to female rats. Three offspring groups were studied: control group (C), R group (maternal restriction until the end of lactation) and R/C group (maternal restriction until birth and nursing by control mothers). At day 1, 7 and 21, pups (5-7) were studied for their insulin content, ß-cell volume fraction and proliferative capacity (analysed by quantitative morphometry and incorporation of BrdU *in vivo*).
Maternal caloric restriction led to small-for-gestational-age newborns and severely growth-retarded weanlings (R pups). Rapid catch-up growth was observed in R/C pups. At all time points, significant reduction in pancreatic insulin content, ß-cell volume fraction and total ß-cell mass were observed:

	Ins content,µg/gland		ßcell mass,mg/gland		%labeled nuclei	
	d1	d21	d1	d21	d1	d21
C	8.4±1.2	48.5±2.9	1.07±0.06	2.78±0.42	3.0±0.1	1.2±0.2
R	5.2±0.9	17.9±4.3	0.70±0.06	0.87±0.23	3.0±0.3	1.3±0.2
R/C	-	38.5±4.5	-	1.58±0.18	-	1.0±0.1

At d21, total ß-cell mass and number were reduced by 70% in R pups and 45% in R/C pups, suggesting long-lasting impairment of this cell population. Beta-cell BrdU labeling index at each time point was not different between groups, suggesting malnutrition did not affect the ability of ß-cells to proliferate. At 3 weeks of life, the calculated mean islet number was reduced by 50% in R pups and 37% in R/C pups, accounting largely for the decrease in ß-cell mass.

In conclusion, perinatal caloric restriction impairs ß-cell development; impaired islet neogenesis can be suggested in this rat model.

472

TYROSINE HYDROXYLASE IN RELATION TO SOMATOSTATIN IN THE PANCREAS AND ISLET GRAFTS

S. Persson-Sjögren[1], S. Forsgren[2] and I.-B. Täljedal[1]. Department of Histology and Cell Biology[1] and Department of Anatomy[2], Umeå University, S-901 87 Umeå, Sweden.

During prenatal development, islet progenitor cells coexpress tyrosine hydroxylase (TH) and somatostatin (SOM). To study the co-localization of cellular TH-like immunoreactivity (LI) with somatostatin in differentiated cells under changed environmental conditions, islets from C57BL/6 mice were transplanted to the kidney of syngeneic hosts. For comparison, freshly isolated islets, cultured islets and islets in adult pancreas were also examined. TH-LI cells were demonstrated in all groups. The cells were about the same size as islet endocrine cells and were randomly scattered in the islet tissue. In the grafts TH-LI cells decreased after 3 days, whereas at all the other time points, up to 52 weeks, the number of TH-LI cells appeared to be the same as in adult pancreas. In the transplanted islets some of the TH-LI cells exhibited TH-LI long smooth nerve fiber like extensions. Restaining revealed co-localization of TH-LI and SOM-LI in islet cells. In normal islets *in situ*, 5 ± 2 % (mean ± SEM, 4 mice) of the cells coexpressed TH-LI and SOM-LI, while in 52-week old grafts the corresponding figure was increased ($p < 0.05$) to 29 ± 7 (5 mice). None of the TH-LI cells with nerve fiber like extensions exhibited SOM-LI. The results indicate that there are two populations of somatostatin cells in the islets, and that transplantation induces an increased expression of TH-LI in somatostatin cells.

Alteration of ß and α cells development in the pancreas of GK rats. A quantitative study.

J. MOVASSAT, C. SAULNIER, P. SERRADAS, D. BAILBE and B. PORTHA. Lab. Physiopathologie de la Nutrition. CNRS - URA 307; Paris France.

In the GK rat, a genetic model of NIDDM, available histological informations concerning the development of the endocrine pancreas are conflicting.We have previously reported that total pancreatic insulin store in GK adult rats from our colony was depleted by 62% and that ß cell mass in GK pancreases was decreased to a similar extent (51%, p<0.05).The aim of this work was to extensively study the development of the endocrine pancreas in GK rat from late fetal life until adulthood.We have determined the relative volume and the mass of ß and α cells by immunohistochemistry and morphometry in 21.5 day-old fetuses, 4, 7 and 14 day-old newborns and 4 month-old adult rats in both GK and Wistar groups. Our results demonstrate that: 1) there is a very early alteration of ß cells development in the pancreas of GK rat: the total ß cell mass in fetal GK pancreas represents only 30% of control value. In newborn GK rats, the total ß cell mass was decreased by 60% compared to that of control newborns. In adult GK rats, the reduced ß cell mass was associated with a noticeable alteration in the architecture of large islets which displayed fibrosis, together with signs of disorganization of the mantle-core relationship. Concerning α cells, the alteration of their development is a late phenomenon compared to the ß cells alteration. A significant decrease of pancreatic concentration of α cells is detectable in 14-day-old GK rats and persists at adult age. In conclusion, these data indicate that the reduction of ß cell mass in GK rats is a n early event and not a consequence of diabetes (hyperglycaemia) and should be considered as a primary feature in the pathological sequences leading to diabetes in GK rats. It is now important to determine the reasons for the delayed fetal ß-cell growth in the GK model and to identify the respective involvement of ß-cell neogenesis and ß-cell replication in the determinism of this alteration.

474

DONOR AGE DOES NOT INFLUENCE THE OUTCOME OF ISLET TRANSPLANTATION.

J-H. Juang, R-S. Hsu, C-H. Kuo and H-S. Huang. Division of Endocrinology and Metabolism, Chang Gung Memorial Hospital, Taipei, Taiwan, R.O.C.

To know the influence of donor age on the outcome of transplantation, we isolated islets from C57BL/6 mice, aged 32 weeks (Gr. A) or 8 weeks (Gr. B). The islet number isolated from Gr. A was higher than that from Gr. B (219±22 vs. 97±4 islets/mouse, P=0.0001). In addition, Gr. A had larger size (0.129±0.001 vs. 0.117±0.001 mm^2, P=0.0001) and contained more insulin (0.92±0.07 vs. 0.47±0.09 µg/150 islets, P<0.005) as compared with Gr. B. Three hundred islets isolated from Gr. A or Gr. B were syngeneically transplanted under left kidney capsule of streptozotocin-diabetic mice. Both groups had similar patterns of the decrease of blood glucose levels and the increase of body weights after transplantation. Normoglycemia was achieved at 4 weeks in both groups and maintained lifelong (43±4 and 42±4 weeks, respectively). In conclusion, the islets isolated from donors with different ages have different characteristics but both of them are effective on transplantation.

475

OFFSPRINGS FROM STREPTOZOTOCIN DIABETIC RATS.LANGERHANS'S ISLETS AFTER BIRTH.

R.R.Rodríguez,A.Renauld,D.Celener,M.C.Susemihl and R.Pérez.Depart.of Physiology and Histology,Medical School,Buenos Aires University,Argentina.

Female Wistar rats,were injected with streptozotocin i.p;one week later they were divided in 3 groups:A)severely diabetic blood sugar level above 16.5mM/l,B)mildly diabetic between 6.5 and 16.5mM/l,and C)nondiabetic controls.All were mated with normal males.The areas of pup's Langerhans islets were measured 1 and 5 days after parturition.On the 1st day,in pups from mildly and severely diabetic mothers they were smaller than those from the nondiabetic controls(P<0.001);the areas in neonates from severely diabetic mothers showed a more intense decrease than those from mildly diabetic rats(P<0.001).On the 5th day,the areas of Langerhans islets in offsprings from normal mothers decrease and those in pups from diabetic mothers tends to normalize(P<0.01)particulary those from the severely sick group(P<0.01).35% of 65 offsprings from diabetic mothers had fasting hyperglycemia at that time.Inmunohistochemically determination of C-peptide in pancreas shows a significative reduction in pups 1, 5 and 15 days old compared with controls.In summary diabetes during pregnancy markedly reduced the development of the islets of Langerhans in fetus,with a tendency to normalize after birth.

476

OPTIMAL INSULIN TREATMENT IN ISLET TRANSPLANTATION

V.Nacher, JF.Merino, M.Raurell, O.Aranda, J.Soler and E.Montanya. Laboratori de Diabetis i Endocrinologia Experimental. Endocrine Unit. CSUB–Hospital de Bellvitge. Barcelona. Spain.

We have previously shown that insulin treatment reduces the beta cell mass needed to achieve normoglycemia in islet transplantation (Tx). To identify the optimal insulin treatment protocol, 6 groups of streptozocin-diabetic C57Bl/6 mice Tx with 100 syngenic islets, an insufficient beta cell mass to restore normoglycemia, were treated with insulin as follows: group 1 (n=9): day 10 before Tx to day 14 after Tx (-10 to 14); group 2 (n=11): day 6 before Tx to Tx day (-6 to 0); group 3 (n=11): Tx day to day 6 (0 to 6); group 4 (n=7): Tx day to day 14 (0 to 14); group 5 (n=8): day 10 to day 24 after Tx (10 to 24); group 6 (n=18): Tx but not treated with insulin. Grafts were harvested 60 days after Tx, and beta cell mass was determined. On day 60, normoglycemia had been achieved in 100% mice in groups 1, 4 and 5, in 73% in group 2, and in only 45% and 33% in groups 3 and 6 respectively (p<0.05 vs the other groups). Intraperitoneal glucose tolerance, determined only in normoglycemic mice, was similar in groups 1, 2, 4 and normal controls; groups 3, 5 and 6 showed high glucose values after glucose injection (p<0.05 vs normal controls). Beta cell mass was similar in grafts of normoglycemic mice. In summary, the beneficial effect of insulin was maximal when insulin treatment was initiated before Tx day and maintained 2 weeks after Tx. Transient severe hyperglycemia after Tx (groups 3, 5 and 6) had a deletereous effect in beta cell function that was not fully corrected when normoglycemia was achieved.

477

TRANSPLANTED FETAL SHEEP PANCREAS: A USEFUL MODEL TO STUDY ENDOCRINE CELL DEVELOPMENT

B.E.TUCH & F.M.PETCHELL Prince of Wales Hospital, Sydney, Australia

The potential of the fetal sheep pancreas as a transplantable source of insulin-producing cells to reverse diabetes after it is grafted, for example, into athymic mice, has been investigated and found to be wanting. This is because ß cells do not differentiate well after they are transplanted. Glucotoxicity is a potential explanation for this because the blood glucose level of recipient mice is higher than that of fetal sheep (7 vs. 1.5 mM). To test the effect of approximating these fetal conditions blood glucose levels of recipient athymic mice were lowered for 4 weeks from 7.3 ± 1.6 mM to a nadir of 3.7 ± 1.7 mM by administration of ultralente beef insulin pellets. This resulted in a 2.7-fold increase in ß cells as a percentage of epithelial-like cells in the graft (controls 17 ± 5, treated 46 ± 14%; P = 0.05) and a 5.9-fold increase in the number of glucagon-containing α cells (controls 7 ± 5, treated 42 ± 14%; P = 0.03). The increase in endocrine cells was probably due to improved formation from undifferentiated cells, but greater proliferation of the mature cells is also a possibility. The effect was transient with endocrine cell numbers diminishing once the effect of insulin administration ceased: ß cells - controls 12 ± 5, treated 10 ± 3; α cells - controls 26 ± 9, trated 11 ± 7%; P = not significant. The predominance of the α cell has been noted previously in transplanted fetal sheep pancreas and is a feature of the adult sheep islet. It is concluded that while transplanted fetal sheep pancreas may not be suitable for reversal of diabetes, it is a useful model for studying how pancreatic endocrine cells develop.

AN EFFICIENT AUTOMATED METHOD FOR ISOLATION OF PANCREATIC ISLETS

Y.Nutku(1), A.O.Gürol(2), G.Yıllar(2), N.Öncan(3), İ.Satman(2) and M.T.Yılmaz(2).

(1)TUBITAK, İzmit, (2)Institute for Experimental Medicine, Diabetes Research Unit, Istanbul University, and (3) Faculty of Science, Istanbul University, Istanbul-TURKEY

The first step in transplantation of islands of Langerhans from healthy donors to diabetic individuals requires an efficient automated method for isolation of the pancreatic islets from donors. Such a mechanism has been developed by Ricordi et al. This automated method has two main chambers, one for isolation and another for recirculation and collection. Recently, we have repeated this work building such an apparatus from glass. We observed that there was considerable loss of pancreatic islets due to path traveled from the isolation chamber to the collecting flask. This was experimentally checked by simply increasing the length of tubing. The shortest path between these chambers is obviously zero! We have therefore reconfigured the apparatus of Ricordi et al so that collection of the islets can take place at the isolation chamber. The isolation chamber remains the same as in Ricordi et al and it is kept at 37° C by immersion in a water bath kept at this temperature which in turn is located on top of a shaker. When tests from a stopcock on the isolation chamber reveal that islets are detected, the whole chamber is lifted from the water bath at 37° C and immersed in ice. There is the added advantage that in this way the number of filters required to isolate the islets reduces to one. The yield of islets obtained through this simplification of Ricordi et al increases even though the digestion chamber is not kept at 37° C continuously, provided extra care is taken in the isolation chamber in ice. The optimum time for stopping the digestion must be determined experimentally. As a conclusion, at this new method, the recovery for count of intact isolated pancreatic islets is found to be higher ($p<0.01$) than the classical reference method.

MECHANISM OF DESTRUCTION OF FETAL PIG PROISLET XENOGRAFTS IN DIABETIC NOD RECIPIENT MICE

J.D. Wilson, C.J. Simeonovic, M.J. Townsend, K.U.S. McKenzie, J.C. Zarb and I.G. Young

Endocrinology Unit, The Canberra Hospital and Divisions of Molecular Medicine and Biochemistry and Molecular Biology, The John Curtin School of Medical Research, Canberra ACT., 2601, Australia.

Analyses of the cytokine mRNA expressed specifically during acute rejection of pig proislet xenografts in CBA/H mice have previously revealed a Th2-type cytokine profile. Autoimmune destruction of islet isografts in diabetic NOD mice has been characterised by others as a Th1-type response. The present study examines the susceptibility of pig proislet tissue to disease recurrence in diabetic NOD mice by comparing the intragraft cytokine mRNA profiles expressed during the destruction of NOD-scid islet isografts, SLA^{dd} pig proislet xenografts and SLA^{dd} fetal pig skin xenografts in diabetic NOD hosts. Isografts of NOD-scid skin were analysed in parallel as controls for the non-specific inflammatory response associated with the surgical procedure. Enhanced cytokine mRNA expression was defined as detection of transcripts at least 5 PCR cycles before corresponding NOD-scid skin isografts. NOD-scid islet isografts at days 3 - 8 post transplant showed enhanced expression of cytokine mRNA for IL-2, IL-3, IFN-γ, IL-4 and IL-5; by day 10 only IFN-γ and IL-2 transcripts were specifically enhanced (i.e. TH1-type profile). Histological analyses revealed the presence of damaged islet tissue from day 3. In comparison, pig proislet xenografts showed a marked delay in both graft damage (from day 8) and the enhanced expression of cytokine transcripts i.e. days 5-10 (IL-3) and days 6-10 (IL-2, IFN-γ, IL-4, IL-5, IL-10)i.e. Th0 -type profile. Absence of significant cytokine mRNA expression in NOD-scid skin isografts together with their histological integrity confirmed lack of disease susceptibility. Significantly, pig skin xenografts showed the same kinetics of enhanced cytokine transcript expression as pig proislet xenografts, suggesting that the cytokine profile in the latter grafts reflected xenograft rejection. This study suggests that pig proislet xenografts may be disease-resistant and that their destruction in diabetic NOD hosts is probably due to xenograft rejection.

A CONTROLLED STUDY OF SIMULTANEOUS ISLET-KIDNEY (SIK) TRANSPLANTATIONS IN EIGHT IDDM PATIENTS.

R.G. Bretzel, B.J. Hering, W. Ernst, S. Friemann, W. Padberg, C. Kelm, D. Brandhorst, H. Brandhorst, H. Jahr, A. El-Ouaghlidi, M. Eckhard, M. Brendel, K. Federlin

Centers of Internal Medicine and Surgery, Justus-Liebig-University of Giessen, Giessen, Germany

Simultaneous islet kidney transplantation is aimed at optimizing metabolic control, prevention of diabetic secondary complications, and improvement of quality of life. We report a controlled study on our last 8 consecutive simultaneous islet-kidney - transplanted IDDM patients and as a control group 8 IDDM patients with kidney transplants alone (KTA). A special immunosuppressive protocol was used and the study was carried out with a mean follow-up of approx. one year. Both patient groups were matched for sex, mean age, body mass index, mean time on dialysis and mean duration of diabetes. Islets were implanted by embolization into the liver via percutaneous-transhepatic catheterization of the portal vein system under local anesthesia. One year survival rate was 100% for patients in both groups, for kidney grafts 8/8 (KTA) and 8/8 (SIK), respectively, and for islet grafts 7/8 (86%). So far, 2 of 8 islet graft recipients (25%) achieved insulin independence, 10 and 12 months after islet implantation, respectively. Kidney rejection episodes were observed in 1/8 and 0/8 recipients, respectively. Mean HbA1c levels were 6.4% in SIK patients and 7.9% in KTA cases, respectively. Mean daily insulin requirement was 10 units in SIK, but 48 units in KTA cases. The number of hypoglycemic episodes per year in kidney transplant alone cases did not change significantly (> 2 pre and post tx) whereas none of the SIK recipients experienced hypoglycemic episodes thereafter (2.6 episodes pre tx). To summarize, ongoing islet allograft function has been documented for an average period of one year after islet grafting in 86% of our SIK recipients with insulin independence achieved in two cases. In contrast to kidney transplanted alone controls, no SIK transplanted patient experienced hypoglycemic episodes during one year follow-up and these patients demonstrated much better metabolic control.

481

DEOXYSPERGUALIN REVERSES XENOGRAFT REJECTION OF ENCAPSULATED ISLETS

Brend R.S. Hsu, J.H. Juang, S.H. Fu, Y.Y. Huang, M.K. Ting, J.S. Tsai and H.S. Huang. Chang-Gung Medical Center, Lin-Kou, Taiwan.

To study whether 15-deoxyspergualin (DSG) reverses xenograft rejection of alginate-polylysine-alginate (A-P-A) microencapsulated rat islets, we subcutaneously injected DSG of 0.625 mg/kg body weight daily for 14 days to graft-failed diabetic BALB/c mice that had been intraperitoneally transplanted A-P-A microencapsulated rat islets. Significant decrease of blood glucose (BG) level was found at the 5th day of DSG injection when compared with BG before DSG rescue (11.96±1.31 vs. 14.92±0.79 mmol/L, n=12, p< 0.05). The mean BG level at 14th day of DSG injection was 9.52±1.75 mmol/L. Five days after ceasing DSG injection, BG raised to level similar to that of before DSG injection. The mean body weight of these mice before and after two weeks of DSG injection was 23.5±1.1 and 23.2±1.2 gm, respectively. In conclusion, DSG reverses xenograft rejection of A-P-A encapsulated islets even when overt hyperglycemia has developed.

482

LONG-TERM RESULTS OF ISLET-AFTER-KIDNEY (IAK) TRANSPLANTATIONS IN IDDM PATIENTS.

B.J. Hering, D. Brandhorst, H. Brandhorst, M. Brendel, M. Eckhard, H. Jahr, A. El-Ouaghlidi, K. Weimar, W. Rau, K. Federlin, R.G. Bretzel
Centers of Internal Medicine and Radiology, Justus-Liebig-University of Giessen, Giessen, Germany

Islet transplantation in IDDM patients with established kidney grafts is aimed at optimizing metabolic control in order to prevent recurrence of diabetic glomerulosclerosis in the kidney transplant, to halt the progression of secondary complications and to improve quality of life. We report long-term results of 14 consecutive IAK-transplants in IDDM patients. Mean age (yrs) 38.7 ± 2.0, sex (m/f) 10 m, 4 f; body weight (kg) 64.9 ± 2.0, body mass index 23.1 ± 0.4; diabetes duration (yrs) 26.7 ± 1.7; years post kidney tx 5.2 ± 0.7. Number of islet equivalents (IEQ) transplanted per recipient per kg bodyweight 8,230 ± 934 yielded from a mean of 1.5 ± 0.3 donor pancreata. Islets were embolized into the liver (in one case into the spleen) after percutaneous-transhepatic catheter injection via the portal vein in local anesthesia. Primary islet function in terms of basal C-peptide ≥ 0.5 ng/ml after 2 weeks of islet implantation was observed in 14/14 cases. Six patients experienced islet graft failure after day 16, 17, 62, 120, 164, and 301. One patient died of recurrent silent myocardial infarction. Ongoing graft function was observed in the remaining 7 cases with basal C-peptide levels of 0.5-3.2 ng/ml and good metabolic control (HbA1c 6.3-8.2%). In 2 cases insulin-independence was achieved, 230 and 400 days post islet tx, respectively, In the other cases daily insulin requirement is so far reduced by 29-73%. No patient experienced hypoglycemic episodes. To summarize, ongoing islet allograft function has been documented for an average period of 2 years after islet implantation in 50% of our IAK recipients and insulin independence was achieved in two cases. These are, in our experience, remarkable results that strongly support the notion that islet replacement, even if not complete, is associated with very beneficial effects and the absence of hypoglycemia requiring assistance.

483

AN IMBALANCE BETWEEN BETA-CELL BIRTH AND BETA-CELL DEATH CONTRIBUTE TO FAILURE OF ENCAPSULATED ISLET GRAFTS

P. De Vos, A. Nieuwenhuizen, B.J. De Haan and R. Van Schilfgaarde. Surgical Research Lab, University Hospital Groningen, The Netherlands.

Alginate-polylysine microencapsulation allows for successful transplantation of allo- and xenogeneic islets in the absence of immunosuppressive therapy. However, the survival of microencapsulated islet grafts is limited, even if capsular overgrowth is restricted to a small percentage of the capsules. In search of other processes than overgrowth contributing to graft failure we have studied the islets in non-overgrown capsules at several time points after allotransplantation in the rat. All recipients of islet allografts became normoglycemic. Grafts were retrieved at four and eight weeks after implantation, and at 15.3 ± 2.3 weeks postimplant *i.e.* two weeks after the mean time period at which graft failure occurred. Overgrowth of capsules was complete within four weeks postimplant. It was usually restricted to less than 10% of the capsules. During the first four weeks of implantation, 40% of the initial number of islets were lost. Thereafter, we observed a decrease in function rather than in numbers of islets, as illustrated by a decline in the *ex vivo* glucose induced insulin response. At four and eight weeks post-implant, Beta-cell replication was ten-fold higher in encapsulated islets than in islets in the normal pancreas. But, these high replication rates were insufficient to prevent a progressive increase in the percentage of necrotic tissue in the islets. This necrosis mainly occurred in the center of the islets, which indicates insufficient nutrition as a major causative factor. Our study demonstrates that not only capsular overgrowth but also an imbalance between Beta-cell birth and Beta-cell death contribute to the failure of encapsulated islet grafts. Our observations indicate that we should focus on finding or creating a transplantation site which, more than the unmodified peritoneal cavity, permits for close contact between the blood and the encapsulated islet tissue.

484

EFFECT OF ISLET TRANSPLANTATION ON HYPOGLYCEMIA AWARENESS AND COUNTERREGULATION IN IDDM PATIENTS.

C. Meyer, B. Hering, R. Grossmann, H. Brandhorst, D. Brandhorst, K. Federlin, R.G. Bretzel
Third Medical Department and Policlinic, Justus-Liebig-University of Giessen, Giessen, Germany

Iatrogenic hypoglycemia is the most frequent acute complication in patients with insulin-dependent diabetes (IDDM). The major risk factors include the clinical syndromes of defective glucose counterregulation, hypoglycemia unawareness and elevated glycemic thresholds. Therefore, intraportal islet transplantation alone (ITA) was performed in three non-uremic, non-kidney transplanted IDDM patients prone to severe hypoglycemia in whom defective glucose counterregulation and hypoglycemia unawareness have been demonstrated. We used the stepped hypoglycemic clamp technique to determine both the magnitude and the glycemic threshold of the secretory response of the major counter-regulatory hormones and of autonomic and neuroglycopenic symptoms during hypoglycemia and post ITx. Control data were obtained from 10 matched non-diabetic volunteers. Prior to ITx, the secretory response of glucagon and of epinephrine was either absent or severely impaired while the secretory response of cortisol was markedly delayed in all patients. No patient noticed any significant autonomic warning symptoms during hypoglycemia. When the same test was repeated one month after successful ITx (exogenous insulin treatment reduced by about 50%), no improvement of the secretory response of glucagon was observed. However, in two patients, both the magnitude (793 vs 75 and 691 vs 58 pg/ml) and the glycemic threshold (64 and 59 mg/dl vs unmeasurable) of the secretory response of epinephrine were even normalized. In one patient only the magnitude increased (241 vs 179 pg/ml) but without any change in the glycemic threshold (54 vs 55 mg/dl). Moreover, the glycemic threshold of the secretory response of cortisol was reduced in all patients (51 vs 45, 55 vs 49, 52 vs 44 mg/dl). All patients noticed autonomic warning symptoms well before severe neuroglycopenia occurred at a glycemic threshold of 48, 52 and 56 mg/dl, respectively. We conclude that intraportal islet transplantation seems to improve the sympatho-adrenal regulatory mechanism and hypoglycemia awareness even in patients with long-standing IDDM by a yet unknown mechanism.

485

DECREASED IMMUNOGENICITY OF NEONATAL COMPARED TO ADULT PIG ISLET ANTIGENS IN NEWLY DIAGNOSED IDDM PATIENTS

K. Bloch, S. Assa, D. Lazard, N. Abramov, B. Sandomirsky *, N. Weintraub, Z. Josefsberg, M. Karp and P. Vardi. The National Center for Childhood Diabetes, SCMCI & FMRC, Tel-Aviv University, Petach-Tikva, Israel; *Institute for the Problems of Cryobiology and Cryomedicine, Kharkov, Ukraine

Porcine islets may substitute human sources for the purpose of islet transplantation to diabetic patients. The aim of our study was to determine whether pig islets derived from neonates differ in their immunogenicity from adult islets through evaluation of T-cell proliferation in newly diagnosed IDDM patients and healthy controls. In addition, we studied the correlation between T-cell reactivity to pig islet antigens and human insulin and the titer of various islet autoantibodies such as ICA, IAA, GAD, and ICA512. T-cells and sera of 16 IDDM patients and 15 healthy controls were studied. Adult pig islets were isolated using the collagenase method while a non-enzymatic procedure was used for the neonatal tissue. Purified islets underwent sonication and adjustment to an appropriate protein concentration. A stimulation index >2 was considered as a positive T-cell response. The percentage of positive responses in the two groups is presented in the table below:

	Insulin		Adult pig islets		Neonatal pig islets	
	0.5µg/ml	5µg/ml	1µg/ml	10µg/ml	1µg/ml	10µg/ml
Controls	0%	0%	20%	29%	0%	14%
IDDM	38%	40%	50%	60%	6%	27%

No association was found between a positive proliferative T-cell response and the titer of the various islet antibodies tested. In conclusion, our results suggest that neonatal pig islets induce a significantly lower T-cell proliferative response as compared to adult islets, indicating that the neonatal source may be immunologically more appropriate for the purpose of future islet xenotransplantation.

486

POSSIBLE INVOLVEMENT OF VON WILLEBRAND FACTOR IN PANCREATICGRAFT THROMBOSIS IN SIMULTANEOUS KIDNEY-PANCREAS TRANSPLANTATION

L. Kessler[1], M.L. Wiesel[2], K. Boudjema[3], E. Lutun[4], B. Moulin[5], J.P. Cazenave[4], Ph. Wolf[2], M. Pinget[1]. [1]Service d'Endocrinologie, [2]ETS, [3]Transplantation, [4]Clinique Béthesda, [5]Néphrologie, Hôpitaux Universitaires, 67000 Strasbourg, France.

Early post operative graft thrombosis remains the second main cause of failure in pancreas transplantation. Thus, the aim of this study was to compare retrospectively coagulation and fibrinolysis in groups of simultaneous kidney and pancreas transplanted type I diabetic patients having, or not, experienced thrombosis of their pancreatic vein. From December 1990 to January 1996, 26 simultaneous kidney-pancreas transplantations with bladder drainage were performed in 26 uremic type I diabetic patients. Acute thrombosis of the pancreatic vein was observed in 4 patients (group A) whereas 22 patients did not develop thrombosis (group B). The control groups, composed of 15 patients each, were : kidney transplanted (group C) or haemodialysed (group D) non diabetic patients and type I diabetics with HbA1C < 8% (group E) or ≥ 8% (group F) who were not in end stage renal failure. Begining at least 6 months after transplantation, we analysed haemostatic factors (fibrinogen, thrombin and prothrombin times), coagulation inhibitors (C and S proteins), fibrinolysis (plasminogen inhibitor) and endothelial cell abnormalities (Von Willebrand factor: VWf). Micro- and macro-vascular complications were evaluated using a score ranging from 0 to 12. Haemostatic factors, coagulation inhibitors and fibinolysis were similar in both groups A and B. In contrast, VWf differed significantly in group A: 3.49±0.93 IU/ml versus group B: 2.04±0.92 IU/ml ($p<0.05$). VWf in group A was also significantly higher than that of control groups C, D, E and F. The score of vascular complications increased in both groups A and B but was significantly higher in group A: 9±0.81 versus 6.07±1.75 ($p<0.01$). A correlation ($R=0.812$, $p<0.05$) between the severity of vascular complications and VWf was observed. These results suggested the possible involvement of VWf in the pathogenesis of pancreatic graft thrombosis in kidney-pancreas transplantation.

487

CHEMOTAXIS OF MURINE MACROPHAGES TOWARDS ENCAPSULATED PANCREATIC ISLETS : *IN VITRO* AND *IN VIVO* STUDIES.

V. Karsten, C. Lencioni*, L. Kessler, P. Marchetti*, A. Belcourt, N. Navalesi*, M. Pinget. CeeD, Strasbourg, France - Istituto di Clinica Medica, Pisa, Italy

The aim of the present work was to study, *in vivo* and *in vitro*, the involvement of pancreatic islets in the cellular reaction observed at the surface of biocompatible artificial membrane after transplantation of encapsulated islets. Two hundred pancreatic rat islets encapsulated with the AN69 membrane (Hospal, France) by means of PTFE rings were cultivated at 37°C in RPMI medium or implanted for 2 and 7 days in the peritoneal cavity of diabetic mice (streptozotocine induced). Empty devices and free islets served as controls. *In vivo*, the cellular reaction observed on removed devices (empty or filled) was identified by SEM and phagocytosis tests. *In vitro*, a modified Boyden chamber was used to evaluate the migration of activated peritoneal murine macrophages toward the supernatant of cultivated islets. The chemotactic index was expressed as the ratio : number of cells attracted by the supernatant / number of cells attracted by culture medium. After 2 and 7 days of implantation, only few cells adhered on the empty devices while numerous cells, mainly macrophages (80%), colonized the devices containing the islets. The cellular adhesion did not modify the fiber network of the membrane (SEM). After 2 days of implantation, macrophages covered 45% of the surface of devices filled with islets versus 5% of the empty ones. These values reached respectively 65% and 15 % after 7 days. *In vitro*, after 2 and 7 days of culture, the chemotactic indexes of encapsulated islets were respectively 1.51±0.31 and 1.37±0.39 whereas that of free islets were higher: 2.40±0.42 and 2.63±0.47 respectively. *In vitro*, preliminary studies showed a stronger chemotactic effect of the supernatant of free islets after 1 hour incubation in 4g/l glucose in comparison with the effect observed with 1g/l glucose. Encapsulation of pancreatic islets decreases the chemotactic effect of islets suggesting that the artificial membrane blocked the chemotactic factor of islets. Insulin in high concentration is suspected to be one of these factors.

488

GLUCAGON LEVEL AFTER PANCREAS AND KIDNEY TRANSPLANTATION. SEVEN YEARS FOLLOW UP.

G.Rosiński, J.Krzymień, A.Dworak and M.Bąk. University School of Medicine, Warsaw, Poland.

The aim of the study was to assess the level of glucagon in plasma of IDDM patients after simultaneous pancreas and kidney transplantation. The study group comprises 6 individuals (2 males and 4 females) aged 30-40 years. These patients had IDDM for 9-26 years complicated by chronic renal failure. Since the transplantation they are on the immunosuppressive treatment. Every 12 months the fasting level of C-peptide was measured to evaluate beta-cells secretion and the level of glucagon as indicator of alpha-cells function was controlled. The average value of fasting glycaemia was 5.0±0.2 mmol/l (90±3.6 mg/dl). HbA_1c fell from 8.3% in the first year after transplantation to 6% in subsequent years. Serum C-peptide values were in normal range (0.95-3.0 ng/ml).

In all patients more than 2-fold increase of plasma glucagon level was observed immediately after transplantation. High levels plasma glucagon sustained during whole period of observation. Plasma glucagon rose significantly - in average by 239.5% (the lowest 350 pg/ml (124%) - in 4th year and 580 pg/ml (284%) in 7th year (normal range 50-200 pg/ml). This increase of plasma glucagon did not correlate with the serum plasma C-peptide levels. Conclusion: Successful pancreas transplantation in patients with IDDM led to hyperglucagonemia which had no influence on carbohydrate tolerance. The reported high levels of glucagon might result from double quantity of alpha cells.

ISLET MICROENCAPSULATION USING A PIEZOELECTRIC DROPLET GENERATOR

W. Zhang, R. Pommersheim, Ch. Laue, M. Döring, W. Vogt and J.Schrezenmeir. Federal Research Center, Kiel, Germany and Gutenberg University, Mainz, Germany

For islet transplantation the size of microcapsules may play a crucial role. The diameter should preferably approximate that of the islets for an optimal diffusion of oxygen, nutrients and insulin. In this study we report a new encapsulation technique that produces small barium-alginat capsules. A piezoelectric droplet generator developed in our laboratory was used instead of the earlier air-jet procedure, by which a minimal diameter of about 700µm can be realized due to inevitable turbulence at the outlet of the nozzle. To evaluate the efficacy of the new method, a comparative study was performed. Porcine islets were microencapsulated in barium alginate beads using the new or old droplet generator. The piezoelectric resulted in 350-500µm transparent, spherical droplets. The whole encapsulation time did not exceed five minutes. comparatively, the diameter of microcapsules made by air-jet were 750 µm and the procedure took more than thirty minutes. Ten days later, the functionality of microencapsulated islets was assessed by determination of the glucose-dependent insulin secretion. The stimulatory insulin response did not differ between both groups ($p>0.05$). It was 140.08±38.04% over the basal secretion ($n=38, p<0.01$) with the piezoelectric generator and 96.98±19.72% ($n=41, p<0.001$) with the air-jet procedure. Haematoxylin-Eosin-stained sections of microencapsulated porcine islets confirmed the well-preserved viability. We conclude that the use of new droplet generator allowed the time-saving-production of small microcapsules and did not impair viability and glucose-dependent insulin secretion of porcine islets *in vitro*. Due to the 4-fold more diffusion-surface it might improve survival of encapsulated tissue after transplantation.

TRANSPLANT THERAPY FOR END-STAGE DIABETIC NEPHROPATHY: A SINGLE CENTRE EXPERIENCE

F. Saudek, M. Adamec, V. Bartoš, P. Bouček, Z. Vlasáková, J. Kožnarová, Š. Vítko. Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

The aim of the present study was to compare the patient and graft survival rate, occurence of complications and metabolic control in 4 groups of transplant (Tx) recipients treated for end-stage diabetic nephropathy. Since 1983, isolated primary kidney Tx was performed in 56 Type 1 (group K1) and 26 Type 2 (group K2) recipients. In 38 recipients, combined kidney and segmental duct-occluded pancreas Tx was done (group Ps+K). Other 42 patients were treated by combined kidney and whole pancreas Tx with bladder drainage of pancreatic duct and extraperitoneal placement of the pancreatic graft (group Pw+K). Cummulative 2-year survival rates (%) are shown in the following table:

Group	n	Recipients	Kidney	Pancreas
K1	56	86	72	-
K2	26	74	54	-
Ps+K	38	72	56	35
Pw+K	42	90	80	78

The highest complication rate was found in the Ps+K group. After switching to the whole-organ technique (group Pw+K) the post-operative morbidity remained significant, but the number of serious complications was reduced. One year after Tx glycosylated hemoglobin was found to be in the normal range in Ps+K and in Pw+K groups but not in the K1 and K2 groups (mean ±SE 6.28±10, 4.85±0.09, 9.01±0.12 and 8.95±0.12 %, respectively). Glycosylated hemoglobin was lower and K value higher (intravenous glucose tolerance test) in the Pw+K than in the Ps+K group ($p<0.01$). We conclude that the results of Tx therapy in diabetic recipients have improved considerably in the recent time and that the combined whole-pancreas and kidney Tx is the most favorable treatment option for the majority of Type 2 uremic diabetic patients.

491

INSULIN SECRETION AND PERIPHERAL SENSITIVITY ESTIMATED BY CIGMA IN PANCREAS-KIDNEY TRANSPLANT RECIPIENTS

YFC Smets, JW van der Pijl, M Frolich, J Ringers, JW de Fijter, and HHPJ Lemkes, Leiden University Hospital, Leiden, The Netherlands

After successful simultaneous pancreas-kidney transplantation (SPK) normoglycemia is established in spite of the presence of insulin resistance and reduced β cell secretory capacity. To assess insulin sensitivity (IS) and β cell secretory capacity (BC) posttransplant, we introduced Continuous Infusion of Glucose with Model Assessment (CIGMA), as described by Turner (Oxford, UK). We performed CIGMA in 29 bladder-drained SPK patients with systemic insulin delivery (24 male/5 female) >1 year posttransplant and in 32 non-diabetic patients (21 male/11 female), matched for impaired creatinine clearance, with a kidney transplant and immunosuppression (KTx, n=18) or without a transplant (NoTx, n=14). The 3 groups were comparable with respect to mean±SD age (44±9 years), BMI (24±3 kg/m^2), HbA_{1c} (5.6±0.5%), and endogenous creatinine clearance (64±28 ml/min). Mean±SD glucose and insulin values after 1 hour infusion of 5 $mg.min^{-1}.kg\ IBW^{-1}$ glucose stimulation, were 8.6±1.8 mmol/l and 43±20 mU/l in the SPK group and 7.3±1.0 mmol/l with 36±21 mU/l and 8.4±1.6 mmol/l with 28±14 mU/l in KTx and NoTx respectively. Stimulated c-peptide measurements were 2.2±0.9(SPK), 2.9±1.1(KTx), and 2.6±0.9 (NoTx)nmol/l, and were inversely correlated with creatinine clearance ($r=-0.49; p<0.001$). Estimated IS was equal in non-diabetic KTx (69±39 U) and NoTx (71±36 U), indicating immunosuppression did not cause insulin resistance in KTx. However, IS was clearly diminished in the SPK patients (42±15 U). C-peptide values, corrected for creatinine clearance, were used to estimated BC to eliminate the effect of the liver's insulin extraction bypass. CIGMA showed no differences in BC between SPK (131±89 U) and NoTx (135±51). We conclude that, using this simple and accurate test, SPK recipients suffer from more insulin resistance than KTx patients, probably mainly due to the pre-existing diabetic state and hyperinsulinemia per se. The effect of immunosuppressive agents appears to be limited. Pancreas graft function is able to reach non-transplanted levels.

DIPEPTIDYL PEPTIDASE IV RESISTANT ANALOGUES OF GLUCAGON-LIKE PEPTIDE-1: *IN VITRO* AND *IN VIVO* STUDIES

CF Deacon, *L Bjerre Knudsen, *N Langeland Johansen, *K Madsen and JJ Holst. Dept Med Physiol, Panum Inst, Univ Copenhagen & *Novo Nordisk A/S, Måløv, Denmark.

The insulinotropic hormone glucagon-like peptide-1 (GLP-1) is a substrate for dipeptidyl peptidase IV (DPP IV), which is responsible for GLP-1 inactivation *in vivo*. The enzyme removes a dipeptide from the N-terminus to form GLP-1 (9-36)amide, which is an antagonist *in vitro*. DPP IV is highly specific and has strict substrate requirements. This study was undertaken to examine whether small modifications of the N-terminus of GLP-1 would confer resistance to degradation by DPP IV. Modified GLP-1 analogues were prepared by solid phase peptide synthesis, substituting the alanine at position 8 of GLP-1 with either threonine, glycine, serine or α-aminoisobutyric acid (Aib). All 4 analogues stimulated cAMP production in BHK cells transfected with the GLP-1 receptor. Incubation of the analogues with porcine plasma *in vitro* at 37°C revealed a prolonged t½ compared to GLP-1 itself (GLP-1, 28.3±1.5; thr^{8}GLP-1, 202±19; gly^{8}GLP-1, 161±21; ser^{8}GLP-1, 173±12 min) whilst degradation of Aib^{8}GLP-1 was undetectable after 6 hr. The analogues were studied in 4 groups of halothane-anaesthetised pigs, in which each group (n=4) received separate 30 min iv infusions of GLP-1 and one analogue, in a cross-over design with 80 min between each infusion. Blood samples were assayed for GLP-1 immunoreactivity using both C- and N-terminally directed antisera, except for Aib^{8}GLP-1 which could be measured only with the C-terminal assay. For all 4 groups, there was no difference between the C-terminal t½ for GLP-1 or the analogue (4.0±0.1 vs 4.2±0.4, thr^8 GLP-1; 4.3±0.5 vs 3.5±0.7, gly^8 GLP-1; 4.1±0.2 vs 4.2±0.2, ser^8 GLP-1; 4.3±0.3 vs 4.4±0.2 min, Aib^{8}GLP-1), but the N-terminal t½ for each analogue was prolonged ($p < 0.01$) compared to GLP-1 (0.7±0.2 vs 3.9±0.2, thr^{8}GLP-1; 0.9±0.003 vs 3.3±0.4, gly^8 GLP-1; 0.9±0.06 vs 3.7±0.4 min, ser^{8}GLP-1). For all 4 groups, the N-terminal t½ was shorter ($p < 0.01$) than the C-terminal t½ for GLP-1, but there was no difference between N- and C-terminal t½ for the analogues. These results indicate that modification of the N-terminus of GLP-1 makes the peptide resistant to DPP IV action. However, the plasma t½ *in vivo* cannot be extended beyond that determined by the C-terminal assay, due to the presence of other non-DPP IV-mediated degradation pathways.

493

EFFECTS OF GLP-1 ON REGULARITY, FREQUENCY, AMPLITUDE, AND MASS OF COORDINATE PULSATILE INSULIN SECRETION IN HEALTHY HUMANS.

N. Pørksen, T. Grøfte, B. Nyholm, J.D. Veldhuis, J.J. Holst, O. Schmitz and P.C. Butler. Medical Department M, Aarhus University Hospital, Denmark, Department of Medicine, Charlottesville, VA, Department of Medical Physiology, University of Copenhagen, Copenhagen, Denmark, and Department of Endocrinology, University of Edinburgh, Scotland, UK.

GLP-1 is a peptide hormone released from the gut upon luminal stimulation. It is a potent insulin secretagogue, and a potential future drug in the treatment of NIDDM. The majority (~70%) of insulin is secreted as series of punctuated secretory bursts superimposed on a basal insulin secretion. In healthy humans insulin secretion is mainly regulated through perturbation of mass and frequency of the secretory bursts, and the mode of delivery of insulin into the circulation seems important for insulin action. To assess effects of GLP-1 on mass, frequency, amplitude and overall contribution of pulsatile insulin secretion, we applied a recently validated deconvolution model on insulin concentration data before and during infusion of GLP-1 and saline in 8 healthy humans. Following GLP-1 infusion there was an abrupt increase in the peripheral serum concentrations of C-peptide (696±65 vs 1538±165 pM) and insulin (49±8 pM vs 138±21 pM). This increase was mainly due to an increase in secretory burst mass (28.2±4.4 vs 100.1±15.8 pmol/L/pulse, $p<0.001$), and amplitude (4.3±2.2 vs 12.7±7.7 pmol/L/min, $p<0.002$), whereas the secretory burst frequency was not affected by the infusion of GLP-1 (11.5±0.7 vs 12.6±0.6 pulses/hour, $p=0.4$). Consequently the detected contribution of pulsatile to overall insulin secretion was increased from 56±4 to 77±4 percent ($p<0.005$). The regularity of the oscillating insulin secretion was not perturbed by GLP-1 as estimated by ApEn values ($p=0.7$). None of the above parameters changed during saline infusion ($p>0.3$) We conclude that GLP-1 infusion stimulates insulin secretion through amplification of the mass and amplitude of the insulin secretory bursts, amplifying the pulsatile component of insulin secretion.

494

THE RECEPTOR MECHANISM INVOLVED IN NEURO-INCRETIN EFFECT OF GLUCAGON-LIKE PEPTIDE-1

M. Nishizawa[1], H. Nakabayashi[2], K. Uchida[1] and A. Niijima[3]. Kanazawa Medical University[1], Uchinada, Kanazawa University[2], Kanazawa, and Niigata University[3], Niigata, Japan.

We have recently found that an intraportal appearance of glucagon-like peptide-I (7-36)amide (tGLP-1), but not full-length GLP-1, is specifically recognized by the hepatic vagal nerve, and this recognition further augments the pancreatic vagal efferent activity in a reflex way, suggesting a novel neuroincretin effect of the peptide. To clarify further the receptor mechanism involved in the hepatic vagal recognition of tGLP-1, the effect of exendin (9-39)amide (EX), a specific antagonist of tGLP-1 receptor in the beta cells, on the recognition was examined. A 1-min bolus intraportal injection of tGLP-1, but not the vehicle, increased by ca. 2-fold the impulse discharge rate of the hepatic afferent vagus for >90 min at a physiological (0.2 pmol) or a pharmacological (4.0 pmol) dose in rats anesthetized with urethan and chloralose ($P<0.01$ vs. the preinjection value, n=6 and n=7, respectively). When a 100 times molar dose of EX to tGLP-1 known to inhibit the insulinotropic effect of the tGLP-1 was administered intraportally 5 min before the tGLP-1 injections, the facilitating effect of the tGLP-1s on the vagal afferents was observed without any modification in the amplitude and time-course of the afferent activities (n=5, each). Moreover, when the EXs were administer-ed 10 min after the tGLP-1s, where the afferent activities had already started to increase by tGLP-1, the tGLP-1s again increased the hepatic vagal afferent activities unmodifiedly (n=5, each). The present results shows that the tGLP-1 receptor system involved in the hepatic vagal recognition for tGLP-1 is different from that in the beta cells, implying existence of subtype(s) in the receptor.

495

STIMULATION OF PULSATILE SECRETION OF INSULIN AND GLP-1(7-36)AMIDE FOLLOWING BY ORAL GLUCOSE.

HJ Balks*, JJ Holst[1], G Brabant, and A Von zur Mühlen. Dept. of Clinical Endocrinology, MH-Hannover Hannover, FRG.

GLP-1(7-36)amide (GLP-1) is secreted from inestinal L-cells of the distal jejunum, ileum and colon within a few min following nutritional stimulation in a pulsatile fashion, as shown previously. As GLP-1 has insulinotropic properties in vivo and in vitro we were interested in the coregulation of GLP-1 and Insulin (I) secretion. This topic was investigated in 5 healthy volunteers (mean age 27.8±3.6 y, BMI 23.4±1.2 kg/m²). A standardized oral glucose load with 100 g glucose (OG; Dextro-O.G.T, Boehringer, FRG) was performed after an overnight fast (app. 10 h) and after 1 h investigation of basal hormone secretion. The changes in plasma concentrations and dynamics of the secretion of GLP-1 and I induced by the glucose challenge were investigated for 1 h. Plasma hormone concentrations were determined radioimmunologicaly, GLP-1 using the C-terminally specific antiserum 89890 and I using an insulin specific ria. Pulsatile elements of GLP-1 and I secretion were determined by deconvolution with the DESADE program. Under fasting conditions we found 5.4±1.95 GLP-1 and 5.20±0.84 I pulses per h and pulse amplitudes for GLP-1 of 8.60±3.76 pmol and for I of 21.7±9.15 pmol. GLP-1 and I plasma levels increased app. +8 min following the OG . the frequency of GLP-1 and I pulses remained unchanged while pulse amplitudes of GLP-1 increased to 19.34±7.42 pmol and of I to 222.2±55.9 pmol ($P<0.05$, ANOVA). The integrated amount of hormone secreted (AUC) was basally 248±17.7 pmol x min for GLP-1 and 1337±50 pmol x min for I. During the 1 h after the OG the AUC of GLP-1 increased to 688±35 and of I to 10485±866 pmol x min. Crosscorrelation analysis revealed no correlation of the basal GLP-1 and I pulses, but a significant crosscorrelation after the OG for a time-lag -2.0±6.3 min; R=0.70±0.28; $P<0.05$). Conclusion: I and GLP-1 secretion is increased in parallel by glucose ingestion. A significant cosecretion of both peptides is found only after nutritional stimulation, but the time-lag between the pulse maxima of GLP-1 and I varies individually. Factors involved in the coregulation of GLP-1 and I might include neuronal or humoral mechanisms.

496

IMMUNOCHARACTERIZATION AND FUNCTION OF GLUCAGON- LIKE PEPTIDE -1 ISLET RECEPTOR IN SYRIAN HAMSTER .

C.Boissard, V.*Leclercq-Meyer, M.Pessah, J.-M.Garel, G.Rosselin and W.J.Malaisse*. INSERM U55, France. *Lab. of Exp. Med., Brussels Free University, Belgium.

Molecular and functional analyses were performed to show the presence of glucagon-like peptide -1 islet receptor (GLP-1R) in normal syrian hamster (SH). Three bands of 44, 71 and 134 kDA were detected using a polyclonal antibody (S. Mojsov) raised against the extracellular part of the rat GLP-1R detected in isolated SH islets (SHI) and HIT-T15. In cryptic intestinal cells and fibroblasts only one unspecific band of 134 kD was observed. Western blot of rat islets and RINm5F cells revealed a similar pattern except the addition of a band at 95 kD. A GLP-1R mRNA in SHI of 2.7 kb was detected using a human cDNA probe of 1.6 kb pair in low stringency conditions. A cDNA probe of 219 bp coding for the rat transmembrane stretchs IV and V of GLP-1R gave no signal in SH although both probes showed the expected transcripts at 2.7, 3.4 and 3.7 kb in rat islet and RINm5F extracts. In perfusion experiments, after 3.3 mM glucose for 25 min, the response at 8.3 mM (min 27-42) was biphasic. tGLP-1 at 10^{-9} M, for 25 min of exposure, caused a dramatic increase in insulin output reaching 705 ± 28 % of controls at 8.3 mM whereas the effect of glucagon reached only 207±8 % ($P<0.001$). Glucagon values, which significantly decreased at 8.3 mM glucose compared to the basal values (3.3 mM) did not decrease further upon perfusion of tGLP-1. In comparison, a human insulinoma showed a similar response to glucagon and tGLP-1 reaching 3.6 and 3.9 times the basal level i.e. 800 and 825 microU insulin /10^6 cells, respectively. Our data demonstrate the presence and the species specificity of the SHI GLP-1R. A GLP-1R recognizing part similar to that of rat with a 44 and a 71 kD forms corresponding to the immature peptidic and the glycosylated peptidic receptor respectively was observed. For mRNAs the nature of the transcripts differs from that of rat and human. The insulinotropic activity of tGLP-1 through its receptor is five times that of glucagon. Thus, evidence for the presence of a functional GLP-1R in the SHI was provided by our experiments.

497

ATROPINE BUT NOT α- OR β-ADRENERGIC BLOCKERS EXERT EFFECTS ON GLP-1(7-36)AMIDE AND INSULIN SECRETION IN HUMANS.

H.J.Balks, B. Hoffmann, J.J. Holst, and A. von zur Mühlen
Dept. of Clinical Endocrinology, MH-Hannover Hannover, FRG

Within a few min following nutritional stimulation GLP-1(7-36)amide is secreted in man in a pulsatile manner as shown previously. Intestinal delivery of glucose seems not to be major mechanism for the stimulation of GLP-1 secretion. Neuronal e.g. vagal mechanisms are under debate and were investigated in the present study in 5 healthy male volunteers (BMI 23.4±1.2 kg/m², age 27.8±3.6 y) during 60 min under resting conditions and during another 60 min following an oral glucose load (OGL, 100g dextrose/400 ml) with and without blockage of cholinergic and α- or β-adrenergic transmission using atropine, propranolol or phentolamine infused from 30 min before and throughout the OGL. Blood was collected every 2 min for the estimation of plasma glucose (G), GLP-1(7-36)amide (GLP-1) and insulin (I). The plasma concentrations were integrated in segments of 30 min (AUC). Basally no effect of the various blockers was detected comparing segment 1 (-blocker) and 2 (+blocker). Following the OGL the G_{AUC} was reduced to 83/86 % of control (segment 3/4), the I_{AUC} to 55/57 % , the GLP-1_{AUC} to 47/63% ($P<0.005$) by atropine, whereas propranolol or phentolamine had no significant effect. Atropine induced a delay in gastric emptying that was not seen after propranolol or phentolamine. But, the inhibitory effect on GLP-1 and I secretion exceeded the motility effect. From our data we conclude that nutrient dependent GLP-1 and also I secretion is modulated by the parasympathetic nervous system in humans in vivo.

498

SOMATOSTATIN IS A MAJOR, PARACRINE REGULATOR OF GLUCAGON-LIKE PEPTIDE-1 (GLP-1) SECRETION.

L Hansen, H Mineo, T Bisgaard, PN Jørgensen, JJ Holst. Department of Medical Physiology, the Panum Institute, University of Copenhagen, Denmark.

GLP-1 secretion from the endocrine cells of the ileum is stimulated by unabsorbed luminal nutrients. Meal responses are rapid, suggesting neural or endocrine control of secretion. We studied GLP-1 secretion from isolated porcine ileum, perfused with synthetic Krebs-Ringer bicarbonate, in response to electrical stimulation (8 Hz, 10 mA, 4 ms imp. duration) of the mixed extrinsic nerves, and infusion of noradrenaline (10 nM) , acetylcholine (1 uM), GRP (gastrin-releasing polypeptide 18-27 (10 nM), intraluminal administration of HCl, and inflation by air (a distension stimulus) with and without alpha-adrenergic blockade (phentolamine , 10 uM). Finally, we infused a high-capacity (final perfusate binding capacity: 6 nmol/ml), high affinity (Kd = 10 pmol/l) monoclonal antibody against somatostatin. Nerve stimulation (n = 6) inhibited GLP-1 secretion to 77 ± 3 % of basal, an effect which was abolished by phentolamine (99 ± 2 %). Noradrenaline (10 nM) inhibited (to 74 ± 6 %) and Ach stimulated secretion (to 136 ± 5 %), abolished by atropine. GRP increased GLP-1 secretion (14-fold). HCL and air distension grossly stimulated motility but weakly increased GLP-1 secretion. Somatostatin antibody infusion increased basal GLP-1 secretion between 5- to 12-fold, but the response to GRP, and nerve stimulation was unchanged. We conclude that GLP-1 secretion is inhibited by sympathetic, noradrenergic nerve activity and tonically inhibited by somatostatin in a paracrine manner. Lifting of sympathetic and somatostatinergic inhibition could provide a powerful stimulus for GLP-1 secretion..

499

IMPAIRED SECRETION OF GLUCAGON-LIKE PEPTIDE 1 AFTER ORAL GLUCOSE IN ACROMEGALIC AND GH-DEFICIENT PATIENTS

C. Drewes, J. Leu, J.J. Holst, W.H. Schmiegel, M.A. Nauck, Medizinische Universitätsklinik (Knappschaftskrankenhaus) Bochum, Germany and Panum Institute, University of Copenhagen, DK.

Glucagon-like peptide 1 (GLP-1) is an incretin from the lower gut with important glucoregulatory actions. It was the aim of the present study to examine plasma glucose, insulin, and GLP-1 responses after oral glucose in patients with acromegaly (growth hormone excess), GH-deficiency (pituitary disease) and normal subjects. In 7 acromegalic (49 ± 11 y.; BMI 31.3 ± 4.6 kg/m^2), 11 GH-deficient patients (57 ± 11 y.; BMI 29.0 ± 1.4 kg/m^2), and 11 normal controls (53 ± 12 y.; BMI 26.9 ± 3.6 kg/m^2), the glucose (glucose oxidase), insulin (IMx), and GLP-1 (RIA) response to oral glucose (75 g/300 ml) was determined over 4 h. Statistics: repeated-measures analysis of variance. Fasting GLP-1 was 11 ± 2 pmol/l in controls vs. 5 ± 1 pmol/l in both acromegalic and GH-deficient patients ($p = 0.016$). Likewise, the AUC over 6 h was 3961 ± 254 in controls, and 2517 ± 319 in acromegalic, and 2562 ± 300 pmol$\cdot$l$^{-1}\cdot$min in GH-deficient patients ($p = 0.0015$). In a multivariate regression analysis, both basal GLP-1 ($p = 0.034$) and the GLP-1 AUC ($p = 0.025$) were significantly related to cortiocotropic insufficiency (present in 3/7 patients with acromegaly and 10/11 GH-deficient patients). There was no significant difference in glucose or insulin responses. In conclusion, GLP-1 release is impaired in patients with acromegaly and growth hormone deficiency. Their common background is pituitary disease. Deficiencies in the corticotropic axis may be especially responsible for reduced basal and nutrient-stimulated GLP-1 release. This points to a hitherto unknown interaction of pituitary and gut hormones.

GLUCOSE ABSORPTION AND GLP-1 SECRETION.

H. Manaka, K. Sugiyama, K. Hama, K. Yamatani and H. Sasaki
3rd Department of Internal Medicine, Yamagata University School of Medicine, Yamagata 990-23, Japan.

GLP-1 secretion from the intestine is stimulated by glucose ingestion in man. The intraluminal administration (*IL*) of 2DG or sucrose did not affect GLP-1 secretion from the isolated perfused canine ileum, and stimulated GLP-1 secretion by *IL* glucose was decreased with *IL* phlorizin and intraarterial administration of ouabain. Thus, GLP-1 secretion is tightly related with glucose absorption and may be coupled with Na/glucose cotransporter (SGLT-1). However, it has been unknown whether SGLT-1 exists in L cell. In this study, we examined SGLT-1 in L cell by immunohistochemical technique. [Materials & Methods] Rat was fixed by transcardiac perfusion with 10% formalin in phosphate buffer. Small intestine was enbetted in paraffin and cut into 10 μm sections. Anti-SGLT-1 rabbit serum and anti- GLI guinea pig serum were used as double immunostaining on the same section. TRITC conjugated anti- rabbit IgG goat γ-globulin and FITC conjugated anti-guinea pig IgG goat γ-globulin were used as second antibodies. Epithelial cells were observed by a conforcal microscope. [Results] SGLT-1 was observed on the brushborder of the epithelium. The basolateral side was not stained by SGLT-1 antiserum. Although L cell was stained GLI antiserum, the luminal side of L cell was not stained with SGLT-1 antiserum. [Conclusion] L cell could not absorb glucose from the intestinal lumen through SGLT-1, and glucose absorption may indirectly regulate GLP-1 secretion from L cell.

501

The ethanol augmentation of glucose-induced insulin secretion is abolished by calcium-antagonism with Nifedipine. No evidence for a role of GLP-1.

J. Svartberg, J.J. Holst*, M. Gutniak† and N. Adner (Karolinska Institute, Department of Internal Medicine, Endocrinology Section, Södersjukhuset; †Vällingby Medical Center, Stockholm, Sweden and the *Panum Institute, Department of Physiology, University of Copenhagen, Denmark).

Ethanol in itself does not affect basal insulin secretion in man. However, ethanol given before a glucose challange, augments the early insulin response by an unknown mechanism. Ethanol might affect the β-cell directly, or indirectly modulate insulin secretion through hormonal or neuronal activation. The aim of the present study was to examine if the ethanol augmentation of insulin secretion to an intravenous glucose challange could be modified by use of the calcium blocking agent nifedipine, and if that effect was mediated by GLP-1. Eight healty subjects volunteered for the study and in each subject four experiments were performed (control, ethanol, nifedipine and combination) in random order. Intravenous glucose tolerance test was performed with and without pretreatment with oral ethanol and nifedipine. Ethanol pretretment was followed by increased insulin (ethanol 5113,0 ± 863,7 vs control 3160,6 ± 413,8 pmol/l; $p<0,01$, n=8) and C-peptide (ethanol 29,6 ± 3,5 vs control 22,7 ± 1,5 mmol/l; $p<0.05$, n=8) areas after intravenous glucose (0-20 min.), indicating that ethanol augments insulin secretion. Calcium antagonism with nifedipine abolished the ethanol augmentation of insulin secretion, (insulin area 0-20 min, ethanol 5113,0 ± 863,7 vs combination 3730,6 ± 433,2; $p<0,05$, and C-peptide area 0-20 min, ethanol 29,6 ± 3,5 vs combination 22,1 ± 1,3; $p<0,01$). The GLP-1 response (area 0-90 min, n=6) was not significantly affected by ethanol. In conclusion, ethanol augmentation of insulin secretion to a glucose challange is supressed by nifedipine. Our results do not suggest that ethanol affects insulin secretion by stimulating GLP-1 secretion.

502

GLUCAGON-LIKE PEPTIDE 1: EFFECTS ON GASTRIC EMPTYING AND ABSORPTION OF SUCROSE IN CONSCIOUS SWINE.

J. Radziuk, J. Davies, S. Pye, S. Myers and L. Stramm Ottawa Civic Hosp., Ottawa, Canada, Lilly Res. Lab, Indianapolis, USA

Glucagon-like peptide 1 (7-37)OH (GLP-1) may participate in the mechanisms, comprising the ileal brake, which slow gastric emptying in the presence of nutrients in the distal bowel. In order to characterize this property of GLP-1, gastric emptying of a 1g/kg sucrose solution was assessed in conscious swine using the dilution of sequential intra-gastric injections of phenol red during the infusion of (a) 0 (b) 0.5 (c) 1 and (d) 4 nmol/kg of GLP-1 (7-37) over a 4h period. The sucrose was labelled with [^{14}C] glucose and the first appearance of label in the portal or peripheral circulation was used to assess absorption.

Dose nmol/kg /4h	n	% remaining in stomach at time (min) 30	60	120	240	Peak Glucose (mmol/L)	Time (^{14}C glucose >0) (min)	Peaks ^{14}C Glucose dpm/ml	Time Min
0	8	53±7	20±5	7±3	1±1	9.4±0.9	15	465±63	60
0.5	5	50±11	22±8	5±1	0.5±0.2	9.7±0.4	15	640±142	30
1	5	72±12	64±13	30±9	18±8	6.3±0.8	30±8	357±67	120
4	4	78±17	70±17	79±11	59±21	5.8±0.3	104±6	86±39	180

There is a dose-dependent slowing of gastric emptying with a resulting decrease in both the glucose and (normalized) label peak. Both the time of first appearance and peak of the label are delayed with increasing dose. The dose-dependent delay in first appearance of label, not correlated to gastric emptying, suggests a separate effect of GLP-1 on glucose absorption. Thus, both gastric emptying and glucose absorption may be independently delayed by this gut peptide.

503

IV GLP-1 LOWERS BLOOD GLUCOSE LEVELS IN NIDDM PATIENTS REGARDLESS OF FASTING GLUCOSE, BMI, AND INSULIN CAPACITY.

M. Toft-Nielsen[1,2], S. Madsbad and J.J. Holst. Dept. of Endocrinology, Hvidovre Hospital and [2]Dept. of Medical Physiology, the Panum Institute, Copenhagen, Denmark.

GLP-1 administration has been shown to lower blood glucose in small groups of patients with NIDDM, but it is not known how this effect is related to the degree of obesity, the fasting blood glucose (f-BG) concentrations or the insulin secretory capacity of the patients. In this study we infused GLP-1 (1.2 pmol/kg/min) intravenously for 4 to 6 hours into 50 fasting NIDDM patients (age: 40 - 71 yrs.; BMI: 20 - 45 kg/m^2; fasting plasma glucose: 5.7 - 24.5 mmol/l; HbA_{1C}: 5.7 - 13.3 %). Antidiabetic treatment was discontinued 3 days before the infusion. Blood samples were drawn every 30 min, and plasma were analysed for glucose, insulin (ELISA), C-peptide (ELISA), and glucagon. Groups were categorised on the basis of A) BMI (group1: 20 - 25.0 kg/m^2; group 2: 25 - 30.0 kg/m^2; group 3: 30 - 35.0 kg/m^2; group 4: > 35 kg/m^2), B) fasting blood glucose concentrations (group 1: < 10.0 mmol/l; 2: 10 - 15.0 mmol/l; 3: > 15 mmol/l), C) fasting plasma insulin concentrations (group 1: < 25 pmol/l; group 2: 25 - 50 pmol/l, group 3: > 50 pmol/l) and C-peptide responses. GLP-1 lowered blood glucose in all patients (12.1±0.6 to 7.0±0.4 mmol/l) at rates ranging between 1-2 mmol/h independent of their fasting blood glucose, fasting insulin concentrations, BMI or insulin secretory capacity. However, because of the similar fall rate in all groups the blood glucose decrements obtained after 4 hs of infusion were for fasting blood glucose group B1: 8.0±0.2 to 5.3±0.5 mmol/l; group B2: 12.3±0.2 to 6.6±0.2 mmol/l; group B3: 17.9±0.4 to 10.4±0.5 mmol/l. We conclude that GLP-1 may effectively normalize blood glucose in all NIDDM patients presumably as a result of its glucagonostatic activity.

504

LIPOLYTIC AND LIPOGENIC ACTIONS OF GLP-1 IN HUMAN ADIPOSE TISSUE

L. Márquez, M. Díaz-Miguel, A. Perea, M.L. Villanueva-Peñacarrillo and I. Valverde. Fundación Jiménez Díaz, Madrid, Spain.

Insulin-like effects of GLP-1(7-36)amide (GLP-1) in rat liver, skeletal muscle and adipose tissue, have been documented. Also, a lipolytic effect of GLP-1 in rat adipocytes was reported. In this work, we have studied the lipolytic and lipogenic effect of GLP-1, and the adenylate cyclase activation, in adipocytes isolated from human subcutaneous fat tissue obtained, previous informed consent given, from eight patients undergoing abdominal surgery. For lipolysis, 10^5 cells were incubated during 60 min in 300 μl KRB-HEPES buffer, pH 7.4, containing 3% BSA and 3.3 mM D-glucose, in the absence (control) and presence of GLP-1 or glucagon; the glycerol released was enzymatically determined. For cellular cAMP content, assayed by RIA, adipocytes were incubated as above, in the presence of 0.1 mM IBMX, during 5 or 60 min. For lipogenesis, cells were incubated during 2 h in 1 ml of the medium containing 0.4 μmoles ^{14}C-Na acetate (0.05 μCi) as precursor, in the absence and presence of GLP-1 or insulin; cell associated radioactivity was toluene extracted and ß-counted. GLP-1 exerted a significant dose related stimulation of glycerol release in the 10^{-11}-10^{-9}M range, from 127±11% of control, n=12, to 154±11%, n=14, respectively, similar to that obtained with glucagon. GLP-1 also induced a rise in lipids generation in the 10^{-13}-10^{-9}M range, from 116±5%, n=18, to 130±8%, n=18, respectively, being the latter value not different to that of 10^{-9}M insulin. 10^{-8}M GLP-1 increased the adenylate cyclase activity in adipocyte plasma membranes to the same extent than 10^{-8}M glucagon. Furthermore, GLP-1 exerted a significant dose related stimulation of cAMP content in adipocytes, in the 10^{-12}-10^{-8}M range after either 5 min incubation, from 186±17%, n=3, to 621±30%, n=3, or 60 min incubation, from 130±11%, n=9, to 156±17%, n=17, respectively. These data document in human adipocytes that physiological levels of GLP-1 exert own counteracting effects on lipid metabolism, suggesting that at least the lipolytic action maybe mediated by cAMP.

505

GLUCAGON-LIKE PEPTIDE-1 RESTORES ACUTE PHASE INSULIN RELEASE TO AGED RATS.

J.M. Egan, K. De Ore, N. Greig, H. Holloway, Y. Wang, and R. Perfetti. Diabetes Section, NIA/GRC, Baltimore, MD, USA.

Glucose intolerance is a common feature of the aging process and aging *per se* is an etiologic factor for Type II diabetes mellitus. To characterize the beta cell abnormalities that occur with aging, we looked at the serum glucose and insulin levels of six young (3-month) and six old (22-month) Wistar rats at 0, 2, 4, 7,10,15, 20, and 30 minutes after an intravenous glucose load (IVGTT, 0.5g/kg glucose). We found that the fasting glucose and insulin levels were not significantly different between young and old rats. However, peak glucose levels were significantly higher in the old (349 ± 10 mg/dl) compared to the young (250 ± 7 mg/dl) animals. Insulin levels in the young animals peaked at 2 minutes (859 ± 171 pmol/l) with a quick return towards fasting levels by 7 minutes. The old animals had a delayed and blunted insulin response to glucose, achieving lower peak insulin levels (656 ± 164 pmol/l) 7 minutes after the glucose load. As insulin levels are also positively modulated by incretin hormones, we quantitated the fasting insulin responses of young and old animals to 0.05, 0.1, 0.2, 0.4, and 0.5 nmol/kg intravenous glucagon-like peptide-1 (GLP-1), the most potent incretin known. Insulin responses were similar in both age groups with maximum insulin responses seen at 0.4 nmol/kg. GLP-1, in conjunction with the IVGTT, restored the acute insulin response to glucose and increased the clearance of glucose in the old animals. It therefore appears that old animals have an impaired glucose-mediated insulin release but maintain their insulin responsivity to GLP-1. This makes it a potentially useful agent for Type II diabetes in the elderly.

506

GLYCOGENIC EFFECT OF GLP-1 ON HUMAN SKELETAL MUSCLE

M. A. Luque, L. Márquez, M. Morales, I. Valverde and M.L. Villanueva-Peñacarrillo. Fundación Jiménez Díaz, Madrid, Spain.

A potent glycogenic effect of GLP-1(7-36)amide (GLP-1) in rat skeletal muscle has been documented. In this work we have studied the effect of GLP-1 on glycogen synthesis in normal human skeletal muscle cells and *cremaster* muscle, both obtained, previous informed consent given, from subjects without alterations of carbohydrate metabolism, undergoing surgery. Cell cultures were stablished from satellite cells of dissociated muscle tissue *(vastus lateralis),* grown in SKGM with 2% FBS and 1% antibiotics up to near confluence, and then fused for 4 days in alpha-MEM with 2% FBS and 1% antibiotics. Differentiated myotubes were used in the first pass only. We measured the incorporation of D-[U-^{14}C]glucose into glycogen during 60 min at 37 °C, in myotubes incubated in alpha-MEM containing 5.5 mM D-[U-^{14}C]glucose (0.545μCi/μmol), and in muscle strips (*ca.* 2mg protein) incubated in KRB containing 5mM D-[U-^{14}C]glucose (0.047μCi/μmol) and 1% BSA, in the absence (control) or presence of GLP-1 or insulin. In human myotubes from four subjects, the control glycogen synthesis (9.6±1.2 nmol/mg protein, n=15) was increased ($p<0.01$) by GLP-1 at 10^{-10}M (169±12% of control, n=41) and at 10^{-9}M (128±8%, n=41), with an apparent higher potency than that of insulin (126±7%, n=24, $p<0.01$ and 166±17%, n=28, $p<0.001$, respectively). In muscle strips from three subjects, the control glycogen synthesis (15.6±4.1 nmol/mg protein, n=7) was also increased by 10^{-10}M GLP-1 (129±5% of control, n=7, $p<0.001$), as it was observed with 10^{-9}M insulin (123±9, n=7, $p<0.05$). These results document the insulin-like effect of GLP-1 upon skeletal muscle glucose metabolism in man.

507

EFFECTS OF VOGLIBOSE AND ACARBOSE ON GLUCOSE HOMEOSTASIS AND GLUCAGON-LIKE PEPTIDE-1 SECRETION IN NIDDM PATIENTS

B.Göke, P.Kleist[1], T.Littke[1], E.Strídde[1] and E.Haupt[2]. University of Marburg, Marburg, Germany; [1]Takeda Euro, Frankfurt, Germany; [2]Saale Clinic, Bad Kissingen, Germany.

The α-glucosidase inhibitors voglibose (AO-128) and acarbose are effective antihyperglycemic agents and were shown to increase plasma glucagon-like peptide-1 (GLP-1) levels in healthy volunteers. The aim of this double-blind study was to compare their effects in diabetics. 170 hospitalized NIDDM patients were randomly allocated to six parallel groups and received 7 days treatment with either three times daily voglibose (0.5, 1, 2, 5 mg), acarbose (100 mg) or placebo. Blood was saved before and 15, 30, 60, 120, 180, and 240 minutes after a standardized test meal on day -1 and day 7 to analyse serum glucose, insulin, plasma gastric inhibitory polypeptide (GIP) and GLP-1. 157 patients (mean age 54,4 years; 135 male) could be analysed. Maximal postprandial serum glucose rise (mean Cmax = 15.2 mmol/l on day -1) was statistically significantly prevented by all active treatments as compared to placebo on day 7 ($p < 0.005$; unpaired one-sided t-test). The strongest effects were seen under 5 mg voglibose (-4.2 mmol/l ≙ -26%; $p < 0.0001$); even 1 mg voglibose (-2.5 mmol/l ≙ -16%; $p < 0.0001$) was superior to acarbose (-1.7 mmol/l ≙ -12%; $p = 0.0044$). Voglibose exerted its antihyperglycemic effect over the total observation period, in contrast to acarbose which did this only for the first two hours. Postprandial increases of insulin (area under the curve = AUC 0-4h; Cmax) were significantly reduced by 1, 2, and 5 mg voglibose in a dose-dependent manner (-34% and -41% under 5 mg; $p < 0.0001$),whereas acarbose did not achieve statistical significance (-9% and -12%; $p = 0.19$ and 0.06). The endogeneous secretion of GIP was suppressed in all active groups. Voglibose increased GLP-1 mean AUC 0-4h by 29 % (under 0.5 and 1 mg) up to 47 % (under 5 mg); due to the high SD only 0.5 and 2 mg voglibose became statistically significant versus placebo ($p < 0.005$). Acarbose induced a weaker increase of 12 %. It is concluded that voglibose ≥ 1 mg three times daily has stronger influence on postprandial glucose / insulin reduction and GLP-1 secretion than acarbose (100 mg three times daily) in NIDDM patients.

508

CHOLECYSTOKININ-INDUCED INSULIN SECRETION MEDIATED BY PLA_2 ACTIVATION IN ISLETS IS CA^{2+}-INDEPENDENT BUT PKC-DEPENDENT

E. Simonsson, S. Karlsson and B. Ahrén. Dept. Med., Lund Univ., Malmö, Sweden.

Cholecystokinin (CCK) induces insulin secretion through stimulation of phospholipase C (PLC), subsequent increase of cytosolic Ca^{2+} and activation of protein kinase C (PKC). Recently, we showed that also activation of phospholipase A_2 (PLA_2) is involved in the insulinotropic effect of CCK. However, the mechanism of CCK-induced PLA_2 activation is not known. Therefore, we examined the importance of Ca^{2+} and PKC in CCK-mediated PLA_2-activation and insulin secretion in isolated rat islets. CCK-8 (100 nM; at 5.6 mM glucose)-mediated arachidonic acid (AA) formation, measured as efflux of radioactivity from islets prelabelled with [^{3}H]AA, was unaffected by the Ca^{2+} ATPase inhibitor thapsigargin (1 μM; n.s.; n=6) as well as by the Ca^{2+} channel antagonist verapamil (100 μM; n.s.; n=6), indicating that intracellular Ca^{2+} stores and influx of extracellular Ca^{2+} are of no major importance in CCK-8-mediated PLA_2 activity. This was in sharp contrast to the AA formation due to the cholinergic agonist carbachol (100 μM), which was reduced by verapamil by 36±6% ($p<0.001$; n=6), implying a mechanistic dissimilarity between CCK-8 and carbachol when activating Ca^{2+}-independent PLA_2. Moreover, PKC down regulation, induced by overnight incubation with 12-O-tetradecanoyl phorbol-13-acetate (TPA; 500 nM), reduced CCK-8-induced AA formation by 17±5% ($p=0.031$; n=6), and insulin secretion by 40±16% ($p=0.021$; n=15-16). Furthermore, the specific PLA_2 inhibitor p-amylcinnamoylantranilic acid (ACA; 50 μM) diminished CCK-8-stimulated AA formation by 40±8% ($p<0.001$; n=6), and insulin secretion by 57±17% ($p=0.002$; n=15-16). No additive action was seen by combined PKC down regulation and PLA_2 inhibition, regarding neither AA formation (n.s.; n=6), nor insulin secretion (n.s.; n=16). In conclusion, our results suggest that CCK-induced activation of PLA_2 is Ca^{2+}-independent, whereas carbachol-stimulated activation of PLA_2 is dependent on Ca^{2+}-influx, that the PLA_2-activating and insulinotropic effects of CCK is partly PKC-dependent, and that CCK-mediated insulin secretion involves at least one additional signalling pathway, which is independent of both PLA_2 and PKC.

509

INFLUENCE OF ACARBOSE ON GLP-1 RELEASE AFTER A SUCROSE LOAD IN NIDDM PATIENTS.

C. Seifarth, J. Bergmann, J.J. Holst, R. Ritzel, W. Schmiegel and M.A. Nauck. Med. Universitätsklinik (Knappschaftskrankenhaus) Bochum, Germany; Panum Institute, University Copenhagen, DK.

In healthy volunteers, α-glucosidase inhibition leads to delayed digestion and to absorption of disaccharides also in the lower gut. As a consequence, release of glucagon-like peptide-1 (GLP-1) after oral sucrose is augmented. This could contribute to the glucose-lowering action of acarbose especially in hyperglycemic NIDDM patients. It was the aim of the study to evaluate the influence of acarbose on GLP-1 release and its possible consequences on plasma glucose, insulin and glucagon levels in NIDDM patients. In a crossover-design, 100 g sucrose were administered orally with 100 mg acarbose or placebo to 11 fasting NIDDM patients (6m/5f; age 62 ± 9 years, HbA_{1c} 9.6 ± 1.5 %) on different days. Plasma levels of glucose, insulin, GLP-1 and glucagon (RIAs) and H_2-exhalation (breath test) were measured over 6 h. The increment in plasma glucose (basal: 166 ± 10 mg/dl) was reduced from (peak) 277 ± 15 (placebo) to 230 ± 15 mg/dl (acarbose; $p < 0.001$). After 60-90 min, H_2-exhalation increased under acarbose ($p < 0.001$). From that time on, acarbose increased GLP-1 plasma levels (6 h AUC) by about 28% (6786 ± 1021 vs. 5302 ± 738 pmol·l^{-1}· min, $p = 0.04$, significant by ANOVA from 210 to 360 min, $p < 0.05$) without enhancing insulin or lowering glucagon concentrations during this time. In conclusion, acarbose augments GLP-1 responses after oral sucrose also in NIDDM patients.

510

GASTROINTESTINAL REGULATORY PEPTIDES IN CHILDREN WITH IDDM: DOES THE GLYCEMIC CONTROL MATTER?

A Vazeou, A Papadopoulou, E Pergantou, E Kitsiou* and C Bartsocas
Pediatric Department, Faculty of Nursing, Athens University, "P & A Kyriakou" Children's Hospital & *Laiko Hospital, Athens, Greece

Gastrointestinal disorders are common in patients with IDDM and hyperglycemia has been accused to be a predisposing factor. Gut regulatory peptides (GRP) are well known to be associated with motility disorders. However, their relationship with the glycemic status in children with IDDM is poorly defined. We therefore measured fasting glucose, motilin, neurotensin, and glucagon levels and HbA1c in 52 children (mean age 15.3 years, 22 males) with IDDM (mean duration 7.1 years). Thirty eight patients (73%) had persistent gastrointestinal (GI) symptoms: recurrent abdominal pain 15; chronic constipation 13; chronic dyspepsia 9; recurrent vomiting 1. Twenty three patients (44%) had fasting serum glucose 4.1-8.3 mmol/L and 29 (56%) >8.3 mmol/L. Fasting motilin levels (mean ± SEM: 62.2 ± 5.2 pmol/L) were significantly lower ($p<0.0001$) in IDDM patients compared with 26 healthy controls (mean ± SEM: 162.7 ± 7.2 pmol/L). However, motilin levels were not different between patients with or without GI symptoms, as so as with or without hyperglycemia. Motilin levels had a significant negative correlation with duration of IDDM ($r=-0.38$; $p=0.005$) but no correlation was found with HbA1c. Neurotensin levels were lower than the previously published lower normal level (<6 pmol/L) in 62% of patients (mean ± SEM: 9.4 ± 2.9 pmol/L); glucagon levels were higher than the upper normal level (>200 pmol/L) in 60% of patients (mean ± SEM: 213.1 ± 13.0 pmol/L/) . No significant correlations were found between glucose levels or HbA1c and neurotensin or glucagon levels. In conclusion, under conditions of euglycemia or hyperglycemia GRP do not directly depend on glycemic status. However, their role in IDDM patients should be further investigated.

511

IMPROVED INSULIN SECRETION AND ORAL GLUCOSE TOLERANCE AFTER *IN VIVO* INHIBITION OF DPP-IV IN OBESE ZUCKER RATS.

B. Balkan, L. Kwasnik, R. Miserendino, M. Mone, T.E. Hughes and X. Li.
Sandoz Research Institute, E. Hanover, NJ, U.S.A.

Glucagon-like peptide 1 (GLP-1), a potent incretin, plays a pivotal role in prandial insulin secretion. GLP-1 is rapidly ($t_{1/2}$:1-2 min) inactivated by the protease dipeptidyl peptidase IV (DPP-IV). DPP-IV is believed to be the sole inactivating enzyme of GLP-1, though a slower process removes both active and inactive GLP-1 from the circulation. Here, we investigated whether DPP-IV inhibition is a feasible approach to improve glucose homeostasis through an enhancement of GLP-1 action. Firstly, the effects of DPP-IV inhibition on insulin secretion stimulated by exogenous GLP-1 were studied in conscious, cannulated rats after 2 hrs food deprivation. Infusion (*iv*)of GLP-1 (5pmol/kg/min in saline with 2% glucose @ 150μl/kg/min for 30 min.) evoked a profound but transient insulin response (area under the curve $(AUC)_{0\text{-}10mm}$ +375±61μU/ml*10 min) after which plasma insulin concentrations returned to basal. Administration of the specific DPP-IV inhibitor SDZ 272-070 (15μmol/kg, *iv*@15min) immediately inhibited plasma DPP-IV activity by 85% and elicited a second insulin response ($AUC_{15\text{-}25mm}$ 223±80 *vs* 45±63μU/ml*10 min (vehicle), $p<0.05$). Thus, DPP-IV inhibition augments the effects of exogenous GLP-1 on insulin secretion. Secondly, the effects of DPP-IV inhibition on oral glucose tolerance were investigated in cannulated female insulin resistant, glucose intolerant, obese Zucker rats and lean controls (8-9 weeks of age). SDZ 272-070 (100μmol/kg, *po*, @ t=-30min) was given 30 min before glucose (1g/kg, *po*, t=0min). DPP-IV inhibition significantly amplified the early phase of the insulin response in obese fa/fa rats and all but normalized glucose excursions. In contrast, DPP-IV inhibition produced no significant effects in FA/?. It is concluded that DPP-IV inhibition improves insulin secretion and impaired glucose tolerance, probably through augmentation of the effects of endogenous GLP-1. This suggests that DPP-IV inhibition might be a useful tool in the treatment of NIDDM.

AUC= area under the curve	fa/fa n=7	fa/fa +DPP-IV inhibitor n=7	FA/? n=9	FA/? +DPP-IV inhibitor n=8

GLUCOSE- AND TOLBUTAMIDE-INDUCED INSULIN SECRETION IN ADULT RATS TREATED WITH NICOTINAMIDE AND STREPTOZOTOCIN.

P. Masiello[1], C. Broca[2,3], R. Gross[3], M. Roye[3], M. Manteghetti[3], D. Hillaire-Buys[2], M. Novelli[1], G. Ribes[3]. [1]Ist. Patologia Generale, Univ. Pisa, Italy; [2]Lab. Pharmacol., Fac. Med. UPRES EA 1677, Bd. Henri IV and [3]UMR 9921 CNRS, Montpellier, France.

We have previously shown that graded doses of nicotinamide (NA) can partially protect adult rats against the beta cell toxicity of streptozotocin (STZ). On this basis, the aim of the present study was to select and test the best NA dose suitable to produce a mild hyperglycaemia without severe reduction in pancreatic insulin stores. Among the various doses of NA (in the range 180-260 mg/kg) tested in 3-mo-old Wistar rats, the dose of 230 mg/kg (NA 230) given i.p. 15 min before STZ injection (65 mg/kg i.v.) yielded a maximum of animals with moderate elevation of non fasting plasma glucose levels (166 ± 12 vs 119 ± 3 mg/dl in controls, $p < 0.01$). Pancreatic insulin content was about 35% of that of controls. IVGTTs revealed glucose intolerance and abnormal insulin response which remained stable for at least 9 weeks after diabetes induction and interestingly appeared to be sensitive to tolbutamide administration. In the isolated perfused pancreas of STZ plus NA-treated rats, insulin response to an increase in glucose concentration (5 to 11 mmol/l) was significantly reduced versus controls ($p < 0.05$), whereas the response to 0.19 mmol/l tolbutamide was similar to that observed in normal pancreas. Furthermore, pancreatic β cells exhibited hypersensitivity to arginine infusion (7 mmol/l) in the presence of 2.8 mmol/l glucose (105 ± 20 vs 10 ± 4 ng insulin x 20 min in controls, $p < 0.001$). In conclusion, our results indicate that adult rats treated with STZ plus NA 230 show a relative deficiency in insulin secretion which is corrected by sulphonylureas, and might represent an attractive experimental model of NIDDM.

513

PROINSULIN BIOSYNTHESIS AND PROCESSING IN NIDDM HUMAN ISLETS

E.F. Usac, B. Nadal, R. Gasa, J. Fernandez-Alvarez and R. Gomis. Fundació Clínic. Endocrinology and Diabetes Unit, Barcelona, Spain.

It has been shown that one of the conversion intermediates together with intact proinsulin are abnormaly secreted by the beta cells of certain NIDDM patients. The **aim** of our study was to investigate the biosynthesis and conversion of proinsulin on NIDDM human islets. **Results**: Pulse-chase and immunoprecipitation techniques gave an evidence 4-fold decrease of proinsulin biosynthesis on the islets from the diabetic vs. islets from two control pancreases. Morphometry analysis shown that it cannot be explained by the loss of beta cell mass. ß-cell mass/pancreas from NIDDM vs. controls: 1.9±0.2% vs. 2.4±0.7% and 2.8±0.1%. We observed, by northern blot, that this defect seems to be focused at the translation level since islets from the diabetic have same proinsulin mRNA content as controls. No particular defects are observed at the proinsulin conversion ratio and neither proinsulin or proinsulin intermediates are secreted into the medium. This low proinsulin synthesis does not seem to be a glucose toxicity related defect because pulse-chase studies performed with control islets exposed for 8 days at 24.4 mM glucose didn't show any diferences on proinsulin biosynthesis, conversion or secretion when were compared to those exposed at 5.5mM. In **conclusion** i) proinsulin mRNA translation is partially bloked on those NIDDM human islets; ii) chronic hyperglicaemia does not affect proinsulin synthesis or conversion, and neither promote proinsulin secretion.

514

EFFECTS OF GLUTAMATE ON GLUCOSE TOLERANCE AND INSULIN SECRETION IN A RAT MODEL OF TYPE II DIABETES.

G. Bertrand[1], M. Ravier[1], R. Puech[1], M.M. Loubatières-Mariani[2] and J. Bockaert[1]. [1]UPR9023 CNRS; [2]Lab. Pharmacol. Fac. Méd.; Montpellier, France.

We have previously shown that glutamate stimulates insulin release via a glutamatergic receptor and improves glucose tolerance in normal rats. In this study, we investigated the effect of glutamate in a rat model of type II diabetes obtained by an i.v. injection of a low dose (35 mg/kg) of streptozotocin (STZ). Glutamate was tested on glycaemia and/or insulin secretion *in vivo* and *in vitro*. After one week, in the postabsorptive state, STZ rats exhibited a moderate hyperglycaemia and a slight decrease of plasma insulin levels (6.9 ± 0.3 mmol/l and 2.6 ± 0.5 mU/l, respectively) compared to controls (5.5 ± 0.1 mmol/l and 4.6 ± 0.7 mU/l, respectively). In STZ rats, during an i.v. glucose tolerance test (0.5 g/kg), insulin response and glucose tolerance were impaired: the increase in insulinemia for 10 min was +40 ± 10 vs +146 ± 29 mU/l ($p<0.01$) and the glucose increment for 30 min was +235 ± 11 vs +191 ± 8 mmol/l ($p<0.01$) in normal rats. The addition of glutamate (9 mg/kg) to the glucose solution increased the insulin response during the first 10 min ($p<0.05$), reduced the hyperglycaemia (20%; $p<0.05$) and increased the glucose disappearance rate ($p<0.001$). *In vitro*, on the isolated perfused pancreas, the biphasic insulin response to a glucose rise from 4.2 to 16.6 mmol/l was reduced by 55% in STZ rats compared to normal animals. Glutamate (400 µmol/l), added simultaneously with glucose 16.6 mmol/l, provoked a 3.6-fold increase of the first phase (5 min) of insulin response ($p<0.001$). In conclusion, glutamate is able to stimulate insulin release and to improve glucose tolerance in moderately diabetic rats. Thus, glutamate receptors of B cells could be a new target for antidiabetic insulinosecretory agents.

515

ACCELERATED PROINSULIN CONVERSION IN HUMAN B-CELLS AFTER OVEREXPRESSION OF PC2 OR PC3 BY RECOMBINANT ADENOVIRUS.

P. Halban, K. Meyer and J.-C. Irminger. Laboratoires de Recherche Louis Jeantet, University Medical Center, Geneva, Switzerland.

Proinsulin conversion involves cleavage at the B-chain/C-peptide and C-peptide/A-chain junctions. Cleavage (and trimming of basic residues) at just one junction leads to generation of des-31,32-split proinsulin (des-31,32) and des-64,65-split proinsulin (des-64,65) respectively. In man, des-31,32 is the major intermediate. Two endoproteases, PC2 and PC3 have been implicated in proinsulin conversion. These enzymes display specificity for just one proinsulin junction *in vitro*, but little is known regarding their substrate specificity and relative activity *in vivo* within human B-cells. To study this, human pancreatic islets were trypsinized, the cells cultured 2-3 days and then infected (1h) with increasing multiplicity of infection (moi) of adenovirus expressing PC2 (Ad-PC2), PC3 (Ad-PC3) or βgal as control (Ad-βgal). After 24h, cells were pulse-labelled (10 min label [^{3}H]Leu) and chased. Radioactive products were separated by hlpc. Expressing β-gal did not affect proinsulin conversion. For controls (Adβ-gal, moi of 200) after 60 min chase there was 38.5% insulin, 25.0% des-31,32, 2.8% des-64,65 and 33.7% proinsulin. For AdPC2: insulin = 48.4, 78.0, 86.6%; des-31,32 = 15.7, 2.7, 1.0%; des-64,65 = 4.7, 5.3, 3.7%; proinsulin = 31.1, 14.0, 8.7% at moi of 2, 20 and 200 respectively. For AdPC3: insulin = 43.3, 69.4, 86.8%; des-31,32 = 21.3, 14.8, 3.7%; des-64,65 = 3.1, 0, 0.7%; proinsulin = 31.1, 14.0, 8.7 at moi of 2, 20 and 200 respectively. Whereas each enzyme shows the same substrate specificity previously observed *in vitro*, with PC2 cleaving preferentially at the C-peptide/A-chain junction and PC3 at the B-chain/C-peptide junction, both endoproteases appear to be able to cleave at both proinsulin junctions (at least when expressed at supraphysiologic levels). The data thus show that PC2 and PC3 when overexpressed in human B-cells accelerate to an equal extent the conversion of proinsulin to fully processed insulin.

516

REDUCED ISLET INNERVATION IN TYPE 2 DIABETIC HAMSTERS

K.D. Kohnert, U. Myrsen, F. Sundler, I. Kloting and B. Ahren, University of Greifswald, Karlsburg, Germany and Lund University, Malmö and Lund, Sweden

It is known that pancreatic islets are innervated and that nerves are involved in islet function. However, whether islet innervation is altered during the development of type 2 diabetes is not known. We therefore examined the adrenergic and cholinergic innervation of the islets in different phases of glucose intolerance in a new subline (CHIG/Han) of the Chinese hamster. The animals were characterized by their glucose tolerance, plasma insulin levels and glucose-stimulated insulin secretion in vitro. Pancreas sections were immunostained for neuropeptide Y (NPY) and tyrosine hydroxylase (TH) as markers for adrenergic nerves, for vasoactive intestinal peptide (VIP) presumably localized in cholinergic nerves, and the main islet hormones. The animals were grouped according to their nonfasting plasma glucose levels into nondiabetic (< 7.2 mmol/L), mildly (7.2-15 mmol/L) and severely diabetic (> 15 mmol/L). Severely diabetic hamsters had marked glucose intolerance and impaired glucose (15 mmol/L)-stimulated insulin secretion (-76%, $p<0.01$) of islets. The group with mild diabetes had a glucose tolerance between these two groups, and glucose-stimulated islet insulin secretion was decreased by 54% ($p< 0.05$) when compared with the nondiabetic group. Plasma insulin was increased in nondiabetic (+81%, $p< 0.05$) and mildly diabetic (+119%, $p< 0.01$) hamsters, while approaching basal levels (354.9±37 pmol/L) in the severely diabetic animals. Immunostaining of the pancreas sections revealed that innervation by both adrenergic and cholinergic nerves was markedly reduced in severely diabetic hamsters, whereas the innervation pattern in the mildly diabetic ones was virtually unaffected. Insulin was reduced in the diabetic animals, whereas glucagon staining was increased. Immunostained somatostatin, pancreatic polypeptide (PP) and peptide YY (PYY) was unchanged as compared with the nondiabetic pancreases. In this animal model, the autonomic nerves (adrenergic as well as nonadrenergic) disappear with the loss of glucose-stimulated insulin secretion. This suggests that altered islet innervation is involved in type 2 diabetes.

517

CELL-FREE TRUNCATION OF C-PEPTIDE TO des-(27-31)C-PEPTIDE

M. Paoletta and P.A. Halban. Laboratoires de Recherche Louis Jeantet, University Medical Centre, Geneva. Switzerland.

Recent studies have shown secretion of a novel form of C-peptide (Cp), truncated C-peptide (tCp), which lacks its 5 C-terminal residues. Truncation of Cp to tCp occurs in both primary and transformed rat B-cells but to a greater extent in the latter. In order to confirm that truncation is a granular event and to establish a cell-free assay to characterize the truncation enzyme, we have now studied rat Cp truncation in two in vitro systems. Granules from INS (transformed rat B-) cells were purified by subcellular fractionation using a Percoll gradient and disrupted by freeze-thaw. Rat Cp was biosynthetically labelled in INS cells and purified by HPLC before use as a substrate. When labelled Cp was incubated with granule contents at pH 6.0 and 37°C there was production of tCP amounting to 30% of total (tCp + Cp) by 4h. There was, however, also extensive degradation of Cp possibly reflecting contamination of granules with lysosomes. To limit such contamination and in order to determine whether truncation activity in granules was soluble or membrane bound, INS cells were incubated for 1h in Krebs-Ringer bicarbonate in presence (stimulated) or absence (control) of a cocktail of secretagogues previously shown to stimulate release of insulin stores (and thus also of soluble but not membrane anchored granular contents). The conditioned medium was concentrated prior to use. Incubation (pH 6.0, 37°C) of the labelled Cp in stimulated conditioned medium led to production of 12.7±4.2% tCp in 4h but only 6.7±0.7% for control. There was no significant difference between control and stimulated medium at 2h. Taken together the data confirm that B-cell granules contain soluble enzyme(s) able to cleave Cp between residues 26 and 27 and demonstrate that the truncation event can be faithfully reproduced in a cell free system.

518

LONG-TERM TOTAL PARENTERAL NUTRITION REDUCES ISLET ACID GLUCAN-1,4-α-GLUCOSIDASE ACTIVITY AND INSULIN RELEASE

A. Salehi[1], B.-G. Fan[2], G. Nordin[3], M. Ekelund[2] and I. Lundquist, Dept of Pharmacology and Surgery[2], University of Lund, Lund, Sweden and Dept of Clinical Chemistry[3], Helsingborg Hospital, Sweden

To study the effects of long term elevation of serum lipids on nutrient-stimulated insulin secretion and the islet acid glucan-1,4-α-glucosidase system, normal healthy rats were subjected to total parenteral nutrition (TPN) for 10 days. Control rats received saline and had free access to food and water. The levels of serum FFA, triglycerides and cholesterol were greatly elevated by TPN infusion. Pancreatic islets isolated from TPN infused rats and then incubated in vitro showed a greatly reduced insulin release when stimulated by glucose or KIC. The insulin response to the muscarinic agonist carbachol, however, was of similar magnitude as observed in controls. The inhibitory effect of TPN treatment on glucose-induced insulin release (-55%) was only slighly ameliorated by exposure to the carnitine palmitoyltransferase I inhibitor, etomoxir. Further, isolated isles from TPN infused rats displayed a markedly reduced activity of the lysosomal enzyme acid glucan-1,4-α-glucosidase, a putative key enzyme in nutrient induced insulin release. This depression of acid glucan-1,4-α-glucosidase activity was accompanied by a similar reduction of several other lysosomal enzyme activities e.g. acid phosphatase , N-acetyl-β-D-glucosaminidase, β-glucuronidase and acid α-glucosidase. In contrast, in liver tissue from TPN infused animals all these enzymes displayed markedly increased activities. The impaired insulin response to glucose was not readily reversible and persisted in islets isolated 12 h after TPN treatment. Also the in vivo insulin response to an intravenous glucose load at 12 h after TPN treatment was impaired. The present data show that TPN treatment for 10 days induced a severe impairment of nutrient-induced insulin release being accompanied by a marked suppression of the islet acid-glucan-1,4-α-glucosidase activity and other lysosomal enzymes. In contrast, the lysosomal system/lysosomal enzyme activities in liver tissue was greatly increased. The results strongly suggest that the islet lysosome-acid glucan-1,4-α-glucosidase system is of key importance for nutrient-induced insulin release and that long term elevation of serum lipids greatly impairs this signal system.

519

NK-lysin, an endogenous antibacterial peptide, exerts an insulinotropic effect in isolated pancreatic islets.

J-C Marie[1], S. Darquy[2], N. Dachicourt[1], C Saulnier[1], G. Reach[2] M. Andersson[3], B. Portha[1]

CNRS-URA 307[1] & INSERM U.341[2], Paris, France. Karolinska Institute[3], BiochemistryII, Stockholm, Sweden.

We investigated whether a recently isolated 78 residue porcine antibacterial peptide, NK-lysin, could have an insulinotropic effect on pig and rat islets. Initially, batches of either pig or rat islets were tested in static incubations at 37°C for 60 minutes. The KREBS-BSA (K-B) buffer contained a low glucose concentration 2.8mM with and without (control) the presence of NK-lysin. A 2-fold increase in insulin release from pig and rat islets was induced by NK-lysin as from 0.1μM as compared to control values. Also, freshly isolated rat islets were perifused at 37°C in K-B buffer containing either 2.8 or 16.7mM glucose. When 0.1μM NK-lysin was present in 2.8mM glucose perifusion studies, it induced a first phase peak of insulin release. This response corresponded to 46% of that induced by 16.7mM glucose only. When NK-lysin was studied in presence of 16.7mM glucose the biphasic pattern of insulin release was amplified. Under these conditions, NK-lysin enhanced only the second phase by 2.5-fold as compared to the measured secretory response with 16.7mM glucose alone. Further, this enhancement returned to normal basal secretory rates upon removal of NK-lysin and in presence of 2.8 mM glucose. These data suggest that this endogenous antibacterial peptide is a novel insulinotropic agent. The mode of action of NK-lysin in stimulating insulin at low and high glucose concentrations remains to be established.

520

ALTERATIONS IN ISLETS' INSULIN SECRETION OF FETUS FROM PREGNANT RATS FED AN ISOCALORIC LOW PROTEIN DIET

H. Cherif, B. Reusens, S. Dahri, C. Remacle and J.J. Hoet. Univ. Catholique de Louvain, B 1348, Louvain-la-Neuve, Belgium.

Fractional insulin release (IR) in vitro of fetal islet cells is significantly reduced when mother is fed a low protein diet (8%) (LP) instead of 20% (C). cAMP content in LP islets is also diminished. Neither forskolin nor theophyline did restore the IR of LP islets but both normalised the cAMP content. To determine the site of alterations of IR in fetal LP islets, the latter were cultured during 7 days in RPMI and were challenged thereafter during 120 min with various secretagogues which stimulate IR at different sites and compared with control islets. Acetylcholine (ACh) (100 mM), cytochalazine B (Cytoc) (10 mM), glutamine (Glut) (10 mM), leucine (Leu) (10 mM), Ba^{2+} (4.54 mM) and a high K^+ (50 mM) were tested. In C as well as in the LP group, all secretagogues significantly increased IR (%). However, when IR % of LP fetal islets was compared to C, it was significantly reduced in response to Glut+Leu (15.83 ± 1.96 vs 8.30 ± 1.35 $p<0.01$), KCl (17.14 ± 1.33 vs 10.70 ± 1.38 $p<0.01$), or to ACh (15.92 ± 0.68 vs 4.71 ± 0.88 $p<0.01$). But, IR (%) of fetuses from LP group was restored when their islets were stimulated with Cytoc B (10.16 ± 0.82 vs 9.23 ± 0.99) or with Ba^{2+} (15.55 ± 0.70 vs 12.01 ± 1.78). The results show thus that the lack in the secretory mechanism of LP B cells should be located in the late phase of the insulin secretion. Ca^{2+} movements might be involved in this B cells secretory alteration and are being investigated.

521

INSULIN RELEASING EFFECTS OF CITRULLUS COLOCYNTHIS FRUIT EXTRACTS IN ISOLATED RAT PANCREAS

R. Gross[1], R. Nmila[2], H. Rchid[2], Roye M.[1], M. Manteghetti[1], P. Petit[1], G. Ribes[1] and Y. Sauvaire[2]. [1]Lab. Pharmacol., Fac. Medicine (UMR 9921 du CNRS and UPRES 1677), Université Montpellier I; [2]Lab. Rech. Subst. Nat. Végétales (UPRES 1677), Université Montpellier II, Montpellier, France.

Infusions of the fruits of *Citrullus colocynthis Schrad.*, cucurbitacceae are traditionally used in Morocco and mediterranean countries as antidiabetic medications. The present study was designed to investigate the possible insulinotropic properties of these fruits. For this purpose, different extracts of the components of *Citrullus colocynthis* fruits were obtained: RN_{II} (crude extract), RN_{VI} (hydro-alcoholic extract) and RN_X (purified extract). The insulin secretory effects of these three different extracts were evaluated *in vitro* in the isolated and perfused rat pancreas in the presence of 8.3 mmol/l glucose. These extracts were perfused for 20 min. RN_{II} at 0.1 mg/ml induced an immediate and significant stimulation of insulin secretion. The increase reached + 90% at min 3 ($P < 0.01$) but was transient (5 min). The area under the curve (AUC) for the first 5 min was 2444 ± 170 ng versus 1941 ± 101 ng in control experiments ($P < 0.05$). The same amounts of RN_{VI} and RN_X (0.1 mg/ml) also elicited an immediate and monophasic increase in insulin output (maximum + 40% and + 60% respectively). AUC for RN_{VI} was 2331 ± 150 ng ($P < 0.05$) and for RN_X 2339 ± 100 ng ($P < 0.05$). Moreover, a significant and persistent increase in pancreatic flow rate appeared during RN_{VI} and RN_X infusions: AUC for the 20 min perfusions were 51.0 ± 1.2 ml and 55.9 ± 0.7 ml respectively versus 46.2 ± 0.5 ml in control experiments ($P < 0.01$). In conclusion, our results show that the three different extracts from *Citrullus colocynthis* fruits display an insulinotropic effect which may, at least in part, account for the antidiabetic activities traditionally described for these fruits.

522

THE EFFECT OF POOR FOETAL AND NEONATAL NUTRITION ON ISLET FUNCTION IN NEONATAL RATS.

MR Wilson and SJ Hughes, Department of Physiology, Imperial College School of Medicine at St. Mary's, London, UK.

It has been suggested that poor foetal-neonatal nutrition may predispose adult animals to impaired glucose tolerance and diabetes. We have previously shown that feeding a low protein (5%) diet to pregnant and lactating rats leads to altered islet function in the adult offspring. To investigate further we have studied islet function in offspring aged 6-7 days from mothers fed a low protein or control diet during pregnancy and lactation. Low protein offspring were smaller than control offspring (10.3±0.3 vs 17.1±0.8 g in controls, n=50, $p<0.001$). Insulin release in response to 10mmol/l glucose was significantly impaired in islets isolated from low protein offspring in both batch incubations (14.1±2 (n=7) vs 35.9±3.4 (n=27) μU/islet/hr in controls, $p<0.001$) and in perifusion (15±12 vs 181±102 μU/40min in controls, n=4, $p<0.001$). This was not due to a decreased secretory capacity, as responses of islets to ketoisocaproate and arginine were not significantly reduced. Also, islet insulin content was not reduced (0.69±0.12 vs 0.93±0.09 mU/islet in controls, n=7, NS). To attempt to identify the underlying defect, islet glucose metabolism was measured. Mitochondrial oxidation of glucose was not impaired in low protein offspring (6.73±0.84 vs 7.32±0.73 pmol glucose oxidised/islet/hr in controls at 10mmol/l glucose, n=12, NS). Glucose utilisation, a measure of glycolytic rate, however was reduced (73.4±11 vs 129±15 pmol glucose utilised/islet/hr in controls at 10mmol/l glucose, n=12, $p<0.01$). These data suggest that poor foetal-neonatal nutrition causes an impairment in glucose stimulated insulin release in islets from neonatal rats, due possibly to a defect in the glycolytic pathway.

523

ENDOTHELIN-1 AND ENDOTHELIN-3 STIMULATE INSULIN RELEASE FROM ISOLATED RAT ISLETS OF LANGERHANS

E. De Carlo, J. Bountis, A. Milanesi, C. Martini, P. Maffei, N. Sicolo*, C. Scandellari. Institute of Semeiotica Medica, Chair of Internal Medicine, *Chair of Endocrinology, University of Padova, Italy

It has been reported, by different experimental models, that insulin induces Endothelin-1 (ET-1) release. Recently, ET-1 has been shown to increase circulating insulin and lower blood glucose in rats. At present, it has not been demonstrated whether this peptide may act at an insular level or influence insulin concentrations by indirect mechanisms. Aim of the present study has been to clarify whether: 1) ET-1 influences insulin release from isolated rat islets, 2) other isoforms of endothelin, like Endothelin-3 (ET-3) show the same action.

Isolated rat islets of Langerhans were employed. 120 minutes incubations with increasing concentrations (10^{-12} to 10^{-9} M) of ET-1 and ET-3 were performed both in presence and in absence of 5.5 mM glucose. At the end of incubation, insulin concentrations were assayed in the medium. No increases of insulin release were observed when islets were incubated in glucose-free medium. Both ET-1 and ET-3 were able to enhance insulin release in presence of 5.5 mM glucose and the increases were statistically significant at 10^{-10} M concentration for ET-1 ($p<0.05$) and at 10^{-9} M concentration for ET-3 ($p<0.05$).

We conclude that ET-1 is able to stimulate directly, in presence of physiological glucose concentrations, insulin release from isolated rat islets. ET-3 exerts, at the insular level, an action similar to that of ET-1.

524

MYELIN BASIC PROTEIN STIMULATES INSULIN SECRETION IN RATS *IN VIVO*

E. Kolehmainen and H. Leskinen. University of Oulu, Oulu, Finland

Myelin basic protein (MBP) stimulates insulin and glucagon release from pancreatic islets *in vitro*. Effects of MBP *in vivo* were studied in anaesthetized rats (n=6-8). A reference sample was withdrawn at -10 min from a. femoralis, MBP (10mg/0.5 ml of 0.9% NaCl) was injected at 0 min via v. femoralis, and blood samples were withdrawn in exp A at 10, 20, 30 and 40 min, and in exp B at 2, 4, 6, 8, 10 and 12 min, and replaced with fresh blood from a donor rat. The control rats (n=6) received 0.9% NaCl with similar protocols. The control levels of insulin and glucose were unchanged in exps A and B except for the 12-min glucose value in B ($p<0.05$: repeated-measures ANOVA/Bonferoni t-test). MBP stimulated insulin release in A by 108±10% at 10 min, 163±17% at 20 min, 192±28% ($p<0.01$) at 30 min and by 164±28% at 40 min (means±SE) over the -10 min level. The changes in individual animals ranged from 133% to 508% stimulation at 30 min. The blood glucose level rised from 6.5±0.3 mM to 8.2±0.3, 8.4±0.6 ($p<0.01$), 8.0±0.8 and 7.2±0.9 mM at the aforementioned times. In exp B, the glucose level rised from 6.5±0.4 mM to 7.0±0.4 mM at 2 min, 8.4±0.4 mM ($p<0.01$) at 4 min, 9.1±0.4 mM ($p<0.01$) at 6 min, 9.8±0.4 mM ($p<0.01$) at 8 min, 10.0±0.6 mM ($p<0.01$) at 10 min and 10.5±0.5 mM ($p<0.01$) at 12 min. Insulin plasma values exhibited oscillatory changes in 7 out of 8 rats, one increasing without oscillations. Three out of the 7 oscillating exhibited maxima at 4 and 8 min, the rest showing one maximum at 4 min and/or additional maxima in reverse phase. The combined data showed stimulation of 123±24%, 243±41% ($p<0.01$), 203±35% ($p<0.05$), 263±54% ($p<0.01$), 204±40% and 236±35% ($p<0.01$) at 2, 4, 6, 8, 10 and 12 min, respectively. Since previous studies have shown that MBP injected into rat circulation enters the liver and accumulates in the pancreas, the changes may result from a combined effect of MBP on these tissues. They could explain idiopathic hyperglycaemia in stroke and head injury patients and disturbances in glucose homeostasis in some multiple sclerosis patients.

525

LACK OF EFFECT OF LEPTIN ON INSULIN SECRETION. STUDY IN THE PERFUSED RAT PANCREAS.

J Rodríguez-Gallardo, RA Silvestre and J Marco. Clínica Puerta de Hierro, and Dept. Physiology, Universidad Autónoma de Madrid, Madrid, Spain.

In human obesity, as well as in some models of rodent obesity, elevated plasma concentrations of both leptin and insulin have been found. Insulin regulates leptin mRNA and increases plasma leptin concentration. Recently, it has been reported that leptin receptor mRNA is expressed in primary rat pancreatic islets and in the insulinoma cell line ßTC-3. These observations raise the possibility of an adipose-insular B cell axis modulating insulin release. Thus, we have investigated the effect of rat leptin on insulin secretion in the perfused rat pancreas. Perfusate consisted of Krebs-Henseleit buffer supplemented with albumin (0.5%), dextran T-70 (4%) and glucose (5.5 mmol/l). Insulin was analysed by RIA. Synthetic rat leptin (a gift from Amylin Pharmaceuticals, Inc., San Diego, CA, USA), at 10 nmol/l - a concentration close to the upper plasma levels found in obese subjects - failed to modify the insulin response to an increase in perfusate glucose level from 5.5 mmol/l to 9 mmol/l (incremental area: 58±13, Mean±SEM, ng/20 min, N=5 vs. 49.4±11 ng/20 min, N=10 in control experiments; p=0.7). At a supraphysiological concentration (100 nmol/l), leptin was without effect on insulin release in pancreases perfused at 5.5 mmol/l glucose ($F_{20,140}=0.63$) or stimulated by increasing glucose levels from 5.5 mmol/l to 9 mmol/l (Incremental area: 71±5 ng/20 min, N=3, vs. 72±17 ng/20 min, N=7 in control experiments; p=0.96). Our results would rule out an obvious effect of leptin on insulin secretion in the normal rat pancreas, thus challenging the concept of leptin as a direct signal from the adipocyte to the pancreatic B-cell.

526

CONSTRUCTION AND EXPRESSION OF RECOMBINANT INSULIN FROM HUMAN INSULIN GENE AND MAMMALIAN EXPRESSION VECTOR PRC/CMV

H Wang, XH Xiao and Q Sun.Peking Union Medical College Hospital, Beijing, China

To develop a model somatic gene therapy system for diabetes, we constructed a human insulin expression vector in non β cells. As the first step, a insulin cDNA fragment, generated by a complete digestion of PBCA with EcoR I and BamH I, was inserted into the EcoR I/BamH I site of plasmid PBS·SK by ligation of cohesive-ended DNA, which constructs a transition plasmid PBS·INS. Then the plasmid PBS·INS was completely digested by Hind III and Xbal I. A small DNA fragment containing insulin cDNA gene, was subcloned into the expression plasmid PRC/CMV to form recombinant PRC/CMV·INS. Cultured mouse fibroblasts of the Ltk^- cell line were transfected with human insulin expression plasmid PRC/CMV·INS, which contains a gene conferring resistance to the antibiotic G418. Finally, 12 clone of the Ltk cells named Ltk^-·PRI-12, was selective because of its higher insulin-releasing activity compared with other clones. Release of human insulin was assessed through a specific human c-peptide assay(RIA). After culturing for 24 h in the RPMI 1640 medium containing 10mM glucose, Ltk^-·PRI-12 cells release c peptide at about 98 pmol/10^6 cells per 24 h. The study offers a potential somatic gene therapy approach to insulin delivery in diabetes mellitus.

527

ISLET AMYLOID POLYPEPTIDE KNOCK OUT MICE DEVELOP A MORE SEVERE FORM OF ALLOXAN-INDUCED DIABETES

H. Mulder[1], S. Gebre-Medhin[2], C. Betsholtz[2], B. Ahrén[3] and F. Sundler[1]. Depts. of Physiology and Neuroscience[1], Lund; Medical Biochemistry[2], Gothenburg; Medicine[3], Malmö; Sweden.

Several studies have shown that islet amyloid polypeptide (IAPP; amylin) is over-expressed in experimental forms of diabetes. This may be harmful in diabetes, because of IAPP's propensity to form amyloid in islets and its negative effects on insulin release and sensitivity. Alternatively, IAPP over-expression could arise as a protective mechanism in diabetes. We recently generated mice with a targeted disruption of the IAPP gene (knock out; KO); this allowed us to examine experimentally induced diabetes in the absence of IAPP. Thus, male IAPP KO (n=10) and wild type (WT) mice (n=10) were given alloxan (70 mg/kg iv). Whereas both KO and WT mice became hyperglycaemic, a more pronounced diabetes gradually evolved in KO mice. At day 7, plasma glucose was 31±3 and 27±4 mM in KO and WT mice (P=0.4), respectively, whereas at day 35 it was 33±3 and 23±4 mM (P<0.05). Furthermore, at day 35, weight loss was greater in diabetic KO than in WT mice (9.0±2 vs 1.9±2 g; P<0.001). IVGTT (1g/kg) was performed at day 7 and 35; glucose and insulin levels were not different in the two diabetic groups. In contrast, control KO mice displayed lower glucose levels than control WT mice at 10-60 min (P<0.05-001), which indicates an enhanced glucose elimination in KO mice. Quantitative *in situ* hybridization revealed that insulin mRNA levels at day 35 were 14±9 and 27±11% of control in diabetic KO and WT mice, respectively (P<0.001 for both); the reduction of insulin gene expression was greater in diabetic KO mice (P<0.001). In conclusion, lack of IAPP in mice is associated with a more severe form of alloxan-induced diabetes. The results suggest that the perturbation of islet function by alloxan is aggravated, because insulin gene expression was lower in diabetic KO mice and the enhanced glucose elimination seen in control KO mice was lost in diabetic KO mice. To speculate, the previously shown ability of IAPP to enhance microcirculation by vasodilatation, which is lacking in IAPP KO mice, may promote islet survival/ regeneration after a diabetic insult, such as alloxan.

528

MOUSE PANCREATIC ISLETS CULTURED ON ECM IS A GOOD PREPARATION FOR MICROFLUOROMETRY

P. O. G. Arkhammar, H. Kofod, B. R. Terry and O. Thastrup. BioImage, Novo Nordisk A/S, Copenhagen, Denmark

We have examined the use of extracellular matrix (ECM) as a substratum for NMRI mouse islet cultures with special reference to microfluorometry. The techniques for obtaining and maintaining ECM-producing cell cultures and subsequent coating of glass is straightforward. Islets seeded out onto ECM attached readily, firmly and with time spread out. Single islet cultures (1/7/14 days, RPMI 1640) were monitored for glucose-induced changes in $[Ca^{2+}]_i$ (Fura-2), NAD(P)H and FAD fluorescence, mitochondrial membrane potential (Vmit, Rhodamine 123) and insulin release. After an increase in glucose from 3 to 9-10 mM, the well-established initial changes in $[Ca^{2+}]_i$, as well as oscillations upon prolonged exposure, were observed. Measurements of Vmit showed hyperpolarisation under similar conditions. Cultured islets remained responsive to the sugar over at least two weeks, but the tendency to display $[Ca^{2+}]_i$ oscillations at 10 mM glucose was decreased at 2 weeks. Simultaneous measurements of NAD(P)H and Flavine Adenine Dinucleotide (FAD) fluorescence changes in response to glucose stimulation showed rapid increases in NAD(P)H fluorescence and decreases in FAD fluorescence. Stable and dose-dependent NAD(P)H/FAD fluorescence ratio levels were observed after prolonged incubation, similar at 7 and 14 days. The islets responded to glucose challenges from 0-3 mM to 10 and 20 mM glucose with increases in insulin release of about 10- and 30-60 fold, respectively ($p<0.05$). In conclusion, we find this preparation excellent for microfluorometry applications. The fact that the islets are still glucose responsive when they become more flat gives an opportunity to single cell imaging with conventional microscopy techniques. In addition, we suggest that the NAD(P)H/FAD ratio may be a useful parameter when monitoring metabolic activation of pancreatic islets.

Hypoglycaemic and insulinotropic effects of stevioside in the non-insulin dependent GK rat.

P. B. Jeppesen, S. Gregersen and K. Hermansen. Dept. of Endocrinology and Metabolism. Aarhus University Hospital, Tage-Hansens Gade 2, DK-8000 Aarhus C, Denmark.

Stevioside, is a glycoside contained in the leaves of *Stevia rebaudiana* Bertoni that has been used in the traditional treatment of diabetes in Brazil. Recently we found that stevioside potently stimulates insulin secretion from mouse islets. The aim of this study was to investigate the impact of stevioside on blood glucose and insulin levels *in vivo* in the non-insulin dependent GK rat. Students unpaired t-test has been applied for statistical analysis. During an i.v. infusion of glucose (2.0 g/kg body weight) over 1 min without or with stevioside (0.2 g/kg body weight) we observed a pronounced increase in the insulin response to stevioside (51116 ± 10967 vs 21548 ± 3101 µU*120 min; $p<0.05$) and a concomitant suppresion of the blood glucose responses (648 ± 50 vs 958 ± 85 mM*120 min; $p<0.05$) in the diabetic GK rat. Also in the normal Wistar rat stevioside potently stimulated the insulin response (79913 ± 3101 vs 17347 ± 2882 µU*120 min; $p<0.01$) whereas no change in the blood glucose response was found (416 ± 43 vs 417 ± 47 mM*120 min). In the GK rat insulin levels were steadily increasing during the entire 120 min observation period. Despite the prominent insulin response to stevioside no increment in the liver glycogen content could be detected in either the normal or diabetic rat. In conclusion the glycoside, stevioside, possess hypoglycaemic and insulinotropic effects in the non-insulin dependent GK rat and may have a potential as a hypoglycaemic drug.

THE POTENT INSULINOTROPIC EFFECT OF ENDOTHELIN-1 IS NOT MEDIATED VIA DIRECT ACTION ON THE ISLET β-CELLS: EVIDENCE FOR AN IMPORTANT ROLE FOR α-CELLS.

Gregersen[1], S., Brock[1], B., Buschard[2], K., Kofod, H., Thomsen[3], J.L. and Hermanen[1], K. Dept. of Endocrinology and Metabolism[1], Aarhus University Hospital, Bartholin Instituttet[2], Kommunehospitalet, Copenhagen, Novo Nordisk[3], Bagsvaerd, Denmark.

The potential involvement of the endothelium derived peptide endothelin-1 (ET-1) in the patophysiology of diabetes has been further strengthened by our recent finding that ET-1 has potent insulinotropic effects on mouse islets. However, the mechanism of action has not yet been clarified. We aimed at exploring if ET-1 interacts directly with the β-cells. For this purpose the action of ET-1 on insulin secretion and insulin mRNA in β-cell lines and purified islet cells was studied. First, we investigated the possible effect of ET-1 (10^{-6} M to 10^{-12} M) on β-cell lines INS-1, βTC-3 and MIN6. At all concentrations studied no significant effects of ET-1 on insulin secretion were found. Corresponding to this, there was no change in insulin mRNA in INS-1 cells. To further strengthen this finding we performed ligand-binding studies on βTC-3 cells with ^{125}I-ET-1 and ^{125}I-glucagon as control. No specific binding of ^{125}I-ET-1 was found on the β-cells at the concentrations studied. This was in contrast to the displaceable binding of ^{125}I-glucagon. Thus we found no evidence of specific ET-1 receptors on the β-cells. In an attempt to study whether these quite unexpected "missing" effects on the β-cells might be due to the use of insulinoma cell lines we used FACS-purified β- and non-β-cells from normal rats. Using the purified β-cells no action of ET-1 on insulin secretion was found. Interestingly, however, when purified β- and non-β-cells (preferentially α-cells) were mixed ET-1 (100 nM) did increase glucose-stimulated insulin secretion. The α-cells therefore seems important for the effects of ET-1 on insulin secretion. In conclusion, the results indicate that the potent insulinotropic effect of ET-1 is not mediated through a direct action of ET-1 on the β-cells but is elicited indirectly via stimulation of the α-cells.

531

DELAYED ONSET OF DIABETES AND PRESERVED INSULIN SECRETION IN TROGLITAZONE-TREATED OLETF RATS.

S. Hokama, I. Komiya, H. Akamine, N. Yagi, K. Yoneda, T. Asawa, M. Shimabukuro and N. Takasu. University of the Ryukyus, Okinawa, Japan.

Troglitazone is thought to improve insulin-resistance. We analyzed whether long-term treatment of troglitazone to insulin-resistant OLETF (Otsuka Long-Evans Tokushima Fatty) rats prevented the development of diabetes or not, and preserved glucose-induced insulin secretion or not. Male OLETF and non-diabetic LETO (Long-Evans Tokushima Otsuka) rats were treated with troglitazone as a 0.2% food admixture from 7 to 60 (65) weeks of age (OLETF+ and LETO+). Others were fed with standard chow (OLETF- and LETO-). Blood samples were taken every 3-4 weeks. At 60-65 weeks of age, rat pancreas was isolated and perfused with 20 mM of D-glucose or 10 mM of L-arginine for 15 min. Post-prandial insulin levels were 606 ± 159 pM (OLETF-) and 260 ± 111 pM (OLETF+) at 30 weeks of age, and 35 ± 4 pM (OLETF-) and 213 ± 151 pM (OLETF+) at 50 weeks of age. Post-prandial plasma glucose levels were gradually increased with age, and reached to 26.3 ± 10.9 mM (OLETF-) and 12.3 ± 1.9 mM (OLETF+) at 50 weeks of age. At 60-65 weeks of age, however, fasting plasma glucose were 12.8 ± 3.0 mM (OLETF-) and 11.0 ± 5.1 mM (OLETF+) (statistically not different). In perfusion study, arginine-induced insulin secretion was preserved in both groups of OLETF rats but glucose-induced insulin secretion was significantly decreased in OLETF- than in OLETF+ rats. In histological examination, loss of islets was less significant in OLETF+ than in OLETF- rats. Troglitazone delayed the onset of diabetes and preserved insulin secretion in OLETF rats. Long-term treatment of troglitazone to OLETF rats appears to attenuate the exhaustion of pancreas caused by insulin-resistance.

DIVERSITY OF THE TRANSDUCTION SYSTEM EXPRESSION IN PANCREATIC A CELLS

A. Astesano, N. Ferrand, A. Arimura*, M. Bendayan# G.Rosselin and S. Emami, INSERM U55, France *US-Japan Lab, US # Univ. de Montreal.

High glucagon levels unaffected by glucose were observed in diabetes, leading us to investigate the molecules involved in the signal transduction in glucagon-secreting pancreatic islet A cells of adult rats. Immunodetection was performed by light and electron microscopy using antibodies (abs) raised against PACAP receptors (R) C-terminal which takes into account the different subtypes of PACAPR which in preliminary study showed three bands around 42, 50 and 60 kD on western blot of pancreatic extracts of newborn mouse. Other abs used, were raised against the 13-29, 13-29, 291-302, 385-394, 100-119 and 100-118 sequences of α_q, α_{11}, α_{o2}, α_s/α_{olf}, α_s and α_{olf}, respectively. PACAPR was seen in A cells and in pancreatic islet B cells, by light and electron microscopy. The labeling intensity appeared specific of each antibody used, 93093-2 (mainly A cells) or 93094-2 (mainly B cells). $G\alpha_{11}$ and $G\alpha_{o2}$ were highly expressed in A cells, and in vascular endothelial system but not in insuline, and somatostatin or in pancreatic exocrine cells. $G\alpha_{11}$ and $G\alpha_{o2}$ were mainly present in the core and the periphery of glucagon granules. The subunits are likely to be coupled to the m1 and m2 acetylcholine receptors, respectively. $G\alpha_q$, probably linked to the m1 cholinergic receptor, was not found in A cells but was detected in B cells, being expressed mostly in the cytoplasm at the vicinity of the ribosomes. A slight labeling in A cells was found with both $\alpha s/\alpha olf$, αs and α_{olf} specific antibodies. Among the adenylate cyclase, AC-II alone was expressed in A cells. These findings indicate that $G\alpha$ subunits are differentially expressed in A and B cells. Colabeling of AC-II with $G\alpha_s$ and perhaps $G\alpha_{11}$ in the A cells suggests a possible association of these molecules required for the signaling of A cells. PACAPR might interfer with both of these pathways through a transduction system involving $G\alpha_s$ or $G\alpha_{11}$.

533

HISTOLOGICAL CHANGES OF CGRP-IMMUNOREACTIVITY IN OLETF RAT PANCREATIC ISLET.

Y. Manaka[1], H. Manaka[2], T. Kato[2], K. Yamatani[2], K. Yamaguchi[1] and H. Sasaki[2] Department of Radiology[1], and 3rd Department of Internal Medicine[2], Yamagata University, Yamagata, Japan

Calcitonin gene-related peptide (CGRP) is a 37 amino acids neuropeptide translated from the calcitonin gene. In the present study, we demonstrate sequential changes of CGRP immunoreactivity in the pancreatic islets of the non-insulin dependent diabetes mellitus (NIDDM) model rat. [Materials and Methods] Otsuka Long-Evans Tokushima Fatty (OLETF) rat were used as NIDDM model rat and Long-Evans Tokushima Ohtsuka (LETO) rat as control. Histopathological changes in the OLETF rat pancreas were classified into three stage, the early stage (6-20 weeks of age), the hyperplastic stage (20-40 weeks of age) and the final stage (over 40 weeks of age) (Kawano et al. 1992). Animals were killed at 7, 16, 24, 32, 50, 65 weeks of age, and were fixed by transcardiac perfusion with 10% formalin in phosphate buffer. Specific CGRP antiserum which does not crossreact with rat amylin1-37 and islet amyloid polypeptide was used. [Results] Diabetes mellitus in OLETF rat was obvious after 24 weeks of age. CGRP immunoreactivity in the pancreatic islets of OLETF rat and LETO rat was localized in the pancreatic D cell and nerve fibers at all three stages. CGRP positive nerve fibers of OLETF rat were more abundant than those of LETO rat in the early and hyperplastic stages. In the final stage, the pancreatic islets of OLETF rat became atrophic due to the decrease of B cells, and CGRP positive cells of OLETF rat were relatively increased in number. [Conclusion] It is suggested that CGRP is one of factors controlling pancreatic islets function.

IMMUNOHISTOCHEMISTRY OF THE PANCREAS IN FIBROCALCULOUS PANCREATIC DIABETES

Mohan V, Govindarajan M, Ashok S and Pitchumoni CS. M.V.Diabetes Specialities Centre, R & D Histopathology Lab and General Surgical Clinic, Madras, India and Our Lady of Mercy Medical Centre, New York, U.S.A.

Nine patients with Fibrocalculous Pancreatic Diabetes (FCPD) had pancreatic biopsies done at time of surgery for abdominal pain. Routine histopathology of all cases and immunohistochemistry in six cases using antibodies to insulin, glucagon, pancreatic polypeptide and somatostatin were carried out. Histology revealed severe atrophy of the entire lobule with replacement by extensive fibrocollagenous tissue. Two cases had evidence of nesidioblastosis. Total number of islets were significantly reduced compared to the normal controls. On immunohistochemistry, the percent of cells positive for insulin, glucagon and somatostatin in each islet was not significantly different from normal, but the overall positivity for these hormones was reduced due to decrease in total number of islets. Pancreatic polypeptide was markedly reduced in all the six cases. In conclusion, in FCPD the islets are destroyed secondary to the inflammatory process. However those that are not destroyed tend to maintain their normal physiological functions.

535

EFFECTS OF DEHYDROEPIANDROSTERONE IN RATS INJECTED WITH STREPTOZOTOCIN DURING THE NEONATAL PERIOD.

M.-H. GIROIX, F. MALAISSE-LAGAE*, B. PORTHA, A. SENER*, and W. J. MALAISSE*. Laboratory of Physiopathology of Nutrition, University Paris 7, Paris, France, * Laboratory of Experimental Medicine, Brussels Free University, Brussels, Belgium.

Dehydroepiandrosterone (DHEA), an adrenal steroid precursor of both androgens and estrogens, could reportedly bring a fountain of youth in advancing age. Anti-diabetic and anti-obesity effects of DHEA have been documented. Interestingly, this steroid has been shown to induce in the liver the thermogenic enzymes mitochondrial FAD-linked glycerophosphate dehydrogenase (m-GDH) and cytosolic NADP-malate dehydrogenase (malic enzyme). A deficiency of the former enzyme in the insulin-producing B-cell has been identified in several animal models of NIDDM, including that found in adult rats that were injected with streptozotocin during the neonatal period (STZ rats). Therefore, it was investigated whether DHEA may also affect the activity of the above-mentioned enzymes in pancreatic islets of STZ rats and, hence, improve their metabolic and secretory responsiveness to D-glucose. Control and STZ rats were either maintained on a standard diet or given access to food supplemented with DHEA (0.2 %) for 11 days before sacrifice. In both control and diabetic animals, DHEA feeding augmented the activity of the m-GDH and malic enzyme in liver, but not so in either the parotid gland or pancreatic islets. DHEA lowered, also in both control and diabetic rats, the ratio between D-glucose oxidation and utilization and the rate of insulin release in pancreatic islets exposed to a high concentration of D-glucose, as well as the insulin concentration and insulin/glucose ratio in plasma. These findings support the view that, in diabetes, DHEA doesn't improve the metabolic and secretory responses of islet B-cells to D-glucose but, by increasing extra-pancreatic sensitivity to insulin, may allow insulin-producing cells to avoid the otherwise unfavourable consequences of chronic hyperactivity.

SER 994 IN THE β-SUBUNIT OF THE HUMAN INSULIN RECEPTOR (HIR) IS INVOLVED IN RECEPTOR TYROSINE KINASE REGULATION.

***V. Strack, +B. Bossenmaier, *B. Stoyanov, *H.U. Häring**
***Eberhard-Karls-Universität, Tübingen, Germany**
+Boehringer Mannheim GmbH, Mannheim, Germany

Human insulin receptor (HIR) is known to be phosphorylated on tyrosine, threonine and serine residues. The functional significance of serine phosphorylation is not understood in detail. We prepared serine to alanine mutations at various candidate positions of HIR to study whether any of these serine residues has an influence on the level of the receptor autophosphorylation or substrate phosphorylation by HIR. The tyrosine phosphorylation pattern in 293 cells overexpressing HIR wild-type (HIR-wt) or the respective HIR mutants were determined by immunoblots using phosphotyrosine antibodies. HIR serine to alanine at position 994 (HIR-994) caused a 2-fold increase both in the receptor autophosphorylation and substrate tyrosine phosphorylation. Our data suggest that serine 994 is a potential inhibitory serine phosphorylation site. In order to evaluate whether this serine is required for the inhibitory effect of high glucose we incubated 293 cells overxpressing HIR-994 with 25 mM 2-deoxyglucose (2-DOG). 2-DOG was able to induce an inhibition of the insulin receptor to the same extent as it was seen with HIR-wt. This suggests that serine 994 is not directly involved in the inhibitory effect of hyperglycemia.

537

INSULIN-INDUCED ACTIVATION OF PHOSPHOLIPASE D IN RAT ADIPOCYTES.

M. Ishizawa, T. Ishizuka, Y. Kanoh, A. Miura, K. Kajita, S. Itaya, M. Kimura, K. Yamada, and K. Yasuda. Gifu University School of Medicine, Gifu, Japan.

It has been reported that activation of phospholipase D (PLD) is thought to be an important role for agonist-induced signal transduction. It is still controversial whether insulin-induced diacylglycerol (DG) production is associated with phosphatidylcholine (PC) hydrolysis by PLD and PLC. DG activates protein kinase C (PKC), which regulates insulin action. In the present study, we investigate whether insulin and phorbol ester (TPA) provoke PLD activity in rat adipocytes.

PLD activity was measured by the formation of phosphatidylethanol (PEt) in the presence of ethanol or the formation of choline during stimulation with insulin. Adipocytes were stimulated by 10nM insulin or 1 μM TPA after prelabeled with [^{3}H] palmitic acid or [^{3}H] choline, and then [^{3}H] PEt and [^{3}H] choline formation was analyzed by thin layer chromatography. Insulin-stimulated PLD activity was increased by approximately 2-fold for 5 min, and reached maximum by 3-fold for 10 min and continued for 20 min. On the other hand, TPA-induced PLD activity was increased by 2-fold for 5 min, and continued for 20 min. These results suggest that insulin provokes PLD activation and subsequent PKC activation which synergistically stimulates PLD activity. Finally, insulin-induced PLD activation contributes to continued DG formation and chronic PKC activation in rat adipocytes.

538

SERINE RESIDUES IN THE C-TERMINAL TAIL OF THE HUMAN INSULIN RECEPTOR (HIR) DETERMINE THE INTERACTION WITH TYROSINE PHOSPHATASE 1D.

+B. Bossenmaier, *B. Stoyanov, *V. Strack, *J. Mushack and *H.U. Häring
+Boehringer Mannheim GmbH, Mannheim, Germany
***Eberhard-Karls-Universität, Tübingen, Germany**

HIR is phosphorylated on tyrosine, threonine and serine residues. The functional significance of serine residues is not understood in detail. We prepared serine to alanine mutations at various candidate positions of HIR. To study whether any of these serine residues is important for substrate phosphorylation by the HIR the tyrosine phosphorylation pattern of 293 cells overexpressing HIR or the respective HIR mutants were determined by immunoblots using anti phosphotyrosine antibodies. HIR serine to alanine at position 1293/94, 1308/1309 and the C-terminal deleted HIRΔCT caused an altered pattern of tyrosine phosphorylated proteins. Increased tyrosine phosphorylation was seen for several bands between 60 and 80 kDa. Using specific antibodies one of the bands at 70 kDa was identified as tyrosine phosphatase 1D (PTP1D). Following the idea that the C-terminal serine residues might be important for the interaction of HIR and PTP1D we cotransfected 293 cells with HIR1293/94, HIR 1308/09, HIRΔCT and PTP1D. We found that expression of HIR1293/94 and 1308/1309 with PTP1D caused a strong tyrosine phosphorylation of PTP1D which is very weak with HIR wildtype and all other $HIR_{ser \rightarrow ala}$ mutants. The data suggest that the C-terminal serine phosphorylation sites are important for the interaction of HIR with PTP1D. An insufficient activation of PTP1D with these receptor constructs might explain the tyrosine phorphorylation of other proteins which is normally supressed by PTP1D.

539

EFFECT OF PROTEIN KINASE C ON INSULIN RECEPTOR SUBSTRATE-1 (IRS-1) AND PHOSPHATIDYLINOSITOL 3-KINASE (PI 3-KINASE) ACTIVATIONS IN RAT ADIPOCYTES

T. Ishizuka, A. Miura, K. Kajita, Y. Kanoh, M. Ishizawa, S. Itaya, M. Kimura, K. Yamada and K. Yasuda. Gifu University School of Medicine, Gifu, Japan

Insulin stimulates tyrosine phosphorylation of IRS-1 and PI 3-kinase via activation of receptor tyrosine kinase. On the other hand, insulin also stimulates protein kinase C(PKC) by synthesis of diacylglycerol (DG) via activation of phospholipase C and D which are coupled by GTP binding protein to receptor. To clarify the relationship between IRS-1-PI 3-kinase and DG-PKC signaling, we studied the effect of protein kinase C (PKC) on PI 3-kinase activity and IRS-1 tyrosine phosphorylation in rat adipocytes. Phorbol ester (TPA) provoked the increase in PI 3-kinase activity using thin layer chromatography and p85 subunit of PI 3-kinase immunoreactivity after anti-phosphotyrosine antibody immunoprecipitation like insulin in time- and dose-dependent manner. TPA also increased IRS-1 immunoreactivity after phosphotyrosine immunoprecipitation like insulin. Incubation of purified conventional PKC containing PKCα, ß and γ with IRS-1 immunoprecipitates using anti-IRS-1 antibody resulted in the phosphorylation of 180 and 165 kDa proteins in the presence of 0.5 mM Ca^{+} +/40 µg phosphatidylserine, and 0.4 µg/ml diolein. These results suggest that conventional PKC phosphorylates IRS-1 and increases tyrosine phosphorylation, followed by PI 3-kinase activation. Finally, activation of PKC and PI 3-kinase by insulin simultaneously induces the translocation of glucose transporter in rat adipocytes.

540

THE INSULIN RECEPTOR RK MOTIF CONTROLS RECEPTOR ASSOCIATION/ACTIVATION OF MULTIPLE PKC ISOFORMS.

P.Formisano, F.Oriente, C.Miele, D.Polese, F.Andreozzi, G.Condorelli, and F.Beguinot. University of Naples, Naples, Italy.

We have previously shown that insulin receptor (IR) phosphorylation by protein kinase C (PKC) is critically dependent on a short consensus (Arg_{1152} - Gln_{1153}; RK motif) in the receptor regulatory domain. Neutral for basic amino acid substitutions in the RK motif lead to constitutive activation of the IR kinase. In the present study, we have used RK mutant IRs to investigate the mechanisms of PKC activation by the IR. After exposure to 10^{-7} M insulin for 30 min., NIH-3T3 cells expressing human wild-type IRs (WT) showed a 2-fold increase in plasma membrane-associated PKC activity ($P<0.001$). In contrast, insulin treatment of cells expressing a similar number of any of three RK mutant IRs (Arg_{1152}->Ala; Lys_{1153}->Ala; Arg_{1152}/Lys_{1153}->Ala) decreased membrane PKC activity by >50% ($P<0.01$). IR immunopreciptates from insulin-stimulated WT cells showed a 2-fold increased recovery of PKC activity compared to those from basal cells ($P<0.001$). In the mutant cells, IR-associated PKC activity was 40% higher than in WT fibroblasts ($P<0.01$), but decreased by 60% upon exposure to insulin ($P<0.01$). Western blotting of IR immunoprecipitates from WT cells followed by probing with isoform-specific PKC antibodies revealed receptor association with PKC α, δ, and ζ. IR association with these three isoforms increased by 3-, 1.5-, and 2.5-fold, respectively, upon insulin exposure of the cells ($P<0.001$). Association of PKC α, δ, and ζ with the RK mutant receptors was 40% higher compared to WT ($P<0.01$) decreasing by 2-fold in insulin-stimulated cells ($P<0.001$). Thus, in NIH-3T3 cells, insulin elicited association of its receptor with multiple PKC isoforms. IR-PKC association is controlled by the RK motif and correlates with insulin-induced PKC activation.

541

HYPERGLYCAEMIA MEDIATED COMPLEX FORMATION BETWEEN PKC AND THE INSULIN RECEPTOR DEPENDS ON PKC ACTIVATION

G.S. Olsen, A.K. Busch, *H. Häring, K. Seedorf and L. Mosthaf. Hagedorn Research Institute, Gentofte, Denmark and *Eberhard-Karls-University, Tübingen, Germany.

High levels of glucose inhibit insulin stimulated insulin receptor autophosphorylation. This effect can be observed in skeletal muscle as well as in a number of cell culture models. The exact mechanism of this inhibition is still unclear, however protein kinase C (PKC) seems to play a crucial role. We have shown previously that hyperglycaemia leads to the formation of a stable complex between the insulin receptor (IR) and PKC α and ζ. Using A293 cells which were simultaneously transfected with the IR and PKC we have now examined all known PKC isoforms with respect to coimmunoprecipitation with the insulin receptor. Using a monoclonal antibody against the IR we detect a basal level of PKC coprecipitation for all isotypes. In response to high levels of glucose (25mM 2-Deoxyglucose) we see in addition to what we observed earlier increased IR/PKC complex formation also for PKC β1, β2, ε and θ. Next we were interested to understand whether complex formation with the IR in itself is sufficient to mediate PKC's effect on IR kinase inhibition, or whether it requires activation of the enzyme. To address this question we constructed kinase negative versions of PKC by introducing a point mutation in the ATP binding site. In all cases, this mutation totally abolished the glucose induced complex formation with the IR. In summary, we show that hyperglycaemia leads to increased formation of complexes between the IR and PKC α, β1, β2, ε, θ and ζ. This association is dependent on an intact kinase activity of PKC. We speculate that PKC mediates its effect on IR kinase by covalent modification of the IR β-subunit. This might contribute to the normal termination of the insulin signal. Prolonged or increased activation of this complex formation might result in insulin resistance.

542

INSULIN ACTIVATION OF INSULIN RECEPTOR KINASE IN INTACT BLOOD CELLS IS NOT IMPAIRED IN NIDDM AND IS NOT INFLUENCED BY HYPERGLYCEMIA.

H. H. Klein, R. Müller and H.L. Fehm. Medical University of Lübeck, Lübeck, Germany

Recent studies suggest that hyperglycemia impairs the insulin effect on insulin receptor kinase(IRK)-activation in certain tissues. The present study explored whether IRK-activation is impaired in blood cells of NIDDM patients and whether a reduction of hyperglycemia in these patients leads to improved IRK-function. Blood was collected from 21 nondiabetic control subjects and 22 patients with NIDDM. Moreover, in 11 NIDDM patients with poor metabolic control blood was collected before (day 1) and after (day 8.6±0.4) therapeutic reduction of hyperglycemia. During this period, mean daily preprandial blood glucose measured at 7 am, 11 am and 5 pm decreased from 16.4±1.2 to 7.7±0.4 mmol/l. Aliquots of the heparinized blood were incubated for 15min at 37°C with insulin (0-400 nmol/l) to activate the IRK in the intact blood cells. The cells were then rapidly solubilized under conditions that preserved the "in situ"-activity state of the insulin receptors. The receptors were then immobilized to microwells coated with anti-insulin receptor antibody. IRK-activity towards recombinant insulin receptor substrate-1 and insulin binding activity were measured in these wells. Control experiments with leukocyte filters showed that insulin binding and IRK-activity stemmed almost exclusively from the erythrocytes. IRK-activities (expressed as amol P / min / fmol insulin binding activity) were similar in the nondiabetic (2.1±0.3 and 34.2±1.2 at 0 and 400 nmol/l insulin, respectively) and NIDDM subjects (2.1±0.3 and 35.1±1.4 at 0 and 400 nmol/l insulin, respectively). Activities were also similar before (2.4±0.4 and 32.2±2.0 at 0 and 400 nmol/l insulin, respectively) and after improvement of metabolic control (2.4±0.5 and 32.0±2.3 at 0 and 400 nmol/l insulin, respectively). There were also no differences at submaximal insulin concentrations. Conclusions: (1)Insulin stimulation of intact blood cells results in a ≈15-fold stimulation of IRK-activity. (2) IRK-activation in blood cells of NIDDM patients is not impaired. (3) Our data indicate that, at least in blood cells, hyperglycemia does not impair insulin-induced IRK-activation.

543

ROLE OF THE JAK-STAT PATHWAY IN INSULIN-SECRETING CELLS

N. Sekine[1], T. Ishikawa[1], T. Okazaki[1], C.B. Wollheim[2] and T. Fujita[1]. [1]University of Tokyo, Tokyo, Japan, [2]University of Geneva, Geneva, Switzerland.

It is well established that the JAK-STAT pathway is implicated in the intracellular signalling of a number of cytokines. We have already shown that two mitogenic factors for pancreatic β-cells, growth hormone (GH) and prolactin (PRL), activate JAK2 tyrosine kinase in the differentiated insulinoma cell line, INS-1. In this study, activation of the STAT proteins by these hormones was investigated in INS-1 cells, since differential activation of these proteins might determine the tissue-specific response to the ligands. Both GH and PRL were found to promote tyrosine phosphorylation of STAT1 and STAT5. Gel mobility shift assay was performed using oligonucleotides representing interferon (IFN)-γ-activation sites (GAS) to examine DNA-binding activities of STAT proteins in INS-1 cells stimulated with either GH or PRL. Both GH and PRL were capable of stimulating the DNA binding to β-CAS (β-casein gene promoter) GAS, a binding site of STAT5. Interestingly, DNA binding activity to IFN-regulatory factor 1 (IRF-1) GASprobe was rather decreased by GH or PRL, whereas no change was observed in the binding to the m67 sis-inducible element (SIE). In contrast to the two hormones, IFN-γ failed to promote tyrosine phosphorylation of JAK1 or JAK2, although this cytokine significantly inhibited glucose-induced insulin secretion and augmented the induction of inducible NO synthase by tumor necrosis factor-α in INS-1 cells. In conclusion, the JAK-STAT pathway, possibly through activation of JAK2 and STAT5, mediates the mitogenic effects of GH and PRL. The inhibitory effect of IFN-γ on insulin secretion as well as induction of iNOS induction are not associated with an activation of this pathway.

544

EXPOSURE TO HIGH GLUCOSE LEVELS IMPAIR INSULIN ACTION IN THE L6 SKELETAL MUSCLE CELLS.

M.Caruso, G.Bifulco, A.Oliva, R.Auricchio, C.G.Tocchetti, and F.Beguinot. University of Naples, Naples, Italy.

The mechanisms responsible for the impairment of glucose metabolism by high glucose levels are still unclear. We have addressed this issue in differentiated L6 muscle cells expressing human insulin receptors ($L6_{hIR}$). Increasing glucose in the medium from 7.0 to 25.0 mM in the absence of insulin led to a 40% increase in total glucose disposal/12h by these cells ($P<0.01$). This effect was accompanied by an 80% increase in 2-deoxy-D-glucose (2-DG) uptake, and by a 2- and 0.5-fold increase in glycogen accumulation and glucose oxidation to CO_2, respectively ($P<0.001$). Following the exposure to the high glucose medium, the activities of glycogen synthase (GS) and pyruvate dehydrogenase (PDH) in the $L6_{hIR}$ also increased by 2- and 0.4-fold, respectively ($P<0.01$). In cells exposed to 7 mM glucose, insulin exposure (100nM; 12h) increased total glucose disposal, oxidation, glycogen accumulation and GS and PDH activities to a similar extent as 25 mM glucose alone. In contrast, in cells exposed to 25 mM glucose, insulin had no effect on any of these functions. With the $L6_{hIR}$, increasing glucose in the culture medium from 7.0 to 25.0 mM in the absence of insulin determined a 2-fold increase in IR kinase toward IRS-1 and 2 ($P<0.01$). Subsequent exposure of the cells to insulin did not further activate the receptor. hIR preparations from cells exposed to the high glucose concentration also exhibited little insulin responsiveness. Glucose effect on hIR kinase was maximum in 20 min and not duplicated by xylose. Thus, high glucose concentrations, *per se*, may activate glucose metabolism in muscle by affecting insulin signalling at the level of IR substrate phosphorylation. In the $L6_{hIR}$, however, the effect of high glucose concentration on glucose metabolism is accompanied by an inhibition of insulin action.

VANADATE BUT NOT INSULIN STIMULATES MAP-KINASE IN INSULIN RESISTANT ADIPOCYTES FROM AGED RATS

J.C.Molero, C.Martínez*, A.Andrés* and J.M.Carrascosa. Dept. Biología Molecular,C.B.M.S.O.,Universidad Autónoma,Madrid (Spain); * Area de Bioquímica,Univ. Castilla La Mancha, Ciudad Real (Spain)

Vanadate is a well-known insulin mimetic agent both *in vivo* and *in vitro*. Although there is some controversy about its mechanism of action,available data suggest that,in the absence of insulin, it acts at a post insulin receptor level. This fact allows its use as a tool to explore specific changes in the insulin signaling cascade that result in cellular insulin resistance. We have previously shown a decreased insulin effect in adipocytes from old rats concerning the stimulation of glucose conversion to CO_2 and triglyceride, hexose transport, MAP-kinase(MAPK), and *in vitro* autophosphorylation of insulin receptor. Since vanadate is able to stimulate partially the hexose transport in this insulin resistant fat cells, we have investigated whether it also stimulates MAPK. Adipocytes were isolated from 3- and 24-month old rats and MAPK was determined as the ^{32}Pi incorporation into myelin basic protein. Fat cells were preincubated alternatively with or without 16 nM insulin or 1mM vanadate, for 5 and 20 min in both cases. Wortmannin (1μM) and PD98059(100μM),an inhibitor of MAPK kinase(MEK), were added in some experiments 10 and 30 min before the hormones, respectively. Phosphorylated MAPKs were immunodetected with an anti-phospho MAPK antibody. In young rats adipocytes insulin transiently stimulates MAPK (1.7 fold) whereas the stimulation induced by vanadate (1.8 fold) remains constant for at least 20 min. In fat cells from old animals the stimulation by insulin reaches 1.2 fold at 5 min and is not observable after 20 min of incubation. In contrast, vanadate fully stimulates MAPK (1.8 fold) and this effect is still relevant (1.55 fold) after 20 min. Preincubation with wortmannin does not modify the stimulation of MAPK in all cases studied whereas PD98059 abolishes the stimulatory effect of both, insulin and vanadate indicating that the later acts via MEK. Changes in MAPK activity correlated well with the amount of phosphorylated erk-1 and erk-2 proteins. These results strongly indicate that MAPK is fully activable in insulin resistant adipocytes from old rats and suggest that the impairment in insulin signaling to this enzyme must be located upstream of the stimulation of MEK and MAPK.

INSULIN RECEPTOR TYROSINE-KINASE AND PC-1 CONTENT IN FIBROBLASTS OF HEALTHY NONOBESE NONDIABETIC SUBJECTS

L. Frittitta, D. Spampinato, B. Costanzo, A. Solini§, R. Nosadini§, R. Vigneri, ID. Goldfine*, and V. Trischitta. Instit Int Med, Univ of Catania and §Padua, Italy,* Diab and Endocr Res, Univ of San Francisco, CA, USA.

A reduced insulin receptor tyrosine-kinase activity (IR-TK) and an increased content of membrane glycoprotein PC-1 is found in both muscle and adipose tissue of healthy, nonobese (nonOb) nondiabetic (nonD) subjects with low insulin sensitivity, suggesting that these two defects are early events in the development of insulin (Ins) resistance. Aim: to verify whether these two defects are intrinsic and/or irreversible or acquired and/or reversible. Methods: In cultured fibroblasts from 17 nonOb (BMI<28), nonD (by OGTT) subjects with a wide range of Ins sensitivity, assessed by either i.v. Ins tolerance test (K_{itt} values:4.2-8.8, n=9) or euglycemic clamp (M values: 4.6-11.6, n=8). Ins effect (0-100 nM) on both glycogen synthesis (GS, 14C-glucose incorporation into glycogen) and IR-TK activity (autophosphorylation detected by ELISA), was measured as well as PC-1 content (by ELISA). Subjects were classified as high-sensitive (HS, n=8) or low-sensitive (LS, n=9) depending on K or M value, being higher or lower than the median value obtained in larger series of nonOb and nonD subjects studied by either ITT (n=67) or euglicemic clamp (n=64). Results: 1) At all concentrations tested ins stimulation of both GS and IR-TK was reduced in LS subjects ($p<0.05$ by 2-way ANOVA, for both measurements); moreover in LS a significantly higher ED50 of Ins stimulation of IR-TK was observed in LS (0.36±0.02 nM vs. 0.14±0.03, $p=0.01$). No difference of 125I-Ins binding was found between HS and LS. 2) PC-1 content was significantly higher in cultured fibroblasts from LS (57.2±6.15 ng/100 mg protein vs. 25.7±2.33, $p<0.01$) and correlated to the ED50 of Ins effect on IR-TK ($r=0.78$, $p<0.01$). In all these measurements, very similar data were obtained in HS vs. LS, whatever measurement of Ins sensitivity. Conclusions: cultured skin fibroblasts of healthy nonOb, nonD subjects having low Ins sensitivity have a reduced IR-TK and an increased PC-1 content, associated to a reduced Ins action on glucose metabolism. The present data demonstrate that these defects are intrinsic and/or irreversible. In accordance with data obtained in muscle and adipose tissue they suggest that a reduced IR-TK and an increased PC-1 content may play a primary, early role in the development of Ins resistance.

INSULIN MODIFIED TGF-β ACTION IN ENDOTHELIAL CELLS AND SMOOTH MUSCLE CELLS.

K. Yamauchi, S. Shigematsu, K. Nakajima, S. Iijima, T. Aizawa and K. Hashizume. Shinshu University , Matsumoto, Japan

Insulin is known to have mitotic activity as well as regulating activity of glucose homeostasis. But, it is not clear whether hyperinsulinemia contributes to atheroscrelosis. Otherwise, transforming growth factor-beta (TGF-β) is a potent regulator of cell growth and differentiation. As the result from the inhibition of the smooth muscle cells proliferation, TGF-β may suppress progression of atherosclerosis. We have examined whether insulin modified TGF-β signaling cascade. We used a human endothelial cell line (PAIEC) or a human smooth muscle cell line (PAISMC) which were stably transfected with an expression construct containing a plasminogen activator inhibitor-1 promoter fused to luciferase reporter gene (PAI-1-Luc). TGF-β rapidly increased PAI-1-Luc activity ~3 to 5-fold at 6 to 12 h which subsequently declined to basal levels within 48 h following the treatment. There is no effect of insulin itself on PAI-1-Luc activity. Surprisingly, physiological dose of insulin was found to strongly inhibit the TGF-β stimulation of PAI-1-Luc activity. Next, we examined PAI-1 synthesis and secretion in the smooth muscle cells. Insulin also inhibit the PAI-1 synthesis and secretion in the presence of TGF-β. These results suggested that insulin accelerates atherosclerosis through inhibition of TGF-β activity. Currently we are investigating the relationship of insulin-modified PAI-1 activity to the SEK/p38 cascade.

ALANINE SCANNING MUTAGENESIS OF INSULIN

C.Kristensen*, T.Kjeldsen*, F.C.Wiberg*, L.Schäffer*, M.Hach*, S.Havelund*, J.Bass #, D.F.Steiner #@, A.S.Andersen*. *Insulin Research, Novo Nordisk A/S, Bagsværd, Denmark. @ Howard Hughes Medical Institute, # University of Chicago, Chicago, USA.

Although a large number of insulin analogs have been studies to date, no comprehensive analysis of the insulin side chains involved in receptor binding has been reported. We have applied alanine scanning mutagenesis to further elucidate the role of individual amino acid residues in receptor binding. A total of 21 new insulin constructs with alanine substitutions were expressed as single-chain insulin precursors in the yeast *Saccharomyces cerevisiae*. Yeast culture medium was treated with *Achromobacter Lyticus* protease to yield mature insulin and then used directly in the binding assay. Binding data on the new analogs revealed that the alanine mutations that were most disruptive for binding were at positions TyrA19, GlyB8, LeuB11, and GluB13 resulting in decrease in affinity of 1000 fold, 33 fold, 14 fold, and 8 fold respectively relative to wild-type insulin. In contrast alanine substitutions at positions GlyB20, ArgB22, and SerA9 resulted in an increase in affinity for the insulin receptor. The most striking finding is that B20Ala insulin retains high affinity binding to the receptor. GlyB20 is conserved in insulins from different species and in the structure of the B-chain it appears to be essential for the shift from the α-helix B8-B19 to the β-turn B20-B22. Thus substituting GlyB20 with alanine most likely modifies the structure of the B-chain in this region but this structural change appears to enhance binding to the insulin receptor. Compiling these data with data in the literature on alanine analogs allows an extensive overview covering the effect of single alanine substitutions at a total of 38 positions of the insulin molecule.

EFFECTS OF BACTERIA TOXINS ON INTRACELLULAR PROCESSING OF INSULIN IN HUMAN UMBILICAL VEIN ENDOTHELIAL CELLS

Y.B. Ahn, K.H. Song, J.M. Lee, H.S. Son, K.H. Yoon, M.I. Kang, B.Y. Cha, K.W. Lee, H.Y. Son and S.K. Kang. Catholic University Medical College, Seoul, Korea

Guanine nucleotide binding proteins(G-proteins) are critically important mediators of many signal transduction systems in hormone action. Recently, possible role of G-protein in insulin action was proposed. So we studied effects of cholera and pertussis toxins on insulin binding, internalization of insulin-insulin receptor complex, and insulin receptor recycling in cultured vascular endothelial cells obtained from human umbilical veins. All experiments were performed on confluent cells attached to the 35-mm multi-well plates at a density of approximately 1 x 10^6 cells/well after one passage. The results were as follows ; 1. Specific insulin bindings to receptors of endothelial cells were time-dependent and reached their maximal levels after 60 min in all cells. The maximal specific insulin binding of control, cholera toxin-treated group, and pertussis toxin-reated group were 2.38± 0.24%, 2.28±0.18%, and 1.86±0.25%, respectively. 2. The internalization of ^{125}I-insulin into endothelial cells assessed by acid washing dissociation method occured rapidly. There was no significant difference in the internalized radioactivity of ^{125}I-insulin among three groups. 3. The recycling of insulin receptor of the pertussis toxin-treated group, was significantly decreased compared with that of control. But there was no significant difference in receptor recycling between control and cholera toxin-treated group. In conclusion, in view of the fact that pertussis toxin inhibited the recycling of insulin receptor, pertussis toxin sensitive G-protein may be closely associated with the insulin receptor and appears to be important in both insulin action and intracellular processing of insulin receptor in endothelial cells.

α_2-HS-GLYCOPROTEIN INHIBITS TRYPSIN-ACTIVATED INSULIN RECEPTOR TYROSINE KINASE ACTIVITY

G. Grunberger, S.T. Mathews, and P.R. Srinivas. Wayne State University, Detroit, MI, USA

α_2-HSG is a specific inhibitor of the mitogenic arm of insulin signaling at the insulin receptor tyrosine kinase (IR-TK) level. In our search for molecular basis of this effect, we took advantage of the previously shown trypsinization of IR. Trypsin treatment of intact cells and partially purified IR activates β-subunit autophosphorylation. Trypsin treatment cleaves the IR-α subunit at Arg^{576}-Arg^{577}, thereby making the β-subunit constitutively active. To understand the mechanism of α_2-HSG action, we compared its IR-TK inhibitory function on insulin- or trypsin-activated IR-TK. Confluent dishes of HIR_cB cells were treated either with PBS or 0.5 mg/ml trypsin at 4°C for 30 min. Trypsin treatment of cells prior to isolation of IR resulted in proteolytic modification of the α-subunit. Removal of insulin binding site by trypsin treatment was confirmed by lack of ^{125}I-insulin binding. From non-reducing gels, it was evident that trypsin treatment separated the α_2-β_2 heterotetramer into heterodimers. The holoreceptor from untreated cells had an M_r ~400 kDa compared to a M_r~ 116 kDa of trypsin-treated IR. Trypsin-activated IR's showed a 10-fold stimulation in basal IR-TK. Insulin did not increase trypsin-activated IR-TK any further. α_2-HSG (0.1-0.3 μM) completely inhibited both insulin-induced IR autophosphorylation and trypsin-activated IR autophosphorylation to the same extent. These findings indicate that the mechanism of IR-TKA inhibition by α_2-HSG is not by an alteration of the conformational change brought about by insulin binding. This study also suggests that α_2-HSG's inhibitory role might be mediated through the IR β-subunit.

EFFCT OF PERTUSSIS TOXIN ON INSULIN-INDUCED SIGNAL TRANSDUCTION IN RAT ADIPOCYTES AND SOLEUS MUSCLES

Y Kanoh, T Ishizuka, M Ishizawa, A miura, K Kajita, S Itaya, M Kimura, K Yamada, and K Yasuda. Sawada Hospital and Gifu University School of Medicine, Gifu, Japan.

It has been reported that pertussis toxin (PTX) suppresses the function of trimeric GTP binding protein. We examined the effect of PTX on insulin-induced glucose uptake, diacylglycerol (DG) production, protein kinase C (PKC) activation and phosphatidyl-inositol (PI)3-kinase activation to clarify the role of trimeric GTP binding protein for insulin-mediated signal transduction mechanism in rat adipocytes and soleus muscles. Isolated adipocytes and soleus muscles were preincubated with 0.01~1 ng/ml PTX for 2 hr, followed by stimulated with 10~ 100nM insulin, 10~100nM IGF-I or 1 μM tetradecanoylphorbol 13-acetate (TPA). Pretreatment with PTX resulted in the dose responsive decreases in insulin- and IGF-I-stimulated [^{3}H]2-deoxyglucose (DOG) uptake, and unchanged TPA-stimulated [^{3}H]2-DOG uptake. In adipocytes insulin-induced DG production, PKC β translocation from cytosol to the membrane, and PI 3-kinase activation were suppressed when treated with PTX, despite of unchanged [^{125}I] insulin specific binding. When soleus muscle protein was incubated with [^{32}P]NAD and activated PTX, 40 kDa α-subunit of Gi was detected in autoradiography. These results suggest that Gi α may interact with phospholipase C, and G βγ may couple insulin receptor with PI 3-kinase activation in insulin sensitive tissues.

552

REGULATION OF GLUCOSE UPTAKE AND GLUT4 GENE EXPRESSION BY CYCLIC AMP AND VANADATE IN 3T3-F442A CELLS.

Z.-W. Yu and J. W. Eriksson, Department of Medicine, Umeå University Hospital, Umeå, Sweden.

To further elucidate the mechanisms for cAMP induced-insulin resistance we investigated long-term effects of cAMP, the tyrosine phosphatase inhibitor vanadate or the combination of both in cultured 3T3-F442A adipocytes. Eight days after reaching confluence, 3T3-F442A cells were treated with insulin (10 mU/ml) for 16 h leading to a ~50% decrease in ^{125}I-insulin binding at the cell surface ($p<0.05$). The cAMP analog 8-bromo-cAMP (4 mM), in contrast, increased cell surface insulin binding ($p<0.05$), whereas vanadate (10 μM) alone had no effect. Insulin-stimulated ^{14}C-deoxyglucose (DOG) uptake was reduced by ~50%, whereas basal DOG uptake was increased (~2-fold, $p<0.05$) after cAMP pretreatment for 16 h. Neither short- (30 min) nor long-term (16 h) vanadate treatment altered basal DOG uptake, but insulin-stimulated DOG uptake was clearly enhanced by vanadate pretreatment (10 μM). Northern blots showed an enhancing effect of insulin (10 mU/ml) on GLUT4 mRNA level and this was found when a low (5.6 mM) but not high (25 mM) glucose was present in the culture medium, whereas 8-bromo-cAMP produced a marked, dose-dependent reduction in basal and insulin-stimulated GLUT4 mRNA. Vanadate (10 μM) alone stimulated GLUT4 gene expression, and was also found capable of preventing the cAMP-induced reduction in GLUT4 mRNA levels. Conclusions: 1) Tyrosine phosphorylation of insulin signalling peptides may be involved in GLUT4 gene expression and this may be opposited by cAMP leading to insulin resistance. 2) A low, physiological glucose concentration surrounding the cells is a prerequisite for the stimulating effect of insulin on GLUT4 gene expression. Insulin insensitivity following high glucose may partly be due to an impaired insulin effect on GLUT4 gene expression.

553

FAILURE OF TUMOR NECROSIS FACTOR-α TO DIRECTLY AFFECT INSULIN-STIMULATED GLUCOSE METABOLISM IN RAT MUSCLE.

S.Neschen, O.Wagner*, M.Roden, M.Bisschop, W.Waldhäusl and C.Fürnsinn. Dept.Med.III, Div.Endocrinol.Metab., and *Dept.Med. Chem.Lab.Diagn., Univ.Vienna, Vienna, Austria.

To better understand the effects of tumor necrosis factor-α (TNFα) on insulin sensitivity *in vivo*, direct interaction of the peptide with isolated rat soleus muscle strips was investigated. Biological activity of TNFα was validated by accumulation of plasminogen activator inhibitor-1 in the supernatant of cultured human umbilical vein endothelial cells (ng/ml after 24h: control, 56±11 *vs.* 1.4 nmol/l TNFα, 275±23; $p<0.01$). Muscles were exposed to TNFα at concentrations ranging from 0.01 to 5 nmol/l and rates of insulin-stimulated glucose metabolism were determined after TNFα-pretreatment for 30 min, 6 h, and 24 h. Independent of exposure time, TNFα failed to exert any significant effect on the rates of ^{3}H-2-deoxy-glucose transport (stimulation by 100 nmol/l insulin after preincubation without *vs.* with 5 nmol/l TNFα, cpm/mg/h: 30 min, 779±29 *vs.* 725±29; 6 h, 652±56 *vs.* 617±60; 24 h, 911±47 *vs.* 936±31) or glucose incorporation into glycogen (μmol/g/h: 30 min, 5.19±0.22 *vs.* 5.25±0.41; 6 h, 2.08±0.10 *vs.* 2.09±0.17; 24 h, 2.51±0.21 *vs.* 2.41±0.26). In parallel, TNFα neither affected insulin-stimulated rates of CO_2 release (from μmol glucose/g/h: 30 min, 0.39±0.03 *vs.* 0.42±0.03; 6 h, 0.83±0.06 *vs.* 0.98±0.06; 24 h, 2.59±0.24 *vs.* 2.28±0.10) and lactate release (μmol/g/h: 30 min, 15.9±0.6 *vs.* 17.0±0.8; 6 h, 17.4±0.6 *vs.* 19.4±0.9; 24 h, 15.4±0.6 *vs.* 17.0±1.1), nor did it induce any change in muscle glycogen content (μmol glucosyl units/g: 30 min, 10.4±0.5 *vs.* 12.4±0.6, 6 h, 11.6±0.9 *vs.* 11.3±1.0, 24 h, 8.7±0.8 *vs.* 7.5±0.3). In conclusion, our findings do not support the hypothesis of muscle insulin desensitization by TNFα via autocrine or paracrine mechanisms. The obtained data favour the concept that TNFα-dependent muscle insulin resistance *in vivo* depends on indirect effects rather than direct interaction of the peptide with skeletal muscle.

554

IN VIVO TISSUE-SPECIFIC MODULATION OF RAT INSULIN RECEPTOR GENE EXPRESSION BY MINERALOCORTICOIDS.

J. Campión, B. Maestro, V. Lahera, V. Cachofeiro, N. Dávila and C. Calle. Depts. Bioquímica and Fisiología. Fac. Medicina. UCM. and Hospital C.P.H. Madrid. Spain.

We have recently reported that aldosterone decrease insulin receptor (IR) mRNA levels in U-937 human promonocytic cells. Nonetheless, there are no studies on the possible "in vivo" effects of mineralocorticoids on IR gene expression. For these reasons, in the present work we comparatively analyze IR gene expression at the mRNA level in liver, hindlimb skeletal muscle and epididymal adipose tissue of rats uninephrectomized and treated with deoxycorticosterone acetate (DOCA) 20 mg/kg, 2 times at week during four weeks ($n=8$) in relation with sham-rats ($n=6$). All the animals were killed without anesthesia. Trunk blood samples were collected, and the three tissues in study were immediately removed and frozen in liquid nitrogen. Rat body weights were unafected by DOCA treatment, and plasma insulin and glucose levels were decreased and increased respectively, as compared to sham rats. Moreover, the DOCA treatment induced hipokalemia with normal plasma sodium concentrations and decreased plasma protein. For Northern blot assays, RNA samples of the tissues were electrophoresed in agarose-formaldehyde gels, blotted onto nitrocellulose membranes, hybridized with a ^{32}P-labeled probe (the 0.98 kb rat IR specific EcoRI fragment of the prIR p16 clone) (Gift from Prof. Goldstein) and autoradiographed. The autoradiographs were scanned with a laser densitometer and the readings normalized with the amount of 28S RNA, as revealed by ethidium bromide staining. Northern assays revealed two IR mRNA species of approximately 9.5 and 7.5 kb, in the three tissues. DOCA treatment induced an approximately 50% increase in the levels of both RNAs in the liver, 20% decrease in adipose tissue but not changes in skeletal muscle. These results provide evidence for an "in vivo" tissue-specific regulation of IR gene expression at the mRNA level, in rats under an experimental condition of excess of mineralocorticoids.

555

EFFECT OF TUMOR NECROSIS FACTOR-α(TNF-α) ON INSULIN SIGNAL TRANSDUCTION IN RAT ADIPOCYTES

A.Miura, T.Ishizuka, K.Kajita, Y.Kanoh, M.Ishizawa, S.Itaya, M.Kimura. and K.Yasuda. Gifu University School of Medicine, Gifu, Japan.

Although much evidence has been accumulated, suggesting that TNF-α is the important mediator of insulin resistance, the precise mechanism is still unclear. Recently, it has been reported that insulin-induced glucose uptake is mediated by each activation of insulin receptor substrate-1 (IRS-1) and phosphatidylinositol 3-kinase (PI3K), and diacylglycerol-protein kinase C (PKC).

We have examined the effect of TNF-α on insulin-induced glucose uptake, activation of IRS-1 and PI3K, and PKC activation in rat adipocytes. Pretreatment with 10^{-8} M TNF-α for 60 min resulted in a decrease in 10nM insulin- or 10^{-6} M phorbol ester (TPA)-induced [^{3}H] 2-deoxyglucose uptake without affecting basal glucose uptake. Insulin- or TPA-stimulated activation of IRS-1 and PI3K after immunoprecipitation with phosphotyrosine antibody, was suppressed by preincubation with TNF-α for 60 min.
TNF-α pretreatment also suppressed insulin- and TPA-induced increases in membrane-associated PKC β.

These results suggest that TNF-α inhibits insulin- or TPA-stimulated both tyrosine kinase, IRS-1 and PI3K activation, and PKC activation in rat adipocytes.

556

INSULIN RESPONSIVENESS IN MICE LACKING LAR PROTEIN PHOSPHATASE ACTIVITY.

A.R, Sørensen, R. Schaapveld, C.L. Brand, B.F. Hansen, N.P.H. Møller, P. Jensen, B. Hansen, S. Rasmussen and W. Hendriks. University of Nijmegen, Netherland and Novo Nordisk A/S, Denmark.

Introduction: Insulin binding to the alpha subunit of the insulin receptor (IR) results in phosphorylation and activation of the intracellular beta subunits. Subsequent inactivation by dephosphorylation is achieved by protein tyrosine phosphatases (PTPs) and the cell adhesion molecule-like PTP LAR has been implicated in the inactivation of the IR on the basis of in vitro studies. Our aim was to test this involvement by studying the insulin response in mice that are deficient in LAR signalling. **LAR Knock-out:** Gene targeting in mouse embryonic stem cells generated mice lacking sequences encoding both LAR phosphatase domains (LAR-/-). **Blood glucose response:** Post-prandial LAR-/- (n=12; 38-44 weeks old) and age matched control (C57BL/6; n=10; 43 weeks old) male mice were subjected to an insulin tolerance test (ITT) (1 U/kg, s.c.). Blood samples were obtained 120 and 0 min pre-dose and at 30 min intervals for 2 hours post-dose enabling calculation of the Δglucose-AUC. LAR-/- mice showed no differences (t-test) in pre-dose (120 min) plasma glucose (8.8±0.3 vs 9.5±0.3 mmol/l in controls, ns) (all values are mean±SE) or insulin concentrations (316±54 vs 393±55 pmol/l in controls, ns) nor in their response to the ITT (-344±38 vs -452±93 min · mmol/l in controls, ns). **Lipogenesis:** Adipocytes isolated from epididymal fat pad were used to determine the ED_{50} for insulin in both control mice and LAR knock-out mice. No significant difference was observed, ED_{50} for both groups were approx. 100 pM. **Insulin Receptor Tyrosine Kinase (IRTK):** The basal IRTK was measured in hindlimb muscles using a microtitre well assay. No significant difference was seen between LAR-/- and controls (2.0±0.5 vs. 3.2±1.1). **Conclusion:** The data provide no evidence of increased insulin signalling in LAR-/- in vivo nor in vitro compared to controls suggesting that LAR is not solely responsible for down regulating the IR signal.

557

A MOLECULAR BASIS FOR INSULIN RESISTANCE: ELEVATED SER/THR PHOSPHORYLATION OF IRS-1 AND IRS-2 INHIBITS THEIR BINDING TO THE JUXTAMEMBRANE REGION OF THE INSULIN RECEPTOR (IR) AND IMPAIRS THEIR ABILITY TO UNDERGO INSULIN-INDUCED TYR PHOSPHORYLATION.

H. Kanety[1], K. Paz[2], R. Hemi[1], .A. Karasik[1], and Y. Zick[2] From [1]the Institute of Endocrinology, Chaim Sheba Medical Center, Tel-Hashomer, and [2]the Department of Molecular Cell Biology, the Weizmann Institute of Science, Rehovot , Israel

Tumor narcosis factor-α (TNF) gained recognition as a key mediator of insulin resistance in obesity and NIDDM. We have previously shown that one important mechanism by which TNF and other insulin-resistance-inducing agents interfere with insulin signaling is through increased Ser/Thr phosphorylation of insulin receptor substrate-1 (IRS-1). To unravel the molecular basis for these inhibitory effects we undertook to study the interaction of Ser/Thr -phosphorylated IRS-1 and IRS-2 with the insulin receptor. We could demonstrate that similar to IRS-1, IRS-2 also interacts with the juxtamembrane (JM) domain (a. a. 943-984) but not with the C-terminal region (a. a. 1245-1331) of IR, expressed in bacteria as (His)6-fusion peptides. Moreover, incubation of rat hepatoma Fao cells with TNF, sphingomyelinase, TPA, or other P-Ser/Thr-elevating agents, reduced insulin-induced Tyr phosphorylation of IRS-1 and IRS-2, elevated their P-Ser/Thr levels, and significantly reduced their ability to interact with the JM region of IR. Similar inhibitory effects were obtained when Fao cells were subjected to prolonged (20-60 min) treatment with insulin. These findings suggest that insulin resistance is associated with enhanced Ser/Thr phosphorylation of IRS-1 and IRS-2, which impairs their interaction with the JM region of IR. Such impaired interactions abolish the ability of IRS-1 and IRS-2 to undergo Tyr phosphorylation by the insulin receptor kinase, and further propagate insulin signaling.

558

NATURAL IRS-1 MUTATIONS WITH IMPAIRED FUNCTION AT DIFFERENT STEPS OF INSULIN SIGNALING PATHWAY

R. Yoshimura, E. Araki, S. Ura, M. Todaka, and M. Shichiri
Department of Metabolic Medicine, Kumamoto University School of Medicine, Kumamoto, Japan

IRS-1 is one of the major substrates of insulin receptor (IR) tyrosine kinase and mediates various insulin signals downstream. To examine if the natural IRS-1 gene mutations contribute to the developement of NIDDM, we have studied the impact of three mutant IRS-1s (G971R, P170R and M209T in which Gly971, Pro170 and Met209 are substituted by Arg, Arg and Thr, respectively) on insulin signaling. 32D-IR cells, stably overexpresing human IR, were transfected with wild-type (WT) or three mutant IRS-1 cDNAs, and analyzed. Cells expressing three mutant IRS-1s exhibited significant decrease in insulin stimulated thymidine uptake as compared with WT. Upon insulin stimulation, cells expressing G971R showed 39% decrease ($p<0.005$) in PI3-K activity and 22% decrease ($p<0.05$) in MAP-K activity, while cells expressing P170R and M209T showed slight decrease [17% and 14% ($p<0.05$)] in PI3-K and greater decrease [41% and 43% ($p<0.005$)] in MAP-K. In addition, both P170R and M209T showed significant decrease in phosphorylation [41% and 43% ($p<0.005$)] and association with IR [32% and 38% ($p<0.05$)], while G971R showed normal phosphorylation and association with IR compared with WT.

In conclusion, two mutations, P170R and M209T, occuring in the PTB domain of IRS-1, showed impaired mitogenic response mainly due to reduced association with IR, while G971R showed impaired mitogenic response mainly due to reduced association with PI3-K. These data suggested the contibution of IRS-1 mutations to the development of NIDDM in humans.

559

OXIDANT STRESS INDUCED IMPAIRMENT IN INSULIN ACTION IS DUE TO DEFECTS IN DISTAL COMPONENTS OF INSULIN SIGNALING CASCADE.

A. Rudich, A. Tirosh, R. Potashnik, N. Kozlovsky and N. Bashan. Dept. of Clinical Biochemistry, Ben-Gurion University of the Negev, Beer-Sheva, Israel 84103.

Accumulating evidence suggest a link between increased oxidant stress in diabetes and insulin resistance. We have previously demonstrated that exposure of 3T3-L1 adipocytes to prolonged, low grade oxidant stress result in impaired insulin action. In this study we aimed at elucidating the cellular mechanisms underlying this observation. Insulin Receptor Substrate 1 (IRS-1) content was reduced dose-dependently by incubation with glucose oxidase (GO) for 18 hours, reaching 60±5% reduction with 50 mU/ml GO. Immunoreactivity of IRS-1 with anti-phosphotyrosine antibodies following insulin stimulation was not affected by GO, suggesting an increased ratio of phosphotyrosine per IRS-1 protein following oxidation. However, this effect of GO did not impair PI3 Kinase activation through its interaction with IRS-1, as PI3 Kinase activity in immunopercipitates of IRS-1 was unchanged following GO treatment. In addition, activation of MAP Kinase by insulin was not altered by GO treatment, as assessed by immunoblot with anti active MAP Kinase Antibodies. As defects in the early events of the insulin signaling cascade did not seem to explain the oxidant stress -induced reduction in insulin action, we assessed the status of the two glucose transporters isoforms GLUT1 and 4. GLUT4 protein and mRNA were reduced following GO treatment by 43±6% and 40±4%, respectively. Concomitantly, GLUT1 protein and mRNA were increased 3.5±0.2 and 4.2±0.3 fold, respectively. GLUT4 down-regulation appeared to represent an independent effect of oxidant stress, as it was observed under inhibition of GLUT1 elevation by co-administration of cycloheximide. Hence, both down-regulation of GLUT4 content and/or a defect in its translocation to the plasma membrane may explain the observed insulin hypo-responsiveness. In conclusion, prolonged oxidant stress appears to impair insulin stimuation of glucose transport by interference with distal effectors of the insulin signaling cascade.

560

EFFECTS OF WORTMANNIN AND OKADAIC ACID ON INSULIN REGULATED GLUCAGON SECRETION

K. Kaneko, T Shirotani, M. Uehara, T. Taguchi, N. Miyamura, E. Araki, H. Kishikawa, and M. Shichiri, Department of Metebolic Medicine, Kumamoto University School of Medicine, Kumamoto, JAPAN

We have previously demonstrated the insulin induced negative regulation of glucagon secretion and the expression of functional insulin receptors in glucagon secreting cell lines. However, the mechanism of these phenomenon is still unknown. In this study, we evaluated the involvement of insulin receptor signaling pathway in glucagon secretion from In-R1-G9 and α TC clone 6 cells, using okadaic acid (an inhibitor of tyrosine phosphorylation of IRS-1) and wortmannin (an inhibitor of phosphatidylinositol 3 kinase (PI3K)). In the presence of insulin (10^{-7} mol/l), the contents of glucagon secreted into culture medium significantly ($p<0.05$) decreased as compared with those without insulin (by 33, 59 and 48% in In-R1G9 cells at 2, 6 and 12 hours after incubation, and by 23, 43 and 33% in α TC clone 6 cells, respectively). On the other hand, in addition of wortmannin (100nmol/l), glucagon secretion returned to the almost same level as those without insulin (99, 102 and 104% vs. those without insulin at 2, 6 and 12 hours in In-R1-G9 cells, and 94, 91 and 97% in α TC clone 6 cells, respectively). Addition of okadaic acid (1μmol/l) also recovered the glucagon secretion to the almost same level as those without insulin (97, 87 and 99% vs. those without insulin at 2, 6 and 12 hours in In-R1-G9 cells, and 107, 89 and 88% in α TC clone 6 cells, respectively). In conclusion, insulin might be involved in the negative regulation of glucagon secretion through PI3K, which is an important component in insulin signaling pathway.

561

INSULIN-INDUCED NITRIC OXIDE AND SUPEROXIDE FREE RADICAL PRODUCTION OF HUMAN PLATELETS

I.Wittmann, *T.Kőszegi, J.Kátai, L.Wagner, M.Molnár, J.Nagy. Second Department of Medicine, *Department of Clinical Chemistry, Medical University of Pécs, Hungary.

Recent data support the possible role of nitric oxide (NO) in the development of insulin signaling. The aim of this study was to examine the effect of insulin on the NO production of platelets. We measured the chemiluminescence of platelet-rich plasma, prepared from the blood of healthy volunteers, in the presence of luminol. Detection of NO by luminol is possible in the form of peroxinitrite produced from NO and superoxide. The results are expressed in percent of area under curves (AUC), taking the AUC of 84 pmol/l of insulin as 100 % (Figure 1). In case of insulin + Nω-nitro-L-arginine methyl ester (L-NAME, inhibitor of nitric oxide synthase enzyme, Figure 2), or insulin + superoxide dismutase (SOD, Figure 3) the AUC of insulin was taken as 100 %. Data are shown as mean±SD, n=9.

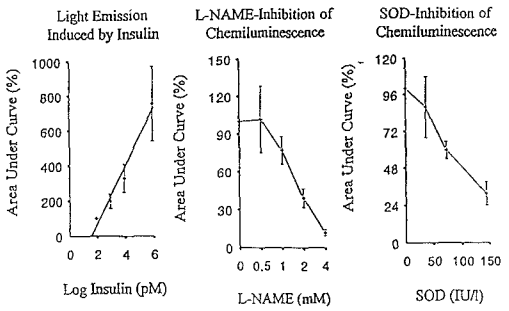

Figure 1.

Figure 2.

Figure 3.

Summarizing this data, insulin evoked a concentration dependent chemiluminescence increase, which was inhibited by L-NAME and SOD. As conclusion, we suppose that the insulin-induced increase of chemiluminescence was due to increased production of NO and superoxide free radicals forming peroxinitrite. This is the first direct evidence demonstrating stimulation of NO-release by insulin.

562

INSULIN STIMULATES THE ASSOCIATION OF PI3-KINASE SERINE KINASE WITH THE INSULIN RECEPTOR AND PDE3 IS A SUBSTRATE.

C. M. Rondinone, E. Carvalho, T. Rahn*, E. Degerman* and U. Smith. Lundberg Lab. for Diabetes Research, Dept. Internal Medicine, Sahlgrenska Hospital, Gothenburg and * University of Lund, Sweden.

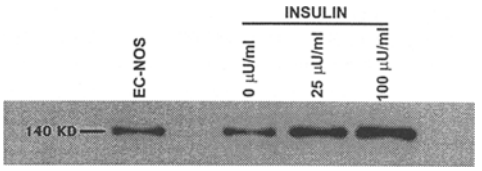
PI 3-kinase, a heterodimer consisting of a 85 kDa regulatory subunit and a 110 kDa catalytic subunit, is a dual enzyme with both lipid and serine kinase activities. The aim of this study was to elucidate the effect of insulin on PI 3-kinase lipid and serine kinase activities and the association with insulin receptor (IR) and IRS-1 in human adipocytes. Insulin stimulated the association of p85 and p110 with both IR and IRS-1. Insulin increased~20-fold the PI 3-kinase lipid kinase activity associated with IRS-1 but not with IR. Protein kinase activity was also assayed in the presence of Mn^{2+} in the same immunoprecipitates in the presence or absence of wortmannin. The results showed that IR, but not IRS-1 immunoprecipitates from cells treated with insulin contained a wortmannin-sensitive kinase that phosphorylated several proteins including p85, p110 and a 135 kDa protein To investigate if this protein could be cGI-PDE (PDE3) we performed protein kinase assays in IR immunoprecipitates using recombinant PDE3. Insulin stimulated the phosphorylation of cGI-PDE by the immunoprecipitates and this activity was inhibited by wortmannin. In conclusion: A) The p85 and p110 subunits of PI 3-kinase are associated with both IR and IRS-1 in response to insulin, B) Insulin stimulated only the PI 3-kinase lipid kinase activity associated with IRS-1, C) Insulin stimulated only the PI-3 kinase serine kinase activity associated with IR that phosphorylated several proteins including p85 and PDE3 suggesting a role of the PI 3-kinase serine kinase in the antilipolytic effect of insulin in human adipocytes.

563

INSULIN INDUCES THE EXPRESSION OF HUMAN ENDOTHELIAL NITRIC OXIDE SYNTHASE

A. Aljada, M. Wagner, K. Thusu, E. Abdel-Rahman, I. Davidson and P. Dandona. Millard Fillmore Health System, Buffalo General Hospital and the State University of New York at Buffalo, Buffalo, New York.

It has recently been shown that insulin induces vasodilatation in human arteries and human veins. This effect of insulin has been shown to be a direct one on the human vein. In view of these observations and the fact that insulin induced vasodilatation is impaired in insulin resistant states like Type II diabetes and obesity, we have now investigated the hypothesis that insulin may induce the expression of endothelial nitric oxide synthase (NOS) in endothelial cells grown from human aorta. Human aortic samples were obtained from transplant donors. Endothelial cells were harvested following collagenase digestion and were grown in 2% Fetal Bovine Serum (FBS) containing media. Identity of endothelial cells was confirmed by their cobblestone morphology, positive staining for EN4, Factor VIII and Ulex europaeous and negative smooth muscle α-actin staining. When the cells reached 90% confluency, media was changed to 10% charcoal/dextran treated FBS containing media and cells were induced with insulin. Media was changed every two days for six days. Cells were homogenized, electrophoresed and blotted. Blots were treated with monoclonal antibody for endothelial NOS. In four separate experiments it was clearly demonstrated that there was a dose dependent induction by insulin of NOS in the endothelium (see figure). We conclude that insulin induces a dose dependent induction of nitric oxide synthase in human aorta and endothelial cells and that this effect may be contributory to the overall vasodilatory effect of insulin directly at the vascular level.



564

TAXOL® INHIBITS INSULIN ACTION WITH A DECREASE IN PHOSPHATIDYLINOSITOL-3-KINASE ACTIVITY.

M. Dea, R. Bergman, M. Hamilton-Wessler, E. Heart, and C. Sung. University of Southern California, Los Angeles, CA, USA.

Paclitaxel (Taxol), a clinical anti-neoplastic agent, stabilizes microtubules, inhibiting intracellular vesicular trafficking. In our previous studies in dogs, interstitial concentration of 8 μmol/l Taxol caused a reduction in the rate of glucose disposal during hyperinsulinemic euglycemic clamps. However, this reduction was not due to reduced transendothelial transport of insulin. To study possible cellular mechanism(s) by which Taxol caused insulin resistance, we employed mouse 3T3-L1 adipocytes and studied the insulin signaling pathway for glucose uptake. Incubating cells with 100 nmol/l insulin increased [^{3}H] 2-deoxyglucose (2-DG) uptake 1.8-fold compared to basal. Preincubation of 3T3-L1 cells with Taxol resulted in a dose-dependent decrease in 2-DG uptake with insulin. At 10 μmol/l Taxol, there was complete suppression of insulin-stimulated 2-DG uptake ($p=0.36$ compared to basal). Insulin receptor (IR) tyrosine kinase activity was measured by immunoadsorption plate assay using poly (Glu, Tyr) (4:1) as an exogenous substrate, and IR tyrosine phosphorylation was measured by Western blot analysis with anti-phosphotyrosine antibodies (α-PY). Insulin stimulation resulted in 5.0-fold increase in IR tyrosine kinase activity and 2.7-fold increase in IR tyrosine phosphorylation. Taxol did not affect either IR tyrosine kinase activity or tyrosine phosphorylation ($p=0.31$ and 0.87, respectively). Since phosphatidylinositol-3-kinase (PI3K) activity has been reported to be crucial for insulin-stimulated glucose uptake, we measured insulin-stimulated PI3K activity in α-PY immunoprecipitates. There was a decrease in PI3K activity with Taxol with a linear correlation between decreases in 2-DG uptake and PI3K activity ($r^2=0.99$). These data suggest that Taxol inhibits insulin-stimulated glucose uptake via suppression of PI3K activity.

565

CHOLESTEROL IS REQUIRED FOR SIGNAL TRANSDUCTION VIA GLYCOSYL PHOSPHATIDYLINOSITOL(GPI)-ANCHORED PROTEINS

TM. Stulnig, M. Berger, H. Stockinger, V. Horejsí, and W. Waldhäusl. Dept. of Internal Medicine III and Inst. of Immunology (H.S.), University of Vienna, Vienna, Austria; Czech Acad. Sciences, Prague, Czech Republic (V.H.).

Glycosyl phosphatidylinositol(GPI)-anchored proteins are cell surface proteins which have no transmembrane domain but are anchored to the outer leaflet of the plasma membrane by a phospholipid moiety. GPI-anchored proteins can transduce signals to the cytoplasm after crosslinking on the cell surface or following release of inositol phosphoglycan which may also serve as an alternative second messenger for insulin action. Moreover, GPI-anchored proteins are clustered in distinct membrane domains, which are formed by an unique lipid composition requiring cholesterol, but the exact mechanism of signal transduction following crosslinking of GPI-anchored proteins is not yet elucidated. Therefore, we studied the influence of metabolic alterations of cellular cholesterol content on the calcium response via GPI-anchored proteins CD59 and CD48 in human Jurkat T-lymphocytes. Lowering cholesterol by different inhibitors of cellular cholesterol synthesis suppressed calcium response via GPI-anchored proteins by about 50% whereas stimulation via the transmembrane CD3 complex was only minimally affected. The decrease in overall calcium response via GPI-anchored proteins was reflected by an inhibition of the release of calcium from intracellular stores. Cell surface expression of GPI-anchored proteins was not changed quantitatively by the treatment, neither was the pattern of immunofluorescence in microscopic examination. In addition, the distribution of GPI-anchored proteins in detergent-insoluble complexes was not altered. In conclusion, cellular cholesterol is an important prerequisite for signal transduction via GPI-anchored proteins beyond formation of membrane domains.

Supported by the Austrian Science Foundation (P11404Med).

ALTERED EXPRESSION OF INSULIN SIGNALLING COMPONENTS IN ADIPOCYTES FROM FETALLY MALNOURISHED MALE RATS.

S.E. Ozanne, B. Nave, C.L. Wang, P.R. Shepherd and G.D. Smith, University of Cambridge, Cambridge, U.K.

Epidemiological studies have suggested that there is a relationship between fetal growth and the subsequent development of non-insulin-dependent diabetes mellitus. In the present study insulin action on rat adipocytes was studied in the offspring of mothers who had been fed either a control (20 % protein) or a low (8 %) protein diet during pregnancy and lactation. Adipocytes isolated from low protein offspring had a significantly higher basal glucose uptake (1202 ± 116 pmol /min/mg protein compared to 584 ± 24 pmol/min/mg protein; $p < 0.01$) and a significantly higher insulin-stimulated glucose uptake (2002 ± 213 pmol/min/mg protein compared to 1598 ± 207 pmol/min/mg protein; $p < 0.05$) than controls. This may be related to a three-fold increase in insulin receptors in low protein adipocytes. Consistant with these observed changes in glucose transport, adipocytes from low protein animals had significantly higher basal ($p < 0.001$) and insulin stimulated ($p < 0.001$) IRS-1 associated PI 3-kinase activities. There was also more p85 associated PI 3-kinase activity in these adipocytes ($p < 0.005$). There was no difference in expression of the p85 regulatory subunit or the p110α catalytic subunit of PI 3-kinase. In contrast there was a six fold reduction in the p110ß catalytic subunit of PI 3-kinase in adipocytes from low protein animals. These results suggest that poor fetal nutrition during pregnancy and lactation can have long term effects on glucose transport and on the expression of key components of the insulin signalling pathway in adipocytes.

567

THE EFFECT OF INSULIN ON POLYMERISATION OF ACTIN IN RAT SKELETAL MUSCLE CELLS

S. Lynn, P. Tong, and T. Thomas, Univeristy of Newcastle upon Tyne, United Kingdom.

We have shown that the effect of insulin on cell membrane dynamics is abolished by disrupting the cytoskeleton in cultured rat skeletal muscle cells (L6 myotubes) and human mononuclear leukocytes. The interaction between insulin and the cytoskeleton remains unclear though the microfilaments may be involved. We therefore developed a novel technique to study the effect of insulin on the polymerisation of filamentous (F) and globular (G) actin in L6 myotubes. L6 myotubes on glass coverslips were studied after 6-10 days in culture. The F and G actin were labelled with fluorescent phalloidin and DNase I respectively. The morphological distribution of the F and G actin in the cell membrane was examined by a confocal laser scanning microscope. The fluorescent intensities per unit area were measured and the ratio of F and G actin (F/G) was compiled using a computer controlled image analyser. The results are expressed as means [S.E.M.] from five experiments.

		Insulin			
	Control	10nM	100nM	500nM	1000nM
F/G	1.432	1.710	3.924[a]	2.719	1.473
	[0.359]	[0.711]	[0.191]	[0.465]	[0.343]

a: $p<0.01$ vs control ; paired t-test

Insulin (100nM) caused a significant change in the F/G actin ratio of L6 myotubes. A bell-shaped concentration effect of insulin on F/G actin was observed. This could be secondary to cross-reaction with other growth factor receptors at higher concentrations of insulin. Insulin has been shown to modulate membrane fluidity and cause a major reorganisation of the actin network in L6 myotubes. Our result suggests that changes in polymerisation of actin may be the underlying mechanism whereby insulin affects cell membrane dynamics in L6 myotubes.

568

DIFFERENTIAL SUB CELLULAR LOCALIZATION OF p110 PI 3-KINASE SUBUNITS IN 3T3-L1 ADIPOCYTES

B.T.Nave and P.R.Shepherd, Dept of Biochemistry, University College London, London,UK

In the current study we have investigated whether differential patterns of sub cellular location of the PI 3-kinase catalytic subunits exist in insulin responsive 3T3-L1 adipocytes. We have previously shown that differential regulation of PI 3-kinase at distinct sub cellular locations may explain differences observed in the PI 3-kinase dependent responses that can be stimulated by insulin compared with those that can be stimulated by other growth factors. In particular sub cellular fractionation studies have shown insulin and PDGF both stimulate PI 3-kinase activity and the level of the p85 adapter subunit in the plasma membrane (PM) while only insulin stimulates these in microsomal membranes (MM) that in 3T3-L1 adipocytes (Nave et.al. Biochem J 318 55-60). In the current study we have characterised antibodies specific for both p110α and p110β . Using these it was found both p110α and p110β are upregulated during fat cell differentiation. The subcellular distribution of p110β closely matched that of p85α with ≈ 10% present in PM, ≈ 20% present LDM and the the bulk being present in the cytosol. Surprisingly though approximately 70% of the immuno-reactive p110α was found in the MM fraction with less than 10% present in the PM and 20% present in the cytosol. The implications for insulin signalling of this differential distribution of p110α and p110β is being investigated.

569

EXTRAPANCREATIC EFFECT OF GLIBENCLAMIDE ON PYRUVATE DEHYDROGENASE ACTIVITY.

Y.Sakamoto , O.Mokuda and N.Shimizu . 3rd. Department of Internal Medicine, Teikyo University, Ichihara, Japan

To know the mechanisms of extrapancreatic action of sulfonylurea, pyruvate dehydrogenase(PDH) activities and 2-deoxy glucose uptake were measured in mouse adipose tissues. Glibenclamide (3mg/kg/day. SU) was orally adminstrated for 10 days prior to the experiment. Basal PDH activity was 5- 6 folds increased in SU treated mouse and PDH activity by the incubation with insulin(250 μU/ml) was 2 times higher in (SU) compared to that in control. 2-deoxy glucose uptake was significantly increased in the adipocytes from (SU) in the presence of high concentration of insulin (0.1-1mU/ml), but there were no effects in low concentration of insulin (0-25 μU/ml). Addition of phlorizin(4mM) did not inhibit insulin-stimulated PDH activity in (SU). No effect of direct addition of SU on PDH activity was observed in the control adipose tissue.There were no differences in insulin binding activity in adipocytes and blood IRI levels between (SU) and control. These results suggest that SU acts on post-insulin receptor systems in insulin action.

570

EFFECT OF TROGLITAZONE ON TROMBIN-INDUCED PLATELET AGGREGATION MECHANISM IN VITRO

S.Itaya, T.Ishizuka, H.Wada, M.Kimura, M.Ishizawa, Y.Kanoh, K.Kajita, A.Miura and K.Yasuda .
Gifu University School of Medicine, Japan

Troglitazone(CS-045), antidiabetic thiazolidinedione, is known to improve insulin resistance. However, it is not unclear the effect of troglitazone on platelet aggregation. We studied the effect of troglitazone on thrombin-induced platelet aggregation, phosphoinositide metabolism, protein phosphorylation and phosphatidylinositol 3-kinase in vitro in human platelet.

Maximum platelet aggregation by ADP, collagen and thrombin was suppressed by the pretreatment with 0.1～1 μM troglitazone for 60min. Pretreatment with troglitazone resulted in decreases thrombin-induced phosphatidic acid production, hydrolysis of phosphatidylinositol 4,5-bisphosphate by phospholipaseC, and 47kDa protein phospholylation. Troglitazone alone stimulated phosphatidylinositol 3-kinase(PI3K) activity, but thrombin-induced PI3K activation was suppressed by the pretreatment with troglitazone for 60 min.

These results suggest that troglitazone has a potent inhibitory effect of platelet aggregation via suppression of both thrombin-induced activation of phosphoinositide metabolism and PI3K activation in human platelet.

571

INSULIN STIMULATES GLYCOGEN SYNTHESIS IN BAKERS' YEAST

Günter Müller, Stefan Welte, Natacha Rouveyre, Claire Upshown
Hoechst-Marion-Roussel, TA Metabolic Diseases, Frankfurt a.M., Germany

Yeast harbors homologs of many human genes involved in transmembrane signalling. This study was performed to test for the putative existence of elements of insulin signaling in yeast. 1) The effect of insulin on glucose metabolism of wild type yeast cells grown in rich glucose medium in the absence or presence of 1 μM human insulin during the transition from late exponential to stationary phase was assayed. Glycogen accumulation was increased by 40-60% in the insulin-induced (85±11 mg/g cells) compared to basal cells (53±8 mg/g cells). The decrease of glycogen phosphorylase activity (45.9+3.8 mU/mg protein) was significantly more pronounced in insulin-induced (5.5±0.9) compared to basal cells (12.0±1.9). Glycogen synthase activity ratio (68.7±7.6 %) declined to 34±8 %, only, in the presence of insulin *vs.* 18±5 % in its absence. Thus, insulin (EC_{50}=150-250 nM) present during logarithmic growth, already, causes glycogen phosphorylase and synthase to become more sensitive and resistant, respectively, to inactivation when the culture reaches saturation. 2) A putative insulin receptor-like protein was partially purified from solubilized plasma membranes by wheat germ agglutinin and insulin-agarose affinity chromatography. It was specifically crosslinked to ^{125}I-labelled porcine insulin using a bifunctional crosslinker. Equilibrium binding using precipitation and subsequent filtration of the receptor revealed specific binding of human insulin and mouse IGF-1 (K_d=1.5±0.5 μM and 0.6±0.3 μM, respectively). 3) Western blotting with anti-phosphotyrosine antibodies of receptor incubated *in vitro* with ATP demonstrated stimulation of autophosphorylation on tyrosine residues in response to 0.5 μM insulin (3.8±0.9-fold *vs.* basal), which was blocked by 0.1 mM Na_3VO_4. Understanding the interaction of the insulin receptor-like protein with downstream components in yeast may help to understand metabolic insulin signalling in mammalian cells.

Glucose Transport and Hormone Action in Vitro

572

GLUCOSE OXIDASE IMPAIRS INSULIN STIMULATED GLUCOSE TRANSPORT IN DIFFERENTIATED 3T3-L1 ADIPOCYTES.

A. Tirosh, A. Rudich, R. Potashnik and N. Bashan. Dept. of Clinical Biochemistry, Ben-Gurion University of the Negev, Beer-Sheva, Israel 84103.

In 3T3-L1 adipocytes, various inducers of insulin resistance including prolonged exposure to insulin and TNF-α were shown to reduce expression of the insulin sensitive glucose transporter GLUT4, while increasing GLUT1 expression. As oxidant stress was recently suggested to be linked to impairment in insulin action, we assessed the effect of prolonged exposure of 3T3-L1 adipocytes to an enzymatic H2O2 generating system. We observed that 18 hours exposure of 3T3-L1 adipocytes to glucose oxidase (GO) resulted in a reduced capacity of insulin to increase glucose transport above basal activity. This could not be attributed to defects in early events of the insulin signaling cascade, but was associated with a 45% reduction in the expression of GLUT4 protein and mRNA, accompanied by a 3.5 -fold increase in GLUT1 protein and mRNA content. In this study we assessed whether this impairment in insulin stimulated glucose transport (ISGT) can be attributed to the alterations in expression of the two glucose transporteres isoforms. 3T3-L1 adipocytes were exposed to GO for up to 4 hours. While exerting no significant effect on basal glucose transport activity, ISGT was reduced by 50% following 1or 2 hour exposure to 100 or 50 mU/ml GO, respectively. ISGT was completely abolished by increasing exposure time to 2 and 4 hours, respectively. Under these conditions, no significant changes in total membrane GLUT1 and GLUT4 content were observed. This effect of GO could not be inhibited by co-administration of okadaic acid (3 nM), H7 (0.1 or 1 mM), or MAP Kinase inhibitor (PD98059, 10 μM), suggesting that neither activation of class 1 phosphatases, PKC or the MAP kinase cascade explains oxidant stress induced ISGT defect. In conclusion, GO induces insulin resistance in 3T3-L1 adipocytes. This relatively early effect appears to represent impaired insulin stimulated translocation of existing glucose transporters to the plasma membrane, by mechanism which remain to be elucidated.

573

THE EFFECT OF ACUTE HYPERGLYCAEMIA AND GLUCOSAMINE ON gp160 AND PI3-KINASE DISTRIBUTION

A. Filippis[1], S.Clark[2], G. Eckardt[1] and J. Proietto[1]. [1]The University of Melbourne, Department of Medicine, Royal Melbourne Hospital, Parkville, Australia and [2]The Baker Medical Research Institute, Prahran, Australia

We have previously shown that high glucose (HG) and to a greater extent glucosamine (GLN) can acutely cause the internalisation of GLUT4, an effect mediated via the hexosamine biosynthesis pathway, however how this occurs is not understood. Two possible regulators that may be involved include: 1) gp160, a glycoprotein found exclusively on GLUT4-containing vesicles in rat adipocytes and 2) PI3-kinase, which is believed to be required for insulin-stimulated GLUT4 translocation. The aim of this study was to investigate the effect of acute hyperglycaemia and GLN on the intracellular distribution of gp160 and PI3-kinase. GLUT4 and gp160 levels were measured in total lysates, high density microsomal (HDM), low density microsomal (LDM) and plasma (PM) membranes, while PI3-kinase activity was measured in cytosolic and particulate fractions of rat adipocytes pre-incubated with HG (30 mM) in the presence of insulin (0.7 nM) or GLN (3 mM) for 2 hours. GLUT4 and gp160 levels were detected by Western blotting using rabbit polyclonal antibodies. PI3-kinase activity was detected by thin layer chromatography of a ^{32}P-labelled phosphatidyl inositol substrate. HG and GLN reduced the basal level of GLUT4 on the PM by 50 ± 9% ($p < 0.005$ n=5) and 80 ± 5% ($p < 0.005$ n=5) respectively, with a concomitant increase in the LDM, suggesting intracellular retention of GLUT4. Lysates and HDM GLUT4 levels were unaltered. HG and GLN reduced the basal level of gp160 by 72 ± 2% ($p < 0.001$ n=4) and 71 ± 2% ($p < 0.0005$ n=4) respectively in LDM, with a concomitant increase in HDM, suggesting retention of gp160 in the endoplasmic reticulum. Lysate gp160 levels were unaltered, suggesting that total gp160 was unchanged. The glycosylation rate of gp160, measured using ^{3}H-mannose incorporation was normal in adipocytes treated with GLN. GLN caused a redistribution of PI3-kinase activity from the particulate, (decreasing by 55 ± 8%, p=0.01 n=4) to the cytosolic fraction. It is concluded that the intracellular retention of GLUT4 caused by acute hyperglycaemia is associated with a hexosamine biosynthesis pathway-mediated decrease of gp160 in LDM and with a redistribution of PI3-kinase activity to the cytosol. It remains to be determined if these events are causally related.

574

EFFECT OF TRIYODOTIRONINE ON GLUT1 mRNA EXPRESSION AND ON ITS SUBCELLULAR DISTRIBUTION IN 3T3-L1 ADIPOCYTES.

E. Rodríguez, R. Romero, B. Casanova, N. Pulido, A. Suárez and A. Rovira.

Triyodotironine (T_3) has an important role in the regulation of glucose metabolism. The aim of this work was to know the effect of T_3 on glucose transport and on the glucose transporter GLUT1 in 3T3-L1 adipocytes. Differentiated cells were incubated in the absence and presence of T_3 (50 nM) for three days. [^{3}H]-2 deoxy-glucose uptake was measured in basal situation. Plasma membranes, low density microsomes and high density microsomes were isolated in order to see the GLUT1 subcellular distribution. Protein GLUT1 was measured by Western-blot and its mRNA levels by Northern-blot. T_3 produced a 4-fold increase (0.5±0.12 vs 0.13±0.05 nmol/500,000 cell/6 min, Mean±EEM, $p<0.05$, n=10) in the basal glucose uptake. Cells treated with T_3 had higher GLUT1 protein levels (761±106 vs 406±108 AU/15 μg of protein, $p<0.05$, n=5) although its percentage in the three subcellular fractions was not modified by this hormone. The specific mRNA levels were similar in the absence and presence of T_3 (2.6±0.7 vs 1.6±0.3 AU/15 μg total RNA, n.s., n=4). In conclusion, thyroid hormone stimulates glucose uptake due, at least in part, to an increase in GLUT1 protein content. The striking discrepancy between GLUT1 mRNA and GLUT1 protein abundance indicates the importance of post-transcriptional regulatory mechanism in the control of GLUT1 expression.

575

5-AMINO-4-IMIDAZOLECARBOXAMIDE RIBOTIDE IS A POTENTIAL MEDIATOR OF GLUCOSE TOXICITY

W. Kirby Gottschalk, Ph.D., GlaxoWellcome, RTP, North Carolina, USA.

Marshall and colleagues demonstrated that a co-product of glucose and glutamine metabolism mediates glucose-elicited desensitization of the glucose uptake system, and identified the likely mediator as glucosamine or a metabolite. Key to their reasoning were the facts that azaserine, an inhibitor of *de novo* glucosamine biosynthesis, blocked desensitization while exogenously added glucosamine induced desensitization in the absence of glucose. Glucose and glutamine metabolism interact at a number of additional azaserine-inhibitable reactions, including key steps in the *de novo* biosynthesis pathway of purines. 5-amino-4-imidazolecarboxamide ribotide (ZMP), an intermediate in this pathway, is a structural analogue of AMP that has significant effects on intermediary metabolism. To learn whether ZMP desensitizes the insulin-stimulated glucose uptake system, primary rat adipocytes were incubated for 5 hours in HEPES buffered salt solution (HBSS) containing 20 mM glucose without or with either 10 ng/mL insulin or 500 μM 5-amino-4-imidazolecarboxamide riboside (AICAR, the dephosphorylated precursor of ZMP), and insulin-stimulated glucose uptake was measured following a 30 minute recovery period in HBSS alone. Incubation with either AICAR or insulin during the induction period reduced subsequent insulin-stimulated glucose uptake by 70% (from 1300 (HBSS w/o AICAR or insulin) to 325 (+AICAR) or 400 (+insulin) dpm, Ave of 3 independent experiments). AICAR was similarly effective in HBSS without added glucose. The AICAR effect was dose-dependent, with an ED_{50} of 250 μM, and the $T_{1/2}$ was 30 minutes. By contrast the $T_{1/2}$ for glucose+insulin mediated desensitization ranged from 50 to 65 minutes (3 independent experiments). The effects of maximal insulin and AICAR were not additive. These data suggest that ZMP may contribute to glucose toxicity as an additional intracellular mediator of glucose-induced desensitization of the glucose transport system.

MECHANISMS OF INSULIN RESISTANCE IN OBESE ZUCKER RATS- TYROSINE PHOSPHORYLATION OF IRS-1 AND PI3-KINASE BINDING AND ACTIVATION ARE REDUCED

Eugénia Carvalho, Cristina Rondinone and Ulf Smith. Lundberg Lab. for Diabetes Research, Depart. of Internal Medicine, Sahlgrenska University Hospital, Gothenburg, Sweden.

The aim of this study was to elucidate the molecular mechanisms for the insulin resistance in obese Zucker rats. Glucose uptake, Glut4 translocation, cellular content of key proteins in the insulin signaling cascade as well as PI3-kinase binding and activity were measured in fat cells from lean and obese Zucker rats of similar age. Insulin increased glucose uptake 4-5 fold in lean animals while obese cells were virtually completely unresponsive to insulin. Glut4 protein content was also reduced accounting for the impaired translocation of the transporters to the plasma membrane in response to insulin. The most pronounced difference in proteins involved in the insulin signaling cascade between lean and obese cells was the marked impairment in insulin-stimulated tyrosine phosphorylation of IRS-1. This impairment far exceeded the slight reduction in IRS-1 protein content in obese cells. Insulin-stimulated PI3-kinase activity was also markedly impaired in the obese cells. Conclusion: Cells from obese Zucker rats exhibit several perturbations in proteins involved in insulin action. However, the most prominent are the low Glut4 protein content and the marked impairment in tyrosine phosphorylation of IRS-1 which in turn is associated with a low binding and activation of PI3-kinase.

HIGH PALMITATE, HIGH GLUCOSE, AND HIGH INSULIN ADDITIVELY BLUNT INSULIN ACTION IN ISOLATED RAT SKELETAL MUSCLE.

M.Bisschop, M.Roden, P.Nowotny, W.Waldhäusl and C.Fürnsinn
Department of Medicine III, Division of Endocrinology & Metabolism, University of Vienna, Vienna, Austria.

Circulating factors believed to contribute to insulin resistance prevailing in obesity and diabetes mellitus include high concentrations of free fatty acids, glucose, and insulin. After 5 h preexposure to high palmitate (1.5 mM), isolated rat soleus muscle strips exhibited decreased rates of insulin-stimulated (10 nM) ^{3}H-2-deoxy-glucose transport (cpm/mg/h, "**GT**": control *vs.* high palmitate, 667±41 *vs.* 529±27, p<0.05) and glycogen synthesis (μmol glucose incorporated into glycogen/g/h, "**GS**": control *vs.* high palmitate, 2.09 ±0.16 *vs.* 1.64±0.18, p<0.02). Insulin desensitization was also found after pretreatment with high glucose (50 mM) (control *vs.* high glucose: **GT**, 620± 41 *vs.* 532±29, p<0.005; **GS**, 1.68±0.14 *vs.* 0.90±0.08, p<0.001) or high insulin (10 nM), which affected glycogen synthesis only (control *vs.* high insulin: **GT**, 633±22 vs. 585±37, n.s.; **GS**, 2.70±0.37 *vs.* 0.89±0.05, p<0.005). We examined the mode of interaction of these factors, and observed a further decrease in insulin action in muscle strips rendered insulin resistant by high palmitate, when additionally exposed to high glucose (high palmitate *vs.* high palmitate + high glucose: **GT**, 608±31 *vs.* 458±23, p<0.001; **GS**, 1.55±0.18 *vs.* 0.97±0.10, p<0.005) or high insulin (high palmitate *vs.* high palmitate + high insulin: **GT**, 520±25 *vs.* 533±36, n.s.; **GS**, 1.76±0.21 *vs.* 1.03±0.09, p<0.01). Likewise, high insulin induced a further decrease in insulin action, when combined with high glucose preexposure (high glucose *vs.* high glucose + high insulin: **GT**, 556±30 *vs.* 436±38, p<0.05; **GS**, 1.69±0.08 *vs.* 0.60±0.05, p<0.001). In conclusion, high concentrations of palmitate, glucose, and insulin decrease insulin-stimulated muscle glucose metabolism in an additive fashion, and will thus independently contribute to insulin resistance *in vivo*.

578

Glucose transporter levels in a spontaneously NIDDM model rat of the male Otsuka Long-Evans Tokushima Fatty (OLETF) strain

K. Toide, Z-W. Man, Y. Asahi, T. Sato, Y. Noma**, Y. Oka*, and K. Shima**
Otsuka Pharmaceutical Co., Ltd., University of Yamaguchi*, and University of Tokushima**, Tokushima, Japan

OLETF rats are NIDDM model animals. To evaluate the role of glucose transporter (GLUT) in the development of diabetes in this model, we examined the action of insulin on the translocation of GLUT4 in isolated adipocytes, GLUT4 protein and GLUT4 mRNA levels in muscles. Long-Evans Tokushima Otsuka (LETO) rats were used as a control strain. In the adipocytes, GLUT4 protein levels in OLETF rats at 30 weeks of age and at a diabetic stage were considerably lower than for the LETO rats. In the prediabetic stage (7 weeks), there were no significant changes in GLUT4 protein levels for either LETO and OLETF rats. The degree of GLUT4 translocation in OLETF rats was lower than that in LETO rats at 7 weeks. In muscles, the decrease in GLUT4 protein was observed in OLETF rats at 30 weeks of age. However, there was no marked difference in GLUT4 mRNA levels between OLETF and LETO rats. The issue of whether such a change is under the influence of hyperglycemia was also examined using rats which were rendered diabetic by 70% pancreatectomy(Px). OLETF rats aged 7 weeks were assigned to partial Px and sham. 4 weeks after surgery, GLUT4 decrease was observed for both tissues of hyperglycemic Px rats compared with euglycemic sham. These findings suggest a defect early in the insulin resistance of OLETF rats probably reflects impaired GLUT4 translocation, intrinsic activation, and/or insulin signaling pathway leading to glucose transporter translocation. GLUT4 decrease, which occurs later in the process appears to be a consequence, rather than a cause of diabetes in OLETF rats.

579

AMYLIN ACTS AS A GROWTH FACTOR DURING THE DEVELOPMENT OF THE RAT KIDNEY

Tikellis C, Wookey P J, Darby I A and Cooper M E. Department of Medicine, University of Melbourne, Austin & Repatriation Medical Centre, Heidelberg West 3081. Australia.

Amylin is a 37-amino acid peptide expressed principally in pancreatic ß-cells in the adult. We have previously demonstrated high affinity binding sites for amylin in the rat renal cortex which have been localised to the proximal tubules. The aim of the present study was to assess gene and protein expression of amylin during embryogenesis with a particular focus on the developing kidney using *in situ* hybridisation and immunohistochemical techniques. Amylin mRNA was transiently expressed between embryo day 17 and postnatal day 7. The location of these amylin gene transcripts was below the nephrogenic zone, associated with the primitive tubules of the developing nephrons. There was no evidence of expression in the normal adult kidney. In the developing kidney (metanephros), amylin peptide could also be detected by immunohistochemistry using a rabbit polyclonal anti-rat amylin antibody (1:2,500), in these primative tubules. In primary cultures of tubular epithelial cells isolated from postnatal day 4 pups, amylin (10^{-7}M) stimulated proliferation of these cells by 125±6% versus control as assesed by incorporation of tritiated thymidine. This stimulation was inhibited by the amylin peptide receptor antagonist, AC512 (91±7% of control). In conclusion amylin is biosynthesized in the developing proximal tubules and acts to stimulate the proliferation of epithelial cells. This role for amylin has implications for our understanding of developmental and pathological processes in the kidney including diabetic nephropathy.

ACTIVATION BY NORADRENALINE OF GLUCOSE TRANSPORT INTO CULTURED BROWN ADIPOCYTES FROM RATS.

T. Shimazu, Y. Shimizu, H. Yano, Y. Minokoshi and S. Satoh.
Department of Medical Biochemistry, Ehime University School of Medicine, Ehime, Japan.

Glucose uptake into brown adipose tissue has been shown to be enhanced directly by noradrenaline (NA) released from sympathetic nerves. In this study we analyzed the mechanism of NA-induced increase in glucose transport using cultured brown adipocytes, which responds to NA as well as insulin. NA and insulin independently stimulated glucose uptake. The effect of NA was mimicked by the β_3-adrenergic agonist, BRL37344, at concentrations much lower than NA. Dibutyryl-cAMP also mimicked the stimulatory effect of NA, and the antagonist of cAMP, cAMP-S Rp-isomer, blocked the NA effect. Insulin caused the increase in the content of GLUT4 glucose transporter in the plasma membrane, whereas NA did not affect the subcellular distribution of GLUT4 as well as that of GLUT1. NA decreased pronouncedly the *Km* value for glucose uptake. Photoaffinity labelling of the exofacial glucose binding sites of GLUT1 and GLUT4 with a membrane-impermeant bismannose derivative revealed that NA increased the labelling of cell surface GLUT1, but not of cell surface GLUT4, without increase in the GLUT1 protein in the plasma membrane. The NA-induced increase in photoaffinity labelling of GLUT1 was completely suppressed by the cAMP antagonist. These results suggest that the mechanism by which NA stimulates glucose transport into brown adipocytes is not due to the recruitment of GLUT1 or GLUT4, but due to an increase in the functional activity of GLUT1, which is mediated by a cAMP-dependent pathway.

B CELL PEPTIDES INFLUENCE ISLET AMYLOID POLYPEPTIDE (IAPP) FIBRIL FORMATION *IN VITRO*

S. Janciauskiene[1], S. Eriksson[1], E. Carlemalm[2] and B. Ahrén[1],
[1]Departments of Med., Lund University, Malmö and [2]The Electron Microscopy Unit, Lund University, Lund, Sweden

Amyloid deposits in pancreatic islets in noninsulin-dependent diabetes mellitus (NIDDM) consist mainly of islet amyloid polypeptide (IAPP). The mechanism of the IAPP fibril formation is unclear. We examined whether the B cell granule peptides, insulin, C-peptide and pancreastatin affect the formation of ß-pleated sheet fibrils *in vitro* from human IAPP. Samples of 32 µmol/l IAPP in Tris buffered saline, pH 7.4, with or without each of the three peptides, were incubated for 48 hrs and fibril formation was examined by electron microscopy, by measuring the radioactivity of soluble IAPP after adding trace amount of ^{125}I-labelled IAPP and by thioflavine (ThT) fluorescence spectroscopy. Under control conditions, IAPP spontaneously formed fibrils, as evident by all three techniques. As judged by electron microscopy, insulin and pancreastatin at ratios 10:1 or 100:1 (peptide:IAPP) inhibited fibril formation, whereas C-peptide had no effect. In contrast, at ratios 1:10 or 1:100, i.e., IAPP in excess, all three peptides increased fibril formation. As quantified by radioassay and ThT fluorescence spectroscopy, insulin, C-peptide and pancreastatin inhibited fibril formation by 60-100% at ratio 100:1 (peptide:IAPP), whereas a potentiated IAPP fibril formation was observed at ratios of each of the three peptides to IAPP of 1:10 and 1:100, i.e., IAPP in excess. We conclude that IAPP fibrillisation is influenced by other B cell secretory granule peptides in a molar ratio dependent manner, which might be of importance for IAPP fibril formation and the cause of islet amyloidosis in NIDDM.

DIRECT STIMULATION BY α-LIPOIC ACID OF GLUCOSE TRANSPORT IN SKELETAL MUSCLE OF ZUCKER RATS.

R.S. Streeper, S. Jacob, D.L.Fogt, H.J. Tritschler, and E.J. Henriksen.
University of Arizona, Tucson, U.S.A.; Eberhard-Karls-Universität, Tübingen, Germany; and ASTA Medica, Frankfurt, Germany

α-Lipoic acid (ALA), a potent biological antioxidant, improves insulin action of skeletal muscle glucose transport and metabolism in both human and animal models of insulin resistance. In order to obtain further insight into the potential intracellular mechanisms for the action of ALA on insulin-stimulated glucose transport in skeletal muscle, we investigated the effects of direct incubation with ALA on 2-deoxyglucose (2-DG) uptake by epitrochlearis muscle from either insulin-sensitive lean (*Fa/-*) or insulin-resistant obese (*fa/fa*) Zucker rats. ALA (2 mM) stimulated 2-DG uptake in muscle of lean animals by 76%, whereas ALA stimulated 2-DG uptake by only 48% ($p<0.05$ vs. lean) in muscle from the obese animals. The stimulation of 2-DG uptake due to ALA was enhanced 30-55% in the presence of insulin in muscle from lean and obese animals. In contrast, ALA action on 2-DG uptake was not additive with the effects of electrically-stimulated muscle contractions in either insulin-sensitive or insulin-resistant muscle. Wortmannin (1 µM), an inhibitor of phosphotidyl-inositol-3-kinase, completely inhibited insulin action on 2-DG uptake, but had no effect on contraction-stimulated 2-DG uptake. Wortmannin inhibited ALA action on 2-DG uptake by only 25% in muscle from either lean or obese Zucker rats. Collectively, these results indicate that although a portion of ALA action on glucose transport in skeletal muscle is mediated via the wortmannin-sensitive insulin signal transduction pathway, the majority of the direct effect of ALA on this process is insulin-independent.

IS NON-INSULIN-DEPENDENT DIABETES MELLITUS ALZHEIMER'S DISEASE OF THE ISLET?

J. Janson, J.E. Parisi, R.C. Petersen and P.C. Butler*. Mayo Clinic, Rochester MN, U.S.A. and *University of Edinburgh, Edinburgh, Scotland.

Brain dysfunction in Alzheimer's disease (AD) is associated with loss of cortical neurons with deposition of amyloid deposits of a locally expressed protein (ß protein). Impaired insulin secretion in non-insulin-dependent diabetes mellitus (NIDDM) is associated with loss of ß cells with deposition of islet amyloid polypeptide derived amyloid deposits. Both AD and NIDDM have strong genetic components with increased phenotype expression with aging. It has been proposed that islet and cerebral amyloidosis are cytotoxic and important in pathogenesis of these diseases. A defect may be common to both diseases. We therefore asked the question is islet amyloid increased in patients with AD? We studied pancreas obtained at autopsy from 28 AD cases (diagnosed in life and confirmed at death) versus 21 cases without AD (non-AD, also diagnosed in life and at death) matched for age but selected at random for presence or absence of diabetes. Prevalence (%) and extent (scale 0-4) of islet amyloid was compared on Congo red sections of the tail of pancreas. Islet amyloid was more prevalent (13.9 vs. 4.4, $P < 0.05$) and extensive (0.40 vs. 0.10, $P < 0.05$) in AD versus non-AD despite a lower BMI (24.3 vs. 27.1 kg/m^2 AD vs. non-AD, $P = 0.06$). Prevalence of NIDDM and mean fasting plasma glucose were slightly (but not significantly) higher in AD than non-AD. We conclude that islet amyloid is increased in patients with Alzheimer's disease implying that there may be an underlying defect in protein trafficking in AD and NIDDM.

BRADYKININ ENHANCES GLUT4 TRANSLOCATION IN DOG SKELETAL MUSCLES AND RAT L6 MYOBLASTS

M. Uehara, T. Taguchi, K. Kaneko, N. Miyamura, H. Kishikawa and M. Shichiri. Department of Metabolic Medicine, Kumamoto University School of Medicine, Kumamoto, Japan

We previously demonstrated that bradykinin infusion could increase glucose uptake into dog peripheral tissues(Diabetologia 37:300-307), and that bradykinin could potentiate insulin induced glucose uptake through GLUT4 translocation in dog adipocytes(Diabetologia 39:412-420). However, it is well known that skeletal muscle is the predominant tissue for insulin mediated glucose disposal. In this study, we evaluated whether bradykinin B2 receptor was expressed in dog skeletal muscles and rat L6 myoblasts, and how bradykinin can affect glucose uptake especially in the insulin signalling pathway and translocation of GLUT4. The bradykinin receptor binding studies revealed that dog skeletal muscles and L6 myoblasts possessed significant numbers of bradykinin receptors (Kd = 88, 76 pmol/l, Bmax=2.5, 20 fmol/mg protein, respectively). An RT-PCR amplification showed the mRNA specific for bradykinin B2 receptor in each cells. Bradykinin significantly increased 2-deoxyglucose uptake in a dose dependent manner in the presence of insulin (10^{-7} mol/l). Bradykinin also enhanced insulin stimulated GLUT4 translocation, and insulin induced phosphorylation of insulin receptor β subunit and IRS-1 without affecting the binding affinities or numbers of cell surface insulin receptors in both cells.

It is concluded that bradykinin could potentiate the insulin induced glucose uptake through GLUT4 translocation. This effect could be explained by the potency of bradykinin to upregulate the insulin receptor tyrosine kinase activity which stimulates phosphorylation of IRS-1, followed by GLUT4 translocation.

585

INTACT BUT NOT TRUNCATED des(27-31) RAT C-PEPTIDE STIMULATES β-CELL Na^+,K^+-ATPase ACTIVITY.

J. Wahren, A. Bertorello, S. E. Kahn, C. B. Verchere, B-L. Johansson and P. A. Halban. Karolinska Institute, Stockholm, Sweden; University of Washington, Seattle, USA; University of Geneva, Geneva, Switzerland.

Recent experiments have demonstrated that C-peptide exerts a stimulatory effect on Na^+,K^+-ATPase activity in several tissues including renal, β- and nerve cells. It has also been found that C-peptide (produced during conversion of proinsulin to insulin) may be truncated in secretory granules and this truncated form lacking the last 5 amino acids (des-(27-31)C-peptide) is released from β-cells in response to classical secretogogues. In the present study the possible effect of such truncation on C-peptide's ability to stimulate Na^+,K^+-ATPase was examined. Single microdissected islets from adult normoglycemic *ob/ob* mice were used as they are made up almost exclusively of β-cells. Na^+,K^+-ATPase activity was determined from the hydrolysis of ^{32}P-ATP in the presence and absence of ouabain. When islets were incubated with synthetic rat C-peptide II there was a linear, concentration dependent stimulation of Na^+,K^+-ATPase activity in the range 10^{-10} - 10^{-7}M. Thus, 10^{-7}M C-peptide increased Na^+,K^+-ATPase activity 2.3 ± 0.1 fold above basal ($P < 0.01$). In contrast, synthetic rat des(27-31) C-peptide II exerted no detectable stimulatory effect (2±2% of C-peptide's effect) even at 10^{-7}M. These findings suggest that truncation of C-peptide in granules prior to secretion may be a physiological mode of C-peptide inactivation.

586

GLUCOSE METABOLISM IS STIMULATED BY PRIOR CONTRACTION IN INSULIN RESISTANT SKELETAL MUSCLE

B. Leighton, J. Franch, D. Leendertse, R. Aslesen, M.E. Young, P. Cassidy and J. Jensen. University of Oxford, U.K. and University of Oslo, Norway

Both during and after exercise there is increased glucose utilization in skeletal muscle. The mechanism(s) responsible for stimulation of glucose metabolism post-contraction (PC) require(s) identification. The aim of this study was to determine whether glucose metabolism is altered in skeletal muscle by prior contraction. We measured rates of glycogen synthesis (from [^{14}C]glucose, μmol/h/g dry wt.) in soleus (Type I fibres) and epitrochlearis (Type II fibres) muscles rested for 1 h, after being contracted *in vitro* for 30 min. The greatest effects on the rates of glycogen synthesis were by PC in epitrochlearis muscles and by insulin in soleus muscles. The effects of insulin and PC were additive in both muscle preparations.

	[Epitrochlearis]	[Soleus]	
Basal (no insulin)	2.2±0.3	3.3±0.4	
Insulin (10000 μU/ml)	16.6±1.4*+	34.5±1.7*	*P<0.0001 from basal
PC	19.9±1.7*+	11.9±1.0*	+P<0.0002 from soleus
PC and Insulin	30.1±2.4*+	41.2±0.9*	

The PC effects on glucose transport (^{3}H-2-deoxyglucose uptake, 2-DOG) were determined in insulin sensitive (lean, *Fa/?*) and resistant (obese, *fa/fa*) epitrochlearis muscles isolated from Zucker rats. In the presence of a basal insulin concentration (10 μU/ml), rates of 2-DOG transport (all results given as dpm/h/mg wet wt.; n≥5) were lower in epitroclearis muscles from obese (127±8, P<0.001) versus lean (206±18) rats. The rates of 2-DOG transport were significantly increased in resting muscles during the hour after 30 min of contraction for both lean (393±34, PC, versus 206±18, not stimulated, P<0.001) and obese (192±8, PC, versus 127±8, not stimulated, P<0.001) rats. This demonstrates that PC effects occur in both insulin sensitive and insulin resistant skeletal muscle. The present study highlights the significant post-contraction effects on glucose metabolism in muscles with Type II fibres that causes increased rates of 2-DOG transport in insulin resistant muscle.

587

C-PEPTIDE FRAGMENTS STIMULATE RENAL TUBULE Na^+,K^+-ATPase ACTIVITY.

J. Wahren, Y. Ohtomo, B-L. Johansson, T. Bergman, A. Aperia, H. Jörnvall, Karolinska Hospital, St. Görans Hospital, Karolinska Institute, Stockholm, Sweden.

C-peptide has been shown to stimulate Na^+,K^+-ATPase (NKA) activity in tissues including renal tubule cells, glomeruli, β-cells and nerve. Active sites in the C-peptide molecule have not been determined. Consequently, in the present study the influence of several different fragments of C-peptide on rat renal tubule NKA activity was examined. NKA activity was assessed as ouabain-sensitive ATP hydrolysis in single proximal tubule segments dissected from collagenase perfused rat kidneys. Rat C-peptide elicited a dose dependent increase in NKA activity in the range 10^{-8} - 10^{-6}M. The C-terminal penta (EVARQ) and tetrapeptides (VARQ) of C-peptide also stimulated NKA activity at $5{\cdot}10^{-7}$M, possessing 103 ± 5% and 92 ± 6%, respectively, of the equimolar intact C-peptide's activity. Likewise, fragments from the middle portion of the C-peptide molecule (ELGG, 36 ± 3%; ELGGGP, 46 ± 5%; ELGGGPEAG, 80 ± 7%) were able to significantly stimulate NKA activity. The non-native d-form of the dipeptide LG but not its l-form stimulated NKA activity. The findings are consistent with specific activity and binding interaction of a C-terminal segment of C-peptide as well as other non-specific effects possibly reflecting the complex enzyme assay.

588

EFFECTS OF GLUCOCORTICOIDS ON THE SENSITIVITY OF GLUCOSE DISPOSAL TO INSULIN IN SKELETAL MUSCLE

G. Dimitriadis*, B. Leighton, S. Sasson+, M. Young, E. Azas*, V. Komesidou*, S. Raptis* and E. Newsholme. Departments of *Medicine, Biochemistry and +Pharmacology, Universities of *Athens, Greece, Oxford, UK and +Jerusalem, Israel.

Glucocorticoids induce resistance of glucose disposal (GD) to insulin, but the mechanisms are unclear. We examined the effects of in-vivo injections of dexamethasone (DX) to rats (0.5 mg/day i.p., 5 days) on the sensitivity to insulin of glucose transport (GT, 3-O-methyl[^{3}H]glucose), glycogen synthesis (GS, [^{14}C]glucose), glucose oxidation (GO, [^{14}C] glucose) and on the total content (CGLUT4, Western blots, [WB]) and insulin-stimulated (100 mU/l) translocation of GLUT4 transporters to the plasma membrane (TGLUT4, surface biotinylation of muscle and WB) in soleus muscle incubated in-vitro. DX decreased GT (2.1±0.1 and 2.6±0.1 vs 3.0±0.2 and 3.9±0.3 µmol/h/g), GS (1.0±0.1 and 1.6±0.1 vs 2.6±0.2 and 4.0±0.2 µmol/h/g), and GO (0.4±0.05 and 0.3±0.01 vs 0.5±0.07 and 0.7±0.03 µmol/h/g) vs control at 10 and 100 mU/l insulin respectively, $p<0.01$; all rates at 1000 mU/l insulin were normal. CGLUT4 was not decreased after DX (scanning analysis of WB band densities, arbitrary units: 1089±30 vs 1226±39 in control for the 54 kDa and 413±59 vs 461±30 for the 44 kDa GLUT4); however, TGLUT4 was lessened by 60% (fold-increase in WB band density: 1.68±0.04 and 1.77±0.06 in control and 1.07±0.06 and 1.08±0.10 in DX for the 54 kDa and 44kDa GLUT4 respectively, $p<0.01$). **Conclusions:** 1) Glucocorticoids decrease GD in muscle by inducing resistance of GT, GS and GO to insulin. 2) The effect on GT is due to a decrease in insulin-stimulated translocation of GLUT4 transporters to the plasma membrane.

589

GIP stimulates the secretion of GLP-1 from canine L-cells through a Protein Kinase A dependent pathway.

A. B. Damholt♠, A.M.J. Buchan♥, H. Kofod♠.♠Diabetes Discovery, Novo Nordisk A/S, Denmark.♥, Dep. Physiology, University of British Columbia, Canada.

We have studied the secretion of Glucagon Like Peptide 1 (GLP-1) from canine L-cells in short term culture. The response of the cells to increasing concentrations of Glucose-dependent Insulinotropic Peptide (GIP) was compared with response to Forskolin and Phorbol Myristate Acetate (PMA) in the presence or absence of Protein Kinase A inhibitor H8 and Protein Kinase C inhibitor Staurosporin, respectively. Single L-cells were isolated by centrifugal elutriation from epithelial cell preparations of canine ileum (Beagle). The cell fractions enriched for GLP-1 content were maintained in culture for 2 days in growth medium prior to the initiation of the release experiments. The cells were then serum-starved for 2 h and then incubated for 2 h under the following conditions: GIP (10^{-12}-10^{-7} M); PMA (10^{-10}-$4x10^{-7}$ M) in the presence and absence of Staurosporin (10^{-6} M); GIP (10^{-7} M) in the presence and absence of Staurosporin (10^{-6} M) and PMA ($4x10^{-7}$ M); Forskolin (10^{-9}-10^{-6} M) in the presence and absence of H8 (10^{-6} M); GIP (10^{-7} M) in presence and absence of H8 (10^{-6} M) and Forskolin (10^{-6} M). The glucose concentration was 5.5 mM in all experiments. Immunoreactive GLP-1 in supernatant and in extract from attached cells was measured and the results presented as percent of total GLP-1 normalised to either basal or GIP (10^{-7} M). Compared to basal, GLP-1 was dose-dependently released from the L-cells by GIP (2 fold at 10^{-7} M), PMA (4 fold at $4x10^{-7}$ M) and Forskolin (3 fold at 10^{-6} M). The two latter were significantly inhibited by Staurosporin and H8, respectively. The effect of GIP (10^{-7} M) was additive to PMA and not changed by Staurosporin. The combined effect of the GIP and PMA was reduced by Staurosporin. The effect of GIP (10^{-7} M) was not additive to Forskolin but significantly inhibited by H8. The inhibition of GIP effect was not altered by the presence Forskolin. Based on these data we suggest that the secretion of GLP-1 from canine L-cells can be stimulated both through a Protein Kinase C and A dependent pathway, and that the effect of GIP is mediated through a Protein Kinase A dependent pathway.

590

EFFECT OF THE ADDITION OF GLICLAZIDE TO INSULIN TREATMENT ON MUSCLE GLUCOSE UPTAKE FROM DIABETIC RATS

N. Pulido, A. Suárez, B. Casanova, R. Romero, E. Rodríguez and A. Rovira. Fundación Jiménez Díaz (U.A.M.). Madrid. Spain.

We have previously shown that gliclazide directly stimulates glucose uptake in perfused rat hindquarters. The aim of this work was to determine whether the addition of gliclazide at the insulin treatment in diabetic rats leads to an increase in muscle glucose uptake. Streptozotocin diabetic Wistar rats were treated for 12 days with either insulin alone (3 units NPH s.c./day, Group I, n=5) or oral gliclazide (5 mg/Kg twice a day p.o.) plus 3 units insulin/day, Group G+I, n=5). A non-diabetic group was used as a control (Group C, n=11). Mean glycemic value throughout the treatment period was lower in Group G+I than in Group I (98±5 vs 139±15 mg/dl, mean±SEM, $p<0.05$) without changes in serum C peptide levels. After 12 days of treatment, both basal and insulin-stimulated (10^{-9} and 10^{-7} M) glucose uptake by the perfused hindquarters were measured. Basal glucose uptake in both groups of diabetic rats were similar to the control group. Insulin stimulated glucose uptake in Group G+I was significantly higher than Group I (Ins 10^{-9}: 8.0±0.3 vs 5.8±0.6, Ins 10^{-7}: 12.0±0.6 vs 8.5±0.6 µmol/g/h, $p<0.05$) and similar to Group C (Ins 10^{-9}: 9.2±0.6, Ins 10^{-7}: 13.4±0.9 µmol/g/h). In partially purified solubilized receptors from skeletal muscle, the insulin binding and the tyrosine kinase activity were similar in the two groups of diabetic rats. In conclusion, the addition of gliclazide to the insulin treatment in diabetic rats normalized the insulin-stimulated glucose uptake by a post-receptor mechanism.

591

EFFECTS OF GLP-1 ON THE KINETICS OF GLYCOGEN SYNTHASE ACTIVITY IN HEPATOCYTES FROM NORMAL AND DIABETIC RATS.

M.I. López-Delgado, M.L. Villanueva-Peñacarrillo, W.J. Malaisse* and I. Valverde. Fundación Jiménez Díaz, Madrid, Spain and *Laboratory of Experimental Medicine, Brussels Free University, Brussels, Belgium.

Glucagon-like peptide 1(7-36)amide (GLP-1) was previously found to activate glycogen synthase in hepatocytes from both normal and diabetic rats. In the present study, the kinetic aspects of such an activation were investigated. Hepatocytes were isolated from overnight fasted male normal Wistar rats and animals that had been injected with streptozotocin either during the neonatal period or at the adult age. The hepatocytes were incubated for 15-20 min, being exposed to 16.7 mM glucose and, as required, either insulin or GLP-1 during the last 5-10 min of incubation. The reaction velocity was measured in cell homogenates over 15 min incubation, at which time it had reached a steady-state value. In both normal and diabetic rats, the increase in glycogen synthase activity caused by GLP-1 was concentration related in the 10^{-12} to 10^{-8} M range, progressively rising from 18±3 to 37±3%. At all hormone concentrations the relative extent of enzyme activation was lower in fed rats than in overnight fasted animals, the former value averaging 63.8±2.5 % of the latter one. In the starved rats, the relative extent of synthase activation by either insulin or GLP-1 progresively decreased when the glucose concentration of the incubation medium was lowered to 8.8 mM or less. At high concentrations of the hormones, activation of synthase reached a steady-state value within 1-5 min exposure of the hepatocytes to either insulin or GLP-1, in both normal and diabetic rats. At increasing concentrations of UDP-glucose (0.1 to 5.0 mM), the reaction velocity yielded a Km close to 0.4 mM. The affinity of synthase *a* for UDP-glucose tended to be higher in diabetic than in normal rats, and to be lowered by GLP-1. These findings indicate that the activation of liver glycogen synthase by GLP-1 displays attributes of rapidity, sensitivity and nutritional dependency that are well suited for both participation in the physiological regulation of enzyme activity and therapeutic purpose.

592

CONCOMITANT EXPRESSION OF TWO RAB PROTEINS IS REQUIRED FOR INSULIN-STIMULATED GLUCOSE TRANSPORT IN CARDIAC MUSCLE CELLS

O. Dransfeld, I. Uphues, H. Lämmerhirt, A. Schürmann*, H.G. Joost* and J. Eckel. Molecular Cardiology, Diabetes Research Institute, Düsseldorf and *Dept. of Pharmacology, University of Aachen, Aachen, Germany

The major mechanism mediating insulin induced glucose uptake in adipocytes, skeletal and cardiac muscle is known to be translocation of the glucose transporter isoform GLUT4 from an intracellular storage site to the plasma membrane. Several lines of evidence suggest that Rab-proteins could also be involved in the regulation of this mechanism, however, functional implications of these small GTP-binding proteins in cardiac glucose uptake have not been investigated so far. H9c2 cardiac myoblasts stably overexpressing the glucose transporter isoform GLUT4 (H9c2-K6) were transiently transfected with Rab4A-cDNA, Rab3C-cDNA or co-transfected with both Rab-cDNAs and basal and insulin stimulated 2-deoxyglucose (2-DOG) transport was assayed. In transfected cells Rab4A and Rab3C were markedly overexpressed, both were not detectable in the controls transfected with blank vector. These controls exhibit basal 2-DOG uptake increased by about 100 % with no further effect of insulin. In cells transfected with Rab4A-cDNA basal 2-DOG uptake was decreased by about 25 % and 60 min insulin stimulation had no significant effect. In contrast, myoblasts transfected with Rab3C-cDNA showed no significant decrease in basal 2-DOG uptake but insulin stimulation resulted in a slightly increased transport rate. Under basal conditions the co-transfection of Rab4A- and Rab3C-cDNAs together resulted in a 55 % decreased 2-DOG uptake in the GLUT4-overexpressing clone in contrast to control H9c2-myoblasts, which showed no change in glucose transport under the same conditions. Furthermore stimulation with insulin resulted in a 2fold increase in 2-DOG uptake in the clonal cell line transfected with both Rab-cDNAs.

In conclusion, our data show that neither Rab4A nor Rab3C alone are sufficient to mediate insulin stimulated glucose uptake but that co-expression renders the cells insulin sensitive. Thus, we suggest that these Rab isoforms are involved in the regulation of both basal and insulin activated glucose transport in a coordinated and synergistic fashion. (Supported by DFG, SFB 351 C2)

593

EFFECT OF GLP-1 ON GLUCOSE TRANSPORTERS IN LIVER, MUSCLE, AND ADIPOSE TISSUE OF DIABETIC RATS

J. Puente, F. Clemente, A. Redondo, I. Valverde and M.L. Villanueva-Peñacarrillo. Fundación Jiménez Díaz, Madrid, Spain.

GLP-1(7-36)amide (GLP-1) has been proposed as a therapeutical agent in NIDDM, and it was found that the peptide exerts insulin actions in some extrapancreatic tissues. In this work we have explored, by Dot-Blot analysis, whether GLP-1 treatment affects the levels of glucose transporters in liver (GLUT-2 and GLUT-1), muscle and adipose tissue (GLUT-4 and GLUT-1) membranes, from rats treated with streptozotocin in the adult age (IDDM) or at day 1 of birth (NIDDM), receiving no treatment or either GLP-1 (0.4 nmol/kg/h) or insulin (450 mU/kg/h) through an osmotic pump during three days. Tissues from untreated normal rats were included as controls. **In the liver**, GLUT-2 was augmented in IDDM (126 ± 11% of normals, $n=3$, $p<0.05$) and decreased in NIDDM (39 ± 5, $n=3$, $p<0.05$), and its levels were normalized in both types of diabetes by either GLP-1 or insulin treatment; GLUT-1 was decreased in NIDDM rats (55 ± 4%, $n=3$, $p<0.05$) and neither treatment modified its level, while in IDDM, insulin treatment increased by 2-fold the GLUT-1 content. **In the muscle**, GLUT-4 was reduced in IDDM rats (55 ± 3%, $n=6$, $p<0.001$), and insulin or GLP-1 treatment normalized its level, and induced a 2-fold increase in GLUT-4 and GLUT-1 content in NIDDM rats. **In adipose tissue**, GLUT-4 levels were decreased in IDDM (50 ± 10%, $n=3$, $p<0.001$) and in NIDDM (24 ± 4%, $n=3$, $p<0.001$) rats, and either insulin or GLP-1 treatment normalized them; GLUT-1 was also decreased in IDDM (59 ± 4%, $n=3$, $p<0.001$) and NIDDM (46 ± 7%, $n=3$, $p<0.001$) rats, and the treatment with insulin decreased, even more, the GLUT-1 content in NIDDM rats. These results add support to the role of GLP-1 in the *in vivo* overall glucose disposal.

594

INSULIN AND CYCLIC AMP REGULATION OF GLUT4 TRANSLOCATION TO THE CELL SURFACE OF INTACT ADULT MYOBLASTS

A. B. Bentz and C. Reynet. Diabetes Discovery, Novo Nordisk, Denmark

Insulin and contraction are the major physiological stimuli of the glucose transport system in skeletal muscle. They each act mainly by recruiting GLUT4 transporters from intracellular vesicles to the plasma membrane, but apparently by different, and as yet unknown, mechanisms. We investigated the regulation of glucose transport and GLUT4 translocation in C2C12 adult murine skeletal muscle cells stably expressing myc-epitope tagged GLUT4 (GLUT4myc). We measured in parallel 2-deoxyglucose (2-DG) uptake and cell surface GLUT4myc content (by myc-antibody binding) in intact cells. Insulin stimulated 2-DG uptake in C2C12 myoblasts expressing GLUT4myc in a concentration-dependent manner from 3.7 ± 0.6 nmol/mg protein/min without insulin to 5.9 ± 0.7 nmol/mg protein/min with 10^{-6} M insulin for 20 min incubation (in parental myoblasts which have no endogenous GLUT4, the corresponding values were 1.9 and 2.6 nmol/mg protein/min). In C2C12-GLUT4myc myoblasts, insulin increased cell surface GLUT4myc content in a time- and concentration-dependent manner with a maximum 2.7 ± 0.3-fold increase after 20 min incubation with 10^{-6} M insulin. We then examined the effect of cyclic AMP (cAMP) levels on GLUT4 translocation using forskolin, a direct activator of adenylate cyclase. Increasing concentrations of forskolin stimulated concomitantly intracellular production of cAMP (2.7 ± 0.3-fold increase at 10^{-5} M forskolin) and cell surface GLUT4myc content (1.6 ± 0.1-fold increase at 10^{-5} M forskolin). Furthermore, the forskolin effect on GLUT4 translocation appeared to be additive to the effect of insulin (3.6 ± 0.1-fold increase with forskolin 10^{-5} M plus insulin 10^{-7} M vs 2.2 ± 0.1-fold increase with insulin alone). In addition, wortmannin, an inhibitor of phosphatidylinositol 3-kinase, suppressed the action of insulin on 2-DG uptake and GLUT4 translocation in a dose-dependent manner (maximum effect 50-100 nM), but not the action of forskolin. Forskolin and cytochalasin B, which both bind to glucose transporters, inhibited 2-deoxyglucose uptake, however cytochalasin B did not increase cell surface GLUT4myc content. Thus, our data suggest that cAMP stimulates GLUT4 translocation to the plasma membrane independently of insulin, and that the C2C12-GLUT4myc myoblasts are a useful system for studying different signalling mechanisms leading to activation of glucose transport.

595

SOMATOSTATIN BUT NOT INSULIN IS AN IMPORTANT PARACRINE REGULATOR OF GLUCAGON SECRETION IN RAT A-CELLS

Erik Renström, Jesper Gromada & Patrik Rorsman. Dept. Islet Cell Physiology, Novo Nordisk, Fruebjergvej 3, Copenhagen, Denmark.

High-resolution capacitance measurements were used to explore the effects of somatostatin and insulin on Ca^{2+}-dependent exocytosis in glucagon-secreting rat pancreatic A-cells obtained by fluorescence-activated cell sorting. This was investigated using the perforated patch whole-cell configuration and increases in cell capacitance were recorded in response to 500 ms voltage-clamp depolarizations from -70 mV to 0 mV applied at 2 min interval. Membrane depolarization was associated with activation of voltage-gated Ca^{2+} current, increased cytoplasmic free Ca^{2+} ($[Ca^{2+}]_i$) and stimulation of Ca^{2+}-dependent exocytosis. Addition of the β-adrenergic agonist isoprenaline or the gut hormone glucagon-like peptide 1(7-36)amide [GLP-1(7-36)amide] potentiated Ca^{2+}-dependent exocytosis by >3-fold. The stimulatory actions of isoprenaline and GLP-1(7-36)amide were completely antagonized by somatostatin (400 nM) which was only associated with approximately 25% reduction in the whole-cell Ca^{2+} current and the increase in $[Ca^{2+}]_i$. The strong inhibition of somatostatin was reproduced in the standard whole-cell patch-clamp configuration in which the cytoplasmic cAMP concentration was clamped to 0.1 mM. This suggests that the ability of somatostatin to suppress exocytosis is unlikely to reflect inhibition of adenylate cyclase or involves a diffusional messenger. Interestingly, insulin (10-100 nM) had no effect on either depolarization-evoked whole-cell Ca^{2+} current or the associated exocytotic response. We propose that somatostatin is an important paracrine regulator of glucagon secretion from the A-cell which principally reflects interference with a late step in the stimulus-secretion coupling and that release of somatostatin from the D-cells, rather than insulin, accounts for the reported inhibitory action of GLP-1 on glucagon secretion in vivo.

596

IMPAIRED STIMULATION OF THE NITRIC OXIDE/cyclicGMP SYSTEM AND GLUCOSE UPTAKE IN INSULIN RESISTANT MUSCLE

M.E. Young, G.K. Radda and B. Leighton. University of Oxford, U.K.

Nitric oxide, which is generated in skeletal muscle by nitric oxide synthase, stimulates glucose transport and metabolism. Nitric oxide release from skeletal muscle is stimulated by contraction. Nitric oxide probably stimulates glucose utilisation by activation of guanylate cyclase leading to increased cyclicGMP formation. Zaprinast inhibits the enzyme, cyclicGMP phosphodiesterase (which hydrolyses cyclicGMP), thus leading to an increase in cyclicGMP levels in skeletal muscle. Since increasing cyclicGMP levels are associated with increased rates of glucose utilisation the main aim of the present study was to investigate the effects of zaprinast (27 μM) on glucose utilisation in soleus muscles isolated from insulin sensitive (lean Zucker) and insulin resistant (obese Zucker) rats. Zaprinast significantly increased the rates (all results given as units μmol/h/g wet wt.) of ^{14}C-lactate release (a good indicator of glucose transport) (7.38±0.68 (6), zaprinast (Z) versus 4.68±0.47 (6), control (C); $P<0.01$) and glycogen synthesis (3.42± 0.39 (Z) versus 1.79±0.05 (C); $P<0.001$) in soleus muscle preparations from lean Zucker rats . Zaprinast failed to stimulate ^{14}C-lactate release (3.11±0.32 (Z) versus 2.59±0.23 (C)) or glycogen synthesis (1.02±0.08 (Z) versus 0.99±0.13 (C)) in incubated soleus muscle preparations isolated from obese Zucker rats. Zaprinast caused a significant increase in cyclicGMP content (80%) in soleus muscles isolated from lean rats, but zaprinast had no effect on cyclicGMP content in soleus muscles isolated from obese rats. These results suggest that in resting skeletal muscle from obese Zucker rats the activity of the endogenous nitric oxide/cyclicGMP system is altered. Future studies will establish if this system can be activated in insulin resistant skeletal muscle (e.g. by contraction) to yield increased rates of glucose utilisation.

CATECHOLAMINE MODULATION OF GLUCAGON SECRETION IN CLONAL PANCREATIC ALPHA CELLS

A.S.Rajan, Baylor College of Medicine, Houston, USA

In diabetes, the frequent and often dangerous occurrence of hypoglycemia is attributable to impaired glucose counterregulation, which is normally mediated by several hormones including the catecholamines and glucagon. The difficulty in using normal pancreatic α-cells and the lack of good alternate *in vitro* models have retarded our understanding of the hormonal regulation of α-cell glucagon secretion. In earlier studies, I have established that the clonal cell line αTC-6, is a useful practical tool for studying the regulation of α-cell glucagon secretion, by demonstrating that the physiological secretagogues arginine and potassium modulate glucagon release in these cells. In the present study I have further characterized the physiology of αTC-6 cells by examining the effects of amino-acids and the catecholamine, epinephrine. The αTC-6 cells were plated in conventional tissue culture- ware and glucagon secretion monitored in static incubation assays. Arginine stimulates glucagon release in a dose-dependent fashion (1-10 mM) with a maximal 2-fold increase over basal levels at 10 mM arginine. An amino-acid mixture consisting of alanine, glutamine and arginine (total 6 mM) also enhances glucagon release. The amino-acid mixture induced a 1.6-fold increase in secretion over basal levels (basal: 20.0 ± 5.8 (S.E.), amino-acid mix: 31.3 ± 2.9 pg/min/well). Epinephrine (1 μM) by itself had no appreciable effect on basal glucagon release (20.3 ± 7.5 pg/min/well). However, in the presence of the amino-acid mixture, epinephrine induced a synergistic effect with a potentiation of stimulated glucagon release to a 2-fold increase over basal levels (40.6 ± 7.0 pg/min/well). In contrast, epinephrine inhibited insulin secretion from clonal beta (HIT) cells. These results are consistent with earlier observations in purified alpha cells by Pipeleers and coworkers. Our results demonstrate the interplay between counterregulatory hormones and further studies with this alpha cell model (αTC-6) may enhance our understanding of the molecular mechanisms involved in the glucose-counterregulatory response and its aberration in diabetes.

ROLE OF OXIDATIVE STRESS IN THE REGULATION OF GLUCOSE TRANSPORT IN VASCULAR SMOOTH MUSCLE CELLS

S. Sasson, A. Davarashvili, *N. Kaiser, *E. Cerasi and R. Reich. Departments of Pharmacology and *Endocrinology & Metabolism, Hebrew University-Hadassah Medical Center, Jerusalem, Israel.

This study was designed to investigate the mechanism by which high D-glucose affects the glucose transport system in bovine aortic smooth muscle cells (SMC). High glucose levels downregulate the rate of glucose transport and the plasma membrane content of the glucose transporter GLUT-1 in these cells. Inhibition of 12- and 15-lipoxygenase by esculetin reverses the effects of high glucose by increasing the total cell content of GLUT-1 and its plasma membrane content. Moreover, the free radical scavenger nitroxide inhibits the glucose-induced downregulation of the hexose transport system when added together with 20 mM glucose to the cells. Treatment of SMC maintained at 20 mM glucose with both esculetin and nitroxide combines the effects of both agents: While nitroxide abolishes the glucose induced downregulation of the glucose transport system, esculetin increases the rate of hexose transport to the control level observed in cells maintained at 5 mM glucose. We suggest that free radical formation by high glucose levels increases the activity of 12- and 15-lipoxygenase. The products of these enzymes (12- and 15-HETE and/or lipoxins) affects the expression and cellular distribution of GLUT-1. Thus, elimination of free radicals with nitroxide abolishes this effects of high glucose.

A MUTANT HUMAN IGF-I RECEPTOR AS A DOMINANT NEGATIVE MUTANT IN L6 MYOBLASTS

H. Yamasaki, Y. Yamaguchi, H. Takino, N. Abiru, H. Kondo, K. Izumino, H. Sakamaki, S. Akazawa, S. Nagataki. University of Nagasaki, Japan.

We previously demonstrated that L6 myoblasts underwent glucose uptake through GLUT1 with the activation of endogenous IGF-I receptor. To clarify the IGF-I signal transduction, mutant human IGF-I receptor was generated to stably transfect into L6 myoblasts. 950 tyrosine in NPXY motif localized in juxta-membrane domain of the IGF-I receptor was substituted for alanine, resulting in failure of the phosphorylation of IRS-1 molecule. The receptor was increased in number at 2.8 fold in wild type expressing L6 transfectants and at 3.4 fold in mutant expressing transfectants. IGF-I stimulation to wild type transfectants induced both IGF-I receptor β-subunit and IRS-1 phosphorylation. In contrast, for the mutant transfectants, IGF-I did not induce IRS-1 phosphorylation but β-subunit phosphorylation. 2DOG uptake was assessed after 24 hours IGF-I stimulation to these transfectants. As compared to the untransfectants at 2.1 nM with ED_{50}, wild type transfectants showed 1.1 nM and mutant transfectants 3.3 nM with ED_{50}. These results indicate that 950 tyrosine is essential for the phosphorylation of IRS-1, and the IRS-1 is required for IGF-I signaling to glucose uptake in L6 myoblasts. The finding that mutant transfectants were less sensitive to IGF-I than that of untransfectants suggests that the 950 tyrosine mutant receptor may play as a dominant negative mutant against to the endogenous intact rat IGF-I receptor by the mechanism of wild-mutant hybrid formation.

600

CHRONIC HYPERLACTATEMIA DECREASES MUSCLE GLUCOSE UPTAKE AND GLUT4 mRNA IN FREELY MOVING RATS.

A.M. Lombardi, *A. Leturque, R. Fabris, F. Bassetto, R. Serra, G. Federspil, *J. Girard, R. Vettor
Institute of Semeiotica Medica - University of Padova
*CNRS Meudon Paris

An increased basal plasma lactate concentration is present in obesity and diabetes. It has been hypothesized that hyperlactatemia may influence glucose metabolism, thus playing a role in the development of insulin resistance. We previously demonstrated that acute lactate infusion in normal rats is able to induce insulin resistance at muscular level. The present study was carried out to elucidate the mechanism of the appearence of insulin resistance. In freely moving, cronically catheterized rats, a 24 hrs sodium lactate or sodium bicarbonate infusion was performed. To study the glucose uptake in different skeletal muscles, a bolus (30 μCi) of 2-deoxy-^{3}H-glucose was injected in basal condition and at the end of a euglycaemic hyperinsulinemic clamp. GLUT4 and PDH mRNA levels were assessed by Northern blot in skeletal muscles. Our results show that hyperlactatemia decreases glucose uptake in skeletal muscles (i.e. soleus: lactate 6.15±1 vs control 16.55±1.7 $p<0,0005$). Besides, the GLUT4 mRNA levels were decreased in the same tissues (i.e. soleus: lactate 13671±7154 vs control 37327±4603 $p<0,005$), whereas the PDH mRNA risulted significantly increased in lactate infused animals. These results indicate that lactate deeply influences peripheral glucose metabolism and suggest a role in the development of insulin resistance.

601

4-HYDROXY-2-NONENAL DOES NOT AFFECT GLYCOLYSIS

I. Miwa and K. Adachi. Meijo University, Nagoya, Japan.

4-Hydroxy-2-nonenal (HNE) is one of the major products of the peroxidative decomposition of polyunsaturated fatty acids of membrane lipids. HNE possessing a number of adverse biological effects is increased under conditions, e.g. diabetes, of increased oxidative stress. It is possible that the compound is involved in the vicious cycle of hyperglycemia in diabetes. To address this issue, we examined whether HNE exerts an inhibitory effect on glycolysis. HNE inactivated the rate-limiting enzymes (from animal sources) of the glycolytic pathway and the pentose phosphate pathway when incubated at 37°C for 1 h in the absence of glutathione (GSH). The HNE concentration for half-maximal inactivation of 6-phosphofructokinase (PFK) and glyceraldehyde-3-phosphate dehydrogenase was 3-10 μM; and that value for pyruvate kinase, glucose-6-phosphate dehydrogenase, and hexokinases I and II was 0.15-0.6 mM. In the presence of 5 mM GSH, however, only PFK, irrespective of the source (muscle, liver, or erythrocyte), was inactivated by 40-50% by 0.1 mM HNE. Even PFK was not inactivated in the presence of both GSH and its substrate, ATP (2 mM). Glycolysis in the human erythrocyte as a model cell was not affected by treatment of cells with 0.1 mM HNE at 37°C for 30 min. The results indicate that HNE, at concentrations observable under physiological and pathological conditions, does not affect glycolysis in cells.

602

THE ROLE OF GLUCOSE TRANSPORTERS AND IGF1 RECEPTORS IN IMPAIRED BONE GROWTH IN DIABETIC MICE.

E. Karnieli and G. Maor Tecnion Inst. of Technology, and Rambam Medical Center, Inst. of Endocrinology & Metabolism[1] Haifa, Israel. Tecnion Inst. Of Technology, Dept. of Morphological sciences, Haifa, Israel.

Uncontrolled IDDM children are characterized by a slow growth rate, which improves upon adequate therapy. While skeletal growth is an energy consuming process involving high glucose utilization, the role of glucose transporters (GLUT) and their regulation in the bone formation process, are not yet fully understood. Thus, we studied both *in vivo* and *in vitro* early endochondral bone formation in control and in STZ- induced young diabetic mice before and after insulin therapy. Using in situ hybridization and immunohistochemistry techniques, we demonstrated the existence of GLUT4, the insulin sensitive GLUT, as well as GLUT1, in neonatal-derived murine mandibular condyles and in the humerus growth plate - two models for endochondral bone formation. Compared to control, while the expression (mRNA and protein) of the core protein of cartilage specific proteoglycans (CSPG) were diminished in diabetic growth centers, osteocalcin gene expression were enhanced. This presents an uncoupling between the chondrogenesis and osteogenesis processes. Further, in the bones of diabetic mice GLUT4 levels, IGF-I and its receptor, but not GLUT1, were markedly reduced and associated with severe histological changes in the mandibular condyles and humerus growth plate. Thus, we propose that GLUT4 and IGF-I receptor have an important role in early bone growth.

603

IDENTIFICATION OF THE MECHANISMS INVOLVED IN THE POTENTIATING EFFECTS OF METFORMIN ON INSULIN-INDUCED GLYCOGEN SYNTHASE ACTIVITY IN *XENOPUS* EGGS.

D. Detaille[1], P. Devos[1] and N. Wiernsperger[2]. [1]University of Namur, Belgium. [2]Lipha, Lyon, France.

In this study, we focused our attention towards the ability of metformin to improve the biological function of insulin in *Xenopus laevis* oocytes. Addition of metformin alone (20μM) to oocytes had no effect on the basal rates (n=4) of glucose uptake (143±16.5pmol/h/oocyte versus 129.1±8.9pmol/h/oocyte) or of glycogenesis, measured by [^{14}C] glucose incorporation into glycogen (14.8±1.7pmol/h/oocyte versus 11.4±0.2pmol/h/oocyte). In contrast, the drug clearly enhanced insulin action on both metabolic events (glucose uptake: 426.8±29.3pmol/h/oocyte versus 301.8±28.2pmol/h/oocyte and glycogen synthesis: 92.6±8.1pmol/h/oocyte versus 51.3±4.9pmol/h/oocyte, n=4). A short term preincubation of oocytes with metformin, but in the absence of glucose, also increased the percentage of glycogen synthase (GS) active form above insulin(50nM)-induced level (basal 17.4±5.7%, metformin 21.3±4.1%, insulin 31.2±4.6%, metformin + insulin 62.7±4.2%, n=5). Interestingly, metformin microinjected into eggs (at a final concentration of 20nM) amplified equally the same biochemical process, whereas a previous injection of tyrphostin B46 (a specific inhibitor of receptor tyrosine kinase activity) prevented the stimulatory effect of this biguanide. As the activation of GS in oocytes might involve a kinase/phosphatase cascade initiated by insulin at the level of its receptor, we further investigated the role of metformin within the insulin signaling pathway. While having no effect alone, metformin together with insulin was able to decrease significantly ($P<0.005$) the level of cAMP in the oocytes (basal 1.83±0.52pmol/oocyte, metformin 1.63±0.49pmol/oocyte, insulin 1.42±0.35pmol/oocyte, metformin + insulin 0.69±0.2pmol/oocyte, n=9). This reduction of cAMP content might lead to the dephosphorylation of GS and hence to its activation. Our results strongly suggested that the potentiating effect of metformin on GS activity was more closely correlated to an alteration of pathways regulating the activity of this rate-limiting enzyme rather than to a secondary effect dependent upon an increased glucose uptake. Together with other data from recent literature, this allows us to conclude that metformin could act at an intracellular site most likely linked to the tyrosine kinase domain but located before the branching of individual signaling pathways of insulin.

604

STUDIES ON THE MOLECULAR EVOLUTION OF GLUCOSE TRANSPORTER GENE FAMILY

Wang Hua, Zhang Zhengxian, Chai Jianhua and Chen Jia-wei. First Affiliated Hospital of Nanjing Medical University, Nanjing, P.R.China

Glucose transporter gene family which was involved in the glucose metabolism in the body has been considered as candidate gene in the development of diabetes mellitus. We compared the nucleotide and amino acid sequences of the family in different species; deduced the hydrophilicity and hydrophobicity distribution of the amino acid; calculated the genetic distance and constructed the phylogenetic trees by UPGMA and N-J method. The results show that the member of glucose transporter gene family are homologous; all the members of this family have a similar topology; It is suggested that the family may derived from a remote common ancestor in which the gene duplication events of different origins took place; this evolutionary process is advantageous to the stability of the structure. The different branch length in the phylogenetic trees constructed by the N-J method indicated difference of evolutionary rates in the process of evolution. Also, the difference between the trees at protein and nucleotide level may result from the hidden substitution in the genome.

605

NITRIC OXIDE LEVELS ARE RESPONSIBLE OF GLUCOKINASE ACTIVITY IN CULTURED RAT HEPATOCYTES. G. Valsecchi, L.D. Monti, P.M. Piatti, S. Costa, C. Stangalini, V.C. Phan, E. P. Sandoli, C. Socci and G. Pozza. Istituto Scientifico H. San Raffaele, Milan, Italy.

Aim of the study was to evaluate the influence of endothelial factors (endothelin-1 and nitric oxide) on glucokinase (GK) activity, a key regulatory enzyme on hepatic glucose fluxes. To this scope, we evaluated the effects of endothelin-1 (ET-1, 2.0 nmol/l) and L-NAME ($4x10^{-5}$ mol/l), an inhibitor of nitric oxide synthase, on GK activity and glycogen content in cultured rat hepatocytes. Nitric oxide levels significantly decreased by 20% both after ET-1 ($p<0.01$) and L-NAME ($p<0.01$). Concomitantly, GK activity decreased by 52% after ET-1 (from 0.56±0.07 to 0.29±0.02 nmol/μg protein/h; $p<0.05$) and by 43% after L-NAME (from 0.56±0.07 to 0.32±0.02 nmol/μg protein/h; $p<0.05$). On the contrary, ET-1 was less effective than L-NAME in decreasing glycogen content (from 47.3±2.2 to 40.5±5.1 mg/g tissue with ET-1, NS; and to 35.4±0.8 mg/g tissue with L-NAME, $p<0.001$ vs basal; NS vs ET-1). When ET-1 and L-NAME were added together in the culture medium, no synergistic effects were observed. In fact, under these conditions, nitric oxide levels, GK activity and glycogen levels decreased by 17%, 45% and 30%, respectively (NS vs ET-1 and L-NAME). L-Arginine (1.72 mmol/l), by increasing nitric oxide levels, was able to report GK activity and glycogen content to basal levels (0.67±0.1 nmol/μg protein/h; NS and 42.1±3.6 mg/g tissue; NS; respectively). In conclusion, nitric oxide pathway seems to be an important regulator of GK activity and glycogen content in cultured rat hepatocytes. ET-1 seems not active *per se* but its activity seems mediated by a decrease in nitric oxide levels.

606

CHARACTERIZATION OF GLUT1-CONTAINING MEMBRANE VESICLES DERIVED FROM FIBROBLASTS OF A PATIENT WITH DEFECTIVE INSULIN-STIMULATED GLUCOSE TRANSPORT ASSOCIATED WITH MALINSERTION OF GLUT1 INTO THE PLASMA MEMBRANE.

C.Kausch*, I.Uphues§, A.Hamann*, H.Greten*, J.Eckel§, and S.Matthaei*, *Dept. of Medicine, University of Hamburg, Hamburg, Germany; §Diabetes-Forschungsinstitut, University of Düsseldorf, Düsseldorf, Germany.

The aim of this study was to prepare and characterize GLUT1-containing membrane vesicles derived from fibroblasts of a patient with clinical features of Werner syndrome and defective insulin-stimulated glucose transport associated with malinsertion of GLUT1 into the plasma membrane in an attempt to examine the molecular cause of the defective docking/fusion process. Microsomal membrane fractions (200 μg) were incubated with protein G-beads for 16h at 4°C. After centrifugation anti-GLUT1 antiserum was added to the supernatant and the mixture was further incubated for 5h at 4°C. Nonspecific adsorption was monitored by identical treatment with a preimmune serum. The precipitate was pelleted, resuspended and incubated with beads for further 16h at 4°C. After centrifugation vesicle proteins attached to beads were washed and subjected to SDS-PAGE, blotted to nitrocellulose and the following proteins were immunodetected: VAMP-2, SNAP-25, Synaptotagmin and interestingly the p85 subunit of PI-3'kinase. Preliminary results suggest that the expression of p85 subunit of PI-3'kinase was reduced in GLUT1-containing membrane vesicles prepared from fibroblasts derived from the patient VH when compared to controls. In conclusion, GLUT1-containing membrane vesicles include VAMP-2, SNAP-25, Synaptotagmin as well as the p85 subunit of PI-3'kinase. Further study is necessary to investigate whether the decreased expression of p85 of PI-3'kinase in vesicles from the patient VH is responsible for the defective insertion of GLUT1 into the plasma membrane.

PRESENCE OF ALDOSTERONE RECEPTORS IN U-937 HUMAN PROMONOCYTIC CELLS.

B. Maestro, J. Campión, F. Mata, N. Dávila, M.C. Carranza and C. Calle. Depts. Bioquimica I and III. U.C.M. and C.P.H. Madrid. Spain.

Earlier studies of our laboratory have demostrated that aldosterone decreases insulin receptor gene expression at the RNA level in U-937 human promonocytic cells. In the present work we examine if such an effect could be mediated by specific aldosterone receptors. U-937 cells were grown in suspension in RPMI-1640 medium supplemented with fetal calf serum, glutamine and antibiotics. For experiments, 10^{-9} M aldosterone was directly applied to the cultures for 36 and 48 h. Binding studies were performed using cells previously washed with incomplete 1640 medium to remove endogenous steroids and serum proteins. Then, the cells (12 x 10^6 cells/ml) were incubated from 60 up to 180 min at 37°C with [^{3}H]- aldosterone (0.5 x 10^{-9} M) either in the absence or presence of unlabeled aldosterone (10^{-10} - 10^{-7} M). After that, U-937 cells were treated with 1% Triton X-100, and centrifuged at 1800 rpm for 10 min at 4°C. Finally, the supernatant cytosols were separated for scintillation counting. The results were expressed in terms of specific binding, subtracting the nonspecific binding in the presence of 5 x 10^{-7} M unlabeled aldosterone. The binding of aldosterone was found to be time-dependent. The maximal percentage of fraction bound (45%) was obtained at 120 min of incubation. Scatchard analysis revealed the presence of a single class of binding sites with high affinity (Kd: 1.1 x 10^{-9} M) and limited capacity (2400 sites per cell). Treatment with aldosterone for 48 h, clearly decreased aldosterone binding in U-937 cells. These findings represent the first demonstration of the presence of aldosterone receptors in U-937 cells, and also, the indication that aldosterone is involved in the homologous regulation of aldosterone receptors in these cells.

METABOLIC EFFECTS OF IGF-I AND INSULIN IN THE PERFUSED RAT LIVER

R. Englisch[1], R. Wurzinger[2], C. Fürnsinn[1], J. Graf[2], W. Waldhäusl[1] & M. Roden[1]
[1]Dept. Internal Medicine III,[2]Dept. Exp. Pathology, Univ. Vienna, Austria

Human recombinant insulin-like growth factor-I (IGF-I) has been shown to exert antidiabetic effects mainly by increasing peripheral glucose uptake, glycogen synthesis and glycolysis in skeletal muscle and adipocytes. This study was designed to compare the effects of IGF-I with those of insulin on glucose metabolism, the release of cyclic AMP and cyclic GMP as well as changes in intracellular calcium concentration $[Ca^{2+}]_i$ (surface photometry using the Fura-2 fluorescence technique) in the perfused rat liver (Krebs-Henseleit buffer, flow-through, 3 ml/g liver.min). Basal incremental glucose-production (area under the curve, AUC within 30 min) was decreased by IGF-I (1nM) by 64% ($p<0.05$ Dunnett test) and by insulin (1nM) by 62% ($p<0.05$). Epinephrine (0.05 μM) - induced incremental glucose-production (control, CON: 42.2±4.5 μmol/g) was inhibited by IGF-I (1nM, 28.0±1.9 μmol/g, $p<0.05$ vs. CON) and insulin (1nM, 16.8±2.1 μmol/g, $p<0.05$ vs. CON). Basal and epinephrine-stimulated lactate release were not affected by insulin and IGF-I. Under basal conditions release of cyclic AMP was reduced by 27% ($p<0.05$, paired t-test) in response to IGF-I and by 40% ($p<0.001$) in response to insulin, while epinephrine elicited an increase by 75% ($p<0.05$ vs. basal). In contrast, cyclic GMP release was not affected by IGF-I, insulin and epinephrine. Insulin and IGF-I constantly increased (+15%) basal $[Ca^{2+}]_i$ ($p<0.05$, Wilcoxon test), but reduced the rapid epinephrine-dependent increase in $[Ca^{2+}]_i$ by 43%. These results show IGF-I to act similar to insulin on basal and epinephrine-stimulated hepatic glucose-metabolism and to counteract intracellular epinephrine mediated signal transduction.

THE EFFECT OF PROGESTERONE ON 2-DEOXYGLUCOSE UPTAKE IS MEDIATED BY CERAMIDE

K. Nakatani, K. Ito, K. Otake, A. Katsuki, M. Fujii, K. Tuchihashi, H. Goto, Y. Yano, E.C. Gabazza, and Y. Sumida.
Third Department of Internal Medicine, Mie University School of Medicine, Tsu, Japan.

Ceramide was reported to induce insulin resistance as a TNF-α mediated intracellular mechanism. The aim of this study was to assess the effect of ceramide on progesterone-induced insulin resistance *in vitro*. L-6 myocytes were treated with progesterone and membrane permeable ceramide analogs (C2) for 16 hours, and then the intracellular ceramide concentration and the 2-deoxyglucose uptake were measured. Progesterone increased dose-dependently the intracellular ceramide concentration. The maximum effect was observed at more than 0.1 μM of progesterone. Although progesterone augmented the basal 2-deoxyglucose uptake, it suppressed the insulin stimulated 2-deoxyglucose uptake. The maximum effect was observed at more than 0.1 μM. C2 (5 μM) mimicked the effects of progesterone on 2-deoxyglucose uptake. The additive effect of progesterone and C2 was not observed. In conclusion, progesterone was suggested to inhibit insulin-induced 2-deoxyglucose uptake by intracellular ceramide.

NO DETECTION, BY REVERSE TRANSCRIPTION-POLYMERASE CHAIN REACTION, OF GLUT 7 mRNA IN RAT LIVER.

N. Bruni, M.C. Rey and G. Mithieux. Institut National de la Santé et de la Recherche Médicale (U.449), Lyon, France

Glut 7 is the most recently described glucose transporter, identified in rat liver. We aimed to study the effect of diabetes and insulin-treatment on the abundance of Glut 7 mRNA. Because of the high homology with Glut 2 mRNA (75% between the two coding sequences) present in the same tissue, only a strategy based on RT-PCR in competition might be suitable. As a first approach, we tried to amplify Glut 7 mRNA specifically with regards to Glut 2 mRNA, involving two 18-mer oligonucleotide antisense primers exhibiting almost no homology (located in exon 10, based on Glut 2 sequence, the Glut 7 gene being not known) and two 18-mer non-homologous sense primers (located in exon 6). Temperatures for annealing were tested from 46 to 62°C and $MgCl_2$ concentrations from 1 to 5 mM. The expected 616 bp-long cDNA product was amplified in all cases, but one, from Glut 2 specific primers and in no cases from Glut 7 primers. Identical results were obtained using : 1) two other non-homologous sense primers located in exon 7 and an other common antisense primer located in a region of complete homology between the two sequences (exon 11) ; 2) other combinations of aforementioned sense and antisense primers ; 3) *Taq* polymerases from different origins ; 4) reverse transcription at high temperature (70°C) with thermostable reverse transcriptase ; 5) additional PCR runs from prior RT-PCR amplification mediums ; 6) total RNAs from other tissues which express Glut 2, eg. kidney, small intestine and pancreas. We conclude that Glut 2 mRNA may be very easily amplified by RT-PCR, whereas Glut 7 mRNA, if existing, may not be detected using the same approach, in spite of its high structural homology with the former.

NON-ISOTOPIC TECHNIQUE FOR STUDYING MICROSATELLITE GENETIC MARKERS; APPLICATION TO BRITISH SIB-PAIRS WITH TYPE 2 DIABETES.

J.C. Alcolado, E.J. Sherratt, J.W. Gagg, S. Davies and A. W. Thomas. University of Wales College of Medicine, Cardiff, Wales UK.

A polymorphic microsatellite marker (D2S125) on chormosome 2 was recently reported to show significant linkage to NIDDM in a population of Mexican American affected sib pairs. We have used a simple non-isotopic screening technique employing the polymerase chain reaction with a biotinylated primer to study the genetic linkage and allele frequency distribution of the D2S125 marker in a population of 109 Europid subjects with NIDDM (62 possible affected sib pairs: 47 sibships with 2 affected and 5 with 3 affected members). Subjects were genotyped using a 5' biotinylated forward amplimer AFM112yd4a (GCAACAGAGTGAGACCCTGA) and the reverse primer AFM112yd4m (TTCTGAGAACCAGATTGTGATTG). After electrophoresis on 6% agarose gels, PCR products were blotted onto a nylon membrane by capillary action for 6 hours. The biotinylated PCR products were detected using the Tropix detection kit (Cambridge Bioscience).

Results;

Allele	size (bp)	frequency	Allele	size (bp)	frequency
1	102	0.013	5	94	0.243
2	100	0.116	6	92	0.158
3	98	0.046	7	90	0.095
4	96	0.134	8	88	0.196

Sib-pair analysis provided no evidence for linkage of the D2S125 marker in the limited number of sib-pairs we have currently available (MLS = 0.029, p>0.05). The PCR screening method proved to be a safe and reliable alternative to the radiolabelling of PCR products.

612

MUTATION SCREENING OF THE HEPATOCYTE NUCLEAR FACTOR -1α AND -4α GENES IN MODY FAMILIES: SUGGESTION OF THE EXISTENCE OF AT LEAST A FOURTH MODY GENE.

JC CHEVRE, E HANI, P BOUTIN, N VIONNET, M VAXILLAIRE, K YAMAGATA and P FROGUEL. CNRS EP10, Lille, France; HHMI University of Chicago, Il, USA.

Maturity-onset diabetes of the young (MODY) is a genetically heterogeneous subtype of non-insulin-dependant diabetes mellitus (NIDDM) characterized by early onset, usually before 25 years of age, autosomal dominant inheritance and a primary defect in insulin secretion. At least 3 genes are responsible for MODY: the glucokinase gene (MODY2) on chromosome 7p, MODY1 and MODY3 genes on chromosomes 20q and 12q respectively. Recent studies have shown that mutations in the two functionally-related transcription factors, hepatocyte nuclear factor 4α (HNF-4α) and -1a (TCF1) are responsible for the MODY1 and MODY3 forms of diabetes.We previously described 8 MODY families with no mutation in the GCK gene and with no evidence of linkage to MODY1 or MODY3 markers. Therefore the aim of our study was to investigate that the MODY phenotype in families with non-conclusive Lod-score (-2 to 0.5) at the MODY loci is not caused by mutations in one of the two HNF genes. Probands from 4 and 5 of those families were screened for mutations in the HNF-1α gene (10 exons) and in the HNF-4α gene (11 exons) respectively by direct sequencing. We also scanned 15 probands from newly recruited MODY families. The exons and flanking intronic sequences of these genes were amplified by PCR using specific primers. After purification, PCR products were sequenced directly from both directions using an AmpliTaq FS dye terminator cycle sequencing kit and an ABI prism 377 automated DNA sequencer. A G to A transition in codon 161 of exon 2 was identified in one of these new families resulting in a Ala to Thr substitution. This new missense mutation localised in the DNA-binding domain of the HNF-1α protein co-segregated with diabetes in this family. Previously described polymorphisms in exon 4 and 7 were also found in other families. Thus we confirmed the existence of at least one other locus responsible for the MODY phenotype. We have identified 22 french families suitable for the search of other MODY genes.

613

NO EVIDENCE FOR EXCESS ALLELE-SHARING ON CHROMOSOME 2q (REGION OF *NIDDM1*) IN A LARGE SIBSHIP COLLECTION

P Cassell[1], PJ Saker[2], M Armstrong[3], T Kumarajeewa[1], RC Turner[4], S O'Rahilly[5], M Walker[3], AT Hattersley[6], GA Hitman[1] and MI McCarthy[2]. [1]St Bartholomew's & Royal London Hospital School of Medicine, London;[2] Imperial College School of Medicine, London;[3] University of Newcastle-upon-Tyne; [4]Radcliffe Infirmary, Oxford; [5]Addenbrooke's Hospital, Cambridge; [6]Royal Devon & Exeter Hospital, Exeter, UK.

Recent analysis in Mexican Americans families has suggested that a susceptibility locus for NIDDM lies on chromosome 2q (*NIDDM1*). To determine whether a 2q locus influences susceptibility to NIDDM in Europeans, we conducted an initial study of families from the British Diabetic Association (BDA) Warren 2 NIDDM repository. Ascertainment into this collection requires that all grandparents be of British/Irish origin and that affected sibs have NIDDM diagnosed between 35 and 70: the resource currently (Dec 1996) stands at ~700 collected pedigrees. To date, we have typed the first 224 pedigrees from the resource (471 affected sibs, 278 possible sibpairs) for markers in the *NIDDM1* region. Microsatellite markers from the telomeric 25cM of 2q (D2S125, D2S336, D2S338, D2S2285, AFMA064ZF9) were assayed by fluorescent genotyping methods: marker order was taken from the Whitehead Institute integrated map, release 11. Multipoint nonparametric analysis was performed using GENEHUNTER and allele frequencies were estimated from the family data. Overall genotyping accuracy was confirmed by close correspondence between interlocus distances inferred from the observed data and those published. Between 63% and 75% of inheritance information was extracted across the region. We found absolutely no evidence for excess allele-sharing across the terminal region of 2q - indeed, NPL scores were negative throughout (peak NPL -1.01, p=0.86). Though we plan to extend this analysis to include additional markers and families, these data indicate that any locus on 2q has little influence on NIDDM susceptibility in this European population. The data obtained are clearly consistent with significant ethnic heterogeneity in the genetic basis of NIDDM and emphasise the problems in replicating positive linkages obtained in diverse ethnic groups.

614

MUTATIONS IN HEPATOCYTE NUCLEAR FACTOR 1α GENE IN MATURITY ONSET DIABETES OF THE YOUNG (MODY3)

P.J.Kaisaki, N.Oda, S.Menzel, H.Furuta and K.Yamagata. The University of Chicago, Chicago, U.S.A.

AIM: To characterize the genomic structure of human hepatocyte nuclear factor 1α (HNF-1α) and identify mutations in the HNF-1α gene in MODY3 patients. METHODS: Fragments of the PAC clone 254A7 which contain the HNF-1α gene were sequenced to determine exon-intron organization and promoter region sequence. This information was used to design PCR primers to amplify and screen each exon of HNF-1α in MODY3 patients for mutations by direct sequencing of both strands of the PCR product. RESULTS: The human HNF-1α gene is comprised of 10 exons that span about 23 kb, of which 6.2 kb were sequenced including 490 bp of the 5'-flanking promoter region. In eight unrelated MODY3 families, eight different mutations were found: three missense mutations (R131Q, C241G, P447L), two splice site mutations (IVS5nt-2A-G, IVS9nt+1G-A), and three frameshift mutations (P291fsinsC, P379fsdelCT, T547E548fsdelTG). Family members were screened for mutations and the mutations were found to cosegregate with affected status. Point mutations changed conserved amino acids and were not seen upon screening 50 unrelated nondiabetic subjects. CONCLUSION: Mutations in the HNF-1α gene are the cause of MODY3. Information on the sequence of the human HNF-1α gene and its promoter region will facilitate the search for mutations in other subjects as well as studies of its role in normal β-cell function.

615

Genome scan for linkage to pre-diabetic traits in Pima Indians

R.E. Pratley, D.B. Thompson, M. Prochazka, L. Baier, D. Mott, E. Ravussin, H. Sakul, T. Foroud, M.G. Ehm, D.K. Burns, W.T. Garvey, W. Knowler, P.H. Bennett and C. Bogardus. NIH, Phoenix, AZ, Sequana, LaJolla, CA, Indiana University, Indianapolis IN, Glaxo, Research Triangle Park, NC, MUSC, Charleston, SC, USA

To investigate the genetic basis of selected risk factors for NIDDM, we performed a genome-wide scan in a group of healthy, non-diabetic Pima Indians who participated in a longitudinal study of the predictors of NIDDM. Glucose (G) and insulin (I) responses to a 75g oral glucose challenge (OGT), a mixed meal (MM) and a 25g intravenous glucose challenge (IVGTT) were measured as was insulin action (2-step hyperinsulinemic glucose clamp). 363 subjects (221M/142F) from 109 families (388 sib-pairs) were genotyped at 524 polymorphic DNA markers evenly distributed throughout the genome (average distance = 8 cM). Two-point linkage analyses (SIBPAL, SAGE) indicated that one marker, D3S1764, was significantly linked (LOD = 3.7) to glucose disposal during the low dose of the clamp. However, this linkage was not as significant (LOD = 1.6) by multipoint interval mapping (Fulker et al.). An additional 29 markers showed suggestive evidence of linkage to one or more sub-phenotypes in two-point analyses. Of these, 6 regions also showed suggestive linkage (LOD > 2.2) in multipoint analyses (Table).

Marker	Phenotype	2-point LOD	Multipoint LOD
D1S1646	OGT-G	3.1	2.9
D1S2125	IVGTT-G	2.7	3.3
D4S2382	Fasting-I	2.8	2.6
D7S798	IVGTT-G	3.2	2.3
GATA35	OGT-I	2.7	3.2
D18S535	MM-G	2.7	2.2

The results of this genome-wide scan suggest several regions which may be linked to aspects of glucose metabolism. Specific genes in these areas may contribute to the high prevalence of NIDDM in the Pimas.

616

MUTATIONS IN THE HEPATIC NUCLEAR FACTOR-1α GENE ARE A COMMON CAUSE OF MODY IN DANISH CAUCASIANS

M. Fridberg[1], T. Hansen[1], H. Eiberg[2], A.M. Møller[1], S.K. Rasmussen[1], S.A. Urhammer[1], J.J. Holst[3], K. Almind[1], S.M. Echwald[1], L. Hansen[1] and O. Pedersen[1]. [1]Steno Diabetes Center and Hagedorn Research Institute, Copenhagen, Denmark; [2]University Institute of Medical Biochemistry and Genetics, Department of Medical Genetics, University of Copenhagen, Denmark; [3]Department of Medical Physiology, University of Copenhagen, Denmark;

One form of maturity-onset diabetes of the young (MODY3) results from mutations in the hepatic nuclear factor-1α (HNF-1α) gene, located on chromosome 12q24.2. The objective of the present study was to examine for genetic variability in the HNF-1α gene in 9 non-related Danish Caucasian subjects with MODY. Direct sequencing of the coding region and intron-exon boundaries of the HNF-1α gene revealed 2 novel ((I128N and H143Y) and 1 previously reported (P447L) missense mutations and 2 novel frameshift mutations (P379fsdelT and A559fsinsA) in 5 of 9 MODY subjects. These 5 mutations were neither found in 84 NIDDM patients nor in 84 control subjects. One glucose tolerant lean male, with a P447L missense mutation which in his relatives caused MODY, underwent an oral glucose tolerance test (OGTT), a tolbutamide modified frequently sampled intravenous glucose tolerance test and a glucagon test in order to examine for a possible early beta cell abnormality. He had a low insulin secretion during an OGTT, but a 2 fold increase in pancreatic beta cell response after intravenous glucose and a 2.5-4 fold increase in beta cell response after either intravenous tolbutamide or intravenous glucagon loads when compared to matched control subjects. In conclusion: 1) mutations in the HNF-1α gene are common in Danish Caucasian MODY patients, and 2) early stages in the pathogenesis of MODY3 caused by the P447L mutation may be characterized by a hyperexcitability of beta cells to intravenous secretagogues.

617

MULTIPOINT LINKAGE ANALYSIS OF NIDDM IN 534 FINNISH FAMILIES IN THE FUSION STUDY.

S. Ghosh, E.R. Hauser, V.L. Magnuson, D.S. Ally, T. Valle, R.M. Watanabe, S.J. Nylund, K. Kohtamaki, R.N. Bergman, J. Tuomilehto, F.S. Collins and M. Boehnke for the Finland-United States Investigation of NIDDM Genetics (FUSION) study. NCHGR, Bethesda, MD, USA; Univ. of Mich., Ann Arbor, MI, USA; National Public Health Institute, Helsinki, Finland; USC School of Medicine, Los Angeles, CA, USA.

The FUSION study is a collaborative effort to map genes for NIDDM in the Finnish population. We are performing a genome scan with an initial 450 microsatellite markers in 734 NIDDM-affected sib pairs (ASPs) from 534 families. To minimize the number of families with late-onset IDDM we excluded families in which an affected individual had low C-peptide levels, high GAD autoantibody levels, and required insulin therapy $\leq$ 4 years after diagnosis. Our analysis strategy includes nonparametric linkage analysis using both single point and multipoint identity-by-descent methods, identity-by-state methods, and association analysis. To date no major susceptibility loci for NIDDM have been identified on chromosomes 1, 2, 7, 8, 11, 12, 15 and 16. In the course of the genome scan, we have investigated in particular two regions recently identified in linkage analyses of NIDDM in other studies: a region on chromosome 2q identified in Mexican-Americans (Hanis et al., Nat Genet 13:161-6) and a region on chromosome 12 near the MODY3 locus in families from the Botnia region of Finland (Mahtani et al., Nat Genet 14:90-4). Using multipoint linkage analysis on the entire set of ASPs we exclude (LOD< -2) both regions at low relative risk to sibs (λ): a 76 centiMorgan (cM) region including the chromosome 2q telomere and D2S125 at $\lambda = 1.32$; and a region at least 13 cM on either side of D12S76 at $\lambda = 1.25$. We are exploring linkage relationships on a subset of our ASPs and their offspring with several measures of glucose tolerance, including glucose effectiveness, insulin action, and impaired insulin secretion.

MUTATIONS IN THE HEPATIC NUCLEAR FACTOR 1 ALPHA IN MATURITY-ONSET DIABETES OF THE YOUNG

M.P.Bulman[1], T.Frayling[1], S.Ellard[1], M.Appleton[1], M.J.Dronsfield[2], G.I.Bell[3], S.C.Bain[2] and A.T.Hattersley[1].

[1]Institute of Clinical Science, University of Exeter, Exeter, UK.
[2]Department of Medicine, University of Birmingham, Birmingham, UK.
[3]Howard Hughes Medical Institute and Departments of Biochemistry and Molecular Biology and Medicine, The University of Chicago, USA.

Mutations in the gene encoding the transcription factor hepatic nuclear factor 1α (HNF-1α) have recently been shown to cause maturity-onset diabetes of the young (MODY), a monogenic subgroup of non-insulin dependent diabetes mellitus (NIDDM). The incidence of HNF-1α mutations is unknown. We performed mutation analysis on fifteen probands from MODY families. All ten exons and flanking introns were amplified by PCR and alterations characterized by direct automated sequencing. We identified six novel mutations, one frameshift (A443fsdelCA) and five missense mutations (P129T, R131W, R159W, P519L, T620I) which involved conserved amino acids. Two previously described mutations (P379fsdelCT and P291fsinsC) were found in one and four families respectively. These mutations cosegregated with diabetes within pedigrees, were not seen in any non-diabetic family members with the exception of one individual who was not diabetic at age 42, and were not present in fifty normal chromosomes. We have demonstrated that mutations in the HNF-1α gene are the most common cause of MODY in UK families. Mutation detection based genetic counselling can now be offered to most patients with MODY.

619

ASSOCIATION OF IRS-1 Asp^{972}->Gly VARIANT WITH INSULIN RECEPTOR MUTATIONS IN INSULIN RESISTANT DIABETES

F. Grigorescu, M. Rouard, F. Macari, O. Bouix, J. F. Brun, E. Renard, P. Lefebvre, C. Lautier, J. Bringer and C Jaffiol. Molecular Endocrinology Laboratory, IURC and Endocrinology Dept., Lapeyronie Hospital, Montpellier, France.

To understand how mutations in the insulin receptor (IR) gene may be pathogenically involved in severe as well as mild forms of insulin resistance we have investigated first-degree relatives of patients with Type A syndrome and *acanthosis nigricans*. The insulin resistance was analysed *in vivo* by minimal model of IVGTT and mutations in IR and IRS-1 genes were scanned by ABI 373A DNA sequencer. A genetic condition of compound heterozygocity for two mutations Asp^{59}->Gly and Leu^{62}->Pro in the insulin binding site (exon 2), reasonably explained the severity of insulin resistance (Si<0.15) and the deterioration of IR functions (insulin binding, tyrosine kinase, PtdIns 3' kinase activity) in the 24 years Type A proband. Paternal mutation Leu^{62}->Pro was associated in the father with obesity (BMI=34), hyperinsulinemia and Si value (3.39) in the range of nondiabetic obese controls (4.3±1.05). Maternal mutation Asp^{59}->Gly was associated with obesity (BMI=38), NIDDM and insulin resistance (Si=0.1) in the mother whereas in the 29 years proband's brother, carrying the same heterozygote mutation the phenotype was normal (Si=10.3), except overweight (BMI=28). Sequencing of IRS-1 gene revealed heterozygote Asp^{972}->Gly variant in the proband and mother while being absent in the brother and father. These data suggest that cumulative genetic defects in proteins involved in insulin signaling may represent a plausible explanation of variable expression of IR mutants and give new insights in the pathogenic mechanism of more common forms of insulin resistant diabetes.

620

IDENTIFICATION OF A BALANCED TRANSLOCATION t (3 ; 20) (p21.2 ; q12) AT THE CHROMOSOMAL LOCATION (20q12) OF THE HNF-4α GENE IN A FAMILY WITH MATURITY-ONSET DIABETES OF THE YOUNG (MODY)

S. Ellard[1], M. Appleton[1], P. D. Turnpenny[2] and A. T. Hattersley[1].
[1]Institute of Clinical Science, University of Exeter, Exeter, [2]Department of Clinical Genetics, Royal Devon & Exeter Hospital, Exeter

Maturity-onset diabetes of the young (MODY) is a sub-group of non-insulin dependent diabetes mellitus (NIDDM) which is characterised by an early age of onset and autosomal dominant inheritance. Linkage studies have localised MODY genes on chromosomes 20q (*MODY1*), 7p (*MODY2*/ glucokinae) and 12q (*MODY3*). *MODY1* and *MODY3* have recently been shown to be genes encoding the transcription factors HNF-4α and HNF-1α respectively. MODY1 is a rare form of MODY, with an estimated prevalence of less than 5%. We have studied a MODY family where two members suffered recurrent miscarriages and were diagnosed with NIDDM at age 15 and 19 years. Karyotypic analysis revealed a balanced translocation t (3 ; 20) (p21.1 ; q12) in both family menbers. Fluorescent chromosome painting showed that MODY co-segregated with the translocation in five pedigree members. We propose that this balanced translocation has disrupted the HNF-4α gene on 20q12. To our knowledge this is the first balanced translocation reported to cause diabetes. Further studies are in progress to determine the precise position of the translocation breakpoint in relation to the HNF-4α gene.

621

ANALYSIS OF TYPE-1 PROTEIN PHOSPHATASE GLYCOGEN-TARGETING SUBUNIT mRNA IN SKELETAL MUSCLE OF PIMA INDIANS

X. Xia, C. Bogardus and M. Prochazka, CDNS-NIDDK-NIH, Phoenix, USA

It has recently been proposed that mRNA level of type-1 protein phosphatase glycogen-targeting subunit may contribute to mechanisms of insulin resistance in Pima Indians. Glycogen-bound type-1 protein phosphatase (PP1G) plays a key role in the insulin stimulation of glycogen systhesis, and a decrease of the enzymatic activity correlates with insulin resistance in the Pima Indians. PP1G in skeletal muscle is a heterodimer between an isoform of the catalytic subunits, and the muscle-specific glycogen-targeting subunit which is encoded by the *PPP1R3* gene. We have previously found an association of amino acid polymorphisms at codon 883 and 905 in *PPP1R3* with insulin resistance and non-insulin dependent diabetes mellitus (NIDDM) in Pima Indians. We have now quantitated *PPP1R3* mRNA by reverse transcription PCR in skeletal muscle biopsies from 20 non-diabetic Pimas, using β-actin as an internal standard. We found that the mRNA is positively correlated with the maximal insulin-mediated glucose uptake rate measured by the hyperinsulinemic-euglycemic clamp (r=0.51; p=0.02). We detected by PCR and sequencing of genomic DNA a T→A substitution approximately 2 kb 5' from the start of *PPP1R3* coding sequence, and a 5-base polymorphism involving an ATTTA motif in the 3' untranslated part of the gene. Both polymorphisms are in linkage disequilibrium (p<0.001), and they can be combined in two alternate haplotypes. We determined that the mRNA levels are significantly different between subjects homozygous for either combination (p=0.03). Measurements of PPP1R3 protein are currently in progress to determine its relationship with the mRNA levels. The ATTTA motif may affect mRNA stability, and we conclude that the polymorphism at this site in *PPP1R3* is a reasonable candidate that could cause the observed mRNA differences, and contribute to mechanisms of insulin resistance in the Pima Indians.

50 YEARS OBSERVATION OF THE CLINICAL PHENOTYPE IN A GERMAN MODY3 FAMILY (MUTATION IN HEPATOCYTE NUCLEAR FACTOR-1α)

R. Menzel*, Rjasanowski*, S. Menzel, P.J. Kaisaki and W. Kerner*, *Klinikum Karlsburg, Germany*; Howard Hughes Medical Institute, The University of Chicago , Chicago , Illinois, USA*

We have shown that mutations in the gene encoding the transcription factor HNF-1α are the cause of one form of maturity-onset diabetes of the young (MODY3). One of the German families (G16) with a recently identified missense mutation (R272H in exon 4) has been in our care since 1947. The aim was to characterize the clinical phenotype, especially the long-term course of diabetes in the affected carriers of the mutation. Grandfather: Diabetes since 1925 (age 19 ys), treatment in Karlsburg-Garz 1947 (start of insulin therapy), 1949 and 1962 (severe proliferative retinopathy, begin of renal insufficiency, severe neuropathy, claudication). 1971 blindness, amputation, death due to renal failure. In 1996 we identified the mutation of the HNF-α1 gene in half of his 12 descendants. Years before, either IGT or diabetes had been diagnosed through careful family screening, in each case around the age of 6 (one exception: a premarital daughter had become ill with typical symptoms at 12), during the 2 to 25 years after diagnosis OGTT, IVGT or glucose-glucagon tests were regularly carried out. Glucose tolerance fluctuates (normal, impaired, diabetic), shifting towards low response of insulin secretion and towards diabetes at differing rates from individual to individual; three receive insulin. 15 and 25 years after diagnosis two have a retinopathy (grade II). HbA1c 6.7 ± 0,1 %. MODY3 caused by mutation in the HNF-1α gene can later be aggravated by serious diabetic complications despite the initially long-term mild course. Complications may possibly be avoided by early diagnosis in the identified carriers and by an extremely good control of the metabolic disorder, diabetes as well as IGT. It is unclear whether additional genetic defects contribute to the diverse clinical appearance of MODY3.

ANALYSIS OF A MET->ILE SUBSTITUTION IN THE REGULATORY SUBUNIT OF PI3-K IN PIMA INDIANS

LJ Baier, C Wiedrich, R Hanson and C Bogardus. National Institutes of Health, Phoenix, USA

Phosphatidylinositol 3-kinase (PI3-K) is one of the signaling molecules activated by IRS-1, and has been implicated in linking the insulin receptor to translocation of glucose transporters. We have begun structural analysis of the gene encoding the regulatory subunit of PI3-K, p85α, in Pima Indians to determine whether any genetic variants can be identified which could explain the high prevalence of diabetes and insulin resistance in this population. We have begun sequencing the entire coding region of p85α in cDNA derived from muscle cells from Pimas. To date, we have identified one missense polymorhism at nucleotide 1020 (G->A) which alters a Met to a Ile at codon 326. This polymorphism was initially reported in a Danish population, and was found to be significantly associated with glucose disappearance (Kg) and glucose effectiveness (Sg) in 380 unrelated healthy Danish Caucasians. In the Danish population, the allelic frequency of the Ile variant was 0.15 in NIDDM patients and 0.16 in matched glucose tolerant subjects; therefore, this substitution does not appear to confer an increased risk of diabetes in this population. In 331 Pima Indians we have found the allelic frequency of the Ile variant to be higher than that observed in the Danish (0.24). In addition, we have noted a difference in the allelic frequency of the Ile variant between Pimas with NIDDM (0.20) and non-diabetic Pimas (0.28), where the prevalence of NIDDM is higher (68%) in individuals homozygous for the more common Met, and lower (38%) in individuals homozygous for the variant Ile. The contradictory associations for this variant in p85α between the Danish and Pima studies could represent true population differences for this variant or could be biased due to the small number of individuals who are homozgous for the variant (2% of Danish population and 5% of Pimas). We are continuing to sequence additional Pimas to confirm our findings.

624

MUTATIONS IN HEPATOCYTE NUCLEAR FACTOR 1 ALPHA GENE ASSOCIATED WITH NIDDM IN FRENCH MODY3 FAMILIES

M. Vaxillaire, J.C. Chèvre, J. Philippe, J. Timsit, G. Charpentier, G. Velho and P. Froguel. CNRS EP10, Institut Pasteur and C.H.U., Lille, France; Hôpital Cantonal Universitaire, Geneva, Switzerland; Hôpital Necker, Paris, France; Hôpital Gilles de Corbeil, Corbeil-Essonnes, France; INSERM U358, Paris, France.

Maturity-onset diabetes of the young (MODY) is a genetically heterogeneous subtype of NIDDM characterised by early onset, autosomal dominant inheritance and a primary defect in insulin secretion. Recent studies have shown that mutations in the two functionally-related transcription factors, hepatocyte nuclear factor 4 alpha (HNF-4α) and hepatocyte nuclear factor 1 alpha (HNF-1α) are associated with the MODY1 and MODY3 forms of diabetes respectively, whereas mutations in the enzyme glucokinase are the cause of the MODY2 form. We have examined 10 unrelated Caucasian families in which MODY/NIDDM co-segregated with markers on chromosome 12q (*MODY3* region) for mutations in the HNF-1α gene (symbol - *TCF1*). Ten different heterozygote mutations were observed in these families, all of which co-segregated with diabetes. These mutations in HNF-1α are highly but not completely penetrant and result in a subtype of MODY characterised by a severe insulin secretory defect. There were no obvious relationship between the nature of the mutations observed (i.e. frameshift, nonsense, or missense) or their location in the gene with clinical features of diabetes (age at onset, severity) in these families. The mechanisms whereby these mutations cause diabetes are unknown, but might include abnormal foetal development of pancreatic islets, as well as impaired transcription of genes implicated in beta cell function. In conclusion, HNF-1α is a major gene for MODY with mutations in this transcription factor being present in 25-50% of French MODY subjects.

CODON 972 POLYMORPHISM OF THE IRS-1 GENE AND INSULIN RESISTANCE IN THE JAPANESE POPULATION.

K. Ito, K. Nakatani, A. Katsuki, M. Fujii, K. Tsuchihashi, H. Goto, Y. Yano and Y. Sumida. Third Department of Internal Medicine, Mie University School of Medicine, Tsu, Japan

To determine the relationship of polymorphism at the locus for insulin receptor substrate-1 (IRS-1) with insulin resistance and susceptibility to NIDDM in the Japanese population, we examined 130 patients with NIDDM and 143 control subjects with normal glucose tolerance for the most common GGG(Gly) to AGG(Arg) substitution at codon 972 of IRS-1 by PCR-RFLP. Six (4.6%) of the patients with NIDDM were heterozygous for the Gly972Arg mutation. Within the control subjects, six were heterozygous and only one was homozygous for the mutation (4.9%). There was no difference in the prevalence of this mutation between patients with NIDDM and control subjects. The age of onset of NIDDM was not different between subjects with and without the mutation (43:0$\pm$14.5 vs 43.8$\pm$11.8 years). Insulin sensitivity was evaluated by the hyperinsulinemic euglycemic clamp in patients with NIDDM. Glucose infusion rate (GIR) did not differ between subjects with and without the mutation (50.2$\pm$3.0 vs 51.3$\pm$12.1 μ mol/kg/min). Fasting plasma insulin concentration in the control subjects did not differ between subjects with and without the mutation (31.0$\pm$11.0 vs 27.9$\pm$16.4 μ mol/ml). A 25-year-old man with Gly972Arg homozygotes, whose parents were both heterozygous for the mutation, had no family history of NIDDM and showed normal glucose tolerance in the 75gOGTT and high insulin sensitivity by the hyperinsulinemic euglycemic clamp (GIR=67.2 μ mol/kg/min). Thus, it appears that the Gly972Arg mutation of the IRS-1 gene may not play an important role in the pathogenesis of NIDDM and insulin resistance in the Japanese population.

626

Studies of the Genetic Variability in the Hepatic Nuclear Factor 1-α Gene in Patients with Late-Onset NIDDM

A.M. Møller[1], S.A. Urhammer[1], S.K. Rasmussen[1], M. Fridberg[1], T. Hansen[1], L. Hansen[1] and O. Pedersen[1]. [1] Steno Diabetes Center and Hagedorn Research Institute, Copenhagen, Denmark.

NIDDM2, a gene for late-onset non-insulin dependent diabetes mellitus (NIDDM) associated with an insulin secretion defect was previously mapped to chromosome 12q in Finnish families. Recently it has been shown that the type 3 form of maturity-onset diabetes of the young (MODY3) is caused by mutations in the hepatic nuclear factor-1α (HNF-1α) gene which is located in the same chromosomal region. The objectives of this study were to examine for genetic variability in the HNF-1α gene in 84 Danish Caucasian subjects with NIDDM and in an association study to test whether genetic variants are associated with NIDDM. Single strand conformational polymorphism and heteroduplex analysis of the coding region and the intron-exon boundaries of the HNF-1α gene and subsequent sequencing revealed 3 missense polymorphisms (I27L, A98V and S487N), 1 missense mutation (R583Q) and several silent polymorphisms in the NIDDM population. An association study demonstrated that the R583Q mutation was present in 2 of 245 NIDDM patients and in none of 242 control subjects. The missense polymorphisms were equally prevalent in diabetic and control subjects (allelic frequencies: I27L: 31.5% (95% CI: 27.4-35.6%) vs. 26.3% (22.4-30.2%); A98V: 3.7% (2.0-5.4%) vs. 4.4% (2.6-6.2%) and S487N: 28.0% (24.0-32.0%) vs. 26.4% (22.5-30.3%)). In conclusion: Genetic variability in the HNF-1α gene is not a common cause of late-onset NIDDM in Caucasians of Danish ancestry.

627

ASSOCIATION OF A VARIANT OF THE VITAMIN D BINDING PROTEIN WITH PLASMA GLUCOSE LEVELS IN NON-DIABETIC PIMA INDIANS

LJ Baier, A Dobberfuhl, P Thuillez and C Bogardus. National Institutes of Health, Phoenix USA.

To identify chromosomal regions containing susceptibility genes for NIDDM, we have undertaken an autosomal genome-scan for DNA markers linked to pre-diabetic metabolic phenotypes in non-diabetic Pimas Indians. 363 Pimas from 109 nuclear families (comprising 388 sib-pairs) were genotyped with 517 microsatellite DNA markers. Sib-pair linkage analysis identifed 4 markers (D4S3255-D4S3248-D4S1645-D4S2367) within a 10 cm region on chromosome 4 which are potentially linked to fasting plasma glucose concentrations ($p<0.005$), the glucose response to a 75g oral glucose tolerance test ($p<0.04$), the glucose response to a 25g intravenous glucose bolus ($p<0.006$), the fasting plasma insulin concentration ($p<0.02$), and maximal insulin action in vivo ($p<0.0003$), after adjusting for age, sex and obesity. The *Gc* locus, which encodes the vitamin D binding protein, maps to this region on 4q.12. Since this locus has previously been associated with NIDDM in a German and 7 southwest Pacific Island populations, and has been associated with fasting plasma insulin and glucose levels in 2 Native American populations, we analyzed this locus as a candidate gene for our linkage findings in Pimas. We sequenced all 12 exons of this gene and identified two polymorphisms. A GAG->GAT polymorphism at codon 416 (frequencies = 0.41 and 0.59) results in a Glu->Asp, while a ACG->AAG polymorphism at codon 420 (frequencies = 0.86 and 0.14) results in a Thr->Lys. Sequencing of these codons in 1200 Pimas identified an association between the polymorphism at 420 and measures of plasma glucose. Homozygotes for the ACG/ACG genotype had higher plasma glucose levels during a 75g OGTT ($p<0.04$), higher plasma glucose responses to a mixed meal ($p<0.002$) and higher glucose levels during an intravenous glucose tolerance test ($p<0.01$) when compared to AAG/AAG homozgotes combined with the heterozygotes.

628

CLINICAL CHARACTERISTICS OF HNF1α (MODY3) AND GLUCOKINASE MUTATIONS

M.Appleton, S.Ellard, M.Bulman, T.Frayling, R.Page[1] and A.T.Hattersley University of Exeter, Exeter & [1]University of Nottingham, Nottingham England.

Maturity Onset Diabetes of the Young (MODY) is characterised by young onset, non insulin dependent diabetes and autosomal dominant inheritance. We have shown that HNF1α mutations are the commonest cause of MODY in the UK (73%). The clinical characteristics of these patients have not been described. We compared the clinical characteristics of 41 patients with HNF1α mutations (34 diabetes or fpg > 6mmol/l) with 18 patients with a missense Glucokinase mutation (GCK) (17 diabetes or fpg > 6mmol/l). Both groups had an early diagnosis (22.6 ± 14 v 30.5 ± 17 years) (HNF1α GCK) and were non-obese (BMI 24.5 ± 4.6 v $25.5 \pm 5.5 kgm^{-2}$). HNF1α mutations results in more sever hyperglycaemia than GCK mutations as shown by osmotic symptoms at diagnosis (18/34 v 1/17, $p < 0.05$) and increased treatment requirements (7 diet, 13 OHA, 14 insulin v 15, 3, $p<0.001$) to achieve a similar fasting blood glucose (8.0 ± 3.5 v 7.3 ± 1.7 $mmol/l^{-1}$, $p>0.05$). Significant retinopathy (registered blind or laser therapy) was seen in 5/34 HNF1α patients (0/17 GCK). We have shown that patients with HNF1α mutations have different clinical characteristics to those with glucokinase mutations. HNF1α has a progressive clinical course with increasing treatment requirements, whereas glucokinase show stable mild hyperglycaemia throughout life. In MODY a molecular genetic diagnosis has important implications for clinical management.

629

LINKAGE ANALYSIS AND MOLECULAR SCANNING OF *THE PC3 GENE IN NIDDM*

K.Kalidas[1], E.Dow[2], P.J.Saker[1], M. Walker[3], S.V.Gelding[4], M.I.McCarthy [1] and D.G.Johnston[1]. [1] Imperial College School of Medicine at St.Mary's, London, [2] Ninewells Hospital, Dundee, [3]University of Newcastle, Newcastle-upon-Tyne, [4]London Hospital Medical School, London. UK.

Proinsulin is processed by the enzymes PC2 and PC3 to produce mature insulin.. Hyperproinsulinaemia observed in some NIDDM patients suggests an underlying impairment in proinsulin processing, which may be caused by mutations in the PC2 and/or PC3 genes.The PC3 gene, mapping to chromsome 5q14-21, was therefore examined as a candidate for susceptibility to NIDDM. Twenty-six large pedigrees of Europid, Afro-Caribbean and Asian ethnicities, segregating for NIDDM, were screened with five polymorphic markers for evidence of linkage. The markers D5S401, Afm205wg7, GATA48A11, D5S409 and D5S433 spanned a 15cM interval in the chromosome 5q14-21 region with genetic distances of 7cM, 4cM, 2cM and 2cM between subsequent markers. Standard two-point linkage analysis using several models, excluded linkage across the region under all models (LOD scores < -2). Multipoint nonparametric analysis with GENEHUNTER revealed no evidence for allele sharing in the region (max NPL scores in the interval containing gene=0.31, P=0.36). In addition, all 14 exons of the PC3 gene were screened for novel and known mutations (exon 2 and exon 14 variants described in Japanese) amongst affecteds (n=80), unaffecteds with high proinsulin levels (n=10) and unaffected spouses (n=25) from the pedigrees, using heteroduplex and PCR-RFLP analysis. No new variants were evident. The exon 2 variant (Arg^{53}-Asn^{53}) was not observed and the exon 14 variant (Gln^{638}-Glu^{638}) occurred at a similar frequency in diabetic and non-diabetic subjects. These results indicate that genetic variation in the PC3 gene is not likely to contribute to NIDDM in these pedigrees.

630

Phenotype of Human Hepatocyte Nuclear Factor 1α Mutations: Diabetes, Late Complications, and Glucosuria.

S.Menzel, P.Kaisaki, R.Menzel*, I.Rjasanowski*, J.Sahm§, H.Ledermann§, G.Sachse¶, W.Kerner* *Howard Hughes Medical Institute, University of Chicago, U.S.A., *Clinic for Diabetes and Metabolic Diseases, Karlsburg, Germany, §Eleonoren-Klinik Lindenfels-Winterkasten, Germany, ¶Deutsche Klinik für Diagnostik, Wiesbaden, Germany*

As we have recently shown, a form of early-onset type 2 diabetes (MODY3) is caused by mutations in the Hepatocyte Nuclear Factor 1α (HNF-1α). We also demonstrated that HNF-1α mutations occur frequently in families with overt early onset type 2 diabetes in a Caucasian (German) population, i.e. probably in more than 30% of these families. Interesting is the comparison of the human phenotype and a mouse model of a homozygous disruption (knockout) of the HNF-1α gene. The knockout mice develop hepatic failure, phenylketonuria (PKU) and Fanconi syndrome with massive glucosuria. The aim of the present study is to evaluate initial data on clinical phenotype and progression of diabetes in 20 patients carrying a mutation in the HNF-1α gene originating from seven families with inheritance of early-onset type 2 diabetes/MODY. Though initially the diabetes seems to be mild, eight of the patients required insulin treatment within 10 years after diagnosis of the diabetes. Complications (retinopathy, nephropathy, neuropathy) developed in 3 out of 6 patients with a known diabetes duration of more than 15 years. A lowered descending kidney threshold for glucose could be demonstrated in at least one of the families studied, and in a different family PKU is present in a twin pair carrying a HNF-1α nonsense mutation. This suggests that a partial overlap of phenotypic features with the mouse model might be present in selected families.

631

A MUTATION OF MUSCLE GLYCOGEN SYNTHASE GENE IS RELATED WITH INSULIN RESISTANCE IN JAPANESE NIDDM

T.Sanke, H.Shimomura, K.Ueda, S.Ohagi, T.Hanabusa, and K.Nanjo.
Department of Medicine, Wakayama University of Medical Science, Wakayama, Japan

Muscle glycogen synthase (GYS) is a key enzyme of non-oxidative pathway of glucose metabolism which has been reported to be related with insulin resistance in NIDDM patients. It has also been considered that impaired GYS activity in the skeletal muscle is an inherited trait in patients with NIDDM. We therefore scanned the GYS gene for mutation in non-obese and late-onset Japanese NIDDM patients (n=244) by polymerase chain reaction/single strand conformational polymorphism analysis and direct DNA sequencing. We detected two types of missense mutation ; Met at position 416 to Ala (M416V mutation) in the exon 10 and Pro at position 442 to Ala (P442A mutation) in the exon 11. The P442A mutation (heterozygote) was found only one NIDDM patient treated with sulfonylureas. She had hypertension and ischemic heart disease. The M416V mutation was also found in non-diabetic subjects (non-DM : n=181, >60 years, non-obese, no family history of diabetes). The M416V mutant allele frequency was slightly high in NIDDM patients (13.7 %) but not statistically significant from non-DM subjects (9.7 %). However, the insulin sensitivity index [SI:10^{-4}/min • (μ U/ml)] estimated by the Minimal Model analysis in the NIDDM patients carrying the mutation was significantly lower than that in NIDDM patients without the mutation (1.16 ± 0.28, n=21 Vs 2.20 ± 0.20, n=60, Mean$\pm$SE, $p<0.01$). The glucose effectiveness (SG), age, body mass index and levels of HbA1c and serum lipids were not significantly different between the two groups. The same trend was observed in non-DM group. These findings suggest that the M416V mutation of GYS gene is one of the factors contributing to reduced insulin sensitivity in Japanese NIDDM patients.

632

DIMINISHED INSULIN AND GLUCAGON SECRETORY RESPONSES TO ARGININE IN MODY1 SUBJECTS

WH Herman, SS Fajans, MJ Smith, KS Polonsky, GI Bell, and JB Halter, Ann Arbor, MI and Chicago, IL, USA

Nondiabetic (ND) subjects who carry the MODY1 gene have impairment of glucose-induced insulin secretion. The purpose of this study was to ascertain the effects of the nonglucose secretagogue arginine on plasma concentrations of insulin, C-peptide and glucagon and on glucose potentiation of arginine-stimulated insulin secretion in 14 ND subjects of the RW pedigree, 7 of whom are MODY1 gene marker positive (+) and 7 negative (-), and in 4 mildly diabetic (DM+) MODY1 subjects. Arginine (A) was given as a 5 gram pulse followed by a 25 minute infusion of 2.9 mM/kg before and after a pulse plus infusion of glucose (G) to clamp plasma glucose at 11 mM. The acute insulin responses (AIR) to secretagogue pulses and the 10-60 minutes areas under the curves (AUC) were compared for the 3 groups. Results: (mean±SEM), insulin in pmol/l, glucagon in ng/l

Group	AIR_{Arg}	AIR_{A+G}	AUC_{Arg}	AUC_{A+G}
ND(-)	288± 60	1626±198	12252±1194	97890±10710
ND(+)	438±114	972±216	3990± 858	23256± 6300
p<	NS	.05	.0001	.0001
DM(+)	162± 42	300± 60	582± 120	3888± 1086
vsND(-)p<	NS	.001	.0001	.0001

Similar differences were obtained when C-peptide levels were compared. The acute glucagon responses were similar for the three groups. AUC glucagon (10-60 minutes) was greatest for ND(-), intermediate for ND(+) and lowest for DM p<.04 (7549 vs 5772 vs 4778). Conclusions: The decreased insulin and C-peptide areas in ND(+) compared to ND(-) subjects in response to constant arginine infusion, magnified by glucose potentiation, indicate that the MODY1 gene defect affects the signalling pathway for arginine-induced insulin secretion. The decrease in glucagon area in response to arginine infusion suggests that mutations in the gene for HNF4, the MODY1 gene, leads to alpha, as well as beta cell defects or reduction in the mass of pancreatic islets.

633

EXPRESSION OF TWO MUTATIONS IN THE GLYCOGEN SYNTHASE (GS) GENE

M. Orho[1], H. Shimomura[2], and Leif Groop[1]. The Department of Endocrinology, Lund University, Malmö, Sweden[1] and The First Department of Medicine, Wakayama University of Medical Science, Wakayama Japan[2].

Although association between the GS gene and NIDDM has been found in several populations, only two aminoacid polymorphisms, M416V (in Japan) and G464S (in Finland) have been identified in the gene. Our aim was to study the frequency of these aminoacid variants in different populations and the biological consequences of these mutations by expressing them in COS cells. M416V was determined by RFLP in 369 unrelated NIDDM patients and 285 controls from Finland and in 95 unrelated NIDDM patients and 91 controls from Sweden. Glucose disposal rate was studied during an euglycemic hyperinsulinemic clamp in a subset of 137 nondiabetic subjects. G464S was determined by RFLP in 518 unrelated NIDDM patients and 274 controls from Finland and in 231 unrelated NIDDM patients and 122 controls from Sweden. The mutated cDNAs (GS-M416V, GS-G464S) were created by PCR, cloned into pcDNA3 vector and expressed in COS7 cells. GS activity was analysed at 0.1 and 10 mM G-6-P with 0.3 and 7.1 mM UDPG. K_M was studied with 0, 0.1, 0.3, 0.6, 1.2 and 7.1 mM UDPG at 0.1 mM G-6-P. The allele frequency of M416V polymorphism did not differ between NIDDM patients and controls (3.3 vs. 4.2%) from Finland and it was detected only in one Swedish subject. Glucose disposal rate did not differ between the nondiabetic subjects with the MM or MV genotypes (6.5±2.6 vs. 5.9±2.1mg/kg.min). The frequency of G464S polymorphism was low in Finnish NIDDM patients and controls (0.6% and 0.7%) and was not detected at all in Swedish subjects. No significant differences were observed in the GS fractional velocities of the wild type GS, GS-M416V or GS-G464S at 0.3 mM UDPG (22.0±3.5, 20.3±2.1 and 19.4±2.1%) or at 7.1 mM UDPG (18.3±2.3, 16.5±0.7 and 16.1±0.8%). Also the K_M (1.1±0.1, 1.2±0.1, 1.1±0.1 mmol/l) and Vmax ($V_{(0.1)}$: 47.8±4.7, 46.7±3.5 and 43.9±1.7 or $V_{(10.0)}$: 264±28, 283±25 and 273±2 nmol/min.mg prot.) did not differ significantly between the expressed enzymes. Conclusions: The observed aminoacid variants had no significant effect on the function of the glycogen synthase enzyme, which is consistent with the normal insulin sensitivity observed in the nondiabetic sujects with the M416V mutation.

634

HEPATIC NUCLEAR FACTOR 1α MUTATIONS RESULT IN BETA-CELL DYSFUNCTION

Hattersley A.T.[a], Appleton M.[a], Smith S.M.[b], Burrows J.A.[b], Ellard S.[a], Frayling T.[a], Bulman M.[a], Clark P.M.[b] [a]Institute of Clinical Science, University of Exeter, UK.
[b]Regional Endocrine Laboratory, Sellyoak Hospital, Birmingham, UK.

We have demonstrated that mutations of HNF1α are the major cause of Maturity Onset Diabetes of the Young (MODY) in the UK. The underlying pathophysiology is unknown. We used specific insulin and proinsulin assays to study 21 patients with HNF1α mutations and 20 age matched, family members without mutations. The hyperglycaemia seen in subjects with mutations (7.2±2.8 v 4.9+0.6 mmol/l [mean ± SD)] $p<0.005$) resulted from severe beta cell impairment as shown by HOMA analysis of fasting insulin and glucose values(65±48 v 121±79%B $p<0.05$). Proinsulin levels were not significantly increased (PI/I ratio 0.32±0.26 v 0.21±0.18). There was no difference in insulin sensitivity (HOMA 89±51 v 94±105). Not all patients with HNF1α mutations had fasting hyperglycaemia. To determine the determinants of FPG we compared 10 subjects with an fpg< 6.0 mmol/l (9.3±2.0) with 11 subjects fpg>6.0 mmol/l. (4.8±0.8). The hyperglycaemic group had marked beta cell dysfunction (30±24 v 100±41) and were more obese (BMI 24.8±3.4 v 1.6±3.2kg/m^2). These results indicate that the primary determinant of hyperglycaemia in patients with HNF1α mutations is beta-cell dysfunction but obesity may modify the phenotype. Weight loss should be considered as a strategy for delaying or treating non-insulin dependent diabetes in patients who have inherited mutations of HNF1α.

635

Diabetic complications in patients with MODY3 diabetes

Bo Isomaa, Marianne Henricsson, Markku Lehto, Carol Forsblom, Auli Hyrkkö, Leena Sarelin, Maja Häggblom, Leif Groop and the Botnia Research Group. Jakobstad Hospital (Finland), Närpes Health Center (Finland), Helsingborg Hospital (Sweden), Helsinki University Hospital (Finland), University of Lund, Malmö (Sweden).

MODY3 diabetes, which is caused by a mutation in the HNF1α gene on chromosome 12 represents a relatively common monogenic form of diabetes in Finland. Age at onset of diabetes can vary from 10 to 60 years. Therefore, previously most cases have been misdiagnosed as IDDM or NIDDM. The possibility of an etiological diagnosis allows for the first time a description of the natural course of the disease. In order to examine the prevalence of chronic diabetic complications in this form of diabetes, we examined 42 carriers of the MODY3 mutation (38 with diabetes and 6 with IGT) for the presence of retinopathy (Wisconsin retinopathy scale through fundus photography), neuropathy (clinical score and vibration threshold with Biothesiometer), microalbuminuria (AER > 20 µg/min in ovbernight urine) and hypertension (lood pressure > 160/95). Of 38 MODY3 patients 21 (55%) were free of retinopathy, while 12 (32%) had mild non-proliferative retinopathy (NPDR) while 5(13%) had severe NPDR or proliferative retinopathy. The prevalence of retinopathy did not differ from a group of 76 NIDDM patients matched for age, duration of diabetes and HbA1c. Distal sensory neuropathy was found in 8 patients (21%), whereas 9 patients (24%) had AER > 20 µg/min (4 of them had macroalbuminuria), which is similar to the prevalence in a group of 138 NIDDM patients with diabetes duration of 8 years (22%). Eight patients had hypertension (21% vs 75% in NIDDM patients). As well retinopathy (r= 0.66;p=0.001) as neuropathy (r=0.38; p=0.19) correlated with HbA1c. In a logistic multiple regression analysis both HbA1c (RR =2.5, 95% CI 0-6.1) and duration of diabetes (RR 1.11, 95% CI 1.0-2.0) were associated with an increased relative risk of retinopathy. In conclusion, microangiopathic complications are observed with the same frequency in MODY3 as in NIDDM and strongly related to glycemic control. In contrast, hypertension is 3 times less commmon than in NIDDM.

NEW VARIANTS IN THE GLYCOGEN SYNTHASE GENE (Gln71His, Met416Val) IN PATIENTS WITH NON-INSULIN-DEPENDENT DIABETES

J. Rissanen, J. Pihlajamäki, S. Heikkinen, P. Kekäläinen, L. Mykkänen, J. Kuusisto, A. Kolle and M. Laakso. University of Kuopio, Kuopio, Finland

Impaired glycogen synthesis after insulin stimulation accounts for most of the insulin resistance in patients with non-insulin dependent diabetes (NIDDM). The glycogen synthase gene (GS), which encodes the rate-limiting enzyme for glycogen synthesis, is a promising candidate gene for NIDDM. Therefore, we screened all 16 exons of this gene by single-strand conformation polymorphism analysis in 40 patients with NIDDM (age 67±2 years, body mass index 28.2±0.6 kg/m^2) from Taipalsaari, eastern Finland. The Gly464Ser mutation (exon 11) and a silent polymorphism TTC342TTT (exon 7) have been reported previously. In addition, we found a new mutation Gln71His (exon 2) and a new amino acid polymorphism Met416Val (exon 10). An additional sample of 65 patients with NIDDM and 82 normoglycemic men (age 54±1 years, body mass index 26.3±1.4 kg/m^2) were screened. The allele frequency of the TTC342TTT silent polymorphism was 0.29 in both NIDDM and normoglycemic subjects. The Gln71His mutation was found in 1 (1%) of the 105 NIDDM patients and in none of the 82 normoglycemic men. Correspondingly, the Gly464Ser mutation was present in 3 (3%) of the 105 NIDDM patients and in none of the 82 normoglycemic men. The Met416Val polymorphism was found in 16 (15%) of the 105 NIDDM patients and in 14 (17%) of the 82 control subjects (all heterozygous). None of the allele frequencies of the variants differed significantly between NIDDM and control groups. In addition, the Met416Val polymorphism was not associated with insulin resistance in two groups of normoglycemic subjects. In conclusion, the new Gln71His and Met416Val substitutions and other variants of the glycogen synthase gene are unlikely to make a major contribution to insulin resistance and NIDDM in diabetic patients from eastern Finland.

637

Association of glucokinase gene with non-insulindependent diabetes mellitus in Chinese

Zhou Jiaqiang Tong Zhonghang He Xingqing et al

Department of Endocrinology, First Affiliated hospital Zhejiang medical University, Hangzhou, 310003

Abstract Using polymerase chain reaction, the microsatellite repeat polymorphisms in the 3'-flanking region (GCK1) of the human glucokinase gene from 60 non-diabetic, 61 NIDDM and 22 IGT subjects were typed. The differences in allelic frequencies among the three groups were compared. The Z+4 allele was found more frequently in NIDDM patients than in nondiabetic subjects (p<0.005). The frequency of Z+4 allele was 9% in IGT group, between NIDDM (16%) and control group (4%), but it didn't reach statistical significance. The presence of the Z+4 allele was estimated to increase the risk of NIDDM by 4.5 times. The frequency of the Z+2/Z+4 genotype was greater in the NIDDM group (p<0.001) and the frequency of the Z/Z+2 genotype less (p<0.005) compared with those in the nondiabetic group. The results indicate that GCK1 is associated with NIDDM in Chinese.

638

MOLECULAR SCANNING OF p85α REGULATORY SUBUNIT OF PI3-KINASE IN HUMAN SYNDROMES OF SEVERE INSULIN RESISTANCE

K.C.R. Baynes and S. O'Rahilly. University of Cambridge, Departments of Medicine and Clinical Biochemistry, Addenbrooke's Hospital, Cambridge, U.K.

Insulin receptor mutations are the only known genetic cause of severe insulin resistance, but account for only 10% of subjects with Type A insulin resistance syndrome. Phosphatidyl inositol 3-kinase (PI3-kinase) activation appears necessary for insulin-stimulated glucose uptake. Using mRNA from skin fibroblasts or Epstein-Barr virus transformed lymphocytes from 21 subjects with features of the Type A syndrome, we have examined the gene encoding the regulatory subunit of PI3-kinase (p85α) by RT-PCR-SSCP. Four subjects were heterozygous for the common amino acid polymorphism Met 326 Ile. Two subjects had a common silent polymorphism at nucleotide 663. One subject with typical Type A insulin resistance was heterozygous for a novel amino acid change Arg 409 Gln. This was shared with her only sibling, who also had acanthosis nigricans. Within the family, median fasting plasma insulin in those with the mutation (n=4) was 218 pmol^{-1} and in those with the wild-type sequence (n = 2) was 69.5 pmol^{-1} (reference range <60 pmol^{-1}). The position of this mutation within the N-terminal SH2 domain provides further support for the notion that it may be contributing to insulin resistance in this family. This is the first scanning study of PI3-kinase in severe insulin resistance and the first description of a naturally-occurring mutation in a known functional domain.

639

Identification of Glucokinase Mutations in Subjects with Post-Renal Transplantation Diabetes Mellitus

Lee H.C., Nam J.H., Song Y.D., Lim S.K., Kim K.R., and Huh K.B., Korea

Background: Mutations in the glucokinase(GK) gene are considered as possible cause of maturity-onset diabetes of young. The purpose of this study was to evaluate the contribution of this gene to the development of post-renal transplantation diabetes mellitus(PTDM) patients.

Method: Identification of GK mutation was attempted on 58 selected renal allograft recipients with PTDM and 45 normal controls. The exons in the glucokinase gene were examined by the polymerase chain reaction(PCR), and by analysis of the single-stranded DNA conformational polymorphism(SSCP). DNA sequences were also performed by direct sequencing analysis. The exons of affected family members were also investigated for the mutations of GK gene.

Results: Two of 58 PTDM patients(3.2%) were found to have mutations on exon 5, and one patient on intron 7 whereas one control subjects on intron 9. The mutation of exon 5 was identified substitution of CCT(proline) for CTT(leucine) at codon 164 which has not ever reported. The family members of PTDM with mutation of exon 5 were analyzed by PCR followed by SSCP, and two of the family had same mutation. The abnormal band on the SSCP analysis of exon 7 was identified the insertion of base C/T at 39th nucleotide in intron 7. Two of the family had same band on SSCP. The 45 normal controls were also analyzed by PCR-SSCP and had one mutation of G→C located 9th nucleotide in intron 9.

Conclusion: We found the glucokinase mutations in subjects with the PTDM and we speculate that glucokinase mutation may be one of the contributing cause of PTDM.

640

COMPOUND HETEROZYGOSITY OF NOVEL INSULIN RECEPTOR MUTATIONS IN A PATIENT WITH LEPRECHAUNISM.

J.P. Whitehead, R. Jackson, M.A. Soos and S. O'Rahilly. University of Cambridge, Cambridge, UK

A patient with leprechaunism, the most severe form of insulin resistance, was identified as a novel compound heterozygote of the insulin receptor gene, Arg1174Trp & Cys274Tyr, by PCR-SSCP and direct sequencing. In order to characterise these mutant receptors we have reconstructed the 1174 and 274 mutants in the expression vector pRc.CMV and performed transient transfections into CHO cells. The 1174 mutant is defective in tyrosine kinase activity, (p=0.0286, compared with wild-type receptor) as determined by *in vitro* tyrosine kinase assays and the absence of receptor autophosphorylation in anti-phosphotyrosine blots. The 274 mutant exhibits significantly decreased pro-receptor processing, insulin binding and cell surface expression compared to wild-type receptor (all $p<0.03$) as determined by Western blotting, *in vitro* binding studies and cell surface biotinylation respectively. These data indicate that it is the combination of the 2 receptor mutations that are responsible for the patient's most severe form of insulin resistance and represent the first case of such a combination being identified.

641

NO RELATION BETWEEN INSULIN SECRETION AND β-CELL SPECIFIC GLUCOKINASE PROMOTER VARIATION IN GESTATIONAL DIABETES.

JT Woo, HC Chang*, SW Kim, IM Yang, JW Kim, YS Kim, YK Choi, Kyung-Hee University, Samsung Cheil Hospital*, Seoul, Korea

There is a large body of evidence that many women with gestational diabetes mellitus(GDM) have abnormal pancreatic β-cell function. Very little is known about processes that underlie the defects in insulin secretion . Therefore we investigated whether the G/A variation at position -30 of the β-cell glucokinase gene promoter is related to insulin secretion in patients with GDM. Twenty six patients with GDM were selected according to NDDG recommendation. The variation of the β-cell glucokinase gene promoter was determined by single-strand confirmation polymorphism and direct sequencing. Pancreatic β-cell function was evaluated using the ratio of the incremental response in immunoreactive insulin(IRI) to that of glucose during the first 30 min of the 75 g oral glucose tolerance test(ΔIRI[30 min - 0 min/Δglucose[30 min - 0min]] performed at postpartum 8 week. Fourteen patients were G/G homozygote for this variant(56 %). G/A heterozygote was determined in 9 patients(36 %), A/A homozygote in 2 patients(8 %). Their BMIs before pregnancy did not differ between patients with G/G and patients with G/A or A/A(22.5± 2.3 *vs* 23.8± 2.9 $P = 0.283$). Fasting IRI(67.6 pmol/l *vs* 61.9 pmol/l as median, $P = 0.775$) and ΔIRI[30 min - 0 min/Δglucose[30 min - 0min](40.1x10^{-9} *vs* 62.8x10^{-9} as median, $P = 0.224$) did not differ between groups. These results suggest that the variation at -30 of the β-cell glucokinase gene promoter is not associated to reduced insulin secretion in Korean patients with GDM.

642

ANTIBODIES TO ICA512 AND GAD65 IN PATIENTS WITH NON-INSULIN-DEPENDENT DIABETES (NIDDM) FROM EASTERN INDIA.

A. Kanungo, A. Shtauvere, K.C. Samal, B.B. Tripathy, A. Falorni and CB. Sanjeevi,. Dept of Endocrinology, Cuttack; Dept of Molecular Medicine, Stockholm; Dept. of Internal Medicine, Endocrine and Metabolic Sciences, Perugia. Sweden, India and Italy.

Antibodies to tyrosine pyrophosphatase (ICA512) and glutamate decarboxylase 65 (GAD65) are markers for IDDM. The aim of our study was to determine the prevalence of ICA512 and GAD65 antibodies (Ab) in NIDDM patients (n=218) and 123 healthy controls from Cuttack in Eastern India.. Early onset (EO) NIDDM (onset <35 years) were 128 and late onset (LO) NIDDM (onset >35 years) were 90. ICA512Ab and GAD65Ab were evaluated by RIA using *in vitro* translated recombinant human 35S-ICA512 and 35S-GAD65 respectively. In controls, ICA512Ab were present in 3/123 (2%) and GAD65Ab in 8/123(7%). ICA512Ab were present in 85/218(39%) of all NIDDM patients ($p<0.001$) and 51/128 (40%) ($p<0.001$ vs controls) EO-NIDDM with a male preponderance and 34/90 (38%) ($p<0.001$ vs controls) LO-NIDDM with a female preponderance. GAD65Ab were present in 15/218 (7%) of all NIDDM (p=ns) and 12/128(9%) (p=ns vs controls) of EO-NIDDM and 3/90(3%) of LO-NIDDM (p=ns vs controls). When ICA512Ab and GAD65Ab positivity was analyzed in relation to age, 0/3 in <20; 30/41(73%) in 20-30; 25/97 (26%) in 31-40; 12/39(31%) in 41-50; 14/23(60%) in 51-60 and 4/15 (26%) in >60 years were ICA512Ab positive showing a distinct peak in 20-30 and 51-60 years. GAD65Ab were found in 0/3 in <20; 7/41(17%) in 20-30; 5/97 (5%) in 31-40; 2/39(5%) in 41-50; 0/23 in 51-60 and 1/15 (7%) in >60 years. Both ICA512Ab and GAD65Ab were negative in 66/128(52%) EO-NIDDM and 53/90(59%) LO-NIDDM; both Abs were positive in 3/128(2%) EO-NIDDM and 0/90 LO-NIDDM; either ICA512 Ab or GAD65Ab were positive in 60/128(47%) EO-NIDDM and 37/90 (41%) LO-NIDDM; ICA512Ab+/GAD65Ab- in 48/128(38%) in EO-NIDDM and 34/90(38%) in LO-NIDDM; and ICA512Ab-/GAD65Ab+ in 9/128(7%) EO-NIDDM and 3/90(3%) in LO-NIDDM. We conclude that patients from Cuttack in Eastern India, have GAD65Ab at a low and ICA512Ab at a significant high frequency in NIDDM compared to controls. ICA512Ab and GAD65Ab account for 47% of NIDDM patients indicating the presence of autoimmune process in the etiology of NIDDM.

643

SCREENING OF SULPHONYLUREA RECEPTOR 1 (SUR1) FOR MUTATIONS IN DIFFERENT TYPES OF NIDDM

Y Hashim, A Gloyn and RC Turner. Diabetes Research Laboratories, Oxford University, Oxford, UK.

Sulphonylurea receptor 1 (SUR1) is a subunit of the pancreas islet β-cell K-ATP channel that regulates glucose-induced insulin secretion. As mutations in a nuclear binding fold (NBF-2) cause neonatal hyperinsulinism, other mutations could impair insulin secretion. Two population association studies have shown that polymorphisms in SUR1, at exon 22 (T761T) and intron 24 splice acceptor site -3 tag GCC to -3cag GCC were significantly more prevalent in patients with NIDDM than normal control subjects, the combined polymorphisms having an odds ratio of 21 (95% CI 2.9 - 160). These polymorphisms thus could be in linkage disequilibrium with a pathogenic mutation in SUR1. We have screened SUR1 for mutations by SSCP in different types of white Caucasian patients with NIDDM who have neither ICA nor GADA: (i) 20 non-obese (BMI <27 $kg.m^{-2}$) who presented age <50 yrs with fpg <8 mmol/l (i.e. similar to glucokinase deficient, MODY2 patients) (ii) 20 non-obese subjects who presented with fpg >12 mmol/l who had marked β-cell deficiency and a family history of diabetes (iii) 20 NIDDM subjects with both the exon 22 and intron 24 mutations (iv) 20 randomly selected patients with NIDDM. No mutations were identified in the exons of any of these subjects. This indicates that mutations in SUR1 are unlikely to be a common cause of diabetes in NIDDM in white Caucasian subjects, but does not exclude mutations in the promoter region of SUR1 or in neighbouring genes on chromosome 11 p15.1.

644

The phenotypes, genotypes and antibodies to glutamic acid decarboxylase (GAD) in young Chinese diabetic patients

JCN Chan, VTF Yeung, CC Chow, KTC Ko, KY Li, WY So, MSW Lau, SH Cheng, JAJH Critchley, *P Zimmet, **AH Barnett and CS Cockram. The Chinese University of Hong Kong, Hong Kong, *International Diabetes Institution, Australia and **University of Birmingham, UK.

The prevalence of diabetes amongst Hong Kong Chinese aged less than 40 years old is 1.3%. The incidence of childhood IDDM is 1.8/100,000/year. In a clinic-based population, 16% of adult patients had onset of disease before 35 years old. In these young patients, 10% had IDDM compared to 2% in patients with disease onset after 35 years. The prevalence of obesity (36% vs 28%), positive family history (42% vs 17%, $p<0.01$) and insulin treatment (50% vs 20%, $p<0.01$) also tended to be higher in these young patients. We examined the phenotypes, auto-immune status and genotypes in a cohort of 140 Chinese diabetic patients with disease onset before 35 years and aged less than 40 years. IDDM was defined as presentation with diabetic ketoacidosis or ketonuria (>3+) or continuous insulin treatment within one year of diagnosis. Insulin deficiency was defined as a post-glucagon plasma C peptide concentration <0.6 nmol/l. The prevalence of insulin deficiency was 50% but anti-GAD (>18 units) was 12% only. The prevalence of anti-GAD was 23% in IDDM and 7.2% in NIDDM [sensitivity: 23% (10/43); specificity: 93% (9097)]; 18.5% in insulin deficient and 6.7% in non-insulin deficient patients [sensitivity: 18.5% (12/65); specificity: 93% (70/75)]. The prevalence of anti-GAD was 29% in patients who had both insulin deficiency and IDDM presentation compared to 6% in those who were non insulin deficient and had NIDDM. The anti-GAD negative patients had higher BMI (26 vs 23 kg/m^2, $p=0.05$), systolic BP (114 vs 107 mmHg, $p=0.03$), triglyceride (1.26 vs 0.7 mmol/l, $p<0.01$), and lower HDL-C (1.23 vs 1.48 mmol/l, $p<0.01$), HbA_{1c} (7.7% vs 9.3%, $p=0.04$) and prevalence of insulin deficiency (43% vs 71%, $p<0.05$). Over 50% of these patients had evidence of microangiopathic complications. In the anti-GAD negative group, 4 patients had mitochondrial DNA mutation. None of the patients had glucagon receptor gene mutation. These findings confirm the rarity of classical IDDM and heterogeneity of both phenotypes and genotypes in young Chinese diabetic patients.

645

IDENTIFICATION AND FUNCTIONAL ANALYSIS OF VARIANT SUR1 IN JAPANESE WITH NON-INSULIN-DEPENDENT DIABETES MELLITUS

Y. Tanizawa, Y. Ota, H. Inoue, V.P. Repunte, M. Yamada, K. Ueda, J. Nomiyama, Y. Kurachi, M.A. Permutt, J. Bryan, L Aguilar-Bryan and Y. Oka. Yamaguchi University, Ube, Japan, Osaka University, Suita, Japan, Washington University, St. Louis, U.S.A., Baylor College of Medicine, Houston, U.S.A.

Mutations of the sulfonylurea receptor 1 (SUR1) gene were examined by means of single strand conformation polymorphism analysis in 100 Japanese subjects with non-insulin-dependent diabetes mellitus (NIDDM). After examining all 39 exons of this gene, we identified 5 amino acid substitutions and 19 silent mutations. A Ser to Ala substitution, located in the second nucleotide binding fold (NBF-2), was common (allelic frequency 0.41) and was also found at an equal frequency in non-diabetic control subjects. Four other missense mutations were rare: an Arg to Gln substitution in exon 6 (6RQ), a Val to Met substitution in exon 12 (12VM), an Asp to Asn substitution in exon 20 (20EN) and an Arg to Cys substitution in exon 21 (21RC) were identified in one patient each, all in the heterozygous state. The 6RQ and 20EN were not found in 67 control subjects. The 21RC and 12VM were present in one and three control subjects, respectively. The 6RQ, 12VM and 21RC did not appear to cosegregate with NIDDM in the probands' families. To analyze possible functional alterations, we introduced 4 rare mutations at the corresponding positions of mouse SUR1 cDNA. We then co-expressed the SUR1 mutants with mouse BIR, a channel subunit of the ß-cell ATP sensitive K channel (I_{KATP}), in HEK293T and COS-7 cells, and examined the channel activities by the patch clamp technique and $^{86}Rb^+$ efflux measurements. The 20EN and 21RC, both located in the NBF-1, did not alter Ki for the ATP of I_{KATP} regardless of the presence or absence of Mg^{2+}. Inhibition of $^{86}Rb^+$ efflux by glibenclamide and activation by metabolic inhibition or diazoxide did not differ between the cells expressing the wild type SUR1 and either of the two mutants. Functional studies of the other two mutations are currently underway. In conclusion, SUR1 mutations impairing I_{KATP} function are rare in Japanese NIDDM patients, and do not appear to be major determinants of the susceptibility to NIDDM in the population.

646

GENETIC INTERACTION BETWEEN IDDM AND NIDDM

H. Li, T. Tuomi, M. Orho, C. Forsblom, L. Groop and the Botnia Research Group, Diabetes and Endocrine Research Laboratory, Dept. Endocrinology, Malmö University Hospital, Sweden and Helsinki, Finland

An overrepresentation of IDDM in the offspring of NIDDM patients supports a genetic interaction between IDDM and NIDDM. To investigate whether sharing an HLA haplotype with an IDDM proband influences insulin secretion in other family members, we studied 26 mixed IDDM/NIDDM Finnish families. HLA DRB1-DQA1-DQB1 haplotypes were typed by PCR and dot-blot hybridisation using oligonucleotide probes. The 173 GAD-antibody negative 2nd or more distant degree relatives (105 NGT, 24 IGT, 44 NIDDM) of 23 unrelated IDDM probands were assigned into 2 groups according to whether they shared one or zero HLA-haplotype with the IDDM proband. The shared haplotype was 0401/4-0301-0302 or 17-0501-0201 in 75% of the families. 80% of the relatives sharing an HLA haplotype with the IDDM proband had an IDDM susceptibility haplotype. Relatives with NIDDM sharing IDDM HLA haplotypes had a lower insulin-response to OGTT (Incremental area 3489.4±1615.2 vs. 8287.6±6919.5 mU/L, $p=0.034$), and a higher fasting glucose level (8.9±2.9 vs. 7.5±3.2 mmol/l, $p=0.048$) compared with those not sharing. In response to OGTT, nondiabetic relatives sharing IDDM HLA haplotypes had higher glucose values than those not sharing (glucose area 243.7±141.5 vs. 180.6±134.7, $p=0.044$). To examine whether the reduced insulin response was due to the presence of the IDDM susceptibility haplotype in general or whether it had to be shared with the IDDM proband, we also studied 101 unrelated NIDDM patients (66±11 yr, 44M/57F) and 205 nondiabetic subjects (104 NGT/101 IGT, 54±15 yr, 93M/112F) without family history of IDDM. The insulin and glucose responses did not differ between subjects with or without IDDM susceptibility HLA haplotypes.

Conclusions: Sharing an HLA haplotype with an IDDM proband is correlated with impaired insulin secretion and elevated glucose response in NIDDM patients and nondiabetic subjects. The findings indicate the presence of a genetic interaction between IDDM and NIDDM, which cannot be explained solely by the presence of IDDM susceptibility HLA haplotypes in the NIDDM population.

647

ASSOCIATION OF SULFONYLUREA RECEPTOR (SUR) GENE VARIANTS WITH JAPANESE NIDDM.
M.Odawara,M.Asano,Y.Tachi,and K.Yamashita.
University of Tsukuba,Tsukuba,Japan.
Sulfonylurea receptor(SUR) has been suggested to play a crucial role in the regulation of insulin secretion. SUR gene abnormalities may result in impaired insulin secretion,leading to glucose intolerance. A recent observation indicates that SUR gene variants are associated with NIDDM in Caucasian populations. We investigated whether three variants of the SUR gene are associated with Japanese patients with glucose intolerance by using PCR-RFLP method. We screened 599 Japanese subjects (NIDDM, n=383,non- diabetic controls,n=216). The c/c mutant genotype in intron 24 splice acceptor site was significantly increased in NIDDM patients compared with that in non-diabetic control subjects (chi square=6.01, p=0.014). A silent variant (Thr761Thr) in exon 22 was not detected in 373 NIDDM patients but was present in only one control subjects, unlike the association of it with Caucasian NIDDM patients. An association of a SUR gene variant with Japanese NIDDM patients,as well as an association of another SUR gene variant with Caucasian counter- part, suggest an important role of the SUR gene in the pathogenesis of NIDDM in Japanese as well as in Caucasian subjects.

648

INSERTION / DELETION POLYMORPHISM IN ANGIOTENSIN CONVERTING ENZYME GENE IN HEALTHY THAIS AND PATIENTS WITH NIDDM
Ploybutr S*, Nitiyanant W*, Sriussadaporn S*, Bejrachandra S**.
Department of Medicine* and Department of Tranfusion Medicine**, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok,Thailand.

Insertion/deletion (I/D) polymorphism in the angiotensin converting enzyme (ACE) gene has been shown to associate with various cardiovascular disorders in diabetic and non-diabetic patients. Its association to the development of NIDDM has been raised. This study was aimed to examine prevalence of I/D ACE genotypes in healthy Thai subjects and patients with NIDDM. The I/D ACE genotypes were determined by polymerase chain reaction technique. Healthy unrelated subjects were hospital staffs and blood bank donors who had no known medical illness at the time of study. They were 151 males and 147 females, aged 17-70 years old (mean±SD = 37.5±10.4). The unrelated diabetic patients were 42 males and 66 females, aged 20-79 years old. (mean±SD = 54.7±12.0). The results were shown in the Table below. There were no differences in the prevalence of I/D ACE genotypes between healthy males and females (p = 0.86), diabetic males and females (p = 0.98), as well as healthy and diabetic subjects (p = 0.81). The frequency of I and D alleles in diabetic patients were 0.69 and 0.31, respectively which were similar to those of healthy subjects, 0.70 and 0.30, respectively (p = 0.69). The frequency of I and D alleles in healthy Thai subjects were similar to those of Japanese (0.66 and 0.34) but different from those of Caucasians (0.44-0.46 and 0.56-0.54). In conclusion, the frequency of I and D alleles may possess a racial difference. The similar frequency of both alleles in diabetic patients and healthy subjects suggests that there is no association between I/D polymorphism of ACE gene and diabetes mellitus in Thai individuals.

Genotypes	Healthy Subjects (%)			Diabetic patients (%)		
	males	females	all	males	females	all
DD	9.3	10.9	10.1	9.5	10.6	10.2
ID	40.4	38.1	39.2	42.9	42.4	42.6
II	50.3	51.0	50.7	47.6	47.0	47.2

649

A NOVEL MUTATION OF AMYLIN GENE (SER20GLY) IDENTIFIED IN JAPANESE NON-INSULIN-DEPENDENT DIABETES MELLITUS.

S. Sakagashira, T. Sanke, T. Hanabusa, S. Ohagi, and K. Nanjo. Department of Medicine, Wakayama University of Medical Science, Wakayama, Japan

Non-insulin-dependent diabetes mellitus (NIDDM) is a multifactorial disease, and the amyloid deposit in pancreatic islets is one of the characteristic finding in NIDDM patients. Amylin, a 37 amino acid peptide which is co-secreted with insulin from islet β cells, is a major constituent of islet amyloid in NIDDM patients. Although its true action(s) is still unclear, recent studies suggest that amylin may have the possible pathogenesis of NIDDM. We therefore scanned the amylin gene for mutations in 294 unrelated Japanese NIDDM patients using PCR/SSCP analysis, and found a single heterozygous missense mutation at the position 20 of amylin molecule (AGC^{Ser} to GGC^{Gly}: Ser20Gly mutation) in 12 NIDDM patients. None of 187 non-diabetic subjects (over 60 years old and negative family history of diabetes) and 59 patients with insulin-dependent diabetes mellitus had the mutation. Eight out of the 12 patients carrying the mutation were diagnosed as having NIDDM before 35 years old, and they had treated by insulin and each of them had a parent having late-onset NIDDM. On the other hand, the remaining 4 patients were diagnosed as having NIDDM after 51 years old. They had mild diabetes without family history of diabetes. Family studies disclosed the mutation was transferred from the parent having impaired glucose tolerance (IGT), not from the parent having NIDDM. The frequency of the mutation among whole NIDDM was 4.1 % and it reached to 10.0 % (8/80) in relatively early onset (≦35 years) NIDDM patients. Amylin immunoreactivities extracted from affected patient's plasma were appeared at the position corresponding not only to the normal amylin (16.0 %) but also to the synthesized Gly20-amylin (84.0 %) in HPLC analysis. These data suggest that Ser20Gly mutation can cause mild diabetes on its own; however, when it is combined with unknown susceptibility genes for late onset NIDDM, it contributes to the earlier onset of the NIDDM and makes it more severe. We present the first report referring to a missense mutation of amylin gene in Japanese NIDDM patients. This Ser20Gly mutation may play a important role in the pathogenesis of early onset NIDDM in Japanese population, and may provide a good model to investigate and interpret the true physiological action(s) of amylin.

I/D POLYMORPHISM OF THE ACE GENE IN PATIENTS WITH HYPERTENSION, NIDDM AND CORONARY HEART DISEASE.

L.M. Chuang, K.C. Chiu, F.T Chiang, K.C. Lee, H.P. Wu, B.J. Lin and T.Y. Tai. Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; Division of Endocrinoloty and Metabolsim, UCLA School of Medicine, Los Angeles, California, U.S.A.

An insertion/deletion (I/D) polymorphism of the angiotensin converting enzyme (ACE) gene has been identified which determined most of the plasma ACE activity genetically. Association of the D-allele with insulin sensitivity, and D/D genotype with coronary heart disease (CHD) have been reported in various ethnic populations. To study the role of this genetic polymorphism in patients with hypertension, non-insulin-dependent diabetes mellitus (NIDDM), and NIDDM with CHD in Taiwanese population, we employed a polymerase-chain-reaction-based genotyping technique with an insertion-specific primer for confirmation of the I-allele. One hundred and ninety-seven unrelated normal controls, 67 subjects with hypertension, 107 subjects with NIDDM, and 70 NIDDM with CHD were recruited for this study. All of them were Han Chinese. Subjects without a history of diabetes were studied by a standard 75 g oral glucose tolerance test. Hypertension was diagnosed according to the 5th JNC criteria and CHD was confirmed by the history of acute myocardial infarction and coronary angiographic intervention. The frequency of I-allele of the ACE gene in the normal population was 64.2% which was higher than those reported in the Caucasian populations. The prevalence of the I-allele of the ACE gene was not significantly increased in subjects with hypertension (73.1%), NIDDM (62.1%), and NIDDM with CHD (65%) as compared to that of healthy controls. I-allele of the ACE gene did not correlate with demographic and metabolic variables. The I/D polymorphism of the ACE gene is not a marker for hypertension, NIDDM or CHD in Taiwanese population.

651

ABSENCE OF THE S20G MUTATION OF THE AMYLIN GENE IN PATIENTS WITH GESTATIONAL DIABETES MELLITUS (GDM).

M. Alevizaki, E. Anastasiou, L.Thalassinou, S.I.Grigorakis, G.Philippou and A.Souvatzoglou. Dept Medical Therapeutics and 1st Endocrine Unit & Diabetes Centre, ALEXANDRA University Hospital, Athens, GR.

A missense mutation in the amylin/IAPP gene has recently been reported in 4.1% of Japanese patients with NIDDM (Ser to Gly at position 20). When this mutation is not combined with other hereditary factors, it is associated with mild glucose intolerance. The aim of the present study was to investigate whether the S20G mutation of the amylin gene could be one of the factors responsible for the development of GDM, which represents a mild form of glucose intolerance, unmasked because of the pregnant state. So far, we have studied 115 patients with GDM (age range 20-46 yrs), who were diagnosed according to the NDDG criteria. All patients were reevaluated 2-12 months after delivery by a standard 75g OGTT; none of them had overt diabetes. 62% had a positive family history for NIDDM (either paternal or maternal side or both). In parallel, we have studied 15 patients with NIDDM with early (<35yrs) onset of the disease, a subgroup in which the original paper from Japan reported a higher (10%) frequency of the mutation. DNA was extracted from peripheral lymphocytes using standard methods. The third exon of the IAPP gene was amplified by PCR and tested for the presence of the S20G mutation by RFLP using the enzyme Msp1, which recognises the mutated sequence. In the sample we have studied so far, no S20G mutation of the amylin gene has been observed in neither the GDM nor the NIDDM group. One explanation is that this mutation may not be present in the Greek population at all, although the NIDDM group is still very small. From the results in the GDM group one may conclude that this mutation is not associated with a temporary disturbance of glucose metabolism. It is therefore possible that the S20G mutation, if present in caucasians at all, should be looked for in patients with glucose intolerance persisting outside pregnancy.

652

THREE CANDIDATE GENES FOR DIABETIC ANGIOPATHY IN GENERAL MOSCOW POPULATION AND NIDDM PATIENTS

V.V.Nosikov[1], D.A.Chistyakov[1], R.I.Tourakoulov[1], Y.Y.Kondratiev[1,2], L.M.Demurov[1], G.G.Mamaeva[2], M.I.Balabolkin[2], and I.I.Dedov[2]. [1]National Research Centre "GosNII Genetika" and [2]Endocrinology Research Centre, Moscow, Russia

Vascular tone abnormalities, polyol pathway activation, and oxidative stress are known to involve in diabetic angiopathy (DA) development. We have begun to study genetic susceptibility/resistance to DA using a set of polymorphic markers attributed to such candidate genes as angiotensin I-converting enzyme (ACE), aldose reductase (ALR2) and catalase (CAT). Polymerase chain reaction (PCR) was used to detect insertion/deletion (I/D) polymorphism of ACE gene and polymorphic microsatellite at 5'-region of ALR2 gene (7 alleles; 132-144 bp). To identify a polymorphic marker nearby CAT gene we used STS (sequence-tagged site) developed for CAT gene. This STS was used for identification of individual YAC clones in a YAC library developed in CEPH (Paris) in collaboration with Dr. I.M.Chumakov. It was shown that YAC clone AFM109ya1 contained both CAT gene STS and D11S907 polymorphic microsatellite (7 alleles; 161-173 bp). The first aim of this work was to study distribution of alleles and genotypes of these markers in control donors from general population and in a group of subjects with NIDDM. The latter composes vast majority of diabetic patients highly predisposed to DA. Distribution of ID/ACE alleles and genotypes in general population (n=168) and NIDDM patients (n=48) was very similar. We observed significant difference in allele distribution for ALR2 and CAT genes between general population and NIDDM patients: ALR2 allele Z+4 frequency was 0.246 vs. 0.152, respectively ($p < 0.05$); and CAT 169 bp allele frequency was 0.321 in general population vs. 0.118 in NIDDM patients ($p < 0.0002$). Differences in distribution of another alleles and genotypes for ALR2 and CAT loci did not reach significance level. In conclusion, the observed differences allow us to suggest that either ALR2 and CAT genes or some another genes located in the same chromosome regions might be implicated in NIDDM and/or its complication development.

653

ANALYSIS OF THE RELATIONSHIP BETWEEN A COMMON CYS282TYR VARIANT OF THE HEREDITARY HAEMOCHROMATOSIS GENE AND NIDDM

S. K. Rasmussen[1], S. M. Echwald[1], L. Hansen[1], T. Hansen[1], S. Urhammer[1], J. O. Clausen[1], R. Wolff[2] and O. Pedersen[1]. [1]Steno Diabetes Center and Hagedorn Research Institute, Copenhagen, Denmark; [2]Mercator Genetics Inc., California, USA.

Hereditary haemochromatosis (HH) is an autosomally inherited recessive disorder causing excessive iron uptake and deposition in various organs including liver and pancreas, ultimately leading to organ failure in untreated cases. Recently, the HH causing gene, HLA-H was cloned, and a Cys282Tyr variant was shown to be responsible for most cases of HH in a US population. Since HH is often associated with decreased glucose tolerance or overt diabetes most likely due to the iron deposition in the pancreas we examined the hypotheses that the Cys282Tyr variant of the HLA-H gene was associated 1) with an increased prevalence of NIDDM, 2) impaired insulin secretion or 3) impaired insulin sensitivity.

We screened for the codon 282 variant by RFLP using *RsaI* restriction enzyme in 2 Danish cohorts: I) In a cohort of 246 NIDDM patients (mean age 55 years) and in 242 age matched glucose tolerant control subjects; the allele frequency of the 282 variant was 3.1 % and 4.8 % respectively ($p > 0.1$). Measurements of fasting insulin, and results of OGTT from all 242 control subjects showed no correlation between specific phenotypes and the Cys282Tyr variant and II) In a cohort of 377 young healthy Caucasians, the allele frequency of the 282 variant was 5.2 %. All participants in this study were tested with an intravenous glucose tolerance test with addition of tolbutamide (Minimal model). Analyses of insulin secretion, insulin sensitivity and glucose effectiveness with or without gender stratification failed to show any significant relationship between the presence of the Cys282Tyr variant and the measured variables. The distribution of genotypes in both cohorts were in Hardy-Weinberg equilibrium and only one homozygous carrier was identified in each cohort.

In conclusion: 1) The codon 282 variant of the HLA-H gene is common in the Danish population with an allele frequency of about 5 %. 2) However, this common variant is not associated with an increased prevalence of NIDDM or alteration in insulin sensitivity or insulin secretion.

654

RELATIONSHIP BETWEEN ACE GENE POLYMORPHISM AND OBESITY IN JAPANESE NIDDM PATIENTS

K. Nakamura, H. Hirose, A. Kasuga, H. Maruyama, and T. Saruta.
Keio University School of Medicine, Tokyo, Japan

Since Cambien reported angiotensin-I converting enzyme (ACE) gene polymorphism was associated with ischemic heart disease (1992), many investigations were carried out about ACE gene D/I polymorphism related to diabetic nephropathy. However, there is no confirmative agreement. We examined age, sex, BMI, blood pressure, plasma glucose, lipid profiles (TC, TG, HDL-C, LDL-C. FFA), UA, duration of diabetes, nephropathy (plasma creatinine, and proteinuria) ,and retinopathy in 104 NIDDM patients (aged 57.4± 10.8, BMI 24.2± 4.5, HbA1c 7.5± 1.7% (SD)). D/I polymorphism was analysed by the PCR method. There was increase in BMI in DD type (II 24.1±3.9, ID 23.6±3.4, DD 26.6±6.9, P=0.049) by ANOVA. Plasma leptin concentration (n=37) was also significantly higher in DD type (II 4.4±2.0, ID 6.1±5.4, DD 9.1±6.4 ng/ml). There was no correlation between ACE gene polymorphism and blood pressure, glucose, lipid profiles, UA, duration of diabetes, nephropathy or retinopathy. In conclusion, the data suggest that ACE gene polymorphism is associated with body mass index and plasma leptin concentration in Japanese NIDDM patients. We found no correlation with blood pressure, diabetic control or severity of complications in this study.

655

AMINO ACID VARIANTS IN HUMAN GIP RECEPTOR AND THEIR IMPACT ON THE PANCREATIC B-CELL RESPONSE

K. Almind[1], L. Ambye[1], S. A. Urhammer[1], T. Hansen[1], S. M. Echwald[1], J. J. Holst[2] and O. Pedersen[1]. [1]Steno Diabetes Center and Hagedorn Research Institute, [2]Department of Medical Physiology, University of Copenhagen, Denmark

The two incretins, glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1), are insulinotropic factors released from the small intestines to the blood stream in response to oral glucose ingestion. The insulinotropic effect of GLP-1 is maintained in patients with NIDDM, whereas, for unknown reasons, the effect of GIP is diminished or lacking in NIDDM patients. We performed a mutational analysis of the GIP receptor to test the hypothesis that genetic variability of the GIP receptor: 1) affects the pancreatic β-cell responses in the fasting state or after oral glucose and 2) is associated with an increased prevalence of NIDDM. The primary screening of 61 random Caucasian NIDDM patients revealed two amino acid polymorphisms, A207V and E354Q, in the GIP receptor gene. In an association study of 227 Caucasian NIDDM patients and 224 matched glucose tolerant control subjects, the allelic frequency of the A207V polymorphism was 1.1% in NIDDM patients and 0.7% in control subjects ($p>0.2$), whereas the allelic frequency of the codon 354 polymorphism was 24.9% in NIDDM patients versus 23.2% in control subjects. The phenotype of the glucose tolerant heterozygous carriers of the E354Q polymorphism was indistinguishable from that of the wildtype carriers. Interestingly, however, compared to subjects with the wildtype GIP receptor the 6% of the glucose tolerant control subjects who were homozygous for the codon 354 variant had a 14% decrease in fasting serum C-peptide level ($p=0.014$) and an 11% decrease in the same variable 30 min after an oral glucose load ($p=0.034$). The 3 control subjects carrying the heterozygous A207V polymorphism also tended to have lower serum C-peptide responses during an OGTT. In conclusion: the reduced fasting serum C-peptide level in homozygous carriers of the common codon 354 amino acid polymorphism in the GIP receptor may suggest, that GIP even in the fasting state exerts a regulatory impact on the β-cell secretory response.

656

POLYMORPHISM OF THE ALDOSE REDUCTASE GENE IS ASSOCIATED WITH ALDOSE REDUCTASE PROTEIN LEVELS AND DIABETIC MICROANGIOPATHY.

M.Ogata, N.Iwasaki, M.Kanamori*, T. Itoh, Y.Takahashi, H.Ohgawara, and Y.Omori, Tokyo Women's Meidcal College, Toho University*, Tokyo, Japan

AIM: Glycation affects the development of diabetic complications such as retinopathy, nephropathy and neuropathy. Aldose reductase (AR) is a key enzyme which plays an essential role in the polyol pathway. We have measured erythrocyte aldose reductase (AR) protein levels and genotyped AR gene polymorphism in 140 NIDDM patients without overt renal dysfunction or a history of taking AR inhibitors. METHODS: Erythrocyte AR protein levels were measured by highly sensitive two-site ELISA using recombinant human AR. Among the NIDDM patients, 53 were without retinopathy, 51 had simple retinopathy, and 36 had preproliferative or proliferative retinopathy (PDR). Microsatellite polymorphisms in the 5'-flanking region of the AR gene were typed using the polymerase chain reaction. RESULT: The average AR protein level in these patients was 9.7±3.2 (mean±SD) ng/mgHb, which is nearly equal to the reported levels of the normal controls. Tandem C-A repeats of the AR gene were highly polymorphilic, 9 alleles were observed in the NIDDM group and 10 alleles were seen in 74 normal control subjects. Patients who had alleles 5 and 10 (the latter one is not observed in the Chinese population) showed higher AR levels. The relationship between AR levels and rate of retinopathy were estimated using the Cox's proportional hazard model. Proliferative retinopathy were significantly associated with AR levels. The frequency of PDR was 4.85 fold higher in patients whose AR levels were over 12.0 ng/mgHb compared to whose levels were lower than 7.4ng/mgHb. This result suggested that high levels of AR may play a role in the development of proliferative retinopathy. Patients with allele 5 of 136 bp in size were the most common in the group with PDR, which corresponded to the size previously reported to be associated with retinopathy in a Chinese population. Allele 10 was found to be significantly associated with PDR in patients with NIDDM ($p<0.03$). CONCLUSION: These observations show that AR protein levels are regulated by genetic factors and are also associated with the development of retinopathy (and nephropathy) in NIDDM.

Is abnormal expression of mitochondrial genes in skeletal muscle genetically determined ?

X. Huang, L. Koranyi, K.F. Eriksson, M. Lehtovirta, A. Vaag and L. Groop. Dept of Endocrinology, Univ of Lund, Malmö, Sweden

Decreased VO_{2max} associated with insulin resistance in muscle of NIDDM patients suggests the existence of defects in mitochondrial respiration. We have isolated four mitochondrial genes (NADH dehydrogenase subunit 1, cytochrome c oxidase subunit 1, $tRNA^{leu}$, and D-Loop region) with abnormal expression in muscle by cDNA differential display. It is, however, not known whether these defects are acquired or inherited. To address this question, we examined the expression of these genes in muscle biopsies from 15 NIDDM patients (age: 65 ± 1 yrs, BMI: 28.2 ± 0.9 kg/m^2 , FBG: 10.8 ± 1.0 mmol/l), 15 IGT patients (age: 66 ± 1 yrs , BMI : 27.1 ± 1.0 kg/m^2 , FBG: 5.4 ± 0.2 mmol/l), and 14 control subjects (age: 65 ± 1 yrs , BMI: 27.6 ± 0.8 kg/m^2 , FBG: 4.7 ± 0.1 mmol/l) and 12 monozygotic twin pairs discordant for NIDDM but concordant for insulin resistance. Muscle biopsies were taken at the end of an euglycaemic insulin clamp combined with indirect calorimetry. As expected glucose disposal (control 6.29 ± 0.64; IGT 4.35 ± 0.45; NIDDM 2.82 ± 0.42 mg/kgmin; $p < 0.01$), glucose oxidation (control 2.12 ± 0.15; IGT 1.95 ± 0.14; NIDDM 1.47 ± 0.17 mg/kgmin; $p = 0.01$) and VO_{2max} (control 31.00 ± 2.06; IGT 28.54 ± 1.44; NIDDM 23.55 ± 1.89 ml/kg; $p = 0.02$) were decreased in NIDDM and IGT vs controls. NADH dehydrogenase subunit 1 (NADH DH 1) mRNA expressed relative to cytoplasmic β-actin was decreased by 54 % in NIDDM and by 14 % in IGT vs controls ($p < 0.05$), while the expression of the other genes was not different between the groups. NADH DH 1 mRNA content correlated positively with VO_{2max} ($r = 0.44$, $p < 0.01$). However, there was no difference in expression of NADH DH 1 between the twins. In conclusion, decreased expression of genes encoding for mitochondrial respiratory chain enzymes may contribute to decreased aerobic capacity in NIDDM. This is an acquired rather than an inherited defect, possibly an adaption to the reduced amount of glucose taken up by the cell.

MUTATION OF THE CALCIUM-BINDING DOMAIN OF THE MITOCHONDRIAL GLYCEROPHOSPHATE DEHYDROGENASE GENE IN A FAMILY OF DIABETIC SUBJECTS

J. Vidal, A. Novials, C. Franco, F. Ribera, A. Sener*, W.J. Malaisse* and R. Gomis. Diabetes Unit and Hormonal Laboratory, Hospital Clinic, Barcelona, Spain, and *Laboratory of Experimental Medicine, Brussels Free University, Brussels, Belgium.

The Ca^{2+}-sensitive and mitochondrial enzyme FAD-linked glycerophosphate dehydrogenase (mGDH) represents an essential component of the pancreatic B-cell glucose-sensing device. This report deals with the first identified case of mutation in the calcium-binding domain of the mGDH gene in a family of diabetic subjects. The diabetic proband was a normal weighed 62 year old male recently found to display an abnormally low activity of mGDH in CD3+ T lymphocyte homogenates. He was examined together with his 60 year old non-diabetic wife, a 65 year old non-diabetic sister, a 30 year old non-diabetic daughter, his 68 year old diabetic brother and a 57 year old glucose-intolerant half sister (same mother). Single-strand conformation polymorphism analysis of the cDNA sequence of interest, namely that coding for the Ca^{2+}-binding domain of mGDH, revealed an abnormal mobility pattern of the ^{32}P-labelled PCR product in the diabetic proband and his glucose-intolerant half sister, such being not the case for the four other members of the same family. In the two affected subjects, base pair mutations were observed at positions 2018, 2069 and 2136, corresponding to $Phe^{635}Ser$ and $Gln^{649}Pro$ amino acid changes. In CD3+ T lymphocyte homogenates incubated in the presence of 0.1 mM L-[2-^{3}H]glycerol-3-phosphate and 0.05 mM FAD, the relative extent of enzymatic activation by Ca^{2+} (10^{-7} to 10^{-4} M) was lower in the diabetic proband than in his diabetic brother with a normal mGDH gene sequence. This anomaly in the intrinsic properties of the enzyme could conceivably represent a contributing factor in the perturbation of islet B-cell responsiveness to D-glucose.

ABNORMAL VITAMIN D BINDING PROTEIN FRAGMENT IN BLOOD OF FIRST DEGREE RELATIVES OF PATIENTS WITH TYPE 2 DIABETES MELLITUS

M. Matsuda, K. Sugaya, L. J. Mandarino, H. Marusawa, and R. A. DeFronzo. University of Texas Health Science Center, San Antonio, Texas, USA

We examined the whole blood protein pattern to identify the existence of specific marker proteins which may relate to genetic or metabolic abnormalities in type 2 diabetic individuals of Mexican American descent. Whole blood was obtained from 29 first degree relatives (including individuals with normal GT, IGT, and overt NIDDM) of patients with type 2 diabetes mellitus (age: 42±15 y; BMI: 30±6 kg/m^2) and from 21 control subjects (age: 29±10 y; BMI: 25±10 kg/m^2) without family history of diabetes mellitus. Blood samples were drawn into a tube containing protease inhibitors and were analyzed first by isoelectric point focusing, followed by molecular weight using high resolutional 2D-gel electrophoresis. Several spots were found to exist more frequently in relatives of NIDDM patients. One of these spots (MW = 20 kDa, pI = 4.9), which was found in 80% of relatives and 32% of controls ($p<0.05$ by Chi-square test), was targeted for further analysis by electrophoretic blotting onto 20 PVDF membranes. The amino acid sequence of the target spot was determined and identified to have a sequence similar to that of vitamin D binding protein. Since the mol wt of this spot was smaller than that of vitamin D binding protein, this spot was considered to represent a fragment of vitamin D binding protein. This finding is consistent with a recent genetic analysis in Pima Indians and suggests that increased production of the vitamin D binding protein may play a role in the pathogenesis of NIDDM in certain ethnic populations.

PREVALENCE OF BLOOD AND MUSCLE MT DNA ANOMALY IN A HIGHLY SELECTED DIABETIC POPULATION AT RISK OF MITOCHONDRIAL CYTOPATHY

B. VIALETTES, H. NARBONNE, V. PAQUIS-FLUCKLINGER, D. BENDAHAN, J.F. PELISSIER, M.F. MONFORT, P. SILVESTRE-AILLAUD, C. DESNUELLE, UNIVERSITY OF MARSEILLE AND NICE, FRANCE

Mitochondrial diabetes (MIDD syndrome) has been recently described. The aim of the study is to evaluate the prevalence of anomaly of mt DNA in a highly selected population of 13 diabetic patients presenting at least 2 parameters of MIDD syndrome : maternal inheritance (observed in 10), neurosensorial deafness (in 12), macular pattern dystrophy (in 11) and clinical myoencephalopathy (in 4). In blood cells deletions, 3243 and 14709 mutations of mt DNA were searched in every patient. The 3243 mutation was found in 3, the 14709 in 1, deletion in none. In 12 subjects a deltoïd muscle biopsy was performed and in 8 cases anomalies suggesting a mitochondrial cytopathy were observed. The measurement of activity of the complexes of the respiratory chain was abnormal in 5. The molecular analysis in muscle sample confirmed the presence of the 4 mutations and showed the presence of 2 additional deletions (by large fragment PCR). In 9 patients a 31-P MR spectroscopy was performed, showing oxidative defect in 6 (4 mutations and 1 deletion). In conclusion, diagnosis of mitochondrial diabetes is difficult as long as all the diabetes-prone anomalies are not extensively identified . Study of muscle by invasive (biopsy) and non invasive (31- PMR spectroscopy) can be useful for this diagnosis.

662

FAMILIAL ASSOCIATION AND λ_s FOR DIABETES, OBESITY, HIGH TRIGLYCERIDES & LOW HDL-CHOLESTEROL IN SIBS OF NIDDM PATIENTS

JC Levy, BA Barrow, DE Lever, RJ Morris and RC Turner. Diabetes Research Laboaratories, Radcliffe Infirmary, Oxford UK

The Diabetes in Families Study (DIF), a population-based collection of sibships of NIDDM patients ('siblings') together with a age and sex-matched randomly selected sample from the same general population ('controls') provides a resource for the study of the heritability and genetics of Type 2 diabetes. To date, 111 sibships and 78 controls have been recruited. The frequency of diabetes (measured fasting plasma glucose >7.8 mmol.l^{-1} plus known diabetes) was 21.4% and 6.4% in the siblings and controls, respectively: relative risk (λ_s) = 3.3 ($p=0.001$). The siblings were more obese than the controls: BMI 28.2 (SD 4.9) and 25.4 (4.0) kg.m^{-2}, respectively ($p=0.0002$). 37% of probands were obese (BMI > 30 kg.m^{-2}). The frequency of obesity amongst siblings of obese type 2 diabetic probands and among controls was 46.8% and 7.3%, respectively: relative risk (λ_s) = 6.4% ($p<0.00001$). The siblings had higher triglycerides than the controls: 1.59 (1SD range: 1.39-1.82) and 1.15 (1.04-1.27) mmol/l ($p<0.0001$). 25% of probands had plasma triglycerides greater than 2.15 ('HighTrig': 90th centile of controls). The frequency of HighTrig amongst siblings of diabetic probands with HighTrig was 40%: relative risk (λ_s) = 4.0 vs controls ($p<0.00001$). The siblings had lower HDL-C than the controls: 1.19 (1SD range: 1.15-1.24) and 1.39 (1.32-1.46) respectively ($p=0.0002$). 25 % of probands had HDL-C less than 0.94 mmol/l ('LowHDL': 10th centile of controls). The frequency of LowHDL amongst siblings of diabetic probands with LowHDL was 35%: relative risk (λ_s) = 3.5 vs controls ($p<0.00006$). BMI, HDL-C (corrected for sex and BMI), triglycerides (corrected for sex, glucose and HDL) showed significant familial association by ANOVA, with 48% ($p<0.0001$), 59% ($P<0.0001$) and 47% ($p<0.0003$) of the variance accounted for by family membership. Conclusion: In addition to the higher risk of diabetes, siblings of NIDDM patients have a higher risk of obesity, high triglycerides and low HDL-C, with a significant family association of these factors.

663

A central European population can be characterized by certain mtDNA haplogroups: one is associated with syndromic diabetes (DIDMOAD)

Sabine Hofmann[2], Michaela Jaksch[1], Reimar Bezold[2] and Klaus-Dieter Gerbitz[1,2]
Institutes of Clinical Chemistry[1] and Diabetes Research[2], 80804 Munich, Germany

Wolfram (or DIDMOAD) syndrome is a neurodegenerative disorder characterized by juvenile-onset diabetes mellitus and optic atrophy as the essential features. The phenotypic characteristics of the syndrome and the systemic involvement suggest an underlying mitochondrial dysfunction. Although Wolfram syndrome has recently been linked to chromosome 4p, there is evidence for heterogeneity (1). On the other side, sporadic cases with DIDMOAD have been ascribed to a distinct defect of the mitochondrial (mt) DNA. In a systematic approach, we screened the mtDNA of eight DIDMOAD patients for known and unknown mutations in all ND, tRNA and cyt b genes by RFLP and SSCP/direct sequencing, respectively. We could not detect any causative mutation, however, we found the DIDMOAD patients being frequently associated with a distinct mtDNA haplotype consisting of the transition mutations at nucleotide positions (nps) 4216, 11251, 4917, 10463, 13368, 14233, 14905, 15607, and 15928 (5/8 patients). As a reference we used the haplotype distribution in a healthy German control group (n=67). The bulk of the controls could be described by a few defined mtDNA haplogroups. The „DIDMOAD-associated haplogroup", presumptively consistent with the European-specific haplogroup T in the nomenclature of Torroni et al. (2), represents 9% of our healthy German controls, but 63% of our DIDMOAD patients (Fisher's exact test: p=0.009). Besides Leber hereditary optic neuropathy (LHON), which has been shown to be frequently associated with a distinct European haplogroup (nps 4216+13708) (3), this is the first report linking another neurodegenerative disorder with a specific mtDNA haplogroup. Since certain haplotype backgrounds might act as susceptibility factors in hereditary disorders, we initiated a respective analysis in a group of selected type II diabetic patients (with a maternal background, n=50). This approach should reveal whether distinct mtDNA haplotypes contribute to the reported predominance of maternal transmission in type II diabetes. The results will be discussed.

INSULIN SECRETION AND INSULIN SENSITIVITY IN MONOZYGOTIC AND DIZYGOTIC TWIN PAIRS

M.Lehtovirta[*], J.Kaprio[§], C.Forsblom[*], J.Eriksson[#], J.Tuomilehto[#] and L.Groop[¤]. Department of Medicine[*] and Department of Public Health[§], University of Helsinki, Helsinki, Finland. National Public Health Institute[#], Helsinki, Finland. Department of Endocrinology, University of Lund[¤], Malmo, Sweden.

There is plenty of evidence that NIDDM is an inherited disease. Both impaired insulin secretion and impaired insulin action are considered to contribute to the development of the disease, but there are conflicting data on which defect is under stronger genetic control. To address this question, we quantitated insulin secretion and insulin sensitivity in 22 monozygotic (MZ) (7 female, 15 male, age 55-73 yrs, BMI 26.6±0.56 kgm^2) and 21 dizygotic (DZ) (8 female, 13 male, age 61-68 yrs, BMI 26.8±0.53 kgm^2) non-diabetic twin pairs of same gender with an intravenous glucose tolerance test (IVGTT, serum insulin response 0-60 min after an i.v. bolus of 0.5g/kg of 50% glucose) and a euglycemic hyperinsulinemic clamp (45mU/m^{2}min).

Results: Intrapair correlations

	MZ	p	DZ	p
Incr. insulin area (0-60min)	0.84	<0.00001	0.32	n.s.
Glucose disposal	0.53	<0.05	-0.03	n.s.
BMI	0.61	<0.005	0.12	n.s.
Waist-hip -ratio	0.87	<0.00001	0.53	<0.05
Height	0.95	<0.00001	0.74	0.0001
Weight	0.73	0.0001	0.51	<0.05

Conclusion: As well measures of insulin secretion as of insulin sensitivity show significant intrapair correlation in MZ but not in DZ twins, indicating that they are under genetic control, which seems to be stronger for insulin secretion than for insulin action.

665

THE MITOCHONDRIAL DNA (tRNA Leu(UUR)) MUTATION IN ITALIAN NIDDM PATIENTS.

D.Cucinotta,L.Rigoli,A.DiBenedetto,G.Romano,F.Corica,S.Campo and G.Squadrito.University of Messina,Messina,Italy.

A point mutation of the mitochondrial tRNA Leu(UUR) gene,consisting in an A to G transition at nucleotide pairs (np) 3243,has been observed in some diabetic patients,especially in those with maternally inherited diabetes.No data,however,concerning the prevalence of this mutation in Italy are actually available.In this study 231 consecutive non-insulin-dependent (NIDDM) diabetic patients,attending an outpatient clinic,were recruited.They were born and lived in Sicily or Calabria regions (South Italy);their mean age was 59±8 years and known diabetes duration was 13±7 year.Of them 87 were treated with insulin and 118 had at least one diabetic parent:72 had the mather,15 had the father and 31 had both parents.Mitochondrial DNA was extracted from peripheral blood and the region encompassing nucleotides from 2770 to 3456 was amplified by means of Polimerase Chain Reaction (PCR).PCR products were then digested with ApaI enzyme,which cleaves the mutant but not the wild-type sequence at np 3243.A positive digestion control with a standard lambda DNA was also included.With this method the tRNA Leu (UUR) mutation was never detected,neither in those patients with maternally inherited diabetes.These results indicate that the 3243 mitochondrial DNA mutation is at least extremely rare,or insufficiently expressed on peripheral blood cells,in Southern Italian diabetic patients and do not suggest a major role for this mutation in our NIDDM population.

FAMILIAL DIABETES MELLITUS IN LAGOS NIGERIANS.

A.E. OHWOVORIOLE, A. OSA, A.O. FASANMADE AND S.F. KUKU. DEPARTMENTS OF MEDICINE, UNIVERSITY OF LAGOS AND EKO HOSPITAL, LAGOS, NIGERIA.

Several studies have shown that relatives of diabetic patients have an increased risk of developing diabetes mellitus (DM). Familial DM in Black Africans appears to have received little attention. We determined the frequency of a family history of DM (FHDM) among Nigerian subjects with and without DM. About 5% of non-diabetic subjects had a positive FHDM in the first degree relatives (FDRs) vs about 25% occurrence in the diabetic subjects (p<0.001). Parents of diabetic probands were more likely to have DM than the children of the same probands. Of all FDRs, the siblings had the highest a history of DM. The more educated the proband, the more likely was the occurrence of a positive FHDM ; this might suggest that among the uneducated, the frequency of positive FHDM might have been underestimated. Probands diagnosed at age 40 yrs, or less showed a higher rate of FHDM than patients diagnosed at older ages. In Nigerians, a positive FHDM is significantly more common in diabetic than in non-diabetics. The positivity rate of FHDM appears similar to reports from other cultures but may be an underestimation due to a low degree of diabetes awareness. Detailed family studies of DM are needed to provide a comprehensive insight into familial DM in Nigerian and other parts of Black Africa.

667

VARIATIONS OF GLUCAGON-LIKE PEPTIDE-1 RECEPTOR IN JAPANESE PATIENTS WITH NON-INSULIN-DEPENDENT DIABETES MELLITUS

J. Nomiyama, Y.Tanizawa, Y.Ota, K.Ueda, K. Noda and Y. Oka.
Yamaguchi University, Ube, Japan.

Glucagon-like peptide-1(GLP-1) stimulates glucose-induced insulin secretion and may regulate feeding behavior. GLP-1 binds to a specific receptor (GLP-1R), which belongs to a Gs protein coupled receptor family, and activates adenylyl cyclase system. GLP-1R$^{-/-}$ mice created by the targeted disruption of the gene, showed increased levels of blood glucose following oral glucose challenge test in association with diminished levels of circulating insulin. Therefore, to assess the possible role of mutations of the gene in the defective insulin secretion in humans, we examined human GLP-1R gene in Japanese patients with non-insulin-dependent diabetes mellitus (NIDDM) at a single nucleotide level. We first determined the nucleotide sequences of exon-intron boundaries of 13 exons of the human gene by analyzing genomic clones we isolated previously. Based on the sequences, oligonucleotide primers were synthesized and polymerase chain reaction-single strand conformation polymorphism analysis was conducted for the entire coding region of the gene in 100 Japanese NIDDM patients. We found three missense mutations (Pro^{7}→Leu, Arg^{44}→His, Phe^{266}→Leu^{266}), and seven silent mutations including polymorphisms in introns. Among the three missense mutations, Leu^{7} and His^{44} are present in the corresponding positions of the rat GLP-1R, suggesting that these substitutions are functionally silent. Since Phe^{266} was conserved between human and rat GLP1R, we compared the frequency of the Phe^{266}→Leu^{266} mutation between NIDDM patients (n=100) and non-diabetic controls (n=96). The allelic frequencies of Phe^{266} did not differ between the two groups (0.50 vs 0.50). We conclude that mutations in the GLP-1R gene are not major contributor to the inherited basis of NIDDM in Japanese, confirming the previous linkage and association studies in Caucasians and African Americans.

668

INSULIN RESISTANCE AND BLOOD PRESSURE IN OFFSPRING OF TYPE II DIABETIC PATIENTS WITH AND WITHOUT NEPHROPATHY

K.Strojek, W. Grzeszczak, E. Morawin, M. Adamski, B. Lacka,
*CK Keller, *S.Schmidt and*E. Ritz
Dept. of Internal and Occupational Diseases, Silesian Med. Academy, Zabrze, Poland and *Dept of Internal Medicine, Ruperto Carola University, Heidelberg, Germany.

Family studies point to an important genetic element in the genesis both to diabetes and diabetic nephropathy. The aim of the study was to assess insulin resistance and blood pressure of healthy offspring of type 2 diabetic patients with and without nephropathy. We examined 425 consecutive type II diabetic patients and examined all available normotensive, normoglycemic, non smoking offspring (n=56; 30 of whom without parental history of nephropathy- nDN, and 26 with- DN) and compared them to 30 healthy offspring of non diabetic parents (controls). All groups had similar age and BMI. Measurements in offspring and controls included: tissue glucose uptake-TGU (euglycemic hyperinsulinemic clamp), 24-h ambulatory blood pressure-ABP and polymorphism I/D of ACE gene (PCR technique). TGU was significantly lower in both DN and nDN groups when compared to controls (6.3±2.5, 5.6±2.2 and 9.5±2.2 mg/kg/min respectively; $p<0.005$). No difference between DN and nDN groups was found. 24h systolic ABP was significantly higher in DN group when compared to nDN and controls (124.5±16.7, 117.2±12.9 and 114.1±8.5 respectively; $p<0.05$). When estimated all examined subjects (n=86) significantly higher risk of systolic BP above 95 percentile was found in DD homozygotes of ACE gene (OR-3.15; CI- 0.68-14.7). No significant relation of ACE ID polymorphism was found in relation to insulin resistance. We conclude: (i) predisposition to type 2 diabetes is manifested by insulin resistance in offspring, (ii) higher blood pressure may be the clinical sign of predisposition to nephropathy, (iii) insulin resistance is not related to nephropathy and ACE I/D gene polymorphism.

669

NO ASSOCIATION BETWEEN THE GLY40SER MUTATION (GCG-R GENE) AND JAPANESE NIDDM.

Y.Tachi, M.Odawara, and K. Yamashita.
University of Tsukuba,Tsukuba,JAPAN.

Significance of a glucagon receptor gene variant in the pathogenesis of NIDDM has been implicated in Sardinian and French populations with NIDDM. The mutation was present with significantly higher prevalence in subjects with NIDDM compare with non-diabetic controls. We investigated 242 randomly selected Japanese NIDDM patients whether a G123A mutation causing Gly40Ser substitution is associated with Japanese NIDDM. We also searched for unknown mutations or deletions in GCG-R gene by SSCP method. We could not find any abnormalities in 30 patients with glucose intolerance and with a family history of NIDDM. By using PCR-RFLP method,no one carried the Gly40Ser mutation in with Japanese NIDDM patients. The C-to-G substitution in exon 5 proved to be very rare in Japanese,unlike Sardinians and French populations. These observations indicate that marked ethnic differences exist between Caucasians and Japanese.

670

NON INSULIN DEPENDENT DIABETES AND PARENTAL HISTORY.

N.R.Oliva, C.D.González, M.H.Figueroa, S.R.Oliva and J. Bortz.UDH Güemes and Dept.of Pharmacology,University of Buenos Aires,Argentina.

Some authors have noticed that diabetic mothers generate as many as twice diabetic sons than diabetic fathers.With the aim of determine the frequency of the parental antecedent and its sexual distribution in a diabetic sample, we analized data from 286 NIDDM patients assisted by one of us (to avoid potential biases) between 1970 and 1996. The studied sample came from a Buenos Aires city suburb. For each patient was registered the familial history,BMI, age,diabetes duration,complications and other relevant clinical data.Satistical analysis:Fleiss quadratic 95% confidence interval(FQ95%CI) was obtained.$X^2$was performed to determine differences between groups.Soft:CSS/Statistica,StatSoft,Tulsa,1993.Results:parental antecedents were distributed as follows:

	Male Patients(n=142)		Female Patients(n=144)	
ANTECEDENT	Proportion	FQ95%CI	Proportion	FQ95%CI
None	40.1%	32.1-48.7	43.0%	34.9-51.5
Mother	26.7%	19.8-34.9	28.4%	21.4-36.7
Father	16.9%	11.3-24.1	7.6%	4.0-13.5
Both	8.4%	4.6-14.6	5.5%	2.6-11.0
Others	7.7%	4.1-13.7	15.2%	10.0-22.4

Between sexes difference:p=0.04.The main contribution to between sexes significance was the difference in the paternal antecedent.Conclusion: although maternal antecedent was more frequent than the paternal one in both sexes,paternal history was significantly more frequent among men.

671

INHERITANCE OF DIABETES IN A NEW MOUSE MODEL OF NIDDM, THE NSY MOUSE

H. Ueda, H. Ikegami, Y. Kawaguchi, E. Yamato, Y. Hamada, J. Fu, G.-Q. Shen, T. Fujisawa, K. Nojima and T. Ogihara
Department of Geriatric Medicine, Osaka University Medical School

The NSY (Nagoya-Shibata-Yasuda) mouse is an inbred strain of mice with spontaneous development of diabetes mellitus with moderate obesity (Ueda H et al. Diabetologia 1995). NSY mice spontaneously develop diabetes mellitus in an age-dependent manner. The cumulative incidence of diabetes is 98% in males and 31% in females at 48 weeks of age. Both insulin resistance and impaired insulin secretion contribute to the development of diabetes in NSY mice. To determine the mode of inheritance of diabetes in NSY mice, two reciprocal crosses, female C3H x male NSY F1 (C3NF1) and female NSY x male C3H F1 (NC3F1) mice, were performed. The cumulative incidence of diabetes reached 100% (25/25) in male C3NF1 mice and 97% (29/30) in male NC3F1 mice at 48 weeks of age, indicating that diabetes in NSY mice was transmitted to F1 hybrids in an autosomal dominant manner with high penetrance. Insulin resistance also showed an autosomal dominant mode of inheritance. In contrast, impaired insulin secretion in response to glucose in NSY mice showed an autosomal recessive mode of inheritance. BMI and fat accumulation showed a co-dominant mode of inheritance. These data suggested that NSY mice were polygenic animal model of diabetes and were expected to be a useful animal model of NIDDM to clarify genetic susceptibility to NIDDM.

672

PATHOGENESIS OF NON-INSULIN-DEPENDENT DIABETES MELLITUS IN THE URBAN BLACK COMMUNITIES OF SOUTHERN AFRICA

B.I. Joffe and V.R. Panz. Carbohydrate and Lipid Metabolism Research Group, University of the Witwatersrand Medical School, Johannesburg, South Africa.

Urban black South Africans show an escalating incidence of non-insulin-dependent diabetes mellitus (NIDDM) (age-adjusted prevalence approaching 7%). The aim of this study was to examine underlying pathogenic mechanisms. We reviewed data from black and white subjects with normal glucose tolerance, obesity, impaired glucose tolerance (IGT) and NIDDM. Stimuli to insulin secretion included oral glucose and maximal beta-cell stimulation. The homeostasis model assessment (HOMA) was used to calculate insulin resistance. Molecular scanning of the insulin receptor (INSR) and insulin-receptor-substrate 1 (IRS-1) genes was undertaken with single-stranded conformation polymorphism and direct DNA sequencing. Insulin secretion was significantly reduced in black subjects compared to white after all stimuli. Calculated insulin resistance in black subjects increased from a low mean value of 1.24 in nonobese to 2.48 in obese nondiabetic, 2.42 in IGT and 6.55 in NIDDM ($p<0.001$). Molecular scanning of INSR and IRS-1 genes revealed polymorphisms with similar frequencies in nondiabetic and diabetic black and white subjects. We conclude that NIDDM in urban black Africans is due to progressive insulin deficiency, with acquired insulin resistance developing as a late contributory factor.

673

COENZYME Q_{10} TREATMENT PREVENTS PROGRESSION OF INSULIN SECRETORY DEFECTS IN MATERNAL-INHERITED DIABETES MELLITUS WITH MITOCHONDRIAL DNA MUTATIONS.

M. Chiba, S. Suzuki, Y. Hinokio, M. Hirai, A. Hirai, Y. Sato, T. Toyota. Third Department of Internal Medicine, Tohoku University School of Medicine, Sendai 980, Japan)

Progressive insulin secretory defect is a clinical feature of diabetes mellitus with mitochondrial DNA (mtDNA) mutations. This study investigated the effects of coenzyme Q_{10} (CoQ) treatment on insulin secretory capacity and clinical symptoms of the Japanese diabetic patients with mtDNA mutations. 44 diabetic patients, 12 impaired glucose tolerance (IGT) , and 20 normal glucose tolerance (NGT) subjects with the 3243 (A-G) mutation, 7 diabetic patients with the 8344 (A-G) mutation, and 7 diabetic patients with multiple deletions, were treated for 3 years with daily oral administration of 150 mg of CoQ. After the CoQ therapy, insulin secretory response assessed by 24 hour urinary C-peptide excretion and glucagon-induced C-peptide secretion were significantly improved in the diabetic patients with multiple deletion and 3243bp mutation, but not changed in the IGT and NGT subjects with the 3243bp mutation and diabetics with 8344bp mutation. Blood lactate concentrations after exercise were significantly reduced in the diabetic patients with multiple deletion, but not changed in the subjects with the 3243bp and 8344bp mutations. CoQ treatment did not improve diabetic complications nor neurosensory deafness. These data demonstrates therapeutic usefulness of CoQ on insulin secretory defects in diabetic patients with mitochondrial DNA multiple deletions and 3243bp mutation.

CASE REPORT
WERNER'S SYNDROME

S. GÜLER, B. ÇAKIR, R. SERTER, G. GÜRSOY and Y. ARAL. Department of Endocrinology and Metabolism, Ankara State Hospital, Ankara, Turkey.

Werner's syndrome is a rare disorder resembling premature aging. This autosomal recessive disorder is frequently associated with endocrinological problems, particularly diabetes mellitus and hypogonadism. Although the diagnosis is not difficult when it is kept in mind it may be so because of its rarity. In this report we present a case of Werner's syndrome who has been hospitalized in our clinic because of diabetic foot. Detailed physical and laboratory examinations revealed that this 53 years old male patient also had hypergonadotropic hypogonadism, gynecomastia and mild mental deficiency. Details of the syndrome with regard to clinical characteristics, diagnosis and therapeutic modalities are also discussed.

Genetics and Pathogenesis of Obesity

675

INCREASED INSULIN STIMULATED GLUCOSE DISPOSAL RATE IN 1161 CAUCASIAN MALES: INTERACTION BETWEEN OBESITY AND THE ASP905TYR VARIANT OF THE GLYCOGEN ASSOCIATED SUBUNIT OF TYPE 1 PROTEIN PHOSPHATASE

L. Hansen[1], R. Reneland[2], T. Hansen[1], L. Berglund[2], S. K. Rasmussen[1], K. Busch[1], H. Lithell[2] and O. Pedersen[2]. [1] Steno Diabetes Center, Denmark. [2] Department of Geriatrics, Uppsala University, Sweden.

The allelic frequency of the E905Y variant of the glycogen associated subunit of type 1 protein phosphatase (PP1G) is 43% in the Pima Indians and it has been reported that the E905Y polymorphism in this ethnic group is associated with NIDDM and in the non-diabetic subjects with increased insulin mediated glucose disposal during a euglycaemic and hyperinsulinaemic clamp. The aim of the present study was therefore to look for an interaction between the E905Y polymorphism and obesity (defined as body mass index (BMI) ≥ 80% percentile) on insulin sensitivity in 1161 Caucasian men born 1920-24 and participating in the Uppsala health survey study and characterized with a euglycaemic hyperinsulinaemic clamp. At the time of examination 174 subjects had developed NIDDM and 147 impaired glucose tolerance (IGT). All participants were genotyped for the E905Y polymorphism of PP1G by PCR-RFLP. The allelic frequency of the E905Y variant of the PP1G was 11%. Subsequent test for interaction showed an interaction of obesity and E905Y on insulin sensitivity index ($p < 0.021$). Furthermore, when obese carriers ($n = 50$) of the E905Y polymorphism were compared to obese non-carriers ($n = 173$) they had a 24% increase in insulin sensitivity index ($p < 0.009$). However, the E905Y variant was not associated with an altered prevalence of NIDDM or IGT. We conclude that the E905Y variant of PP1G in obese males of Caucasian origin is associated with an increased insulin sensitivity.

676

PPARγ EXPRESSION IS DOWN-REGULATED BY VITAMINS A AND D DURING ADIPOCYTE DIFFERENTIATION

T.Kawada, Y.Hida, S.Kayahashi, Y.Kamei, T.Fushiki and E.Sugimoto#, Dept. of Food Sci. & Technol., Kyoto University, Kyoto, Japan and #University of Shiga Prefecture, Hikone, Japan.

Recently, it was leveled that the characteristics of trans-acting proteins and their presumptive roles in the program of transcriptional activation of genes expressed during adipocyte differentiation. We and other investivators reported that active forms of vitamins A (retinoic acid; RA) and D (1,25-dihydroxyvitamin D3; VD) inhibit adipocyte differentiation. At the early stage of adipocyte differentiation, ligand-dependent transcriptional factors, especially peroxisome proliferator-activated receptor (PPAR), regulate positively the expression of target differentiation genes.

So we investigated the effect of RA and VD on the expression of master regulator, PPARγ, during adipocyte differentiation by Western and Northern blot analyses in 3T3-L1 cells. We revealed that the receptor members of retionoid (RAR,RXR) / vitamin D (VDR) / PPAR subfamily genes expressed during adipocyte differentiation. These cells were strongly inhibited differentiation by the addition of RA or VD3 even in the presence of PPARγ specific ligans, thiozolidinediones (a new class of antidiabetic agents). These agents strongly stimulate adipocyte differentiation *via* PPAR. The expression of PPARγ2 was increased during adipocyte differentiation with or without thiazolidinedione. At that time, the presence of RA or VD led to strongly inhibition of the expression of PPARγ2. Concomitantly, at this stage the presence of RA or VD3 causes the increase of RAR or VDR. These findings suggest that the signal of these ligands may be cross-talked at the level of nuclear receptors (RAR/VDR/PPAR) and then regulate positively and negatively the signal transduction of adipocyte differentiation at the level of gene transcrition.

677

NO ASSOCIATION OF INTESTINAL FATTY ACID BINDING PROTEIN POLYMORPHISM WITH INSULIN RESISTANCE IN JAPANESE

H. Mochizuki, G. Egusa, M. Okubo, H. Hara, M. Yamakido
Hiroshima University School of Medicine, Hiroshima, Japan

A mutation from alanine (Ala54) to threonine (Thr54) at codon 54 of intestinal fatty acid binding protein (FABP2) was identified. FABP2 has been reported as a possible genetic factor in determining insulin resistance in Pima Indians, a population known to have higher prevalence of diabetes. We investigated the association of polymorphism at FABP2 codon 54 mutation with insulin resistance in Japanese subjects. 75g oral glucose tolerance test (75gOGTT) was performed and serum lipids, blood pressure and percentage of body fat (%BF) were measured in 133 unrelated individuals who underwent regular medical examination (male/female =118/15, mean age 50.5 years old, mean BMI 24.0kg/m^2). Of these 133 subjects, 13 were diabetic and 120 were nondiabetic. DNAs were isolated from white blood cells and typed as FABP2 codon 54 restriction fragment length polymorphism (RFLP) by HhaI after PCR proliferation. Allele frequencies of Ala54 and Thr54 were 0.68 and 0.32, respectively. The frequencies did not differ from those of Pimas and Caucasians. RFLP of FABP2 did not show any association with BMI, %BF, plasma glucose, plasma fasting and 2-h insulin concentrations, HbA_1c, total cholesterol, HDL-cholesterol, or category of glucose tolerance. Subjects with Thr54 allele showed higher triglyceride levels (164±73mg/dl) than those with Ala54 (142 ± 58mg/dl), but the difference was not significant (p=0.07). We conclude that FABP2 codon 54 polymorphism may not be significantly associated with insulin resistance in Japanese subjects.

678

MELANIN CONCENTRATING HORMONE STIMULATES LEPTIN SECRETION FROM ADIPOCYTES

V. Emilsson, N. Cheung, M. Sennitt and M.A. Cawthorne, Clore Laboratory, University of Buckingham, Hunter Street, Buckingham, Bucks. MK18 1EG. UK

The mouse obesity gene (ob) product (leptin), which is expressed exclusively in white adipose tissue (WAT) inhibits food intake and stimulates energy metabolism. Leptin acts at sites in hypothalamus, but non-neuronal tissues are also targeted. Thus, we have previously shown that administration of leptin inhibits insulin secretion from perfused pancreas and isolated pancreatic islets of mice and suggest that high leptin production, associated with adiposity, could lead to development of overt diabetes. Another molecule associated with hypothalamic regulation of food intake is melanin concentrating hormone (MCH). In contrast to leptin, it has been shown to stimulate food intake in mice. Furthermore, the hypothalamic concentration of MCH is drastically increased in ob/ob mice, which are deficient in functional leptin. We have studied the effects of MCH on the secretion of leptin in freshly isolated adipocytes from Sprague Dawley rats. Adipocytes were incubated for 6h in Hepes pH 7.5 (10mM), bovine serum albumin (5mg/ml), FCS (5mg/ml) and penicillin/streptomycin with or without 100nM MCH. MCH significantly increased leptin release into the medium from 0.06 ± 0.02 to 0.17 ± 0.02ng/10^{-6} cells, $P < 0.001$. These results demonstrate a novel interaction between MCH and leptin that could help in understanding how body weight homeostasis is maintained. It is suggested that MCH and leptin might participate in a feedback loop between the hypothalamus and WAT to regulate body weight in mammals.

679

THE SIGNIFICANCE OF THE TRP64ARG MUTATION OF THE β3-ADRENERGIC RECEPTOR GENE IN INSULIN RESISTANCE.

N.Azuma, Y.Yoshimasa, H.Nishimura, Y.Yamamoto, J.Suga, H.Masuzaki, K.Hosoda, S.Nishi and K.Nakao. Kyoto University, Kyoto, Japan.

It has been shown that the Trp 64 Arg mutation of the human β3-adrenergic receptor (β3-AR) gene is related to an earlier age of onset of non-insulin-dependent diabetes mellitus (NIDDM), features of insulin resistance and weight gain in morbidly obese patients. However, such findings have not been consistent in different ethnic populations.

In the present study, we investigated the frequency of the Trp 64 Arg mutation in Japanese control subjects (n=253), NIDDM (n=314) and impaired glucose tolerance (IGT) patients (n=100). We compared the frequency of the mutation with the body mass index (BMI) in these groups,and with the metabolic clearance rate (MCR) of glucose in the NIDDM patients. A Trp 64 Arg mutation was observed in 36.7%, 31.6% and 37.0% of the control, NIDDM and IGT subjects, respectively. The frequency of the homozygotes for the mutation was 4.3%, 4.8% and 3.0%, respectively. Neither the genotype frequency (Trp/Arg, Arg/Arg) nor the frequency of the mutated allele was significantly different among the three groups. The BMI of the subjects with the mutation was not significantly higher than that of the subjects without the mutation in each group. Futhermore, the allele frequency (A) was not different among the subjects with different BMI (BMI < 22.0, 22.0 ≦BMI ≦26.4, BMI > 26.4) in each group. In a separate group of NIDDM patients, the MCR of the subjects with intermediate BMI (22.0 ≦BMI ≦ 26.4) with the mutation tended to be lower than that of those without the mutation. In addition, the MCR of the subjects with the mutation in this group was significantly lower compared with that of those with a BMI less than 22.These results indicate that the Trp 64 Arg mutation of the β3-AR gene may not contribute to the development of NIDDM or be a determinant of obesity in the Japanese population. However, the mutation may contribute to insulin resistance in NIDDM patients with intermediate BMI.

680

INSULIN ANTAGONIZES THE STIMULATION OF OB GENE EXPRESSION BY DEXAMETHASONE IN CUTURED EXPLANTS OF HUMAN VISCERAL ADIPOSE TISSUE.

S.M. Brichard, B. Reul, I. Servais and C. Halleux. Unité d'Endocrinologie et Métabolisme, University of Louvain, Brussels, Belgium.

The ob gene, specifically expressed in fat cells, encodes leptin, a hormone which induces satiety and increases energy expenditure. Visceral fat plays a determinant role in obesity-linked disorders. To assess the direct role of hormones on the expression of fat genes, cultured explants of adipose tissue have decisive advantages over clonal cell lines or stromal cells differentiated by long-term exposure to pharmacological doses of "adipogenic cocktails" : the approach is more physiological, the model highly responsive to insulin and interactions between cells are preserved. We thus investigated the hormonal control of ob gene expression in explants of human visceral adipose tissue cultured in MEM supplemented with FCS for up to 48h. We more particularly focussed on the interactions between insulin and glucocorticoids. Adipose tissue (15-100g) was obtained from patients undergoing elective abdominal surgery (age: 51 ± 9 yr; BMI: 25.6 ± 2.5 kg/m2). In response to dexamethasone, ob mRNA levels rose progressively to a maximum of ~ 10-fold starting values after 48h. This increase was concentration-dependent : the glucocorticoid was effective at concentrations above 1nM and, if the effect of 100 nM dexamethasone was maximal, half-maximal stimulation was produced by 10 nM. Unlike dexamethasone, insulin added to the medium at 100 nM, for up to 48h, did not stimulate ob gene expression. Unexpectedly, insulin prevented the dexamethasone-induced accumulation of ob mRNA. Thus, after 24 and 48 h of culture, the effect of dexamethasone was respectively 55% and 50% inhibited by 100 nM insulin. In conclusion, unlike dexamethasone, insulin had no direct stimulatory effect on ob gene expression in cultured explants of human visceral adipose tissue. On the contrary, insulin even inhibited dexamethasone-induced accumulation of ob mRNA. This suggests that the in vivo stimulatory effect of insulin on ob gene expression is indirecty mediated.

681

POLYMORPHISMS IN THE UNCOUPLING PROTEIN (UCP) AND β3 ADRENERGIC RECEPTOR (β3-AR) IN NONDIABETIC (ND) AND NIDDM SUBJECTS.

M. Carlsson, M Orho and L. Groop. Department of Endocrinology, Malmö University Hospital, University of Lund, Malmö, Sweden

The mechanisms linking obesity and insulin resistance are not known. Genes influencing basal metabolic rate and weight gain, as the UCP and β3-AR, could be putative candidate genes for NIDDM. To test this hypothesis, using PCR-RFLP we studied whether the A->G (-3826) polymorphism in the UCP gene, previously claimed to be associated with weight gain, or the Trp64→Arg64 mutation in the β3-AR, could influence prevalence of obesity and NIDDM in Swedish subjects. UCP gene polymorphism was determined in 1097 subjects from 257 families (652 NIDDM, 364 ND first degree relatives and 81 unrelated healthy controls). The frequency of the G allele was increased in the NIDDM subjects compared to the controls (25% vs 20% p= 0.04) In ND relatives and controls, carriers of the G allele, had higher incremental glucose area during OGTT compared to the AA genotype carriers (267 vs 231 mmol/l; p= 0.02). No differences were seen in insulinarea, BMI or lipids between the carriers of G allele, compared 'A allele carriers. β3-AR mutation was determined in 1063 subjects from 253 families (643 NIDDM, 360 ND relatives and 60 controls). No differences in allele frequences of the Arg mutation were seen between NIDDM subjects (7%), ND relatives (7%) and controls (6%). Sibpairs discordant for the Arg mutation (n=47) were also discordant for BMI (27.0 vs 26.0 p=0.05) and waist hip ratio (males n=18, 0.99 vs 0.96 p=0.04; females n=22, 0.89 vs 0.85 p=0.02). Five subjects homozygous for the Arg allele were found (1 NIDDM, 3 relatives and 1 control). No subjects homozygous for both UCP G allele and β3-AR Arg allel were found but 5 of the NIDDM patients vs none of the ND subjects had the genotype combination GG (UCP)/ ArgTrp (β3-AR). In conclusion the study proposes a role for the UCP gene in the pathogenesis of glucose intolerance and NIDDM and confirms in a sibpair study the association of the β3-AR Trp64→Arg64 mutation with abdominal obesity.

682

PERIPHERAL ACTIVITY OF LEPTIN: DESENSITIZATION OF ADIPOCYTES *IN VITRO* FOR INSULIN ACTION

G. Preibisch, J. Ertl, and G. Müller. HMR TA Metabolism, Frankfurt, Germany

Leptin, an adipocyte hormone, reduces food intake and increases metabolic rate in rodents by a central mode of action. Aim of this study was the search for leptin actions on metabolically relevant cells. Isolated rat adipocytes were kept for 15 h in primary culture in the presence or absence of recombinant murine leptin and then key metabolic pathways were tested. Leptin *per se* had no significant effect on glucose uptake, glycogen synthase activity, lipogenesis, lipolysis, and protein synthesis but impaired insulin effects on these pathways. Leptin preincubation caused an increase of insulin EC_{50} from 0.2 nM (without leptin) to 0.45 and 1.6 nM (at 0.5 and 1 nM leptin, resp.) for glucose transport. At 10 nM leptin, the stimulation of glucose uptake by 10 nM insulin was reduced from 13.5-fold to 3.6-fold. Insulin at higher concentrations could not overcome this decrease of responsiveness. The antilipolytic effect of insulin on isoproterenol-induced lipolysis was also antagonized by leptin. The IC_{50} of leptin for the inhibition of insulin effects was around 3 nM in all these assays. Time-course for onset of leptin-induced desensitization of adipocytes for insulin action is slow, reaching its maximum only after 15 h at 2 nM leptin. Leptin effects are reversible and regain of insulin sensitivity is more rapid than desensitization. Stimulation of glucose uptake or lipogenesis by vanadate can not be inhibited by leptin preincubation. We conclude, that leptin at physiological concentrations reduces sensitivity of adipocytes for insulin action after long-term incubation in primary culture. At higher concentrations, leptin also reduces insulin responsiveness. Leptin might be involved in the development of insulin resistance in obese people.

ASSOCIATION IN THE β 3-ADRENERGIC-RECEPTOR GENE WITH CLINICAL FINDINGS IN JAPANESE NIDDM SUBJECTS.

R.Ito,A.Tanaka,T.Miwa,K.Arai,G.Fukuda,S.Shirabe,J.Sato,M.Kanazawa, Y.Notoya and T.Hayashi. Tokyo Med.Coll.,Tokyo,Japan

〈Purpose〉 There are reports that the Trp64Arg mutation of the β 3-Adrenergic-Receptor (β 3AR) is associated with obesity and the onset of diabetes mellitus.In the present study, we examined association in the β 3AR gene with diabetic complications in Japanese NIDDM subjects. **〈Methods〉** We studied the frequency of the Trp64Arg mutation of the β 3AR and investigated diabetic complications in 182 Japanese NIDDM subjects,84 male patients (the mean duration of diabetes was 10.6 years),98 female patients(the mean duration of diabetes was 10.1 years) .Genotic DNA was extracted from leukocytes,we determined genotype using method of E.Widen et al(1995). **〈Results〉** A Trp64Arg mutation was detected with allelic frequencies of 0.16 in Japanese NIDDM subjects. When we compared patients with normal homozygotes and Trp64Arg homo- or heterozygotes,there was no significant difference in the Body Mass Index, the mean age at the onset of NIDDM and chemical data. There was no difference in diabetic retinopahy,neuropathy or nephropathy. **〈Conclusion〉** Environment and life history are more important role than the Trp64Arg mutation of the β 3AR for diabetic complications.

	with mutation (n=51)	without mutation (n=131)	p value
Age at onset(yr)	50.9	50.0	0.8452
BMI	22.61	23.43	0.0992
Retinopathy (+/-)	16/35	51/80	0.3260
Neuropathy (+/-)	20/31	46/85	0.6053
Nephropathy (+/-)	10/41	32/99	0.4883

FAILURE OF LEPTIN TO COUNTERACT THE EFFECTS OF GLUCOSE ON INSULIN AND GLUCAGON RELEASE BY THE PERFUSED RAT PANCREAS

V. Leclercq-Meyer and W.J. Malaisse. Laboratory of Experimental Medicine, Brussels Free University, Brussels, Belgium.

It was recently postulated that leptin may inhibit insulin release, as part of an adipoinsular feedback loop. This proposal was based on the finding that leptin receptor mRNA is present in rat islets and that unlabelled leptin decreases the binding of ^{125}I-leptin to insulinoma cells. In subsequent work, however, we documented that the prevailing leptin receptor in rat islets corresponds to the ubiquitous short isoform, for which no signalling activity has yet been assigned. Moreover, when tested at a 1.0 nM concentration, human leptin failed to affect glucose-stimulated insulin release from the isolated perfused rat pancreas. The concentration of leptin used in these experiments was not higher, however, than that found in the plasma of obese human subjects. Therefore, we have now examined the effect of a ten times higher concentration of leptin upon both insulin and glucagon release from the isolated perfused pancreas of fed female Wistar rats. The glucose concentration of the perfusate was raised from 3.3 to 8.3 mM between min 25 and 70 and leptin (10 nM) administered from min 40 to 55. The rise in glucose concentration provoked a biphasic stimulation of insulin release and rapid and sustained suppression of glucagon output. Leptin failed to affect the release of the two hormones. Whether in the absence or presence of leptin, the rate of insulin release progressively increased during stimulation by 8.3 mM glucose. The paired ratio in secretory rate at min 55/min 40 averaged 243 ± 36 % (n = 4) in the presence of leptin, as compared ($P > 0.1$) to 180 ± 6 % (n = 3) in its absence. These findings reinforce the view that leptin does not exert any direct and immediate effect upon the secretory activity of the endocrine pancreas.

GENETIC VARIATION IN β3-ADRENERGIC RECEPTOR AND FATTY ACID BINDING PROTEIN IN JAPANESE.

Tetsuo Hayakawa, Erika Nohara, Haruhisa Yamashita, Yukihiro Nagai and Ken-ichi Kobayashi. First Department of Internal Medicine, Kanazawa University, Kanazawa, Japan.

A mutation of β3-adrenergic receptor gene (Trp64Arg) has been reported to be associated with obesity, insulin resistance and earlier onset of NIDDM. It has been reported that a polymorphism at codon 54 of the intestinal fatty acid binding protein locus (FABP2) was associated with insulin resistance in Pima Indians. We therefore studied the frequency of these mutation and polymorphism in Japanese, and investigated the association of genetic variation with obesity, dyslipidemia and hypertention. 114 Japanese subjects were recruited from the general health check-up center (92 male, 22 female, mean age 53.2 years, NGT 58 IGT 49 NIDDM 7). The allele having Trp64Arg mutation or Ala54Thr polymorphism was detected by PCR-RFLP method using restriction enzyme BstNI and HhaI. The frequencies of Trp64Arg and Ala54Thr were 0.27 and 0.38, respectively. Both frequencies were similar among NGT, IGT and NIDDM. There were no differences in BMI, systolic and diastolic blood pressure, fasting insulin levels and dyslipidemia between subjects with and without these mutation and polymorphism.

These data suggest that β3-adrenergic receptor gene mutation and polymorphism of FABP2 may not be associated with obesity and dyslipidemia in Japanese.

686

GLUCOCORTICOID AND GENDER REGULATE PLASMA LEPTIN LEVELS IN HUMANS

Hiroaki Masuzaki, Kiminori Hosoda , Yoshihiro Ogawa, Takashi Miyawaki, Junko Hiraoka, Ikuko Hanaoka, Akiko Yasuno, Kohshi Natsui, Akira Sugawara, Shigeki Arii, Yasunao Yoshimasa, Shigeo Nishi, Yukio Yamori, and Kazuwa Nakao. Kyoto University, Kyoto, Japan.

Using the radioimmunoassay (RIA) specific for human leptin, which we have developed, we showed that a significant amount of leptin was present in the circulation, and that the plasma leptin levels were positively correlated with adiposity. In order to assess the mechanisms regulating leptin secretion in humans other than adiposity, we have studied plasma leptin levels in subjects without metabolic or endocrine diseases. At the same percentage of body fat, plasma leptin levels in premenopausal females were doubled and significantly elevated as compared with those in age-matched males by analysis of covariance ($p<0.05$), and the levels in premenopausal females were almost equivalent to those in age-matched postmenopausal females at a given percentage of body fat. Furthermore, suppression of estradiol by LH-RH analogue did not at all decrease the plasma leptin levels. These results indicate that there is evident sexual dimorphism in the plasma leptin levels, although estrogen is unlikely, at least directly, to affect the gender difference. Moreover, in the patients with Cushing's syndrome of various causes including adrenal adenoma, pituitary adenoma and iatrogenic Cushing's syndrome with collagen diseases, plasma leptin levels were approximately doubled and significantly higher than those in control subjects at a given percentage of body fat ($p<0.05$). The resection of adrenal and pituitary adenoma caused remarkable decrease in plasma leptin levels with concurrent attenuation of plasma cortisol levels. In the organ culture of human adipose tissue, dexamethasone potently induced the leptin gene expression and subsequent secretion of leptin from adipose tissue. The results presented here demonstrate that glucocorticoid and gender are involved in the regulation of plasma leptin levels in humans.

687

GENETIC VARIATION IN THE ß$_3$-ADRENERGIC RECEPTOR GENE AND NIDDM

J. Vendrell, C. Gutiérrez, M. Broch, C. Aguilar, I. Simón and C. Richart. Endocrinology Unit and Research Unit. Hospital Universitari Joan XXIII. Tarragona. Spain.

Introduction: Obesity is the most powerful risk factor for Non-Insulin-Dependent Diabetes Mellitus (NIDDM) and, like NIDDM, has clear genetic determinants. Recent works have evidenced that molecular abnormalities in the ß$_3$-adrenergic receptor may lead to obesity and NIDDM; however, some studies have failed in finding such associations. We have studied the possible association between the Trp64Arg mutation in the ß$_3$-adrenergic receptor gene and either NIDDM and its long-term complications in a Mediterranean population. **Material and methods**: We have used the polymerase chain reaction to amplify a region of the gene for the ß$_3$-adrenergic receptor to analyze the frequency of a C→T mutation that results in a replacement of Trp by Arg at position 64 (Trp64Arg) in 187 NIDDM patients and 87 healthy controls. A plasmatic lipidic profile, glycated haemoglobin and microalbuminuria were quantified. **Results**: The frequency of the Trp64Arg allele was similar in the controls and in the NIDDM patients (0.096 and 0.075, respectively). Neither was the mutation associated with a greater body mass index nor with an earlier age at onset of NIDDM. There were not any differences in the NIDDM group when studying the presence of either nephropathy or retinopathy. **Conclusions**: The Trp64Arg mutation of the ß$_3$-adrenergic receptor is not associated with NIDDM and with any of its long-term complications in our population.

LEPTIN INHIBITS INSULIN BINDING IN ISOLATED RAT ADIPOCYTES.

K. Walder[1], A. Filippis[2], S. Clark[3], P. Zimmet[4] and G. R. Collier[1]. [1]School of Nutrition and Public Health, Deakin University, Geelong, Australia, [2]Department of Medicine, Royal Melbourne Hospital, Parkville, Australia, [3]Institute of Human Nutrition, Deakin University, Toorak, Australia, and [4]International Diabetes Institute, Caulfield, Australia.

Leptin is thought to be an important regulator of energy balance and body weight homeostasis. It is secreted from adipose tissue and circulating levels correlated with body weight, BMI and plasma insulin concentration in humans. Leptin is thought to act centrally to reduce food intake and increase energy expenditure. However, leptin has also been shown to affect fertility and neuroendocrine function, and leptin receptors have been found in various tissues outside the hypothalamus, including liver, lung and adipose tissue. These findings suggest that leptin may have significant effects on peripheral tissues, and several studies have investigated a possible link between leptin and insulin in the regulation of metabolism. In this study we investigated the effects of leptin on insulin binding by isolated rat adipocytes. Sprague-Dawley rat adipocytes were isolated by collagenase digestion and incubated with varying amounts of unlabelled insulin (0, 2, 10 & 40 ng/ml, 10 µg/ml) and ^{125}I-labelled insulin, with or without 50 nM murine leptin (kindly supplied by Amgen Inc, California, USA). Leptin reduced total insulin binding (no unlabelled insulin present) by 25%. In addition, 50 nM leptin reduced insulin binding at each insulin concentration by between 15 and 25%. Analysis of the binding data suggested that leptin affected the affinity of insulin for its binding site. In summary, leptin directly inhibited insulin binding by adipocytes, and therefore may impair insulin action in fat cells. These results raise the possibility that the hyperleptinemia found in obese states could contribute significantly to adipose tissue insulin resistance which is characteristic to obesity. The precise effects of leptin on adipocytes, and on other peripheral tissues, requires further investigation.

689

SIGNIFICANCE OF β3-ADRENERGIC RECEPTOR GENE POLYMORPHISM IN THE PATHOGENESIS OF NIDDM IN KOREANS.

KJ Ahn*, KA Kim, YS Kim, JH Jung, YK Min, MS Lee, MK Lee and KW Kim. Samsung Medical Center, Seoul, Korea.

The β3 adrenergic receptor (β3-AR) may play an important role in the regulation of energy expenditure and lipolysis. A mutation of the β3-AR gene(Trp64Arg) has been reported to be associated with early onset of non-insulin dependent diabetes mellitus (NIDDM), obesity and syndrome X which are related with insulin resistance. It is well known that Korean NIDDM patients, in contrast to Caucasians, are mainly non-obese and have experienced severe weight loss during the course of disease. We studied the frequency of the mutation in Korean NIDDM patients and non-diabetics control and evaluated the clinical characteristics of Korean obese NIDDM patients.We investigated the frequency of the mutation in NIDDM patients and clinical characteristics of the patients with the mutation in order to elucidate the significance of the mutation in the pathogenesis of NIDDM in Koreans. We studied 401 NIDDM patients and 99 controls. The NIDDM patients were divided into two groups, non-obese group and obese group, according to their body mass index at diagnosis of the disease. The Trp64Arg mutation was detected by the PCR/RFLP method using restriction enzyme Mva I. The Trp64Arg allele frequency (16%) of NIDDM did not differ from that (16%) of controls. Although the mutant allele frequency was not different between non-obese and obese group both in NIDDM patients and controls, the frequency of patient with the mutant allele was significantly higher in obese NIDDM patients than in non-obese NIDDM patients (38.5% vs. 26.9%, p=0.04). However, no significant difference was found in clinical and laboratory findings between the NIDDM patients with the mutant allele and those without the mutant allele.These data suggest that β3-AR mutation might be associated with Korean obese NIDDM, and other factors might also be associated with the development of obesity and insulin resistance in NIDDM patients.

690

LEPTIN DIRECTLY STIMULATES BASAL INSULIN RELEASE FROM PANCREATIC ß CELLS.

S. Okuya, Y. Tanizawa and Y. Oka. Yamaguchi University, Ube, Japan

Leptin, a 16-kDa peptide released from adipocytes, plays an important role in regulating body weight via its effect on the satiety center in the brain. There are strong positive correlations among the percentage of body fat, plasma leptin levels and fasting plasma insulin levels. We hypothesized that the increased leptin levels contribute to fasting hyperinsulinemia in obese subjects, and thus examined the possibility of direct leptin effects on insulin secretion from pancreatic ß cells. The leptin receptor isoforms, a and b, are present in the pancreatic ß cell line MIN6 and in rat pancreatic islets, based on RT-PCR. Incubation with 1 nM recombinant mouse leptin, the concentration observed in obese subjects, stimulated basal (at 5 mM glucose) insulin secretion by approximately 40 % in both MIN6 and rat islets. Stimulatory effects of leptin were dose-dependent, and not observed without glucose, while 1 nM leptin did not induce an increase in insulin mRNA or tyrosine-phosphorylation of STAT3 in the presence of 5 mM glucose. In conclusion, leptin acts directly on pancreatic ß cells, and this stimulatory mechanism may account in part for the fasting hyperinsulinemia observed in obese subjects.

ASSOCIATION BETWEEN POLYMORPHISM OF THE ß3-ADRENERGIC RECEPTOR GENE AND BODY WEIGHT GAIN IN PREGNANT DIABETICS

Yanagisawa K.[1], Iwasaki N. [1], Sanaka M. [1], Minei S. [1], Kanamuro R. [1], Suzuki N. [1], Nagashima T.[1], Kanamori M.[2],Omori Y.[1] Tokyo Women's Medical College[1] and Toho University[2], Tokyo JAPAN

AIM: Obesity is a risk factor for toxemia and hyperglycemia during pregnancy in diabetic women, and also affects fetal growth. However, the pathogenesis of obesity during pregnancy has not been elucidated. The ß3-adrenergic receptor (ß3-AR) plays an essential role in fat metabolism and thermogenesis. Polymorphism of the ß3-AR gene has been reported to be associated with body weight gain in NIDDM subjects. The aim of this study was to clarify the relationship between the ß3-AR gene and body weight gain during pregnancy. MATERIALS AND METHODS: The 127 subjects consisted of 81 NIDDM patients and 46 IDDM patients treated in the pregnancy clinic of the Diabetes Center. Their mean age at the onset of diabetes was 22.1±7.7 years (mean±SD), and their average age at delivery was 29.5±4.4years. Genomic DNA was prepared from peripheral blood leukocytes. Polymorphism of the ß3-AR gene was detected by restriction fragment length polymorphism after polymerase chain reaction using Bst OI, which recognizes Trp64Arg substitution. RESULTS: The allele frequency of the Trp64Arg allele was 0.19 in NIDDM and 0.16 in IDDM. The prevalence of heterozygotes and homozygotes was 25% (20) and 6% (5), respectively, in the NIDDM subjects, and 24% (11) and 4% (2), in the IDDM subjects. The basal BMI before pregnancy was 21.5±3.2 in the wild type, 21.1 ±3.4 in heterozygotes and 23.0±3.2 in homozygotes (NS). Among the NIDDM subjects, excess weight gain during pregnancy, judged by maximum BMI minus basal BMI exceeding 5, was observed in 8.9% (5) in the wild type, 25.0% (5) in the heterpzygotes and 40.0% (2) in the homozygotes. The homozygotes were significantly associated with excess weight gain during pregnancy (Odd's ratio: 6.80; 95% confidence interval: 1.10-41.71). None of the IDDM homozygotes showed excess weight gain. CONCLUSION: These results provide evidence that the ß3-AR gene is a genetic factor in the pathogenesis of body weight gain during pregnancy in NIDDM in Japanese.

692

HUMAN SKELETAL MUSCLE NITRIC OXIDE SYNTHSE CHARACTERIZATION AND ITS ACTIVITY IN OBESE SUBJECTS.

Zecharia Madar, Juleen R. Zierath Lorraine A. Nolte, Anders Thorne Hillary Voet and Harriet Wallberg-Henriksson Hebrew University, Faculty of Agriculture, Rehovot, Israel and Karolinska Institute, Clinical Physiology, Stockholm, Sweden.

Recent observations have identified nitric oxide (NO) as a physiologic modulator of skeletal muscle metabolism. The enzyme responsible for NO production is nitric oxide synthase (NOS). Three isoforms of NOS are known to exist. The constitutive enzymes, neuronal and endothelial NOS, are calcium-calmodulin dependent, while the inducible NOS is independent of calcium levels. The main aim of the present study was to characterize the NOS activity in human skeletal muscle and its maxmial activity in obese subjects muscle. Tissue was homogenized in 50 mM Tris-HCl, pH 7.4 containing protein inhibitors and centrifuged at 20000 x g (10 min, 4°C). The pellet was washed with 1M KCl and centrifuged for 20 min. Both supernatants were combined. The NOS activity was determined in both pellet and supernatant by conversion of [^{14} C]-L-arginine to [^{14}C]-L- citrulline. Results are expressed as pmol of citrulline per min per mg protein. We demonstrated that (a) the pellet contains most of the NOS activity (90%); (b) human skeletal muscle NOS is calcium and calmodulin dependent, reaching maximum activity with 1.25 mM and 10 U, respectively; (c) NOS activity was inhibited by EGTA (2mM) and by the calmodullin antagonist (100µM); (d) the apparent Km Values for arginine is 25 µM. Muscle strips from hyperinsulinemic (23.8±3.1 µU/ml) obese subjects with BMI 0f 40.6±3.4 % , demonstrated a dramatic decrease in insulin sensitivity as expressed by glucose transport and glucose oxidation. NOS activity in obese subjects (n=9) was significantly lower (30%) than in healthy subjects . In conclusion, human skeletal muscle contains a constitutive NOS regulated by Ca^{++} and calmodulin. The reduced NOS activity demonstrated in skeletal muscle from insulin resistant obese subjects may lead to decreased NO availability. It is suggested that this alteration may play a role in skeletal muscle insulin resistance associated with obesity.

693

ASSOCIATION OF THE GLN223ARG POLYMORPHISM IN THE LEPTIN RECEPTOR GENE WITH PLASMA LEPTIN LEVELS, INSULIN SECRETION AND NIDDM IN PIMA INDIANS.

DB Thompson, RA Norman, E Ravussin, WC Knowler, P Bennett, and C Bogardus, NIDDK, NIH, Phoenix, AZ, USA.

The human leptin receptor gene (LEPR) lies on chromosome 1, just distal to the microsatellite marker, D1S198, where we previously mapped a locus that contributes to variation in insulin secretion in the Pima Indians. The Gln223Arg polymorphism of LEPR was typed in 1244 Pima Indians, allele frequencies Gln=0.33 and Arg=0.67, compared to 54 Caucasians, Gln=.46 and Arg =.54. This polymorphism was not associated with body mass index or percentage body fat as determined by underwater weighing. In a subset of non-diabetic individuals, after adjusting for obesity, sex and family membership, the Gln homozygotes (N=22) had lower fasting plasma leptin concentrations than the heterozygotes (N=137) or the Arg homozygotes (N=135) - geometric means 13, 18 and 23 ng/ml, respectively ($p<0.002$). Also, the mean fold increase in plasma insulin concentration 2 hours after ingesting 75g glucose was 24% lower in the Gln homozygotes (N=28) compared to the heterozygotes and Arg homozygotes combined (N=311), ($p<0.03$), after adjusting for obesity, sex, insulin action and family membership. Among full-blooded Pimas, the Gln homozygotes (N=100) had a higher prevalence of NIDDM (72%) compared to the heterozygotes and Arg homozygotes (N=896) (58%) ($P=0.007$). Whether these associations are causally related to the Gln223Arg polymorphisms per se, or due to another polymorphism in LEPR, or another gene in linkage disequilibrium with LEPR, remains to be determined.

694

LIPOLYTIC CATECHOLAMINE RESISTANCE IN NON-OBESE WOMEN WITH POLYCYSTIC OVARY SYNDROME

H Wahrenberg, I Ek, A Bergqvist, K Carlström and P Arner. Departments of Medicine and Gynecology and Obstetrics, Huddinge University Hospital, Huddinge, Sweden.

The polycystic ovary syndrome (PCOS) is characterized by a high rate of metabolic disturbances and cardiovascular mortality. Lipolysis regulation was investigated in isolated abdominal subcutaneous adipocytes from 10 non-obese women with PCOS and 11 age and BMI matched healthy women. Eight PCOS women were re-investigated after 3 months treatment with combined oral contraceptives (OC). PCOS women showed a marked resistance to the lipolytic effect of noradrenaline due to defect at two different levels in the lipolytic cascade. First, the seven-fold reduction in sensitivity of the beta$_2$-selective agonist terbutaline ($p<0.005$) which could be ascribed to a 50% lower beta$_2$-adrenoceptor density ($p<0.02$). Second, the maximum lipolytic response was also 40% lower ($p<0.02$) in the PCOS women compared to the healthy women regardless if lipolysis was stimulated with beta-adrenergic agonists or post-receptor acting agents as forskolin and dibutyryl-cyclic AMP. There was no difference as regards beta$_1$ or alpha$_2$-adrenoceptor functions or densities. Neither of the lipolytic defects or receptor density reduction was restored by 3 months of OC treatment. The results indicate the existance of marked impairment of catecholamine induced lipolysis in non-obese PCOS women displaying an early feature of the insulin resistance syndrome due to multiple lipolysis defects as a lower beta$_2$ adrenoceptor density and reduced function of the protein kinase-hormone sensitive lipase complex.

695

AMINO ACID POLYMORPHISMS IN THE LONG ISOFORM OF THE LEPTIN RECEPTOR IN JUVENILE ONSET OBESITY.

S.M. Echwald[1], T. Duelund[1], T.I.A. Sørensen[2], T. Andersen[2], A. Tybjærg-Hansen[2], W.K. Chung[3], R.L. Leibel[3] L. Hansen[1] and O. Pedersen[1]. [1]Steno Diabetes Center and Hagedorn Research Institute, Copenhagen, Denmark, [3]Danish Epidemiological Science Center at the Institute of Preventive Medicine, Copenhagen University Hospital, Denmark, [3] Rockefeller University, NY, USA

The recently uncovered putative lipostat system controlled by leptin and its hypothalamic receptor provides good candidate genes for the molecular basis of inherited obesity in humans based upon the profound obesity observed in *obese*, *diabetes*, and *fatty* rodents in which leptin or its receptor are mutated. Numerous studies have shown that obesity prevails in spite of increased circulating leptin levels and the concept of leptin resistance as a basis of obesity has evolved. In this study we tested the hypothesis that juvenile onset obesity in humans may be caused by leptin resistance mediated through genetic variations in the hypothalamic leptin receptor. One hundred and fifty-eight obese subjects were selected at the draft board examination having a BMI > 31 kg/m^2 and for having a history of juvenile onset obesity. From the same geographical area, a matched cohort of 200 lean subjects were selected. Single strand conformational polymorphism (SSCP) scanning of the entire long isoform of the leptin receptor in 60 subjects with juvenile onset obesity on genomic DNA revealed a total of three frequent amino acid variants located in coding exons 2, (Lys109Arg), 4 (Gln223Arg) and 12 (Lys721Asn), respectively. The frequencies of all variants were determined in the cohort of 158 subjects with juvenile onset obesity and 200 lean subjects, shown in the table.

Exon	Position base #	Variant	Allele frequency (%) Obese	Lean	Carrier frequency (%) Obese (ho/he)	Lean (ho/he)
2	326	K109R	24,5	19,5	7,0 / 35,0	7,0 / 25,0
4	668	Q223R	44,0	44,7	19,5 / 49,2	17,2 / 51,8
12	1968	K721N	17,0	15,0	3,6 / 26,6	2,7 / 25,0

The prevalence of the three mutations was not significantly different between the obese and the lean cohorts both in regards to allele- and carrier frequency ($p > 0.1$ in each case). The distribution of the alleles was in Hardy-Weinberg equilibrium (not shown). In conclusion: It is unlikely that mutations in the coding region of the long isoform of the leptin receptor are a common cause of juvenile onset obesity.

696

ADIPOSE CELL APOPTOSIS IS REGULATED BY TUMOR NECROSIS FACTOR -α AND INSULIN-LIKE GROWTH FACTOR 1

JB Prins[a,b], CU Niesler[b], S O'Rahilly[a,b] and K Siddle[a]. Departments of Medicine[a] and Clinical Biochemistry[b], University of Cambridge, Cambridge, U.K..

Adipose tissue mass reflects the balance of factors affecting average adipose cell volume (triglyceride content) and adipose cell number. Adipose cell number is determined by relative rates of preadipocyte proliferation/differentiation and adipose cell apoptosis. We have investigated the roles of serum deprivation, TNF-α and IGF-1 in the induction and modulation of adipose cell apoptosis *in vitro*. Apoptosis was assessed using morphological (light and electron microscopy, acridine orange staining) and biochemical (DNA fragmentation and annexin V staining) criteria, and apoptotic indices were determined by cell counting. Cell types studied were cultured human adipocytes (in explants), human preadipocytes and murine 3T3-L1 preadipocytes. Under control conditions in serum-containing medium, apoptotic indices were low (<2%) in all cell types. Human adipocytes cultured in 50-500 pM TNF-α for 12-24 hours had apoptotic indices of 16-24 % ($p < 0.01$), whilst serum deprivation of 4-12 days induced apoptotic indices of between 2-14 % ($p < 0.05$). Human preadipocytes showed maximum apoptosis of 5.6 % ($p<0.05$) after 4 hours culture in TNF-α, but the cells showed resistance to serum deprivation of up to 96 hours. Apoptosis of 3T3-L1 cells was induced by serum deprivation or addition of TNF-α (5 nM), reaching levels of 8.6% ($p <0.01$) and 12.6 % ($p<0.01$) respectively after 24 hours. The combined effects of serum deprivation and TNF-α were additive. IGF-1 (100 ng/ml) inhibited apoptosis induced by serum deprivation (by 50%, $p <0.05$) but not TNF-α, indicating that distinct apoptotic biochemical pathways may be utilised by these stimuli. We conclude that apoptosis of adipose cells is modulated by endocrine/paracrine factors, and suggest that this process may be an important determinant of adipose tissue mass.

697

THE PUTATIVE ROLE OF THE LEPTIN RECEPTOR GENE IN THE PATHOGENESIS OF LEPTIN RESISTANCE

T. Tuomi[1], M. Orho[1], P. Kleyn[2], S. G. Kovats[2], O. Tayber[2] and L. Groop[1]. The Department of Endocrinology, Lund University, Malmö, Sweden[1] and Millennium Pharmaceuticals Inc, Boston, USA[2].

Mutations in the leptin-receptor gene cause leptin-resistance, obesity and diabetes in several rodent strains. To evaluate the role of leptin receptor gene in the pathogenesis of leptin resistance, obesity and NIDDM we screened 30 obese NIDDM patients and 30 control subjects for mutations in this gene by heteroduplex analysis. We also measured serum leptin levels (S-LEP), BMI, fatmass (FM), and glucose and insulin response to oral glucose tolerance test in 404 unrelated NIDDM patients (186M, 218F) and 233 control subjects (115M, 118 F) from a population-based NIDDM family study in Western Finland (Botnia Study). We identified two polymorphisms; in exon 2 (E2; A→G; Lys to Arg) and in exon 4 (E4; A→G; Gln to Arg). These polymorphisms were typed by PCR-RFLP in 404 unrelated NIDDM patients and 233 controls. The main determinators of S-LEP in both NIDDM patients and controls were sex, FM and fasting insulin; in NIDDM patients also fasting glucose ($p<0.00001$). After adjustment for these confounders, NIDDM men, but not women, had higher S-LEP levels than controls (mean ± SEM 5.75±1.0 vs. 4.81±1.0, $p=0.018$). The E2 and E4 polymorphisms, in marked linkage-disequilibrium with each other, did not significantly affect the S-LEP levels or measures of obesity. However, the E4 1/1 genotype was significantly associated with higher fasting and 2-hour glucose levels in NIDDM patients (median [interquartile range]: 1/1 vs. 2/2 homozygotes: 8.2 [3.5] vs. 7.4 [3.1], $p=0.008$; and 13.8 [7.4] vs. 12.3 [6.4], $p=0.005$) and with 2h-glucose in control women (5.4 [1.3] vs. 4.7 [1.4], $p=0.021$). We conclude that the aminoacid variants in the leptin receptor gene do not explain leptin resistance in obesity, but could contribute to the development of glucose intolerance. Sex, fat mass and insulin levels are the main determinants of serum leptin levels.

698

TUMOR NECROSIS FACTOR α AS A LINK FACTOR BETWEEN OBESITY AND NON-INSULIN-DEPENDENT DIABETES MELLITUS

G.Winkler (1), F. Salamon (2), I. Szilvási (3), D. Salamon (3), G. Speer (3), I. Karádi (3), L. Romics (3) and K. Cseh (3). 1st Department of Medicine (1), 2nd Department of Medicine (2), St. John Hospital, 3rd Department of Medicine, Semmelweis University (3), Budapest Hungary.

In animal models of obesity and NIDDM the overexpression of tumor necrosis factor alfa (TNFα) in adipocytes led to insulin resistance by decreasing the signal transduction of insulin receptors. The aim of the study was the investigation of the role of TNFα in the human obesity-diabetes link. In a follow up study of 9 months (samples taken in every 6 weeks) plasma TNF bioactivity was measured by using the L929 cell cytotoxicity assay in the following groups: 59 patients with NIDDM (group 1), 16 patients with IDDM (group 2), 28 patients with obesity (BMI>30, group 3) and 30 matched healthy controls (BMI<24, group 4). TNF concentrations were compared to the patients' basal C-peptide and glucagon levels. Recombinant human TNFα (Sigma) was used as a standard. Monoclonal neutralizing anti-TNFα immunoglobulins (Boehringer) were applied to detect the TNFα cytotoxicity in the samples. A significant elevation of the TNFα concentration was observed in group 1 (x±SE pg/mL:90±10) and group 3 (78±12) as compared to group 2 (40±11) and group 4 (22±8). TNFα levels positively correlated with the BMI values in the NIDDM and obesity groups A positive correlation between TNFα and the increased C-peptide concentration in these groups was also found. These correlations were not observed in group 2 and 4. The increased plasma TNFα levels in NIDDM and obesity can contribute in humans to hyperinsulinemia and insulin resistance.

Identification of variants in the genomic leptin receptor sequence, and a comparison of frequencies in African American NIDDM and control probands

PS Behn, CA Iannotti, WK Chung, H Inoue, K Clement, C Welling, J McGill, P Froguel, RL Leibel, MA Permutt.

Obese, non-insulin dependent diabetes mellitus (NIDDM) phenotypes are manifest in animals with mutant leptin receptor, suggesting that leptin feedback may play an important role in an adipocyte-hypothalamus-beta cell axis of metabolic regulation. We have tested the hypothesis that genetic variations in the leptin receptor may be associated with human obesity and NIDDM, by screening a population of 15 morbidly obese hyperleptinemic French probands (diabetic and non-diabetic) for variants in the 5 leptin receptor isoforms, using single stranded conformation polymorphism (SSCP) analysis. Six variants were found, including 3 missense, 1 silent and 2 intronic variants; SSCP analysis of 15 African American obese (NIDDM and non-diabetic) probands revealed seventh variant, a 5 bp insertion in the leptin receptor b isoform 3'UTR. A population of 94 diabetic and non-diabetic African Americans (controlled for age and sex) were genotyped for the missense and 3'UTR variants, using PCR-RFLP and length polymorphism assays. Although allele frequencies in the lean and obese or NIDDM and non-diabetic phenotypes were not significantly different, evaluation using age of diabetes onset ($\leq$ 45 vs. > 45) yielded a p=0.026 for the K109R (26% vs. 12%) variant and p=0.026 for the Q223R variant (67% vs. 51%). Stratification of the diabetic age groups using BMI did not a show significant difference for either variant. Evaluation of the other 5 variants revealed no significant difference within the diabetic group (age of onset or BMI) or between the diabetic and control groups (diabetic status or BMI). These results suggest that an association may exist between early onset NIDDM and leptin receptor sequence variants.

ASSOCIATION BETWEEN A POLYMORPHISM IN THE HORMONE-SENSITIVE LIPASE GENE AND THE METABOLIC SYNDROME

M. Klannemark[1], M. Orho[1], C. Holm[2], H. Laurell[2] and L. Groop[1]. Dept. of Endocrinology[1] and Dept. of Cell and Molecular Biology[2], University of Lund, Sweden.

Clustering of glucose intolerance, abdominal obesity and hypertriglyceridemia has been described as the metabolic syndrome (MS) and considered to have strong genetic background. Hormone-sensitive lipase (HSL; chrom 19q13.2) is the key enzyme in adipose tissue lipolysis. Genetic alterations in the HSL gene could therefore be involved in the pathogenesis of MS. To address this question we have studied whether a polymorphism in intron 7 of the HSL gene (15 alleles, amplified with radioactive PCR) is associated with MS in 101 unrelated patients with MS (53M/48F, age 60±13yrs, BMI 30.0±3.9 kg/m^2, WH 1.00±0.07 (men) and 0.89±0.05 (women), plasma triglycerides (TG) 4.8±2.6 mmol/l, 75% with NIDDM and $HbA1_c$ 7.6±2.1%), 204 unrelated patients with NIDDM but without signs of MS (99M/105F, age 63±15yrs, age at diagnosis 53±17yrs, BMI 23.9±2.0 kg/m^2, WH 0.92±0.05 (men) and 0.82±0.04 (women), TG 1.2±0.4 mmol/l and $HbA1_c$ 7.5±1.8%) and 197 unrelated healthy controls with no family history of NIDDM (100M/97F, age 56±11yrs, BMI 23.6±2.2 kg/m^2, WH 0.91±0.05 (men) and 0.79±0.05 (women), TG 1.0±0.4 mmol/l and $HbA1_c$ 5.2±0.5%). A significant difference in the allele frequency distribution (DF:7, p<0.005) was found between patients and controls but not between NIDDM and controls (cells of <5 alleles were combined). We therefore performed a linkage study in 39 Scandinavian families including 100 affected subjects (55M/45F, age 59±14yrs, BMI 30.0±4.0 kg/m^2, WH 1.00±0.05 (men) and 0.90±0.06 (women), TG 4.0±2.2 mmol/l, 60% with NIDDM and $HbA1_c$ 7.6±2.4%) and 87 unaffected subjects (49M/38F, age 53±19yrs, BMI 26.6±4.8 kg/m^2, WH 0.96±0.05 (men) and 0.85±0.06 (women), TG 1.7±0.7 mmol/l and $HbA1_c$ 5.4±0.9%). Using an IBD-APM approach, no linkage between the HSL gene and MS could be shown (Z-score -0.51). Finally, we screened the 9 coding exons of the HSL gene for mutations using SSCP in 30 subjects with MS. No variant forms of the gene were found. In conclusion, the association between a polymorphic site in the HSL gene and MS suggests a role for HSL in the pathogenesis of MS. Absence of linkage points at a polygenic etiology of MS, in which HSL together with other genes may increase the susceptibility to MS.

701

AUTOSOMAL GENOME-SCAN FOR GENETIC LINKAGES TO ENERGY METABOLISM IN PIMA INDIANS

R. A. Norman, P. A. Tataranni, C. Bogardus, and E. Ravussin and the Pima Diabetes Gene Group, CDNS, NIDDK, Phoenix AZ 85016 USA.

Since both a low "relative" metabolic rate and a low fat/carbohydrate oxidation ratio are risk factors for weight gain and are familial traits, an autosomal search for linkages of energy metabolism to DNA markers was completed in Pima Indians, a population with a high prevalence of obesity. 24-hour energy expenditure (24EE), sleeping metabolic rate (SMR) and 24-hour respiratory quotient (24RQ) were measured in a respiratory chamber. 24EE and SMR were adjusted for fat-free mass, fat mass, age and sex; whereas, 24RQ, a measure of average daily fat vs carbohydrate oxidation, was adjusted for the effects of energy balance and percent body fat. Trait values were selected from multiple measures at the lowest body weight and when subjects were non-diabetic. Genetic linkage (236 sib-pairs from 82 families) was tested by single-marker sib-pair linkage (SM) and by multipoint interval mapping (MI) to quantitative traits. Two regions showed evidence of possible linkage to metabolic rate: a region near D20S103 to 24EE (LOD=2.7 by SM) and a region near D4S1629 to SMR (LOD=2.2 by SM). For 24RQ, possible linkages were found in in three regions: near D1S1631 (LOD=2.7 by SM), near D10S189 (LOD=1.5 by MI) and near D3S2387 (LOD=2.2 by MI). Searching for candidate genes underlying the variability in energy metabolism seems warranted in these regions of the genome.

702

GENETIC POLYMORPHISM OF LIPOPROTEIN LIPASE GEN IN AN ABORIGINAL GROUP FROM TEMUCO, CHILE.

Pérez-Bravo F (1), Santos JL (1), Calvillán M (2), Larenas G (3), Carrasco E (2).
(1) Molecular Biology and Epidemiology Department. Nutrition and Food Technology Institute (INTA), University of Chile. (2) Faculty of Medicine, Diabetes Unit, Hosp. SJ. de Dios. University of Chile. Santiago, Chile. (3) Faculty of Medicine, University of La Frontera, Temuco, Chile.

Lipoprotein lipase (LPL) plays a crucial role in the lipoprotein metabolism. Several LPL gene polymorphisms have been found associated with lipid disturbances, premature atherosclerosis and cardiovascular disease. We have been investigating for the first time, the genotype distribution of LPL polymorphism in the Mapuche population, an aboriginal group from Chile, and their relation with lipids levels and obesity. We have determined the Hind III and Pvu II polymorphism by means of PCR and restriction fragment lenght polymorphism in 50 mapuche indians upper 20 years old without non insulin dependent diabetes mellitus (NIDDM). The homozigous genotype for Hind III with cut (+/+) was more frequent in this group (+/+=0.56, +/-=0.36 and -/-=0.08, p<0.05) for the Pvu II genotype the frequency between homozigous and heterozigous was similar (+/+= 0.46, +/-=0.54) .We analyzed the impact of both genotypes on plasma lipid levels and we found that the Hind III (+/+) genotype was associated with high levels of total cholesterol (TC) (54% of the indians with TC>200 mg/dl) and with high levels of Triglycerides (TG) (78% of the indians with TG>150 mg/dl were Hind III +/+). We did not find this relationship for the Pvu II polymorphism. Finally, we determine the association of these genotypes according to body mass index (BMI) and waist/hip ratio (WHR) respect to obesity in this population. Hind III (+/+) polymorphism was effectively associated with increase in BMI and high WHR (56% of the indians with BMI>30 Kg/m^2 and 60% of the indians with WHR>0.9, were +/+ for Hind III). Pvu II polymorphism was also related with high WHR in this group. In conclusion, we confirmed the association of genetic variation of LPL locus (Hind III polymorphism) with high lipid levels and with possible predisposition to obesity in this aboriginal population.

703

AUTOSOMAL GENOME-WIDE SCAN FOR OBESITY SUSCEPTIBILITY GENES IN PIMA INDIANS

R. A. Norman, D. B. Thompson, C. Bogardus, and E. Ravussin and the Pima Diabetes Gene Group, CDNS, NIDDK, Phoenix AZ 85016, USA.

An autosomal search for linkages of obesity to DNA markers was completed in Pima Indians, a population with a very high prevalence of obesity and NIDDM. Data collected on non-diabetic Pima Indians from 127 nuclear families provided 451 sib-pairs for linkage analysis. Fat distribution was assessed by waist/thigh circumference ratio and body composition by hydrostatic weighing. Trait values were selected from multiple measures at the highest body weight and adjusted for the effects of age and sex by linear regression. Genetic linkage for quantitative traits was tested by single-marker and multipoint sib-pair linkage. Regions containing markers or intervals showing evidence of linkage (LOD>1.2) were further analyzed by the multipoint methods of Mapmaker/Sibs. For waist/thigh ratio, four markers in intervals) — D1S2127, D3S1307-D13S218 and D13S887 — showed single marker linkage (1.2<LOD<2.6). Multipoint analyses did not result in improved evidence for linkage. For percent fat , eight markers (seven intervals)— D2S1363, D2S427, D5S1716, D11S2366, D14S1280-D14S617, D17S785 and D18S877 — showed single marker linkage (1.2<LOD<2.4). Multipoint analyses did not result in notably improved LOD scores for any region except the region near D11S2366. Here, the LOD score increase from 1.8 to 2.5 when analyzed by the variance estimation method. This linkage at 11q21-q22 is the best evidence for a gene influencing body composition in Pima Indians.

704

The novel lipoprotein lipase(LPL) activating compound NO-1886 prevents weight gain in high-fat fed NIDDM model rats

M. Kusunoki, T. Hara, F. Sakakibara, K. Chikada, K. Usui, K. Yamanouchi, *Y. Nakaya, S. Kakumu and **L.H.Storlien. 1st Department of Internal Medicine, Aichi Medical University, Aichi, Japan. *Tokushima University, Tokushima, Japan. **University of Wollongong, Wollongong, Australia.

[Aim] The accumulation of fat in the internal organs is an important risk factor of diabetes. We examined wether the novel LPL activating compound NO-1886 prevents the accumulation of fat in the internal organs or not.

[Method] SD rats(9 months, n=6) were fed a high fat diet containing NO-1886(50mg/kg) for 3 months. After 3 months we measured respiratory quotient (R.Q.) and took blood sample, heart and fat in the internal organs and subcutaneous tissue. We also measured the LPL activity and the total amount of fat in the organs and subcutaneous tissue.

[Result] After high-fat feeding, the total amount of fat in the internal organs increased 3.3 times of normal rats. High-fat fed rats with NO-1886 increased 1.5 times of normal rats. At the same time NO-1886 prevented the accumulation of subcutaneous fat. NO-1886 increased the activity of LPL in heart, but did not increase the activity of LPL in fat tissue. R.Q. decreased significantly in NO-1886 administrated gruop (by Dunnett's-test).

[Conclusion] The novel LPL activating compound NO-1886 prevented the accumulation of fat in the internal organs and subcutaneous tissue. This phenomenon is thought to result from the increased combustion of fat as evidenced by the decreased rate of R.Q.

CANDIDATE GENES FOR HUMAN OBESITY: ASSOCIATION AND SIB-PAIR STUDY

L. Oksanen, M. Öhman, K. Kainulainen, P Mustajoki, J. Kaprio, M. Heiman,V. Koivisto, M. Koskenvuo, O.A. Jänne, L. Peltonen and K. Kontula. University of Helsinki, National Public Health Institute; Helsinki; University of Turku; Turku; Eli-Lilly Research Laboratories, Indianapolis

The aim of our study is to identify major genes predisposing to human obesity and to investigate their metabolic effects. We studied the possible association between microsatellite markers near the *ob* gene and morbid obesity in 252 morbidly obese patients (mean BMI 43 ± 7 kg/m^2) and 151 lean controls (mean BMI 22 ± 2 kg/m^2). The genomic regions homologous to murine obesity genes *ob, db, tubby, agouti and RIIβ* were analyzed in 102 affected sib-pairs (BMI ≥ 32 kg/m^2). Highly polymorphic microsatellite markers flanking the areas of interest were analyzed on polyacrylamide gels using radioactive PCR products. Serum leptin levels of the probands were determined by radioimmunoassay. Markers of the human *ob* gene region failed to show association with morbid obesity, whether tested in the case-control study or the affected-sib-pair analysis. There was a strong positive correlation between serum leptin levels and BMI in morbidly obese women ($r = 0.41$, $p = 0.0001$) and men ($r = 0.56$, $p = 0.0001$). A carrier status for either of the two most prevalent alleles of the microsatellite marker D7S530 in the vicinity of the *ob* gene were associated with serum leptin levels in the obese subjects ($p = 0.04$). One allele of the *ob* gene marker D7S649 showed a statistically significant association with the amount of weight lost ($p = 0.006$) on a 16-week weight-loss program. The affected-sib-pair study of the murine homologous regions failed to show linkage. In conclusion, in contrast to some earlier studies we were not able to find any association between the *ob* gene area and obesity although two different approaches were used. Serum leptin levels were statistically significantly associated with BMI even in morbidly obese subjects, and allelic variation near the *ob* gene is associated with minor variations in leptin levels and response to treatment for obesity. A candidate gene approach based on murine obesity genes could not provide evidence favoring the role of equivalent genes in human obesity.

706

LIPOPROTEIN LIPASE (Asn291→ Ser) MUTATION IN CZECH NON–INSULIN DEPENDENT DIABETES MELLITUS PATIENTS

B. Bendlová, J.Včelák, I. Mazura and J. Perušičová. Institute of Endocrinology, Prague, Czech Republic.

Lipoprotein lipase (LPL) is the key protein in the clearance of plasma triglycerides. Recently seven genetic variants of the lipoprotein lipase gene has been found, which may affect the individual´s lipaemia in obesity and NIDDM and other hyperlipidaemias. The LPL (Asn291→Ser) mutation was found in 9,3% of Dutch patients with familial combined hyperlipidaemia and those carriers had signif. higher plasma and VLDL–triglycerides, VLDL– and HDL–cholesterol. Therefore we searched for the occurence of this mutation in Czech NIDDM patients (n=95). The LPL (Asn291→Ser) mutation was detected by PCR and Rsa I restriction. Six of NIDDM patients were heterozygous for this mutation (6,3%). Our carriers and non–carriers did not differ in levels of total serum cholesterol (6,40 ± 2,00 vs. 6,64 ±1,42 mmol/l), HDL cholesterol (1,22 ± 0,32 vs. 1,32 ± 0,38 mmol/l) and triglycerides (2,61 ± 1,91 vs. 2,42 ± 2,15 mmol/l). The only difference between those two groups was found in systolic blood pressure (130 ± 14 vs. 141 ± 24 mmHg, p=0,04, Student´s t test). It is obvious that the LPL (Asn291→Ser) mutation could contribute to elevated plasma lipids, but this polymorphism is the only one out of several causes giving rise to this pathological state.

Supported by grants IGA MH CR 3414–3 and COST B.5.

SCREENING OF CANDIDATE GENES INVOLVED IN REGULATION OF THERMOGENESIS AMONGST GESTATIONAL DIABETIC SUBJECTS.

PJ Saker[1], E Kousta[1], DG Goulis[1], S Robinson[1], A Dornhorst[2], DG Johnston[1], GA Hitman[3] and MI McCarthy[1]. [1]Imperial College School of Medicine at St Mary's London, UK; [2]Royal Postgraduate Medical School, London, UK; [3]St Bartholomew's and Royal London Hospital School of Medicine, London, UK.

Women with previous gestational diabetes mellitus (GDM) have a substantially-increased risk of overt NIDDM in later life.GDM is associated with a reduction in postprandial thermogenesis (PPT) compared to pregnant control women: this reduction continues in the non-pregnant state. This defect in PPT may reflect variation in genes regulating thermogenesis and contribute to progression to NIDDM. We are screening the genes *B3AR* (β_3 adrenergic receptor) and *UCP* (uncoupling protein) to document the total extent of candidate genetic variation in (i) 40 women with GDM (mixed ethnicity) and (ii) a cohort of Bengali women, 21 with GDM and 50 with normal glucose tolerance during pregnancy. Single-stranded conformational analysis has not identified any novel significant variations in the coding regions of the *B3AR* gene; four variants found within exons of the *UCP* gene are under evaluation. In the small cohorts used for mutation screening, we see no increase in prevalence of the previously-reported variants in *B3AR* (Trp64→Arg) and *UCP* (A→G;-3826bp) in GDM subjects. However, within the Bengali control women, we find significant associations between weight at 30 weeks' gestation (the only weight measure available for these women) and presence of each of the variants (*B3AR* : 58.0 (12.7)kg [Trp/Trp] vs 63.8 (20.9)kg [Trp/Arg], p=0.035; *UCP*: 55.0 (9.6)kg [A/A] vs 59.5 (13.0)kg [G/-], p=0.034) (data as median (IQR): analysis by Mann-Whitney U). To the extent of the survey completed and the sensitivity of the methods employed, we have identified no novel variants in either the *B3AR* or *UCP* genes thus far. The associations with weight seen with the known mutations offer confirmation of previous findings in a new ethnic group: this supports a direct pathogenic role for these variants. Further studies of additional aspects of these genes in larger cohorts are in progress.

708

LDL PARTICLE SIZE AND APOLIPOPROTEIN E POLYMORPHISM IN NONDIABETIC JAPANESE-AMERICANS

T. Watanabe, M. Okubo, G. Egusa and M. Yamakido
Hiroshima University School of Medicine, Hiroshima, Japan

Small dense LDL is associated with insulin resistance syndrome and is considered a risk factor of coronary heart disease. A recent study suggested that LDL particle size is associated with apolipoprotein E (apoE) polymorphism. We examined the LDL particle size, apoE phenotype and lipid metabolism in nondiabetic Japanese-Americans. LDL particle size was determined on plasma samples by the method of Krauss and Burke. The apoE phenotype was determined on plasma samples by using isoelectric focusing followed by immunoblotting. Phenotypes were subdivided into three groups : E2 phenotype (E2.2+E3.2), E3 phenotype (E3.3), and E4 phenotype (E4.3+E4.4). The mean LDL particle size was similar in men being 254.4, 259.7, and 258.2 Å for phenotypes E2, E3, and E4, respectively, but the women with the E4 phenotype showed significantly smaller LDL particle size (259.6Å) than those with the E3 phenotype (264.2 Å)($p<0.05$). LDL particle size did not show any correlation with fasting insulin (FIRI), triglyceride (TG), or HDL-cholesterol (HDL-C) in either men or women with the E2 phenotype. On the other hand, LDL particle size was significantly associated with HDL-C positively and with TG and FIRI negatively in both men and women with the E3 and E4 phenotype ($p<0.0005$). Furthermore, LDL particle size was significantly correlated with FIRI in women ($p<0.05$) but not in men with E4 phenotype after adjustment of TG, HDL-C and body mass index (BMI). Thus, FIRI, TG and HDL-C might be associated with LDL particle size in both men and women with the E3 and E4 phenotypes. Insulin resistance might play an important role for determining LDL particle size in women with the E4 phenotype.

THIAZOLIDINEDIONES PROMOTE THE DIFFERENTIATION OF HUMAN BROWN PREADIPOCYTES *IN VITRO*.

J.E. Digby, S. O'Rahilly, C.T. Montague, W.O. Wilkison*, E. Foot*, J. Prins., L. Sanders, and C. Sewter, Department of Medicine, Unversity of Cambridge, Cambridge, U.K., and *Molecular Biochemistry, Glaxo Wellcome, Research Triangle Park, North Carolina, U.S.A.

Thiazolidinediones are insulin-sensitizing compounds effective in the treatment of NIDDM. They are ligands for the nuclear hormone receptor PPARγ, a transcription factor expressed at high levels in white and brown adipocytes. Thiazolidinediones are adipogenic *in vitro* but animal and human studies do not indicate significant increases in total fat mass. One possible explanation for this could be that the compounds stimulate brown adipose tissue, as demonstrated in animal studies, and hence increase overall energy consumption. Using UCP as a specific marker, we have investigated the distribution of brown adipocytes in adult humans. Using RT-PCR, UCP mRNA was measured in total RNA from isolated adipocytes prepared from perirenal, omental and subcutaneous adipose tissue biopsies. UCP mRNA was detected in 7 out of 10 omental, 3 out of 3 perirenal and 5 out of 12 subcutaneous samples. We have also investigated the effect of thiazolidinediones on differentiation of brown adipocyte precurser cells obtained from the same depots. UCP mRNA abundance was compared by semi-quantitative RT-PCR in total RNA isolated from cells differentiated for 10-20 days in the presence of thiazolidinedione compound BRL 49653 or vehicle. Compared to the vehicle-treated cultures thiazolidinedione treatment induced an increase in UCP gene expression in 4 out of 5 omental samples, 7 out of 8 subcutaneous and 3 out of 3 perirenal samples. In addition, immunocytochemistry demonstrated UCP protein in perirenal preadipocytes cultured for 5 days in the presence of BRL 49653. The detection of UCP mRNA in total RNA from cells isolated from adult human 'white' adipose tissue depots demonstrates that brown preadipocytes and brown mature adipocytes are present within these sites. This is the first demonstration of UCP in human subcutaneous adipose tissue. Furthermore, these data suggest that thiazolidinediones promote the *in vitro* differentiation of human brown preadipocytes derived from different adipose depots.

TRIVANDRUM DISTRICT DIABETES SURVEY:PREVALENCE OF KNOWN DIABETES IN DIFFERENT POPULATION

A. Cheriyan and A.A. Cheriyan, St. Vincent Diabetes Centre, Trivandrum, India.

This study for the prevalence of known diabetes was carried out to get an insight in to the depth of diabetes problem in Trivandrum District of Kerala State in South India. A house to house survey for patients with known diabetes was made at all residents with in the defined areas of urban Trivandrum City, Semiurban Nedumangad Muncipal Town and the rural Karode Panchayath of Trivandrum District. 15250 urban, 31349 Semiurban and 17128 rural people were surveyed and the number of known diabetic patients among them were 610,504 and 103 respectively. The prevalence of known diabetes was 9.8% for urban, 3.4% for semiurban and 0.9% for rural in all subjects aged 40 or over and the prevalence rose to 19.2%, 8.1% and 1.4% respectively in those aged 60-69. The overall crude prevalence of known diabetes was 4% for urban, 1.6% for semiurban and 0.6% for the rural population. The findings reveal the high magnitude of diabetes problem in the urban population when compared to the semiurban and rural population.

712

ANALYSIS OF MORTALITY IN DIABETIC PATIENTS COMPARED TO THE GENERAL POPULATION

C. Weng, D.V. Coppini and P.H. Sönksen. Department of medicine, St. Thomas' Hospital, London, U.K.

We calculated the standardised mortality ratio (SMR) in a sample of diabetic patients based on the annual death rates of the general population from England and Wales. Using a computerised diabetic clinical records system which has been recently linked to the National Health Services Central Register in U.K., we have identified all patients who died between 1980 and 1995. 802 out of 4633 patients (17.5%) attending the clinic died over this 15 year period. The cause of death was retrieved from death certificates. The overall SMR was 1.47 [95% Confidence interval 1.31~1.62] for women and 1.14 [95% Confidence interval 1.04~1.25] for men. The SMR was 2.11 [95% CI 1.67~2.55] for ischaemic heart disease and 2.77 [95% CI 2.24~4.96] for cerebrovascular disease in patients <65 years. The SMR was 0.89 [95% CI 0.65~1.25] for cancer related deaths. We conclude that excess mortality in diabetic patients is higher mainly due to increased mortality in diabetic women compared to the general population. As expected vascular events contributed to the high mortality seen in diabetic patients, but cancer related mortality was not significantly different from that in the general population.

713

THE PREVALENCE OF DIABETES AMONG ABORIGINAL POPULATION OF CHUKOTKA PENINSULA

E.Shubnikof, E.Kotyt and J.Choubnikova. Institute of Therapy, Center "SibDiab", Novosibirsk, Russia

The main task of the study was to reveal the prevalence of diabetes among Chukotka Natives according to data of official statistics and screening. The first diabetic native person was registered in 1983. At this moment the prevalence of diabetes among people older than 15 years does not exceed 2 cases per 1000 inhabitants. The survey, with the use of standard (75 g) glucose load, was conducted at 1991 year. Overall 55% of native male and female costal population of Chukotka, 25-64 years old, in four villages, were randomly selected and invited to participate. The response rate was 65,5%. We examined 170 men and 192 women. The average fasting glucose level among women-5,05 mmol/l(95% CI 4,92-5,18) was higher than among men-4,77(4,65-4,89), as was true of the average postloading level and of the fasting insulin level. We confirmed just one case of NIDDM concerning eskimo woman during the screening. The prevalence of IGT was 1.2% in men and 4.2% in women. These data indicate the lowest diabetes prevalence among Natives of Chukotka in comparison with the other circumpolar native populations.

714

CAUSES OF DEATH AMONG DIABETICS IN THE STATE OF SÃO PAULO, BRAZIL: AN ANALYSIS OF MULTIPLE CAUSES OF DEATH.

LJ Franco; H Pagliaro; C Mameri; LC Iochida; P Goldenberg and SRG Ferreira. Federal University of São Paulo - São Paulo, Brazil.

Death certificates from the State of São Paulo, an industrialized area in the Southeast of Brazil with a population of 30 million inhabitants, were analysed through the system ACME - Automated Classification of Medical Entities, for the year 1992. From 202,141 deaths, diabetes was mentioned in 13,786 (6.8%), being the underlying cause in 5,303 (2.6%). The proportion was higher for women than men (10.1 vs 4.6% as mentioned and 6.1 vs. 2.9% as underlying cause). Among deaths with mention of diabetes, the main underlying causes were diabetes (38.5%), cardiovascular (37.2%) and respiratory diseases (8.5%), and neoplasias (3.8%). When diabetes was the underlying cause, the most common associated causes were cardiovascular (42.2%) genitourinary (10.8%) and respiratory diseases (10.7%). As associated cause, the most common underlying causes were cardiovascular (62.9%) and respiratory diseases (12.6%), and neoplasias (6.9%). Among deaths by neoplasias, with diabetes associated, it calls attention the high proportion of pancreatic cancer (10%), corroborating the hypothesis of a possible role of diabetes as a risk factor for this neoplasia. In spite the limitations of death certificates they could provide useful information about the importance of diabetes as a health problem. Also, the analysis by multiple causes of death gives an idea of the morbidity profile associated with diabetes by the time of the death, emphasizing the high frequency of cardiovascular diseases among these individuals.

715

EPIDEMIOLOGY OF DIABETES , IMPAIRED GLUCOSE TOLERANCE AND CARDIOVASCULAR RISK FACTORS IN NORTH-EAST MALAYSIA

M. Mafauzy, N. Mokhtar, W.B. Wan Mohamad and M. Musalmah. Universiti Sains Malaysia, Kota Bharu, Malaysia.

Two thousand five hundred and eight subjects from the state of Kelantan in North-East Peninsular Malaysia were included in this study to determine the prevalence of diabetes mellitus and impaired glucose tolerance and their association with cardiovascular risk factors. Oral glucose tolerance test was performed on all subjects. The overall prevalence of diabetes mellitus was 10.5% and impaired glucose tolerance was 16.5%. There was no difference in the prevalence of diabetes mellitus between the males (10.5%) and females (10.5%) but the prevalence of impaired glucose tolerance was higher in the females (19.0%) than in the males (11.5%). The prevalence of both diabetes mellitus and impaired glucose tolerance was higher in those above 60 years' age group (DM- 30.3%; IGT-36.9%). Subjects with diabetes mellitus were more obese (38.4%) than normal subjects (24.1%). They also had a higher prevalence of hypertension (14.8%) and hypercholesterolaemia (71.9%) than normal subjects (hypertension-7.0%; hypercholesterolaemia-57.0%). Subjects with impaired glucose tolerance also had a higher prevalence of obesity (35.5%), hypertension (10.4%) and hypercholesterolaemia (63.0%) than normal subjects. Females were more obese than males in the diabetes mellitus (42.6% vs 29.9%), impaired glucose tolerance (38.5% vs 26.3%) and normal subjects (27.4% vs 18.1%).

In conclusion, the prevalence of diabetes mellitus and impaired glucose tolerance was high and they were associated with a high prevalence of obesity, hypertension and hypercholesterolaemia.

716

MORTALITY OF JAPANESES-BRAZILIAN WITH AND WITHOUT NON-INSULIN DEPENDENT DIABETES MELLITUS IN A COHORT STUDY.

SGA,Gimeno; SRG,Ferreira; LJ,Franco; Miunes; K,Osiro and JBDSG. Department of Preventive Medicine, Federal University of São Paulo, São Paulo, Brazil.

As a part of a prospective study on Japanese migrants, living in a developed city in the Southeast of Brazil, we describe and compare four-years experience of mortality among diabetic and non-diabetic subjects. In 1993, a cohort of 530 first and second-generation of Japanese-Brazilians of both sex, aged 40 to 79 years old, were identified; at the beginning, 91 subjects (17%) were classified (according to WHO criteria) as non insulin-dependent diabetics (NIDDM), 90 (17%) as impaired glucose tolerance (IGT) and 349 (66%) as normals. An up date of mailing list allowed to identify those who died during this period. Family information and death certificates were used to record the date and the causes of death. The mortality rates for all causes and for specific causes (ICD-9 code 390-459: circulatory disease and ICD-9 code 580-599: renal disease) were obtained for the three groups of subjects. Proportional hazards regression models were used to compare the mortality rates, adjusted to several covariates (sex, age, generation, hypertension, dyslipidemia, obesity and plasma creatinin). The crude mortality rates for all causes for NIDDM, IGT and normal subjects were 31.5, 6.9 and 10.7 per 1,000 person-year and the mortality rates for specific causes were 24.7, 3.4 and 5.4 per 1,000 person-year, respectively. After simultaneous adjustments to the covariates, no difference was observed in the mortality experience for all causes between NIDDM and IGT subjects as compared with normals. However, higher mortality rates due to specific causes were observed among NIDDM than in the normal subjects (Incidence Density Ratio: 3.86; 95%CI: 1.11 - 13.38). These results in Japanese-Brazilians are consistent with previous reports of increased mortality in other diabetic populations, independently of other classical cardiovascular risk factors.

717

NON-INSULIN DEPENDENT DIABETES MELLITUS IN KUWAIT - A PREVALENCE STUDY

N. Abdella[1], M. Al-Arouj[2], A. Al-Nakhi[2], ,A.Al-Assousi[2], A. Shaltout[1] and M. Moussa[1]. [1]Faculty of Medicine, Kuwait University, and [2] Ministry of Public Health, Kuwait.

Non-insulin dependent diabetes mellitus (NIDDM) is a major public health problem in Kuwait. The objective of the study is the estimation of the prevalence rate of glucose intolerance among a sample of the national adult population aged 20 years and above in two out of the five Governorates of Kuwait. A total of 3007 subjects (1106 men and 1901 women) were interviewed by a physician who completed a standard questionnaire and carried out a physical examination which included height, weight and blood pressure measurements. Blood tubes were centrifuged immediately and refrigerated. Interpretation of oral glucose tolerance tests were based on the WHO diagnostic criteria for DM, 1985. The study span was between September 1995 to June 1996. The denominator used for computing the prevalence was obtained from the 1995 Kuwait census. The overall prevalence of glucose intolerance (IGT and NIDDM) in this study was found to be 17.78 (17.3% in men , 18.1% in women). In the population survey glucose intolerance was presented at a relatively young age, prevalence rate in the age group 20-39 was 8.18% (95% CI, 6.6 - 9.7) and in the age group 40 - 59 was 22.10% (95% CI 19.6 - 24.6). Obesity was a significant risk factor, ($p < 0.001$; as a consequence of recent life style and dietary changes. The strong association in patients with a positive family history of NIDDM (adjusted odds ratio = 2.4, $p < 0.001$) strongly suggests a genetic component. Hypertension was markedly associated with the relative risk of developing NIDDM (adjusted odds ratio = 1.5, $p < 0.001$) with the demographic transition which already started among the Kuwaiti population and if the prevalence of glucose intolerance remains the same, ageing of the population will contribute to an even more accentuated upward trend in the prevalence of glucose intolerance and its serious impact on the morbidity and mortality among the Kuwaiti population. The strong association between hypertension and NIDDM may recommend a common approach to the prevention and control of these two conditions.

This study was supported by grant MM 024 from Kuwait Universiy.

718

TRENDS OF METABOLIC EMERGENCIES ADMITTED IN A CENTRALISED INTENSIVE CARE UNIT FOR DIABETIC PATIENTS. M.Grigorescu, E. Farcasiu, A. Barnea, I.Limbasanu and C.Ionescu-Tirgoviste, Clinic of Diabetes, Institute "N.C.Paulescu", Bucharest, Romania

The aim of our study was to analyse the demographic characteristics of diabetic patients admitted consecutively for various types of metabolic emergencies in three different years at ten years interval (1974,1984,1994). The main data are presented in the following table:

Characteristics	1974	1984	1994
No. of cases	825	931	762
Sex distribution (M/F)	382/543	411/520	351/411
Mean age ± SD	42.3 ± 21.6	49.5 ± 19.6	56.5 ± 22.1
< 20 yrs.	292	274	82
21-42 Yrs.	316	317	199
> 40 yrs.	217	340	481
Type of diabetes:			
IDDM	572	478	346
NIDDM	253	453	416
Type of emergency:			
- Diabetic ketoacidosis	511	391	232
- Hypoglycemic coma	76	85	109
- Hyperosmolar coma	29	56	72
- Myocardial infarction	28	76	114
- Cerebrovascular accident	67	71	94
- Others	114	252	141

Conclusions: The principal changes noted along the years were: dimunition of the frequency of emergencies in youths and an increase in older age groups; reduction of the percentage of ketoacidosis with an increase in the percentage of hypoglycaemic and hyperosmolar comas (the latter is often associated with myocardial infarction and cerebrovascular accidents). Mortality in the first 24 hrs. decreased from 12%,7% and 5% respectively.

719

INCIDENCE OF NIDDM AND THE EFFECTS OF GENDER, OBESITY AND HYPERINSULINEMIA IN TAIWAN CHINESE S.-L. Wang and W.-H. Pan. Institute of Biomedical Sciences, Academia Sinica, Taipei, TAIWAN

Objective: The aim of this study is to determine NIDDM incidence in Taiwan and to examine its relation to obesity and hyperinsulinemia in men and women. **Methods:** A total number of 995 men and 1195 women aged 35-74 years free from diabetes in two townships in Taiwan were followed up to 5 years from 1991 to 1996. Baseline data include a questionnaire on general and metabolic information, the assessment of detailed anthropometric parameters and plasma glucose and insulin. Multivariate regression analysis was performed to examine the effect of the risk variables on NIDDM incidence. **Results:** The age-standardized incidence rate was 9.45/1,000 in men and 9.13/1,000 in women. Plasma glucose at baseline had RR of 3.0 in men and 2.9 in women. In men, waist circumference (RR=2.2) and plasma insulin level (RR=2.1) had the highest standardized RR values for diabetes incidence next to glucose. In women, both sub-scapular skinfold and Body Mass Index (BMI) had a notable impact on diabetes incidence with relative risk of 3.1 (C.I. 2.1-4.6) and 2.8(C.I. 2.1-3.8) respectively; whereas insulin had a moderate effect with RR of 1.5 (C.I. 1.1-1.9). In women the incidence increased with a dual occurrence of obesity and hyperinsulinemia (12 folds, compared to 3 folds in men) compared to those with only obesity (2.8 folds, 3 in men) or hyperinsulinemia (4.4 folds, 3 in men). **Discussion:** The present study demonstrated a slightly larger incidence of NIDDM in Taiwan than in western countries with comparable age distributions. The importance of obesity is indicated in preventing NIDDM in the community. Hyperinsulinemia played a significant role in NIDDM incidence independent of obesity. Moreover, the effect of synergistic interaction of hyperinsulinemia and obesity was profound in women.

720

Diabetic admissions in rural Zaire.

J.T. Burdon. Centre Médical Evangelique, Nyankunde, Zaire.

Case records of diabetic admissions to the Centre Médical Evangelique were reviewed in the light of clinical observation that suggested diabetres presented in a different manner to that seen in 'Western countries'. The case records were retrieved for 60 out of 61 diabetic admissions between November 1994 and February 1996. 53 patients were admitted once, 2 were admitted twice and 1 patient was admitted 3 times. 56 individuals needed inpatient treatment for their diabetes during the study period. 59% were male and 41% were female. Median age at admission was 47 years (range 16 - 74 years). Diabetes was relatively uncommon below the age of 35 years (17% stating an age of onset below 35 years). 35 % of admissions were new cases of diabetes. The main reason for admission was symptomatic hyperglycaemia without ketoacidosis (71.6%). Other reasons for admission included ketoacidosis (8.3%) and various infections (11.7%). 5 (8.3%) patients died during their admission, 2 from renal failure and three from infection. There were no deaths from ketoacidosis. On admission the majority of patients were taking no treatment but 71.7% needed insulin to control their symptoms and return the blood glucose to normal. The two most striking observations were firstly the rarity of ketoacidosis even amongst younger diabetics and secondly the high proportion of patients who needed insulin to control their symptoms and normalise their blood glucose levels. Insulin was relatively expensive ($20-30 a month) during the study period and so it was only used after a full trial of available oral hypoglycaemic agents had failed to control the situation. Many of these patients do not fit readily into Type-1 or Type-2 diabetes and it may be that so-called 'Tropical Diabetes' is the predominant form of the disease seen in Northeast Zaire. Tropical diabetes has been linked to cassava consumption and this crop provides the main staple diet in the region. A further prospective trial may help to clarify the situation.

721

DIABETES IN JAPANESE POPULATIONS - A COMPARISON BETWEEN JAPAN AND BRAZIL. LC Iochida, LF Marcopito, LJ Franco, A Sekikawa, M Tominaga, H Eguchi and H Sasaki. Universidade Federal de Sao Paulo, Sao Paulo, Brazil and University of Yamagata, Yamagata, Japan.

Migrant studies are powerful tools in epidemiological studies. However, comparisons between data obtained in different countries are difficult, due to differences in methods and populations. Japanese were considered of relative low risk for NIDDM, until the early 1980's, but ethnic Japanese migrants showed very high prevalences of the disease. This study compares two genetically identical Japanese populations (Yamagata, Japan and Bauru, Brazil), in the same age-group and with the same diagnostic criteria. Data were collected during 1991-93 in Japan and in 1993 in Brazil. Individuals of both sexes, aged 40-79 years, were submitted to OGTT with 75g glucose load after fasting for 10-16 hs. Plasma glucose was determine by the glucose-oxidase method on fasting and 2h after load samples. DM and IGT were diagnosed by WHO criteria. Poisson regression was used to analyze the data. Participation rate was of 74.5% in Japan and 83.3% Brasil. Number of participants (n) and cases, and prevalences of DM and IGT (%), are shown in the table.

	Japan			Brazil		
	n	DM	IGT	n	DM	IGT
Men	1146	104 / 9.1	137 / 12.0	263	60 / 22.8*	37 / 14.1
Women	1478	160 / 10.8	244 / 16.5	267	33 / 12.4	49 / 18.4
Total	2624	264 / 10.1	381 / 14.5	530	93 / 17.6*	86 / 16.2

*p<0.05

The Japanese-Brazilians showed significantly higher prevalence of DM, with a higher prevalence in males, controlling for age. The higher prevalence of DM in the Japanese-Brazilians points to the influence of the "western" environment in the development of the disease.

722

Hospitalized diabetic patients. Clinical epidemiology

Bragagnolo JC, Martí ML, Lobo P, Ferrari N. Hospital de Clínicas, Buenos Aires Argentina.

The aim of the study was to determine the prevalence and clinical characteristics of the diabetic patients hospitalized in the Hospital de Clínicas and to compare them with the non diabetic patients in a one day survey. A census was taked at the whole hospitalized population. The patients were divided in: 1) Non diabetics (Nd) and 2) Diabetics (D).The group Nd was analyzed in age, sex and hospitalization length. The group D was studied about living place, hospitalization area and clinical and diabetic characteristics (type, metabolic control, chronic complications, treatment). The statistic analysis was the non paired t test (significative $p \leq 0.05$). The prevalence was 13.3% of hospitalized D patients (37:279). The duration of hospitalization was 25 days for D vs. 21 Nd. The age was 65 years vs. 61 in D and Nd respectively. The ratio male/female 2,7/1 in D y 0,98/1 in Nd. The admission was related with diabetes in 51% (59% in male and 30% in women). The chronic complications and predominant related illness were: hypertension (19%), peripheral artery disease (12%), infections (12%), coronary artery disease (11%), diabetic foot (11%), retinopathy (10%), amputation (10%).The ratio of diagnostic age <30/>30 years was 1/10. The diabetes duration was over 10 years in 46%, 27% between 1 and 10 years and 27% less than 1 year. There were 24% insulin users (71% pork), 66% take oral hypoglycemic agents and the 85% were in a dietetic plan. The diabetic population of the Hospital de Clínicas has its own characteristics related with the kind of patients that consult or are referred, and the specialized servicies. There is a high prevalence of diabetes in hospitalized patients, 20% in males, mainly with podal and vascular pathology. Frecuently coexist cardiovascular disease, insulinic treatment and frecuent hospitalizations, denoting a high risk population that need special atention.

723

NORTHERN CYPRUS: ANOTHER HIGH PREVALENCE AREA OF DIABETES AND IMPAIRED GLUCOSE TOLERANCE IN THE MEDITERRANEAN

İ.Satman(1), N.Dinççağ(1), M.T.Yılmaz(1), A.M.Şengül(1), G.Yıllar(1), S.Salman(1), F.Salman(1), Y.Tütüncü(1), S.Gedik(1), K.Karşıdağ(1), Ş.Karadeniz(1), A.Taşyürek(2), and H.Sav(2).
(1)Division of Diabetes, Istanbul Faculty of Medicine, and Institute for Experimental Medicine, Diabetes Research Unit, Istanbul University Istanbul-Turkey, (2)Dr.Burhan Nalbantoğlu Hospital, Northern Cyprus.

A nationwide epidemiology study was carried-out to determine the prevalence of diabetes mellitus and impaired glucose tolerance (IGT) in randomly selected 2726 (urban; 52%, rural; 48%) Cypriot subjects, aged 20 years (overall response rate 73%). Female to male ratio was 1678/1048. Based on WHO's criteria (2h capillary blood glucose after 75g OGTT), subjects were defined as diabetic (DGT), IGT, or normal glucose tolerant (NGT). According to "SEGI's world population" (95% confidence limits), an overall prevalence of 11.3% (11.3% female, 11.3% male) for DGT and 13.5% (16.1% female, 9.2% male) for IGT was found. No urban/rural difference was observed. Diabetes prevalence increased with age, being highest in the 75 years age group (36%), no gender difference was noticed. In contrast, IGT was found to be highest in the 70-74 years age group and more prevalent among female than in male (20% vs. 15%). The prevalence of known diabetes was 7.3%, additionaly nearly one-third of the diabetics was unaware of their disease (4%). Of the screened population, a positive family history for diabetes was found in 49% of DGT, in 47% of IGT and in 41% of NGT subjects. Prevalence of hypertension was higher both in DGT (34%) and in IGT (20%) than in NGT (13%). The age-standardized prevalence of diabetes increased clearly across tertiles of both body mass index and waist to hip ratio and it was also found to be higher in subjects with lower physical activity, lower income and lower education (p=10-8). Compared to other Eastern Mediterranean countries, particularly to Turkey, this study have indicated that diabetes is a common health problem in Northern Cyprus. The finding of higher prevalence rate of both DGT and IGT will certainly have an implication in establishing a national diabetes program in order to improve the quality of diabetes care in this country.

724

NONINSULIN DEPENDENT DIABETES OF YOUNG (NIDDY)-OVERLAP WITH MALNUTRITION RELATED DIABETES(MRDM) : S.S.GUPTA, DIABETES CARE CENTRE, NAGPUR, INDIA

Study aims to correlate factors which might be responsible for some of differences seen between young diabetics of tropics and of West. Of 1760 diabetics, 237 NIDDY and MRDM with onset of diabetes(DM) before 40Yrs age were selected and correlated clinically. NIDDY were 190(80.2%), PDDM 39(16.5%) FCPD 8(3.3%). BMI in NIDDY male (m)-24.7±4.3kg/m^2,female(f)-26.9±5.4;kg/m^2;PDDM m-17.9±3.4,f-16.9±2.5;FCPD m-20±2.3,f-18.2 Waist hip ratio in NIDDY m-0.97±0.07,f-0.95±0.13;PDDM m-0.89±0.05,f-0.87±0.06;FCPD m-0.92±0.02,f-0.86. Duration of DM in NIDDY-4.4±5.6Yr PDDM 2.8±3.7Yr FCPD-4.3±4.9Yr. Family history of DM present in 69.7% NIDDY and 25%FCPD while absent in PDDM.80% NIDDY and 50% FCPD responded to sulfonylurea(SU) while PDDM didn't. 25.8% NIDDY had hypertension (HT),3.7% had coronary artery disease which were absent in MRDM. Macroangiopathy was absent in NIDDY;12.5% FCPD & 5.1% PDDM had retinopathy + nephropathy.Thus, tropical NIDDY have more of central than generalised obesity seen in West. FCPD have genetic predisposition, they do respond to SU,thus overlap NIDDY.Microangiopathy appear early while macroangiopathy and HT is rare in MRDM. Meaning,tropical diabetes, though not a homogenous entity, does have certain characteristics of it's own.

725

PREVALENCE OF DM IN DEAN FUNES,CORDOBA,ARGENTINA.De Loredo,L;Luquez,H;Madoery,R;Rolter,H;Sereday,M de;Libman,C. Universidad Nacional de Córdoba.

The objective was to assess the prevalence of DM and his association with others risk factors of cardiovascular disease,mainly obesity, hypertension, dislipidaemia,insulin resistance and sedentarism.A random sample of 388 persons aged 30-70 y, was selected by a multietapic,sistematic and sex-age representative method,from a population of 18511 inh.with 95 and 2.3% precision.Fasting capillary glucose was measured by Haemoglukotest 20-800 and Reflolux II.Values≥7.8 mmol/l were, confirmed by venous plasma glucose by autoanalizer.Values≥5.5<7.8 mmol/l and one every six <5.6 mmol/l were submitted to the OGTT.WHO recommendations and diagnostic criteria for DM were applied.Known diabetics were identified as having a confirmed diagnosis and were treated.Obesity was diagnosed by NHANES III criterion:BMI≥27.3 for women and≥27.8 for men.Insulin-resistance was measured by fasting plasma insulin by ELISA.WHO criteria was applied for hypertension and Argentine Forum for Dislipidaemia criteria for lipids alteration.The X^2 test was used to characterize significant differences.The total prevalence of DM was 8.2%(9.7%M,6.9%W)and increased with age from 3.4%(30-39y)to 19.2%(60-69y);62.5% were known diabetics.Obesity was present in 68.8% of diabetics(D)and 47.2% of non diabetics(ND)(RR 1.45 CI 1.12-1.88).Hypertension was associated with DM in 56.3% and in 38% with ND.(RR 1.48 CI 1.06-2.0).Fasting insulin was higher in D:$\bar{x}$ 14.06 μU/ml(SE 1.52) than in ND:$\bar{x}$ 10.84 μU/ml(SE 0.40)p<0.02.There was sedentarism in 43,8% of D and in 27,2% of ND(RR 1.94 CI 1.0-3.7).There was no significant differences for dislipidaemias.In conclusion the prevalence was similar to the most recent data from South America.As a expected there was a significant association of DM with obesity,hypertension,fasting insulin and sedentarism.

726

PREVALENCE OF DIABETES BY THE CAPTURE-RECAPTURE TECHNIQUE-ADVANTAGES AND LIMITATIONS

AI.Aziz, G.Gill, N.Beeching and S.Macfarlane.
The University of Liverpool, Liverpool, England.

Capture-recapture (C-R) is a promising method for assessment of diabetes prevalence, but has not been widely used or validated. Aims: We have explored the accuracy and feasibility of C-R in determining community diabetes prevalence in an urban area of North Liverpool, UK. In a recent 12 months period, we obtained lists of diabetic patients from three sources - Diabetic Clinic, Hospital Discharges and General Practioner (GP) lists. Other clinical data was recorded where possible. Names were computer-matched by surname, date of birth and post-code. C-R calculations were determined by log-linear modelling. Total population sampled was 178,365. Diabetes "captures" were 1,692 (Diabetes Centre), 486 (Hospital Discharges) and 702 (GP lists). Estimated known diabetes prevalence was 2.63% (95%CI 2.56-2.70%). Mean age was 57.6 years (SD=16.1); female:male ratio was 1:1.2; 82% were NIDDM and 18% IDDM; treatment was diet 25%, tablets 42%, insulin 33%; and prevalence increased markedly with age. This study shows a relatively high diabetes prevalence, with close confidence intervals. C-R is a rapid and cheap method for diabetes prevalence determination, provided easily computer-accessible lists are available. Ideally, results should be validated by other epidemiological techniques.

727

HIGH PREVALENCE OF DIABETES MELLITUS SECONDARY TO ACUTE NECROTIZING PANCREATITIS

K. Sandholzer, A. Festa, S. Kriwanek, A. Schwarzmeier, C. Armbruster, P. Beckerhinn and G. Schernthaner. Dept. of Med. I and Dept. of Surgery I, Rudolfstiftung Hospital, Vienna, Austria

The prevalence of diabetes mellitus (DM) secondary to chronic pancreatitis is known to be high, whereas few and controversial information exists about the diabetogenic potency of acute necrotizing pancreatitis (ANP).
A follow-up study was performed to investigate prevalence and risk factors of impaired glucose tolerance (IGT) in patients after ANP. Of 124 patients with a single episode of ANP 28 had died, 19 were lost for follow-up and from the remaining 76 patients glucose tolerance and clinical parameters were assessed in 37 patients (follow up: 4.0±2.9 years). After exclusion of patients with overt diabetes an oGTT was performed according to WHO criteria, with a result defined as borderline if blood glucose was >200mg/dl in any of the measurements. A clinical risk score including family history of DM, signs of metabolic syndrome before ANP and initial therapy was defined for each patient (range: 0-5).
Only 11 (30%) out of 37 patients had normal glucose tolerance, 14 (38%) had overt diabetes, 6 impaired (16%) and 6 borderline (16%) glucose tolerance. All patients with risk scores 0 and 1 (n=8) had normal glucose tolerance, whereas risk scores 4 and 5 (n=9) were 100% predictive for IGT/DM. In surgically treated patients (n=30) IGT/DM was found significantly more often than in patients with a conservative (n=7) treatment (67% vs. 0%, $p<0.002$). Fasting blood glucose (117±35 mg/dl vs. 98±8, $p<0.02$) and fructosamine levels were higher (262±68 mol/l vs. 218±12, $p<0.03$), whereas fasting insulin was lower (11±6 μU/ml vs. 17±5, $p<0.03$) in surgically treated patients, with no differences in age (46±11 years vs. 51±20) and follow up duration (4.3±3 years vs. 2.9±2).
In summary, we found a high prevalence of abnormal glucose tolerance in patients after a single episode of ANP, comparable to the prevalence found in chronic pancreatitis. Patients at risk were identified with an easily applicable clinical score. Our data strongly support recent trends in the initial treatment of patients with ANP towards a conservative approach.

728

PREVALENCE OF DIABETES MELLITUS AND IMPAIRED GLUCOSE TOLERANCE UTILIZING TWO DIFFERENT METHODS

MR Rifaie, NI Laymon, M Abul Magd, N Sayed-Ahmed. Mansoura University, Mansoura, EGYPT.

The aim of this work was to evaluate the size of the problem of both diabetes mellitus (DM) and impaired glucose tolerance (IGT), as diagnosed according to the WHO (1985) criteria, in an Egyptian rural area. Five hundreds villagers, chosen at random from a village in Dakahlia province, were screened by measuring blood glucose both fasting and 2-hour following a 75 gm glucose load (Method 1). Another group of 500 age- and sex-matched villagers were screened by measuring blood glucose both fasting and post prandial following the ordinary breakfast meal (method 2). The prevalence of DM was found to be 6.2% and that of IGT 7% by method 1, while by method 2 the respective prevalences were 5.2% and 6.2%. The differences between both methods of screening were found statistically insignificant ($p>0.05$) in both conditions. This suggests that the 2-hour post prandial blood glucose estimation can be a good substitute for that following a 75 gram-glucose load. The former is certainly more convenient, physiological and palatable, and less expensive method for screening in mass epidemiological studies.

729

PREVALENCE OF DIABETES MELLITUS AND VASCULAR RISK FACTORS IN THE URBAN POPULATION OF THE NORTHWEST OF B.A. PROVINCE, ARGENTINE REPUBLIC.

Giorgini, D; Carretero, L; Mon, M; Sereday, M. de; Libman, C; DIAFA Pehuajó.

OBJETIVES: To establish prevalence of DM and IGT in the city of Pehuajo(B.A.) and its spreading according to sex and age. To know the percentage of IDDM, NIDDM and IGT. To set the proportions of new diabetics and the known ones. To establish the prevalence of other factors of vascular risk and its association with Diabetes Mellitus.

MATERIAL AND METHODS: Random sample from subjets aged 20-80 (from no Institutions), located in Pehuajo, was determined by a multistage technic, by ranking sex and age (n: 603), a glucemia postloading was done, according to WHO recommendations. Cholesterol, triglycerides, blood pressure and BMI were tested.

RESULT: Prevalence of DM: 7.8% (n:47); 5.3% known and 2.5% new diabetics. Prevalence of IGT: 1%. The 25% of the known diabetics are under insuline treatment. The risk of presenting arterial hypertension increases according to age, high cholesterol and high BMI, and so is the risk of developing a heart attack as becoming older and DM. (Multivariate Logistic Regression).

CONCLUSION: An increase in the prevalence of DM is observed in relation to previous research carried out in Latinàmerica The high percentage of known diabetics, puts in evidence the efficient community educational work. The Diabetes Mellitus, high BMI and high Cholesterol increase the profile of the vascular risk.

730

APPROPRIATE FASTING PLASMA GLUCOSE LEVEL FOR DETECTION OF DIABETES MELLITUS

Nitiyanant W*, Ploybutr S*, Sriussadaporn S*,Yamwong P**,Vannasaeng S*. Department of Medicine* and Preventive Medicine, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand.

Inconsistency in the prevalence of diabetes mellitus (DM) diagnosed by current WHO recommended guideline has been observed. This study was aimed to determine fasting plasma glucose (FPG) level that can be appropriately used for early detection of DM. Standard 75 gm OGTT was performed in 393 subjects. They were 84 males and 309 females, aged 14-76 years old (mean±SD = 43.8±12.7 years). All of them had one or more of the following indications to undergo OGTT: DM in first degree relatives, overweight, hypertension, dyslipidemia and previous abnormality of glucose tolerance. Plasma glucose levels were determined in NaF preserved plasma using glucose oxidase method. Plasma glucose levels of ≥11.1 mmol/l at two hours after 75 gm oral glucose load were used as a gold standard for diagnosis of DM. Diagnosis of DM was made in 24.7% of cases by gold standard criteria compared to that of 5.8% by FPG values of ≥7.8 mmol/l (WHO criteria). Using various FPG values as cut-off points for diagnosis of DM gave different prevalence rates with varying degree of sensitivity and specificity as shown in the Table below. Diagnosis of DM by FPG of ≥7.0 mmol/l had improved sensitivity of 37.1% while retaining specificity at 100%. Cut-off value of FPG at 6.0 mmol/l gave nearest prevalence rate of DM to the gold standard criteria with Youden index (sensitivity + specificity - 1) of 0.63. Receiver operating characteristic curve revealed the best cut-off value being 6.2 mmol/l. We concluded that FPG of 7.0 mmol/l or more can be accurately used for detection of DM. Individuals with FPG values between 6.0-6.9 mmol/l should have OGTT for definitive diagnosis of DM.

FPG(mmol/l)	5.9	6.0	6.2	6.6	7.0	7.4	7.8
Prevalence of DM	25.4	21.6	17.8	14.2	9.2	7.9	5.8
Sensitivity	74.2	69.0	63.9	54.6	37.1	32.0	23.7
Specificity	90.5	93.9	97.3	99.0	100	100	100

731

CLINICAL CHARACTERISTICS OF CHINESE YOUNG NON-INSULIN-DEPENDENT DIABETICS IN TAIWAN

K-W. Chen, W-T. Lu,J-H. Juang, Y-H. Wu, J-D. Lin and H-S. Huang. Chang Gung Memorial Hospital Taipei, Taiwan, R.O.C.

To know the clinical characterastics of young non-insulin-dependent diabetics (NIDD), we studied 50 cases (24M, 26F) who had been admitted to our metabolic ward from 1985 to 1996. The criteria for patient selection included: onset of diabetes before the age 30 years; absence of history of diabetic ketoacidosis; fasting or postprandial serum C-peptide $\geq$ 1.0 ng/ml; and no insulin requirement for over 2 years. There were 60% patients had body mass index (BMI) over 27 kg/m^2, and 54% had hypertriglycemia. Family history of diabetes in first degree relatives was noted in 35 (70%) patients. As compared with patients with shorter duration, those cases with history over 10 years had lower BMI (25.1 vs 30.0 kg/m^2, p=0.04), lower triglyceride (143.8 vs 310.0 mg/dl, p=0.006), and higher occurrence of retinopathy (50.0% vs 18.4%, p=0.03). In conclusion, NIDDM may develope in young age among Chinese. Most of them are obese, hyperlipidemic and family history of diabetes. Retinopathy occurs significantly higher in patients with longer duration.

732

FREQUENCY OF CARBOHYDRATE METABOLIC DISORDERS IN PERIMENOPAUSAL AND POSTMENOPAUSAL WOMEN IN ŁÓDŹ (POLAND)

I. Nadel, K. Cypryk, T. Stetkiewicz, T. Pertyński, A. Sobczuk and J. Wilczyński. Polish Mother's Memorial Hospital, Łódź, Poland

The prevelance of diabetes mellitus (DM) and impaired glucose tollerance (IGT) in perimenopausal and postmenopausal women in Poland is unknown.
Aim of study:Evaluate the prevelance of carbohydrate metabolic disorders in perimenopausal and postmenopausal women admitted to Polish Mother's Memorial Hospital in Łódź during 1995-96
Materials and methods: The study group consists of 500 women aged between 45 to 65, mean 52,3 ± 5,3 admitted to the Department of Menopausal Diseases and Outpatient Clinic of PMMH for menopausal signs and symptoms. All women underwent clinical examination. Fasting blood glucose levels were evaluated in all cases. When FBG level was more than 105mg%, 75 gms OGTT was administered according to WHO protocol guidelines. Selected diabetes mellitus risk factors were evaluated.
Results: In the study group DM was diagnosed in 4,8%. For nearly 2/3 of the women this was the first time DM had been diagnosed. IGT was diagnosed in another 8%. In 87,2% of the women there was no carbohydrate metabolic disorder. Elevated Body Mass Index (BMI) was noted in 52,4% of women. Hypertension was observed in 18,2% of women and coexisted with DM and IGT in 13 and 10 cases respectively. Hypercholesterolaemia and hypertriglyceridaemia was noted in 27% of DM and 7% of IGT women. In the study group lipid metabolic disorders occured in 25 (39,1%) of women with carbohydrate disorders.
Conclusion: Screening for DM and IGT leads to the detection of most unknown cases of these deseases. Approximately 5% of perimenopausal and postmenopausal women have DM and additional 8% have IGT. Common associated disorders were hypertension and dyslipidaemia.

733

CLINICAL PRESENTATION OF YOUNG DIABETES IN BANGLADESH

F. Pathan, L. Nessa and A.K. Azad Khan. *Bangladesh Institute of Research and Rehabilitation in Diabetes, Endocrine and Metabolic Disorders (BIRDEM), Dhaka - 1000, Bangladesh*

Four hundred and fifty three diabetic subjects with onset on age below 30 years of age has been studied on the first day of diagonsis. 67 (14.8%), 22 (4.9%), 159 (35.1%) and 205 (45.3%) were diagnosed as FCPD, IDDM, PDDM and NIDDY subjects respectively according to WHO criteria. Male predominancy was found in FCPD, IDDM and PDDM and female in NIDDY subjects. Subjects of first three classes reported mostly from rural areas and NIDDY mostly from urban areas. NIDDY subjects had higher age 26±2 (M±SD) than FCPD, IDDM and PDDM subjects with identical age 21±1 (M±SD) years (p<0.05). Sixty six percent of FCPD, 46% of IDDM and 53% of PDDM subjects had education below class V contrast to 83% of NIDDY subjects above class V. Fifty two percent FCPD, 46% IDDM and 43% PDDM subjects were unskilled labour. Mean annual income (in US Dollar) of FCPD (813±136), IDDM (873±213) and PDDM (904±94) subjects were much lower than NIDDY (2258±163) subjects (p<0.05). Typical symptoms of diabetes mellitus (DM) were obtained in 97%, 95% and 93% of FCPD, IDDM, PDDM subjects respectively in comparison to 63% of NIDDY subjects. Signs of malnutrition were revealed in 93% of FCPD, 91% of IDDM, 92% of PDDM subjects in contrast to 40% of NIDDY subjects. Ninety four percent of FCPD and 91% of IDDM subject had BMI<19 whereas only 27.3% of NIDDY and 4.5% of IDDM subjects had BMI >25. History of DM in family were obtianed in 56% of NIDDY, 19% of FCPD, 14% of IDDM and 24% of PDDM subjects. Glycemic status (FPG and HBA1c) was significantly higher in FCPD (21.9±0.8, 11.3±1.1), IDDM (22.2±1.5, 11.3±1.2) and PDDM (20.0±0.6, 10.6±0.4) subjects compared to NIDDY (11.4±0.3, 8.1±0.2) subjects (p<0.05). Retinopathy was observed in 6%, 3.8% and 2.9% in FCPD, PDDM and NIDDY subjects respectively. Neuropathy was found in 56%, 45%, 43% and 4.5% of FCPD, IDDM, PDDM and NIDDY subjects. Twenty three percenr of IDDM, 7.5% FCPD, 8.8%PDDM and 9.3% NIDDY subjets had clinical proteinuria. Detailed biochemical investigation is needed to correlate clinical behavior and etiopathogenic mechanism.

734

THE EFFICACY OF A SINGLE SCREENING METHOD FOR THE METABOLIC SYNDROME X

T.Halmos,I.Suba, L.Kautzky Korányi Institute for Pulmonology Budapest, Hungary

A simple method was adopted for studying the occurrence of the features of syndrome X and for early detection of the syndrome in jeopardized individuals.Out of 343 patients 255 with central obesity and hypertension /group 1/,24 with obesity /gr.2/,35 with hypertension /gr.3/,29 without obesity and hypertension /gr.4/ were examined. Blood sugar and immunoreactive insulin levels during oral glucose tolerance test,fasting plasma lipids,body mass index,waist/hip ratio,blood pressure were determined.Hypertension,central obesity and high blood sugar levels for corresponding insulin levels were regarded as basic criteria of the syndrome.89% of gr.1 patients met these criteria.Type 2 diabetes mellitus,impaired glucose tolerance or"diabetoid"glucose curves could be detected in in 53-45-28-20%,hyperinsulinism in85-70-61-41%,dyslipidemia in 80-62-71-45%, high blood sugar / insulin levels (presumably insulin resistance)in 90-83-66-52% of the groups 1-2-3 and 4.Syndrome X could be effectively screened byinspection and hypertension in 89% of gr.1,but fragments of the syndrome were present in lesser amount in the other groups as well.A delayed peak and slow decline of insulin curves could be seen in patients with glucose intolerance including "diabetoid"individuals compared to normals suggesting an early abnormality of the beta-cell function and/or insulin resistance

735

METABOLIC CONTROL AND QUALITY OF LIFE FOR DIABETES PATIENTS IN VILJANDI, ESTONIA – A POPULATION BASED STUDY

H Vides[1,2], P Nilsson[2], V Sarapuu[1], T Podar[3], Å Isacsson[2], and B Scherstén[2].
[1] City Policlinic, Viljandi, Estonia, [2] Department of Community Health Sciences, Lund University, Lund, Sweden, and [3] Department of Endocrinology, University of Tartu, Tartu, Estonia.

Objective – To investigate aspects of metabolic control, treatment and complications, as well as the quality of life, in patients with diabetes mellitus from a defined population in Estonia.

Design – We invited 220 randomly selected diabetes patients from a local diabetes register of 1,100 patients, to a clinical investigation.

Setting – The city Policlinic in Viljandi, Estonia.

Main outcome measures – Medical history, physical examination (height, weight, blood pressure), laboratory variables (blood glucose and glucated hemoglobin A_1, serum cholesterol and creatinine, urinary protein), questionnaire on quality of life variables.

Results – In all 181 diabetes patients were investigated, of whom 90% were non–insulin–dependent diabetes mellitus (NIDDM). Mean diabetes was 8.9 years, and mean HbA_1 level 7.3%. The overall proportion of patients treated with insulin was 20.4%, and with anti–hypertensive drugs 27.6%. Smoking was present in 14%. The proportion of patients with various diabetes complications was high (73.5%), mostly consisting of different manifestations of cardiovascular disease. Foot ulcers or gangraende were observed in 11.7%. A low level of quality of life was registered in many patients, mostly due to difficult living conditions. QoL and subjectively perceived health was significantly lower than for Swedish patients.

Conclusion – Diabetes patients in Viljandi showed an acceptable degree of glucose metabolic control, but reported a high degree of diabetes complications, as well as impaired quality of life. The diabetes complications may therefore be due to other detrimental factors than hyperglycaemia, e.g. the standard of care during previous years and current living conditions.

736

IMPACT OF GENDER AND OVERWEIGHT ON PARAMETERS OF THE METABOLIC SYNDROME IN NIDDM RELATIVES.

E. Ryder, H. Florez, H. Valbuena, G. Campos, V. Fernández, S. Castillo, L.M. Morales, M. Semprún-Fereira, M.E. Gómez and X. Raleigh.
University of Zulia, Maracaibo, Venezuela.

First degree relatives of NIDDM patients present metabolic disturbances that can be taken as predictors for developing diabetes, depending of ethnicity. Being hispanic more prone to develop NIDDM we studied 24 non-obese first degree relatives (14 F/10 M) of NIDDM patients (DR) matched for age, gender and body mass index (BMI) with 22 controls (12 F/ 10M) from Venezuelan families, to compare with other hispanic groups. In DR, the subscapular (SC) and tricipital (TC) skinfolds measurements were higher. Separating by gender and BMI, this increase was observed mainly in overweight women (SC = 30.5 ± 1.9 *vs* 19.3 ± 3.5 mm TC = 27.9 ± 3 *vs* 20.0 ± 2.8 mm) indicating upper body and peripheral adiposity. Diastolic blood pressure (DBP) was elevated in DR but mainly in overweight men, who represented 70% of the total. None of DR had glucose intolerance, however the insulin was elevated at fasting and in response to a glucose load, resulting a high I/G ratio. The ΔI30/ ΔG30, indirect measure of insulin secretion, was elevated in overweigth men (87.9 ± 3.4 *vs* 76.2 ± 2.9). In women, it was observed a lower increment in the first phase insulin release as the BMI increases. Most lipid parameters were elevated in DR, except Chol and LDL-C. TG was elevated in normal as well as in overweight women (< 25 BMI 1.5 ± 0.2 *vs* 0.7 ± 0.1 mmol/l; > 25 BMI 2.3 ± 0.5 *vs* 1.3 ± 0.2 mmol/l). Low HDL-C was seen in both, women and men (women 1.0 ± 0.1 *vs* 1.2 ± 0.1 mmol/; men 0.8 ± 0.1 *vs* 1 ± 0.1 mmol). Insulin was significantly correlated with TC and lipid parameters in women, mainly in overweight, while in men the association was observed with lipids and DBP. (CONDES-CONICIT).

737

PREVALENCE OF DIABETES MELLITUS ON PYGMIES IN KRIBI SUBDIVISION, SOUTH CAMEROON (CENTRAL AFRICA)

Sone Mpondo, P.Receveur, J.Solle, S. Boni Mbassi,H.Achu Joko, H.Luma Namme, Kouda Ze, J.C.Mbanya, M.Amouretti; Hôpital Laquintinie de Douala, Cameroun

On June 29th and 30th 1996, we conducted a screening exercice for diabetes mellitus in the pygmy population in Kribi Sub-division South Cameroon (Central Africa). The objectives were to find out if this condition existed the pygmy population and determine it's prevalence. Five camping villages were visited. Two of them were located deep into the forest, while the three others because of their proximity to the roads and Kribi toen, have undergone relatively on modernization (Lende, Dibamba and Bibuba). Capillary blood glucose, analysis, with rapid reading on Gucometer (AMES) was used as a scrrening tool. The population was informed to come fasting, but because we reached Kilombo and Bibuba late, the villagers had eaten two to three hours prior to our arrival. A total of 108 Pygmies were examined, comprising 63 females and 45 males, 41 of whom were children under fifteen years, while 67 were adults. We found 5 cases of high blood glucose levels (>1.40 g/l). None however attained 1.80 g/l. We estimated the diabetes prevalence at 4.6% for the whole and 7.5% if only the adult population was considered. All the positive cases were observed in the relatively modernized camping villages: Lende (5 cases), Dibambe (1 case) and Divuba (3 cases).In these camping villages, we noticed the presence of non-Pygmies who came for native treatment (the Pygmies are reputed to be very good herbalists). From this intermingling may result changes in food habits of Pygmies or mixted born babies into the Pygmy population. No child was seen with signs or symptoms of diabetes; probably because insulin dependent diabetes is absent in this population or because affected childen die rapidly due to the lack of insulin. All the adults with abnormal blood sugars were asymptomatic. Was this because the renal threshold for glucose was lower than 1.8 g/l or did the Pygmies benefit from some protection against diabetes mellitus through the use of traditional drugs. This study shows that diabetes exist among the Pygmies. The prevalence found in this study was 4.6%. However these are preliminary results which must be confirmed by other studies using more standardized methodolgy.

738

SYNDROME X IN JAPANESE-BRAZILIANS: IS INSULIN OR ITS PRECURSOR INDEPENDENTLY ASSOCIATED TO HYPERTENSION?

SRG Ferreira, LJ Franco, SGA Gimeno, LC Iochida, Hirai A, M Iunes and JBDSG. Federal University of São Paulo, São Paulo, SP, Brazil.

Hyperinsulinemia and hypertension are associated in the spectrum of syndrome X, but large studies adjusting for confounders are still required. Japaneses living outside Japan are more susceptible to chronic diseases; our group has previously reported high prevalence of NIDDM among Japanese-Brazilians. The present study aimed to evaluate if insulin (I) or proinsulin (PI) is associated with hypertension after adjustment for other risk factors, in first (1G) (n=238) and second (2G) (n=292) generation Japanese-Brazilians, aged 40-79 yrs. Blood pressure (BP) was measured by random-zero sphygmomanometer. Persons with systolic/diastolic BP ≥ 140/90 mmHg or taking antihypertensive drugs, were considered hypertensives. Diagnosis of diabetes was based on oral GTT by WHO criteria. Fasting and 2-hr after glucose load I and PI were determined by immunofluorimetric assays. 1G was older than the 2G (65.6±9.2 vs 53.6±8.4 yrs, $p<0.01$) and male/female ratios were 1.14 and 0.87, respectively. Age-adjusted prevalence of hypertension was 29.2% with no difference between genders or generations. Higher BMI, waist/hip ratio, plasma glucose and cholesterol were found among the hypertensives. Logistic regression showed that 2-hr I remained associated with hypertension (OR=1.43, 95%CI 1.13-1.81) after adjustment for age, gender, generation, family history, smoking, obesity, waist/hip ratio, glucose intolerance, and dyslipidemia. Japanese-Brazilians have higher prevalence of hypertension than the general population in Brazil. This finding, associated to the increased rates of NIDDM, reinforced the unfavorable impact of westernization to syndrome X. 2-hr hyperinsulinemia, seen in hypertensives, may be interpreted as an independent risk factor for hypertension in this population.

739

EPIDEMIOLOGY OF ALLOPATHIC ANTIDIABETIC TREATMENT IN INDIA

PRADEEP G. TALWALKAR AND VIRAJ SALGAONKAR, TALWALKAR CLINIC, MUMBAI, INDIA.

With estimated 20 million people with diabetes, India is already world's most populated country as regards people with diabetes. Even though traditional systems of medicine are widely practiced and are the mainline systems in rural areas, they do not offer a single effective antidiabetic medication. We decided to estimate the number of Indians with diabetes, who are on allopathic antidiabetic medications[Oral Hypoglycemic Agents (OHA), belonging to sulphonylurea and biguanide families and insulins.]The Operation Research Group published all India Sales figures of all the OHAs and insulins marketed in India, were studied to work out total number of OHA tablets/capsules and insulin vials sold in India during October'95 to September '96. By allocating average daily dose for each agent, we estimated the number of patients on each antidiabetic medication. We then worked out formulas to account for polytherapy and calculated total number of patients with allopathic antidiabetic medications. In our estimation only 474000 patients (out of 20 million) were receiving allopathic antidiabetic medications. We conclude that only a small fraction (approx. 2.5%) of Indian patients with diabetes are taking allopathic medications. The dual task of identifying undiagnosed and untreated persons with diabetes and providing them with appropriate medications, needs to be tackled on war footing.

740

BASAL INSULIN LEVELS ACCORDING TO AGE, SEX AND BODY MASS INDEX IN NORMAL SUBJECTS IN KOREA

SA Chang, KH Song, JM Lee, HS Son, BY Cha, KW Lee, HY Son and SK Kang. Catholic University Medical college, Seoul, Korea

To determine the basal insulin levels in normal Korean subjects and the factors influencing with basal insulin levels, 1917 normal subjects whose fasting blood sugar levels were below 6.4 mmol/L, were assessed basal insulin levels, total cholesterol, triglyceride and their anthropometric charateristics (body weight, height and body mass index). Mean basal insulin levels was 34 pmol/L, the basal insulin levels in men and women were 35±1 and 32±1 pmol/L, respectively. Fasting blood sugar levels was 5.4±1 mmol/L and insulin(uU/ml) to glucose(mg/dl) ratio was 0.06. The basal insulin levels of obese (BMI≥ 25) subjects was significantly higher than that of non-obese subjects (43 ± 1 pmol/L vs 31 pmol/L p< 0.001). Basal insulin levels according to age and body mass index was as follows;

Insulin(pmol/L)* / Age (years)	Men (n=1235)		Women (n=682)	
	obese (BMI≥25)	non-obese	obese (BMI≥25)	non-obese
20-29	74±13 (n=12)	29± 3 (n=34)	45± 18(n=2)	30±2 (n=54)
30-39	48±2 (n=121)	32±1 (n=269)	39± 5 (n=22)	29±1 (n=153)
40-49	42±2 (n=142)	31±1 (n=322)	39± 4 (n=46)	29±1 (n=172)
50-59	41±2 (n=73)	30±1 (n=183)	37± 2 (n=60)	31±2 (n=113)
≥60	36±5 (n=21)	29±2 (n=51)	44± 5 (n=15)	35±2 (n=46)

* Values are mean±S.E.M.

There were no significant difference in the basal insulin levels between the age group, however the basal insulin levels of obese group in each age group was significantly higher than that of nonobese group. In a multiple stepwise regression analysis, body mass index, fasting blood sugar and triglyceride were significantly positive contributing factors on the basal insulin levels, and age was significantly negative contributing factors on the basal insulin levels.

741

DIABETES MELLITUS IN THREE ALASKAN ESKIMO POPULATIONS

C. Schraer, S. Ebbesson, P. Risica, A. Adler, and A.M. Mayer. University of Alaska and Alaska Native Health Service, Anchorage, Alaska, U.S.A.

Diabetes has historically been relatively uncommon among Alaskan Eskimos compared to other populations. However, no large scale screening involving glucose tolerance testing of all subjects had been carried out. The objective of this study, a population based survey, was to determine the prevalence of glucose tolerance abnormalities, body fat content and distribution, and insulin levels in three Alaskan Eskimo populations, >=25 years age, in the Bering Straits region of northwestern Alaska. Data included body mass index, waist-hip ratio, glucose tolerance status by World Health Organization criteria, fasting insulin and lipid levels, and family, dietary, and exercise histories. A total of 454 of 899 (51%) eligible participants were screened, including 239 Siberian Yupik, 106 Central Yupik, and 109 Inupiat Eskimo people. The prevalences of diabetes in these groups were 9.6%, 2.8%, and 3.7% respectively, while the rates of impaired glucose tolerance were 7.5%, 13.2%, and 6.4%. Mean insulin levels were 45 and 38 pmol/l for men and women respectively. Age-adjusted overall rates of diabetes in these populations were 9.2% for women and 6.6% for men, similar to 8.8% and 7.8% for U.S. white women and men. Compared with Siberian Natives across the Bering Straits ages 45-64, our diabetes rate was much higher (8.2% versus 0.8%). Our mean insulin levels were much lower than those in the Strong Heart Study of American Indians which ranged from 114 to 165 for women and 97 to 128 for men (measured in the same laboratory, same units). In summary, our data indicates that: diabetes among Alaskan Eskimo people is more common than previously thought; our rates are higher than those among closely related populations across the Bering Straits; and lower insulin levels may indicate a lower degree of insulin resistance than among American Indians. Further comparisons of our findings to those among other indigenous populations should help define the relative contributions of genetic and life style related risk factors, which hopefully can lead to preventive strategies.

742

PREVALENCE OF INSULIN RESISTANCE IN METABOLIC DISEASES. RESULTS FROM A POPULATION-BASED STUDY (BRUNECK STUDY).

E. Bonora, S. Kiechl, J. Willeit, F. Oberhollenzer, Georg Egger, M. Muggeo. University of Verona, Italy, University of Innsbruck, Austria, Hospital of Brunico, Italy.

Insulin resistance is thought to be a common finding of several clinical conditions, including IGT, NIDDM, hypertension, dyslipidemia and hyperuricemia. This concept emerged from case-control studies in which insulin sensitivity was assessed by insulin clamp or alternative methods. We examined the prevalence rates of insulin resistance in the above mentioned clinical conditions among subjects participating in the Bruneck Study, a population-based study including 888 subjects aged 40-79 years in whom insulin sensitivity was estimated by homeostasis model assessment (HOMA). Subjects in the top quintile of HOMA distribution values (n=177) were regarded as insulin resistant. The prevalence of IGT, NIDDM, hypercholesterolemia, hypertrigliceridemia, low HDL cholesterol, hyperuricemia and hypertension (as defined by conventional criteria) significantly increased (p=0.05-0.0001) across quintiles of HOMA. This was found in either nonobese and obese individuals, in both men and women and in younger (40-59 years) like in older (60-79 years) subjects. The prevalence of insulin resistance was 41.2% in IGT, 62.9% in NIDDM, 24.6% in hypercholesterolemia, 53.9% in hypertriglyceridemia, 57.1% in subjects with low HDL cholesterol, 37.2% in hyperuricemia, 29.3% in hypertension. The prevalence of insulin resistance in subjects with the combination of glucose intolerance, dyslipidemia, hyperuricemia and hypertension (n=21, 2.4% of the entire population) was 81%. Twenty-eigth subjects (3.1% of the whole population) were insulin resistant but free of IGT, NIDDM, dyslipidemia, hyperuricemia and hypertension. These results document in a population-based sample that i) insulin resistance in hypertriglyceridemia is as common as in glucose intolerance (50-60%) whereas it is less frequent in hypercholesterolemia, hyperuricemia and hypertension (25 to 35%); ii) the vast majority of subjects with multiple metabolic defects are insulin resistant; iii) in a significant proportion of the general population insulin resistance can be found even in the absence of any metabolic diseases.

743

INCIDENCE OF DIABETES AND ITS RISK FACTORS IN AMERICAN INDIANS -- THE STRONG HEART STUDY

ET Lee, JL Yeh, and OT Go for the Strong Heart Study Investigators. University of Oklahoma, Oklahoma, USA

Diabetes mellitus (DM) is very common in American Indians. Results reported are from the Strong Heart Study (SHS), a cohort study of cardiovascular disease and its risk factors in American Indians. Phase I (baseline) data of the SHS show that the prevalence rates of diabetes in American Indians, aged 45-74 years, in Arizona (AZ), Oklahoma (OK), and South and North Dakota (SD/ND) were 70%, 40%, and 40%, respectively. The prevalence rates of impaired glucose tolerance (IGT) were respectively 14%, 17%, and 17%. DM and IGT status were defined by the WHO criteria. At Phase II, after an average of 4±0.7 years of follow-up, 3638 of the original 4549 participants (413 died before examination, 499 refused re-examination) completed the study. The cumulative incidence of DM from participants with normal glucose tolerance (NGT) and IGT are given below:

	WOMEN			MEN		
	AZ	OK	SD/ND	AZ	OK	SD/ND
NGT to DM	17%	10%	17%	8%	8%	11%
IGT to DM	45%	33%	33%	53%	36%	27%

Stepwise logistic regression was used to determine the risk factors for the development of DM. In women with NGT at baseline, fasting plasma insulin level and degree of Indian blood were found to be significantly associated with the incidence of DM. Whereas in men, only body mass index was significant. In women with IGT at baseline, only fasting plasma insulin level was significantly associated with the development of DM. In men with IGT, age was the only significant risk factor. The data indicate that diabetes is continuing to plague the American Indians. There is an urgent need to implement effective preventive programs and intervention strategies to reduce the burden of this devastating disease in this population.

744

BLACK-WHITE DIFFERENCES IN INSULIN METABOLISM IN YOUNG NON-DIABETIC SUBJECTS.

R Ratner, R Katz, R Cohen, E Eisenhower, D Verme. Medlantic Research Institute, George Washington University, Washington DC, USA.

As part of a study on the pathogenesis of coronary artery disease, we profiled glucose handling and β-cell secretory dynamics in 79 Blacks (36 males, 43 females) and 84 Whites (54 males, 30 females) ≤55 years old (mean 47) without diabetes. Subjects underwent a 3hr, 75gm oGTT with measurement of glucose, specific insulin (INS,μU/ml) and C-peptide (C-pep). Fasting glucose and glucose tolerance were similar across ethnic groups (mean fasting glucose 100 mg/dL in Blacks and 99 mg/dL in Whites). Fasting INS was higher in Black vs. White males (15.5±9.2 vs 11.3±7.0, p<.01) and Black vs. White females (15.2±7.7 vs 13.0 ± 10.4, p= .04); however, Black females had the highest BMI (32.2 kg/m²). After adjusting for BMI, fasting and post glucose load INS (±SE) were compared by race and gender: (*=p<.05 Blacks vs. Whites)

	Fasting INS		30 min INS		Area under curve	
	Males	Females	Males	Females	Males	Females
Blacks	14.3 ± 1.1*	13.8 ± 1.1	72.5 ± 9.7	72.6 ± 7.4	17760 ± 2006*	15625 ± 1446
Whites	11.9 ± 0.9	15.2 ± 1.3	51.7 ± 7.9	63.6 ± 9.2	11455 ± 1634	14514 ± 1753

Although differences disappeared between females after adjustment for BMI, differences in fasting, 30 minute, and AUC INS persisted at $p < 0.05$ when adjusted only for waist/hip ratio. β-cell secretion did not differ as manifested by similar glucose and C-pep responses. We conclude that INS elevation observed in these Black women is attributable to obesity, independent of body fat distribution. In contrast, fasting and AUC INS are high in Black men without increased C-pep, independent of either obesity or body fat distribution. These finding suggest greater intrinsic insulin resistance and reduced INS distribution and/or metabolism in non-diabetic Black males.

745

CLINICAL CHARACTERISTICS AND STATISTICAL EVALUATION OF 93.000 DIABETIC PATIENTS FROM AN ITALIAN REGION

M.E. De Feo, F. Palumbo*, G. Fabbrocini**, F. Santonastasi*, R. Boni and P. Mariniello; XI Dept. of Med. and Diabetology "A. Cardarelli" Hospital; *Reg. Epidem. Obs.- Assessorato alla Sanità Regione Campania; **Medical Statistic-Dept. of Biology and Pathology Molecular-Federico II University- Naples - Italy

Following a national legislation that hypotizes a personal card for each diabetic patient (D), in our region (Campania in southern Italy) we activated a regional data-bank with anagraphical, anthropometric and therapeutical informations. From 1989 to 1994 we collected data about 92.758 D (F 56.3%, M 43.7%); we believe that our sample can represent half of diabetic population of the region (inhabitants=5.2 milions): the aim of this study was to evaluate these data. Statistical univariate analysis performed on all data showed that the distribution for age is different between the two sex (males are more represented in age's range 0-49 yrs, over this age the ratio is inverted). The 11.7% of patients were insulin-dependent (ID), 88.1% were non-insulin-dependent (NID) and 0.2% had a secondary diabetes. The D were treated by General Practitioners (GPs) in 57.9% of cases and in 25.1% by specialists, diabetologists or diabetes centre (DC), 17% of D were treated by both. Referring to therapy 6.5% of D was only on diet, 66.5% was in therapy with oral agents (OH), 22.4% was on insulin (I) therapy (median dosage 32 U.I./die) and 4.6% was in therapy with both drugs. Only 20.7% of D performed blood glucose self-monitoring. Body mass index (BMI) calculated for each patient showed that 42% of D was overweight and 28% was obese with an high prevalence of females among obese(F 33% vs M 21.6%). We found a statistical significative difference ($p<0.001$) between the BMI values of patients from different towns (obeses in the 5 region's chief towns 27.8% vs obeses in the other towns and rural zone 31.4%). On 4093 randomly selected patients we performed a stepwise logistic regression using as dependent variable the BMI (non obese <30, obese ≥30) and as independent variables: sex, age, type of therapy, type of diabetes, and glycaemic self-control. The results showed an higher risk of obesity among the females (Odds ratio=2.00), among the diabetics in therapy with OH (OR=1.64) or with OH+I (OR=1.96). The risk of obesity is lower among ID (OR=0.4).

746

GLUCOSE TOLERANCE IN THE ELDERLY (>40 YRS) IN RURAL INDIA.

A.A.Joglekar, S.Rolls, S.Hirve, K.M.Shelgikar, C.V.Joglekar and Yajnik C.S. Diabetes Unit, K.E.M. Hospital & Research Centre, Pune, India.

We studied glucose tolerance in 321 subjects >40y in the village of Pimpale Jagtap near Pune (158 men: 58 y, 1.63 m, 52 kg, BMI 19.5 kg/m^2 and WHR 0.88; 163 women: 53 y, 1.50m, 45 kg, 19.8 kg/m^2 and 0.78). In men 2h plasma glucose was related to age ($r=0.24$, $p<0.01$), BMI ($r=0.23$, $p<0.01$), WHR ($r=0.21$, $p<0.01$), and to height ($r=-0.16$, $p<0.05$); in women to BMI ($r=0.15$) and head circumference ($r=-0.15$, $p=0.07$ both). Four percent (7 men, 7 women) had diabetes, 4% (5 men, 8 women) had IGT (WHO 1985). Hyperglycaemic subjects (IGT+diabetic) were older and more 'obese' (men 22.3 & women 21.6 kg/m^2), men had higher WHR and women a smaller head circumference compared to normoglycaemic subjects; they also had higher 2h plasma immunoreactive insulin & triglycerides, lower HDL cholesterol and higher blood pressure. Thus, in the elderly of rural India diabetes and IGT are relatively rare but are associated with other cardiovascular risk factors suggesting a metabolic syndrome.

747

Diabetes mellitus Survey in Zhejiang Province

Tong Zhonghang Gu Weizheng
Department of Endocrinology, First Affiliated hospital
Zhejiang medical University, Hangzhou, 310003

According to the operating rules of national dibetes epidemiologic survey formulated in 1993. We investigated over 25yrs 7949 subjects in Zhejiang province, among them, 1060 persons in Hangzhou city, 1158 people in Xhao Shen Village, 1846 subjects in Wenzhou City and fisherman village, 1846 subjects in Ningpo Urban and rural areas, Dong Yong Heng Dian industrial group and 1000 subjects in pu two fisherman Village.

In this survey we discovered newly diagnosed Diabetes mellitus 73 cases (54 males, 14 females) , Known diabetes 93 cases (male 65, female 28) all diabetic patients were NIDDM except one was IDDM. The overall diabetic prevalence is 2. 71%, standardized prevalence is 3.1% (male 3.40%, female 2.54%), newly diagnosed IGT 99 case (66 males, 33 females). The prevalence is 2. 09% (male 2. 6%, famele 1.64%). Standardized prevalence is 2. 04% (male 2.33%, female 1.47%).

The diabetic prevalence in those over 55 increases sharply, peaking at 64-74 yrs in both sex. The ratio between the prevalence in overweight and nonoverweight group after standardization is 3.54%.

748

PREVALENCE OF GLUCOSE INTOLERANCE IN BERMUDA.

M.H.Tan, D.J.Jones, L. Andrew-Koolkin, G.Smith and B.Willis. Bermuda Diabetes Association, Hamilton, Bermuda.

Diabetes is a major health problem in Bermuda. To assess its magnitude we determined the prevalence of glucose intolerance (known diabetes [KD], undiagnosed diabetes [UD] and glucose intolerance [IGT]) in a random sample (n=999) of adults (19+ years) in a nation-wide survey. All subjects, except those with known diabetes, had a 75 gm oral glucose tolerance test. The prevalence of KD = 8.5%, UD = 3.3% and IGT = 6.2%, giving an overall prevalence of glucose intolerance of 18.0%. For each group, the prevalence was higher in the females (KD: 5.5 vs 3.0, UD: 2.2 vs 1.1 & IGT: 3.4 vs 2.8%). The prevalence of KD & IGT were low in the 19-30 yrs group (2.1 & 2.1% respectively), peaked in the 61-70 yrs group (15.1 & 13.2%) and decreased thereafter (11.5 & 10.2%). The prevalence of UD increased steadily from 0 % in the 19-30 yrs group to 0.5% in the 31-40 yrs group and to 14.1% in the 71+ yrs group. All 3 groups had higher serum total cholesterol [KD = 5.34 + 0.21 mM, M + SEM, UD = 5.14 + 0.16 & IGT = 5.24 + 0.11 vs Normal = 4.77 + 0.03], and triglycerides [KD = 1.69 + 0.15 mM, UD = 1.72 + 0.15 & IGT = 1.65 + 0.16 vs Normal = 1.09 + 0.02] but lower HDL-cholesterol [KD = 1.1 + 0.04, UD = 1.12 + 0.08 & IGT = 1.1 + 0.05 vs Normal = 1.19 + 0.01] than the normal group. Only the KD [3.5 + 0.19 mM] and IGT [3.43 + 0.1] had higher LDL-cholesterol than the Normal [3.08 + 0.03] group. The glucose intolerant groups did not have higher serum apo A-I levels than the Normal group. However, all 3 groups had higher serum apo-B levels [KD = 112 + 3, UD = 108 + 5 & IGT = 112 + 3 mg/DL] than the Normal group [97 + 1]. Glucose intolerance is common in Bermuda. The prevalence of UD is highest in the 71+ yrs group. Bermudians with KD, UD, and IGT have higher serum cholesterol, triglycerides, LDL-cholesterol and apo-B but lower HDL-cholesterol levels than those without glucose intolerance.

749

Prevalence and incidence of diabetes mellitus in Japan

Yoshiharu Akazawa, on behalf of Japan diabetes study group of Prevention and Epidemiology.

The purpose of this study is to obtain accurate data on the prevalence and incidence of IDDM and NIDDM. In order to make international comparisons, the survey had to be performed to the same internationally recognized standard methods using WHO criteria. The data are taken from 1989 to 1995. The prevalence and incidence of childhood IDDM are chiefly derived from the records of patients who received free medical care for diabetes, which is available for children younger than 18 years of age.

The mean prevalence of childhood IDDM per 100000 is 14.7 which is rather uniform for the different areas of Japan. From 1974 to 1994, childhood diabetes increased from 577 to 6146 children. The incidence per year was about one tenth of the prevalence, that is to say about 1.5 per 100000.

The population-based survey of NIDDM among adults aged 40 years or older using WHO criteria showed mean 9.4% (Male 10.0% Female 6.0%) from northern Japan(YAMAGATA) to Southern Japan(OKINAWA).

The incidence rate of adult NIDDM calculated from the new occurrence of diabetes in subjects who had previously been examined was 0.8 to 4%. On the other hand, the person year incidence rate calculated from several year's trends showed 2-3 per 1000 person years. The IGT group comprises the group at high risk of developing diabetes and macrovascular diseases. The prevalence of IGT ranged from 17 to 26% in most surveys, about 2 to 2.5 times higher than diabetes. These studies showed the number of Japanese diabetic patients reached more the 6 million people. Another survey of our study group showed Japanese Americans who live in Hawaii and Los Angels suffered from diabetes 2 to 3 times more than Japanese in Japan. These data suggest that a westernized life style promotes the development of diabetes in Japan. The traditional Japanese life style may prevent the incidence of diabetes and its complications.

750

PREVALENCE OF GLUCOSE INTOLERANCE IN NORTH EASTERN REGION OF INDIA

SHAH SHEKHAR KUMAR[a], SAIKIA M., BARMAN N.N., RAMCHANDRAN A[b]

a - Diabetes Clinic & Research Centre, Guwahati, India.

b - Diabetes Research Centre, Chennai, India.

There is no epidemiological data on the prevalence of diabetes from North Eastern India. Therefore, a survey was conducted in the urban population of the city of Guwahati, Assam to evaluate the prevalence of glucose intolerance and associated risk factors. In a total of 1016 randomly selected adults aged 20 years & above (595 men, 421 women) glucose tolerance was tested by 2 hr post glucose (75 gm) plasma glucose estimation (WHO criteria). The age-adjusted prevalence of NIDDM was 8.2% in total, 8.7% in men, 7.8% in women. The age-adjusted prevalence of IGT was 4%, 4.1% in men and 3.4% in women. In 83.3% of NIDDM, diabetes was detected earlier. In the multiple regression analysis age, family history, increasing socio-economic strata and decreasing physical activity were significantly associated with NIDDM. Sex and BMI were not contributory. In the IGT group, the results were similar to NIDDM but BMI also was a contributory factor. This study showed that the prevalence of NIDDM in urban areas of Assam was also high, as reported from urban population in Southern India.

751

TROPICAL PANCREATITIS FROM WESTERN INDIA

Joshi SR, Shah PS, Menon M, Deshpande AK, Shah SC, Pitchumoni CS*. Department of Gastroenterlogy & Medicine, Grant Medical College and Sir JJ Group of Hospitals, Bombay. *Department of Gastroenterlogy, Our lady of Mercy Medical centre, NY 140 60.

AIM: To study Tropical pancreatitis and prevalance of Malnutrition - Related Diabetes Mellitus (MRDM) from ethnic population of Western India.

METHODS & MATERIALS :-40 cases meeting the following inclusion criteria viz (1) Abdominal pain (2) Evidence of chronic pancreatitis on ERCP (3) Evidence of Pancreatic calcification on plain x-ray abdomen, ultrasound, CT scan (4) Excluding all known causes of chronic pancreatitis viz alcoholism, biliary etc. were included in the study.

OBSERVATIONS: There were 36 males and 4 females .30 were from Maharashtra (18 Maharashtrians, 8 Gujarathi,3 UP ites, 3 Apites); 8 from Gujarat (7 Gujarathi,1 Kerla) &1 each from MP and UP. Abdominal pain was the predominant presenting complaint. Diabetes was seen only in (3/40) 7.5% and Malabsorption (5/40) 12.5 %. ERCP revealed (22/40) 55% had dilated pancreatic ducts ,(12/40) 30% stricutre in pancreatic duct and (6/40) 15% normal pancreatic duct apart from calcification in all. Mean duration of symptoms in dilated pancreatic duct group was 42 months, 9 months in stricture pancreatic duct group and 23 months in normal pancreatic duct group. Mean duration of follow-up was 70 months.

CONCLUSION : This study highlights that western Indian population behaves differently in its manifestations of tropical pancreatitis & MRDM as compared to classical features as described from South India. Abdominal pain predominates, malnutrition, parotid enlargement and diabetes were rare and overall prognosis was good in the Western Indian population.

752

A SEARCH FOR IMPAIRED GLUCOSE TOLERANCE IN INDIVIDUALS WITH HYPERTENSION AND OBESITY AND THEIR OFFSPRING.

G. Mardarowicz, J. Łopatyński, Z. Butrym, A. Abramczyk - Medical Academy of Lublin, Poland.

During the examination of 11 000 villagers from Eastern Poland we estimated the prevalence of hypertension at 22.5%, obesity at 40%, overweight at 30 %, diabetes at 2,3% and impaired glucose tolerance at 8,3%. In one of the local districts of ca. 5000 inhabitants, we undertook an active search for hypertension and obesity in families from rural areas. Family nurses visited all the families in the district in their households and measured body weight, waist to hip ratio and blood pressure. People with earlier and newly diagnosed hypertension and obesity (BMI>30) as well as their parents and children consequently underwent clinical and laboratory examinations. Oral glucose tolerance test, estimation of total cholesterol, HDL cholesterol, triglicerides, fasting serum insulin level and urine albumin excretion were performed. The analysis was made in case of 30 three-generation families where parents with hypertension and/or obesity were the probants and who had at least three children aged 7 - 16. None of the 105 examined children did not have hypertension or state of impaired glucose tolerance. The average concentration of HDL cholesterol in children was 0,94 ± 0,45 mM/L and was substantially lower as compared with the one in the control group (1,43 ± 0,24 mM/L). Percentage of HDL cholesterol in the investigated group was 26,2% and 34,1 in the control group. In 7,3% of the examined children proved to have microalbuminuria > 50 µg/ml. 39% of the children had elevated fasting serum insulin level over 10 µJ/ml. Our results point to the necessity of introduction of early preventive measures in offspring of parents with hypertension and obesity.

753

EPIDEMIOLOGICAL ASPECTS OF NONINSULIN DEPENDENT DIABETES MELLITUS IN MOSCOW REGION.

I.V.Misnikova, A.V.Dreval and Yu.A.Redkin, Moscow Regional Research Clinical Institute, Moscow, Russia.

The first stage of this work was the creation of the NIDDM patient's register in Mytishinsky district of Moscow Region. Up to now all the NIDDM's patients are registered. In total the quantity of these patients is 1345 persons. The anticipated results of this work were the description of general situation of mobidity in Mytishinsky district and the treatment received data as a model. Computer's treatment of the register's data has permit to represent the invalidity structure of the NIDDM's patients. Desease, which are not connected with diabetes mellitus, is at the first place in this structure. Diabetes mellitus, as a reason of invalidity, is on the second place. Cardiac decease is on the third place. From this, NIDDM is developing on the background of the existing hard deseases. The carried out large-scale investigation have permitted prevalence of complication among NIDDM's patients The quantity of autonomous neuropathy was negligible. Which can be connected with imperfection of the diagnostic methods. The analysis of medicines, which subscribed of the patients, had show the following: injections of insulin were subscribed 1.43% of patients, first generation's sulfanilamides were used by 8,4%, 71.68% got second generation sulfa drugs, 1,18% got biguanids drugs. These will permit to formulate the nessasary recommendations as well.

754

RETROSPECTIVE STUDY OF GLUCOSE INTOLERANCE AMONG WOMEN ATTENDING FOR ANTENATAL CHECKUP

Y.RAMU, S.ANDAL, S.BHASKAR and E.TANUJA
RAMAKRISHNA DIABETES CENTRE, NELLORE, INDIA

AIMS OF STUDY: To evaluate the prevalence of Glucose intolerance in high risk group of women attending for Antenatal Checkup (A.N.C.)

DESIGN METHODS: Women attending for A.N.C. were subjected to a common questionnaire. Data regarding family history of Diabetes, Past Obstetric history, height, weight, B.P. and B.M.I. were documented. Ultra sound screening was done on routine basis. Risk group women were identified and were subjected to O.G.T.T. according to N.D.D.G criteria.

RESULTS:	TOTAL NO.OF PATIENTS	835	--
	TOTAL O.G.T.Ts DONE	324	38.75%
	I.G.T.	34	4.06%
	G.D.M.	11	1.31%
	KNOWN CASES OF NIDDM	4	0.57%

Out of 49 patients with Glucose intolerance, 17 patients required insulin for better Glycemic control.

CONCLUSION: The prevalence of glucose intolerance among women attending for A.N.C. at an Obstetric clinic in Nellore is 5.86%

755

EPIDEMIOLOGICAL CHARACTERISTICS OF DIABETES MELLITUS IN CHINA

Ke-An Wang, et al. Chinese Academy of Preventive Medicine, Beijing, P. R. China

To investigate the prevalence characteristics of diabetes, a community based prevalence study on diabetes mellitus was carried out in 12 provinces of China. the study population comprised 45,000 persons, who lived in the community for no less than five years, and with age of 20-74 years. 2-hour venous blood was collected after an oral glucose load (75 g) for each subject. Diabetes and IGT was defined according to diagnostic criteria proposed by the WHO Study Group on diabetes mellitus. The preliminary data showed: 1.The prevalence rate of diabetes was 3.4% for males, 3.0% for females, and it was 3.1% for the whole population. The prevalence rates of IGT were 4.1%, 4.4% and 4.3% respectively. 2.The prevalence rates of diabetes or IGT were related to the economic status, diet habits, physical activities and education levels Detailed information on nutrition and diet was also investigated. 3.There was a positive correlation between age and the prevalence rate of both diabetes and IGT. The highest age-specific prevalence rate was 10.1% for diabetes, and 12.1% for IGT, both of which were found in the age-group of 60 years or more. 4.The prevalence rates also varied in different ethnic groups.

PS 16

Prevention and Risk Factors for NIDDM

756

LOWERED CARBOHYDRATE INTAKE IMPAIRS GLUCOSE TOLERANCE IN HEALTHY ADULTS.

T. Kaneko[1], P.-Y. Wang[1], M. Tawata[2], T. Onaya[2] and A. Sato[1]
[1] Department of Environmental Health, [2] Department of Internal Medicine, Medical University of Yamanashi, Tamaho, Yamanashi, Japan.

Eight volunteers (21.6±1.2 years, 58.9±11 kg, 3 females and 5 males) were recruited for this study. They underwent medical examinations and found to be "healthy". Written informed consent was obtained from each participant. Eight subjects consumed either a high-carbohydrate (CH) diet (CH calorie; 80 %) or a low-CH diet (CH calorie; 10 %) at predetermined times (08:30, 13:00, 18:00) for 3 days with a 2-week interval. Total caloric intake of the each diet was 30 kcal/kg/day. They were told not to exercise and consume any other food or beverages except for non-caloric drinks during the experimental periods. Subjects underwent 75 g oral glucose tolerance test (OGTT) at 10:00 on the day following the end of the diet. The result of OGTT was that 6 subjects showed impaired glucose tolerance (5 borderline and 1 diabetic) after a low-CH diet, although all subjects showed normal glucose tolerance after a high-CH diet. Hemostatic model assessment and fasting insulin values (both; indices of insulin sensitivity) did not significantly differ between the two test diets. However, insulinogenic index (ability to secrete insulin) was significantly different between the two test diets (low-CH diet < high-CH diet). Fasting plasma free fatty acid level after a low-CH diet was significantly higher than that after a high-CH diet. Fasting plasma triglyceride and total-cholesterol levels were not significantly different between the two test diets. These results indicate that decreased insulin secretion, not deterioration of insulin sensitivity, is likely associated with impaired glucose tolerance after a low-CH diet. Randle effect, which is the activation of glucose-free fatty acid cycle, is thought to be one of the mechanism of impaired glucose tolerance after a low-CH diet.

757

THE PROGRESSION OF IGT TO NIDDM IN CHINESE - IS THERE A ROLE IN DIET AND DRUG TREATMENT?

J.K.Y.LI, G.T.C.KO, J.C.N.CHAN, V.T.F.YEUNG, C.C.CHOW, W.Y.SO and C.S.COCKRAM. Diabetes and Endocrine Centre, Department of Medicine, Prince of Wales Hospital, Chinese University of Hong Kong, Hong Kong.

The effect of drug treatment on the progression of IGT to NIDDM remains controversial. We examined the effects of glipizide on the progression of glucose intolerance over a seven-year period in 68 Chinese subjects diagnosed to have IGT according to the WHO criteria. The study design was single blind, randomized and placebo-controlled. 35 subjects received glipizide 2.5 mg daily and 33 subjects received placebo. Neither of the two groups received dietary advice. A 75g OGTT was performed yearly. At each 3-monthly follow up visit, fasting plasma glucose, blood pressure, heart rate and BMI were measured and diet and drug compliance was assessed by direct questioning and tablet counting. All data are expressed as mean±SEM. The treatment group had similar clinical and biochemical characteristics as the control group. No difference was found in the age(37±1 vs 34±1 years,p=0.11), BMI(25.98±0.73 vs 25.40±0.79kg/m^2, p=0.59), systolic BP(117±3 vs 108±4 mmHg,p=0.06), diastolic BP(76±2 vs 71±3mmHg, p=0.17), fasting plasma glucose (5.6±0.1 vs 5.6±0.9 mmol/l,p=0.72)and insulin(11.9±1.7 vs 17.9±5.8μU/ml, p= 0.33).The mean follow up period was 3.15 ± 0.21years. The last available OGTT was used for analysis. Of the 68 subjects, 57 were followed up for 2 years or more and 43 subjects were followed up for 3 years or more.During the study period, 14 subjects (40%) in the treatment group and 13 subjects (39.4%) in the control group developed NIDDM. Six subjects(17.1%) in the treatment group and eight subjects(24.2%) in the control group remained having IGT. 15 subjects(42.9%) and 12 subjects (36.4%) in the treatment and control group had normal OGTT(p=0.74).The mean time to develop NIDDM was 4.74 and 4.96 years for the treatment and control group (p=0.75) respectively.The rate of conversion of IGT to NIDDM is 12.7 % per year, which is comparable to other ethnic groups such as the Dutch(13.8%) and the South African Indians(12.6%).Our study suggests that there is no effect of glipizide on the progression of IGT to NIDDM. However, since the number of our patients is relatively small, further large scale studies are necessary.

758

DISORDERS OF CARBOHYDRATE AND LIPID METABOLISM IN RELATION TO CHROMIUM STATUS. M.Vrtovec[1], J.Štupar[2], A.Briški[3], A.Kocijančič[1], A.Gantar[4]. Dept.of Endocrinol. & Metab.[1], University Medical Centre, Ljubljana, Institute Jožef Stefan[2], Ljubljana, Laboratory of the University Medical Centre Ljubljana[3], Laboratory of the IUV Tannery[4], Vrhnika, Slovenia.

The presence of chromium in man has been shown to be necessary for maintaining normal carbohydrate and lipid metabolism. In our study, the incidence of disorders of carbohydrate and lipid metabolism was compared between the population of tannery workers (n=149, M58/F91) and workers in wood industry (n=150, M55/F95) from the same region. There were no statistically significant differences between the two groups regarding age (40.6 ± 8.11 Vs 41.5 ± 7.04 years), sex and body mass index (27.28 ± 4.34 Vs 27.48 ± 4.52 kgm^{-2}). Assessment of the chromium status of both populations was made on the basis of chromium content of their scalp hair. The mean chromium content in tannery workers was significantly higher (2.68 ± 1.85 Vs 0.24 ± 0.32 μgCr/g). We found significantly lower fasting blood glucose (5.36 ± 0.86 Vs 5.71 ± 1.3 mmol/l) and lower incidence of diabetes mellitus (3 Vs 5) in the group of tannery workers but higher incidence of impaired glucose tolerance (6 Vs 4). Serious hypertriglyceridemia (TG > 2.2 mMol/l) was also less frequent among tannery workers (12.1 % Vs 18 %; average 1.57 ± 1.17 Vs 1.85 ± 1.81). Lower incidence of serious hypercholesterolemia (chol > 6.5mMol/l) was also found among tannery workers (10.7% Vs 12.7%; average 5.32 ± 1.19 Vs 5.42 ± 0.97) but it can be at least partly attributed to the lower HDL cholesterol levels (1.15 ± 0.33 Vs 1.32 ± 0.29 mmol/l) in the group of tannery workers ($p < 0.05$). Conclusion: The lower fasting blood glucose values and lower incidence of serious hypertrigliceridemia in tannery workers could be attributed with high probability to the protective role of chromium in human metabolism.

759

DIET IN ASIAN INDIANS WITH GLUCOSE INTOLERANCE.

P.V. Rao and M.M.S. Ahuja.
Nizam's Institute of Medical Sciences, Hyderabad and Sitaram Bhartia Institute of Science and Research, New Delhi, India.

Diet information in Asian Indians by recall, estimates of cooked food in a day and monthly purchases was obtained from 85 diabetics at four teaching hospitals in a 1988 Pilot Study, 142 subjects with abnormal glucose tolerance by OGTT in the National Diabetes Survey of 1989, 10 IGT and 4 diabetics diagnosed in a High Altitude Center Study of 1989, and 37 newly ascertained diabetics of a Tropical Diabetes Study of 1991. The minimum and maximum mean daily intakes among these populations were - total calories (1156-2586 C), carbohydrates (720-1981 C, 53-69 %), cereals or complex carbohydrates (486-1478 C, 55-70 % of total carbohydrates), refined sugars (0-137 C, 0-8 % of total carbohydrates), proteins (177-302 C, 11-16 %), animal proteins (52-121 C, 18-46 % of total proteins), fats (259-693 C, 17-32 %), animal fats (54-503 C, 30-54 % of total fats). These population nutrient intakes among rural Asian Indians were within the limits set by WHO recommendations for 'population nutrient goals' in relation to effects of chronic, non-deficiency diseases in 1990. There is as yet insufficient evidence to allow specific dietary goals in primary prevention of diabetes to be given in Asian Indians.

760

PROINSULIN, IMMUNOREACTIVE INSULIN AND SPECIFIC INSULIN IN RELATION TO CONVERSION TO NON-INSULIN DEPENDENT DIABETES MELLITUS: THE MEXICO CITY DIABETES STUDY

SM Haffner, C Gonzalez, L Mykkänen and M Stern, University of Texas Health Science Center, San Antonio, Texas.

Although insulin resistance and decreased insulin secretion are characteristic of established non-insulin dependent diabetes mellitus (NIDDM), which of these metabolic abnormalities is the primary determinant of NIDDM is still controversial. A disproportionate increase in the proinsulin to insulin ratio has been proposed as a marker for compromised insulin secretion. We examined the association of fasting immunoreactive insulin (which cross-reacts with proinsulin), specific insulin (which does not cross-react with proinsulin), proinsulin, and the fasting proinsulin/specific insulin ratio to the risk of developing NIDDM in the 3.25 year follow-up of the Mexico City diabetes Study. These measurements were made in 85 subjects who subsequently converted to NIDDM("prediabetics") and in 95 age and gender matched subjects who remained non-diabetic at follow-up ("controls"). Immunoreactive insulin, proinsulin and the proinsulin/specific insulin ratio were significantly higher in prediabetic than in control subjects. However, the relation between specific insulin and the development of NIDDM was weaker than for proinsulin or immunoreactive insulin. After further adjustment for obesity, body fat distribution and glucose tolerance status, proinsulin and the proinsulin/specific insulin ratio (but not specific or immunoreactive insulin) predicted conversion to NIDDM. A high proinsulin/specific insulin ratio predicted conversion to NIDDM both in subjects with normal and those with impaired glucose tolerance at baseline. We conclude that in prediabetic subjects increased proinsulin, a marker of islet cell distress or compromised insulin secretion, is associated with rapid conversion (within 3.25 years) to NIDDM even in obese populations.

761

DYNAMIC OBSERVATION OF PATIENTS WITH IMPAIRED GLUCOSE TOLERANCE

H. Khanina-Drozdov. Maccabi Hospital, Be'ersheba. Israel.

The paper is concerned with preventing diabetes mellitus (DM) at early stages. Our aim was to assess the effect of diet and biguanides on patients with impared glucose tolerance (IGT). The method of patient selection was employed, where 275 patients with IGT were diagnosted among 3,312 people underwent an epidemiologic study with the standard glucose tolerance test (GTT). To estimate the reliability of statistical results, the χ^2- and Fisher criteria were employed. The patients have been under our observation during 3 years. A diet instruction was provided for all the patients, but only 91 (33%) followed these recomendations. 154 patients (56%) run there usual meal habits, and 30 patients (11%) were treated with diet and biguanide during 6 months. All these groups had no statistically significant differences in family histories of diabetes mellitus, ages, and obesity. During the observation period none of the biguanide treated patients had developed DM. The GTT normalization was observed in 21 cases (70%), and 9 cases (30%) remained with IGT. Among those followed diet, 1 (1%) developed NIDDM, 64 (70%) had normal GTT, and 26 (29%) remained with IGT. Among 154 patients which run their usual diet, NIDDM was diagnosted in 15 cases (10%), while normal GTT in 70 cases (45%); 69 patients (45%) remained with IGT. In the group treated with biguanide, weight loss and positive changes in lipidogramms were more significant than in the group treated with diet only ($P \leq 0.05\%$). In the group with free diet, nonsignificant weight gain was observed. As a conclusion, we would like to emphasize that biguanide treatment may be useful in the DM prevention for patients with IGT, obesity, and abnormal lipidogramms.

762

GUT HYPERPLASIA AS A POSSIBLE FACTOR TO INDUCE POSTPRANDIAL HYPERGLYCEMIA IN NIDDM MODEL RATS.

H. Kojima, A. Kashiwagi, Y. Fujita, K. Matumura, H. Hidaka and R, Kikkawa.
Shiga University of Medical Science, Ohtsu, Japan.

Otsuka-Long-Evance-Tokushima-Fatty (OLETF) rats are useful model animals for the study of the development of non-insulin-dependent diabetes mellitus (NIDDM) with hyperphagia and obesity. We found that gut in OLETF rats was enlarged compared with that in its non-diabetic control (LETO; Long-Evance-Tokushima-Otsuka) rats. To clarify the relation of intestinal enlargement and glucose absorption efficacy, we examined oral glucose tolerance test (OGTT) and oral xylose test (OXT) in these animals. Both rats were pair-fed for 2 weeks (4-6 week age). Significant increases of intestinal area (1.4-fold), wet weight (1.3-fold) and cell numbers on a villus column (1.3-fold) were observed in OLETF compared with LETO, indicating that epithelial hyperplasia was independent of hyperphagia in OLETF ($p<0.01$). Though OLETF in this stage did not have increased fasting plasma glucose level and was free from insulin resistance by glucose-clamp technique, both plasma glucose level at 1 hr by OGTT and plasma xylose level at 1 hr by OXT were significantly ($p<0.01$) increased in OLETF in comparison with LETO by 1.5-fold and 1.4-fold, respectively. Since plasma insulin levels during OGTT had no significant difference among those animals, and increased plasma xylose levels during OXT did not cause the increase in plasma insulin levels, glucose and xylose increments after oral loading in OLETF may reflect increased glucose absorption from the small intestine. These results indicate that gut epithelial hyperplasia may have important roles for the pathogenesis in both the postprandial hyperglycemia and the resulting NIDDM in this model animal.

763

INSULIN RESISTANCE AND METFORMIN

Rosas J., * Navarrete P. *, Aceves P.**, Navarro J.**, Herrera C*.
Centro de Espec.Med.de Celaya* y CDM**, Celaya, Gto., Mexico.

Objective: To investigate in a group of patients without Diabetes Mellitus but insulin resistance, anthropometric (weight, body mass index [BMI]), ratio of waist to hip circunference [RWH]), metabolic (glucose, insulin, ratio glucose/insulin, cholesterol, HDL, LDL, VLDL cholesterol, triglicerides, urea, uric acid and aspartate aminotransferase [AST]) and clinical changes (tolerance, side effects, vital signs, etc.) with the administration of different doses and withdrew period of Metformin. **Participants:** 12 obesity and/or hypertensive patients without diabetes mellitus, age average 49 years old (24 to 72 years), with BMI 31.24 +/- 5.4 and RWH 0.95 +/- 0.13. They were in good arterial hypertensive control. Measurments and laboratory described above were taken basal and at the end of each period (1 month each). We considered insulin resistance those with ratio of glucose/insulin < 6. We prescribed metformin 850 mg/day the first month. Increase the dose to 850 mg twice a day the second month and 850 mg tid the third month, and at the end of the 3 months we withdrew the metformin and take the measurments at the end of the fourth month. **Results:** Metformin lowered the levels of insulin (178.2+/-84 vs. 55.2+/-32.4 pmol/l, P=0.0007),cholesterol, triglicerides and LDL cholesterol; raised the ratio glucose/insulin from 3.4+/-1.1 to 10.56+/-6.2. P=0.001, was well tolerated and minimun of side effects. 850 mg/day of metformin got an important decline of the variables above. No hypoglucemia was reported. **Conclusions:** Metformin is an effective drug to lower insulin resistance and the metabolic changes seen in obese or/and hypertensive patients. Maybe it's possible with the correction of this abnormality to prevent or modify the natural clinical history of non-insulin dependent diabetes mellitus, and other entities related to insulin resistance.

POSSIBLE ASSOCIATION OF DIABETES MELLITUS AND HELLP SYNDROME

R.Weitgasser[1], D.Spitzer[2], M.Zajc[2], I.Kartnig[1], S.Sailer[1] and A.Staudach[2].
2nd Dept. of Medicine[1] and Dept. of Gynaecology and Obstetrics[2],
Salzburg General Hospital, Salzburg, Austria

Following the observation of development of type 1 diabetes mellitus in a patient with HELLP syndrome, a rare but severe form of preeclampsia with haemolysis, elevated liver enzymes and low platelet count, we assumed a possible disease association based on autoimmune pathogenesis. We therefore investigated all 55 women with HELLP syndrome who were admitted to our hospital during the last 4 years for the presence of diabetes and autoimmune diseases. An oral glucose tolerance test (OGTT) with 75g glucose load, HbA1c, islet cell antibodies (ICA), insulin auto-antibodies (IAA), anti-glutamate decarboxylase antibodies (GAD), free thyroxine index, T3, thyroid stimulating hormone, thyroglobuline antibodies, thyroperoxidase antibodies, antinuclear antibodies (ANA), anti DNA antibodies and routine laboratory parameters were determined during their post partum stay in hospital. In 5 patients diabetes mellitus was diagnosed, 13 patients showed impaired glucose tolerance, only one being borderline-positive for ICA and antiGAD. In 6 of these cases a positive history of type 2 diabetes in parents or grandparents was reported. 7 patients were repeatedly found positive for ANA titers of 1:160 to 1:2560, four of which were patients within the group who's glucose tolerance was impaired. 3 patients had a history of Hashimoto's thyreoiditis. In 4 patients hypothyroidism was detected, 2 patients of which had impaired glucose tolerance. Thus we found abnormal glucose tolerance in about 30% and features of autoimmunity other than preeclampsia in about 20% of patients. In conclusion we may say that our data shows evidence for a correlation of autoimmune disease other than diabetes with HELLP syndrome. In addition a high prevalence of impaired glucose tolerance was found, but a true association with autoimmune diabetes seems unlikely. If impaired glucose tolerance is due to insulin resistance or other causes remains to be determined by further investigation.

765

THE COMMUNITY DIABETES PREVENTION PROJECT (CDPP)

R. Bergenstal, A. Monk, S. Leite, J. Nelson, S. List, P. Upham,
International Diabetes Center, Minneapolis, Minnesota, USA.

The CDPP characterized a population at risk for NIDDM before the development of the complete insulin resistance syndrome (IRS). CDPP is using lifestyle interventions to alter this progression. Using a diabetes risk assessment tool, we identified 418 people (321 F, 91 M, mean age of 46 ± 9.8 yrs.) After a baseline evaluation, they were randomized into a standard (S) and intervention (I) group. The I group received an annual assessment with feedback, quarterly newsletters, behavior change program and monthly phone calls for motivation to change diet, exercise and stress behaviors. After one year 7 people developed NIDDM, 5 had IGT, 27 dropped and 13 pregnant couldn't be assessed. Below, are the baseline and year 1 data.

	Baseline		Year One	
Variables	Intervention	Standard	Intervention	Standard
BMI (kg/m^2)	29.6 ± 6.5	29.1 ± 5.6	29.6 ± 6.8	29.0 ± 6.0
Cholesterol (mg/dl)	207 ± 37	209 ± 37	205 ± 37	214 ± 45
LDL-C (mg/dl)	130 ± 31	128 ± 31	134 ± 28	129 ± 32
HDL-C (mg/dl)	48 ± 17	46 ± 15	46 ± 14	46 ± 14
Triglyceride (mg/dl)	166 ± 108	155 ± 110	166 ± 98	149 ± 91
Glucose (mg/dl)	99 ± 10	100 ± 12	99 ± 10	101 ± 13
BP Systolic (mmHg)	126 ± 15	127 ± 14	125 ± 14	123 ± 16
BP Diastolic (mmHg)	80 ± 8	81 ± 8	80 ± 8	78 ± 11
Waist/Hip Ratio	84 ± 8	84 ± 9	83 ± 12	82 ± 10
VO_2max (mg/kg/min)	21 ± 6	22 ± 7	21 ± 7	21 ± 8
Insulin (μU/ml)	7.9 ± 5.5	7.3 ± 5.4	7.4 ± 4.8	7.4 ± 4.8
C-Peptide (ng/ml)	2.7 ± 2.4	2.3 ± 1.3	2.2 ± 1.0	2.2 ± 0.9
HbA1c (%)	5.4 ± 0.4	5.3 ± 0.5	5.6 ± 0.4	5.5 ± 0.7
Alb./Creatinine Ratio	9.2 ± 11.4	9.3 ± 11.5	13.9 ± 33.5	8.5 ± 12

The CDPP study is defining the natural history of the development of IRS and whether lifestyle interventions over 5 years can prevent the progression to NIDDM.

766

MATERNAL DIABETES STATUS DOES NOT INFLUENCE ENERGY EXPENDITURE NOR PHYSICAL ACTIVITY IN 5-Y OLD CHILDREN.
AD Salbe, AM Fontvieille, DJ Pettitt, and E Ravussin.
NIH/NIDDK/CDNS, Phoenix, AZ, USA.

Offspring of women who have diabetes during pregnancy have a greater prevalence of obesity in early adulthood than offspring of women who are normoglycemic. Obesity can result from excess food intake, low levels of energy expenditure, or both. We tested whether maternal diabetes status influences resting metabolic rate (RMR, by ventilated hood), total energy expenditure (TEE, by doubly-labeled water) or the level of physical activity (TEE/RMR) in 95 5-y old Pima Indian children. Maternal diabetes status was assessed by an oral glucose tolerance test using a 75 g glucose load during pregnancy. Twenty-four women had diabetes (2 h plasma glucose ≥11.1 mmol/l) and 71 had normal glucose tolerance (2 h plasma glucose <7.8 mmol/l with no past history of abnormal glucose tolerance).

	Diabetic Mother		Normoglycemic Mother
Number/Sex of Offspring	(13 M/11 F)		(31 M/40 F)
Weight (kg)	26.4 ± 6.9		24.1 ± 6.0
Relative Weight (%)	127 ± 25	p =0.07	118 ± 22
Percent Fat (^{18}O)	33 ± 8		31 ± 7
Birth Weight (kg)	3.9 ± 0.8	p <0.02	3.5 ± 0.5
TEE (kJ/d)	6508 ± 1109		6097 ± 957
RMR (kJ/d)	4674 ± 786		4491 ± 678
TEE/RMR	1.40 ± 0.12		1.36 ± 0.13

TEE and RMR were similar in both groups after adjustment for body size and sex by linear regression analysis, indicating that maternal diabetes does not affect energy expenditure nor physical activity in young children. Thus, increased energy intake is the likely cause of obesity in early adulthood among offspring of women with diabetes.

767

LIFE STYLE INTERVENTION IN NIDDM: FIRST REPORT OF JAPAN DIABETES COMPLICATIONS STUDY (JDCS)
N. Yamada, K. Ohashi, Y. Akanuma. JDC Study Group, Tokyo, Japan

Rapid changes in life style such as diet and physical activity in last 50 years are a major cause of an increasing number of diabetic subjects with diabetic complications in Japan. In the present study, we have performed life style modification to prevent the progression of diabetic complications including retinopathy, nephropathy, and macroangiopathy in 2066 non-insulin dependent diabetes mellitus without complications or with background retinopathy whose HbA1c is greater than 6.5%. 2066 diabetic subjects were randomly divided to two groups; a group of intensive life style modification and a group of conventional treatment. In a group of intensive life style modification, diet and physical activity are intensively managed to achieve a following goal of treatment; HbA1c, BMI, blood pressure, plasma cholesterol, triglyceride levels, W/H ratio should be less than 6.0%, 22 kg/m^2, 140/85 mmHg, 220 mg/dl, 150 mg/dl, 0.9 for men, 0.8 for women, respectively, and plasma HDL cholesterol level should be greater than 40 mg/dl, and patients should quit drinking alcohol and smoking. We have started the JDCS since April in 1996, and initial HbA1c was 7.8 ± 1.2% in intensive group and 7.9 ± 1.3% in conventional group. This is the first report of JDCS which is a prospective study performing 6 year-follow up.

768

AUTOIMMUNE PROFILE OF NON-INSULIN-DEPENDENT DIABETES IN NORTH INDIANS
E Bhatia, K Modi, P Dabadhghao and P G Colman*, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India and *Royal Melbourne Hospital, Victoria, Australia.

Non-insulin-dependent diabetes in the young (NIDDY) is frequent among North Indian Asians and differs clinically from MODY. NIDDY may have a heterogenous etiology. We studied pancreatic islet cell antibodies (ICA) and glutamic acid decarboxylase antibodies (GADA) in NIDDY subjects and in patients with Type 1 diabetes and healthy controls. ICA were measured by indirect immunofluorescence and GADA by immunoprecipitation of 35 S recombinant human GAD. Results: The frequency of autoantibodies is shown in the table.

	NIDDY	Controls	Type 1 DM
ICA	1/49 (2%)	4/130 (3%)	22/62 (36%)*
GADA	16/28 (57%)**	1/67 (1%)	-

* p<0.001 vs NIDDY ** p < 0.001 vs controls

When NIDDY patients having duration of diabetes of > 2 years (42/49) were compared to Type 1 diabetic patients of similar duration the ICA frequency was similar (1/42 vs 4/20, p=0.06). Mean GADA titre in NIDDY subjects was 25±33 U vs 3±2 U in controls (p < 0.001). Conclusion: A significant proportion of NIDDY patients have GADA positivity, suggesting that in North Indian Asians this entity may be heterogenous.

769

LONG-TERM TOLERABILITY PROFILE OF ORLISTAT, AN INTESTINAL LIPASE INHIBITOR.
W. Canovatchel, Pharma Research Clinical, Hoffmann-La Roche, Nutley, New Jersey.

The risk of Type 2 diabetes is increased 2-10 times in obese individuals, as a result of various factors, including insulin resistance, impaired glucose tolerance and dyslipidaemia. In a 1-year Phase III study of 322 diabetic obese patients, orlistat 120 mg tid in conjunction with a hypocaloric diet (estimated energy expenditure minus 600 kcal/day, minimum 1200 kcal/day, with 30% of calories as fat) resulted in maintained weight loss and significantly improved glycaemic control. The long-term tolerability of orlistat was assessed in a meta-analysis including this study and 6 Phase III studies of obese non-diabetic patients. All studies had a 4 or 5 week single-blind lead-in period with placebo and a hypocaloric diet. Patients were then randomised to a double-blind, placebo-controlled treatment period lasting up to 2 years. A total of 1740 patients received placebo; 2038 patients received 120 mg orlistat tid with meals. Significantly increased incidences of adverse events (AEs) were only reported in the gastrointestinal (GI) tract, as expected from orlistat's mode of action and negligible absorption. Most of the GI AEs were of mild intensity and experienced within the first week of treatment. The incidence of GI AEs reduced greatly after 12 weeks of treatment, indicating that long-term treatment does not increase the risk for these events. Indeed, there was a substantial decrease in reported GI AEs in year 2 compared with year 1; GI AEs with the highest frequencies (8-27%) in year 1 decreased by 6-22 percentage points in year 2. During year 1, 35% of patients in the placebo group withdrew prematurely from the trial versus 29% of orlistat-treated patients. The rates of premature withdrawal were lower for all treatment groups in year 2 compared with year 1. Moreover, over 1 year of treatment, only 7% of patients in the orlistat 120 mg group withdrew because of GI AEs. Statistically significant decreases in plasma levels of vitamins D, E and beta-carotene were reported following orlistat treatment, however, these values remained within the normal clinical range. In conclusion, a large patient population with extensive exposure to orlistat has been assessed for tolerability. Although there was an increase in GI AEs, these were well tolerated and did not lead to an increased drop-out rate overall compared with placebo. There were no major CNS or cardiovascular events. Orlistat 120 mg tid is well tolerated for long-term use in the treatment of obese patients at risk of Type 2 diabetes.

770

TITLE: FACTORS INFLUENCING THE CONVERSION OF IMPAIRED GLUCOSE TOLERANCE TO DIABETES MELLITUS

Authors: AS Mollah, AKA Khan and H Mahtab. Bangladesh institute of Research and Rehabilitation in Diabetes, Endocrine and Metabolic Disorders(BIRDEM),Dhaka, Bangladesh

Abstract: The aim of this study was to find out the infulence of certain factors like age, sex, family history of diabetes, blood pressure, obesity and glycaemic status on the conversion of impaired glucose tolerance (IGT) to diabetes mellitus. All newly diagnosed IGT (according to WHO criteria) subjects attending the outpatient depertment of BIRDEM, Dhaka, Bangladesh were considered for the study. One hundred thirteen subjects with IGT were followed for 4 to 13 months (mean 10.3 months). Diabetes mellitus developed in 23 (20.35%), glucose tolerance remained impaired in 69 (61.07%) and glucose tolerance returned to normal in 21 (18.58%). Of the baseline variables examined , plasma glucose and HbA_{1c} levels at the time of the initial examination were consistent in predicting conversion of IGT to diabetes, when the data were examined by univariate method. Both fasting (P< 0.001) and 2-h (P< 0.001) plasma glucose levels were useful predictors. Although HbA_{1c} level was within the normal range, but it was highly predictive in conversion to diabetes (P< 0.001). The IGT subjects with family history of diabetes in their first degree relatives showed a higher tendericy to become converted to diabetes. None of the other baseline variables was found predictive for conversion of IGT to diabetes. Chi-square and student's 't' test were used for statistical analysis. We conclude from our study that glycaemic status at the initial examination in subjects with IGT has an influence on the conversion of IGT to diabetes mellitus. We also conclude that heredity may be a predictive factor in conversion of IGT to diabetes mellitus.

771

THE LONG TERM EFFECTS OF ORLISTAT, A NEW LIPASE INHIBITOR, IN TREATMENT OF OBESE NIDDM PATIENTS

P.Hollander (on behalf of the NM14336 Study Group). Ruth Collins Diabetes Center, Dallas

A strong association between obesity and the development of NIDDM has been well established. Weight loss can improve glycaemic control and lower cardiovascular risk in such patients. Orlistat, a new agent for the long-term management of obesity, decreases the absorption of fat through inhibition of lipase in the gut. A 57-week multicentre, randomised double-blind, placebo-controlled group study was undertaken to determine its effect in obese NIDDM patients treated with oral hypoglycaemic agents. After one year of treatment, patients receiving 120 mg orlistat tid (n = 162) lost an average of 6.2±5.7% of initial body weight compared with 4.3±6.2% for placebo (n = 159), a difference of 2.4 kg ($p<0.05$). Moreover, 49% of orlistat-treated patients lost more than 5% of their initial body weight versus 23% of the placebo group. Fasting blood glucose fell by 0.02 mmol/l in the orlistat group and increased in the placebo group by 0.54 mmol/l ($p<0.05$). A significant improvement in HbA1c was seen in the orlistat group, a decrease of 0.2% compared to an increase of 0.3% in the placebo group ($p < 0.01$). Patients with HbA1c >8% at baseline on orlistat had a mean decrease of 0.5% compared to a mean decrease of 0.05% in the placebo group. A significant reduction in the dose of oral agent was seen in the orlistat group ($p=0.0019$). Improvement of mean levels of total cholesterol, LDL-cholesterol, triglycerides, LDL/HDL ratio and apoliprotein B were seen in the orlistat group as compared to the placebo group ($p\leq0.04$). The incidence of adverse events was similar in both treatment groups in all body systems other than the gastrointestinal (GI) system. As was expected, due to the mechanism of the drug, a higher incidence of mild GI events, 20.5% greater than the placebo group, were reported in the orlistat group. There were no clinically significant decreases in vitamin levels in the orlistat-treated patients. The study showed that orlistat is well tolerated and effective in causing weight loss in NIDDM patients with attendant improvement of glycaemic control and lipid parameters. It also demonstrates that anti-obesity drugs provide an additional approach for the treatment of NIDDM.

772

SMOKING, GLUCOSE INTOLERANCE AND INSULIN LEVELS IN SWEDISH MIDDLE-AGED MEN.

P-G. Persson, S. Carlsson, V. Grill, S. Efendic, A. Norman , C-G. Östenson and the SDPP study group. Departments of Epidemiology, Endocrinology, Social Medicine and Diabetes Prevention, Stockholm County Council, Sweden.

Smoking is suggested to cause non-insulin-dependent diabetes (NIDDM) by way of insulin resistance. It is not known whether smoking also affects insulin secretion. The aim of this study was to study the association between glucose tolerance, insulin levels and smoking accounting for body mass index (BMI) and family history of diabetes. We performed a cross-sectional study of 3129 men aged 35-56 years selected from four communities in Stockholm. The sample consists of 52% with at least one first or two second degree relatives with diabetes and 48% without relatives with diabetes. In a glucose tolerance test (WHO) we detected 55 men with NIDDM (previously not diagnosed) and 172 with impaired glucose tolerance (IGT). We also identified 502 men with glucose concentrations in the upper part of the normal range defined as 2h plasma glucose levels 5.8-7.7mM. Information on body weight, length, cigarette smoking and other life habits were obtained by a questionnaire. The analyses were done with adjustment for age, BMI and family history of diabetes. The relative risk of NIDDM was 1.7 (95% confidence interval 0.8-3.4) for cigarette smokers and 2.7 (1.3-5.7) for men smoking 16 or more cigarettes per day. Corresponding estimates for IGT were 1.1 (0.7-1.6) and 1.2 (0.7-1.9). These estimates were also close to unity for high normal glucose concentrations. The relative risks associated with smoking were more pronounced for lean men and for men without a family history of diabetes in NIDDM. The results indicate that smoking was not significantly associated with indicators of insulin resistance (fasting insulin ≥21mU/l) or low insulin response (delta 2h insulin ≤60mU/l) in IGT. In conclusion, high consumers of cigarettes have increased risk of NIDDM after controlling for age, BMI and diabetes in the family. It is unclear, however, whether this increase in risk is due to insulin resistance, a decreased insulin response or both.

773

THE EFFECT OF ORLISTAT ON GLUCOSE TOLERANCE IN OBESE NON-DIABETIC INDIVIDUALS. T. Taylor, Georgetown University Medical Center, Division of Endocrinology, Washington, D.C.

Obesity is often associated with a series of metabolic disturbances, including insulin resistance and impaired glucose tolerance. Indeed, insulin resistance and impaired glucose tolerance are the fundamental links between obesity and the development of diabetes. A new compound, orlistat, an inhibitor of dietary fat absorption, has been shown to promote maintained weight loss in obese diabetic patients. This weight loss was also associated with a significant improvement in patients' glycemic control. In order to investigate the effects of orlistat on glucose tolerance in obese (average BMI 35 kg/m^2) non-diabetic patients, a meta-analysis of 1 and 2-year Phase III USA and European clinical trials has been undertaken. In total, 1096 patients received placebo and 1521 patients received orlistat 120 mg tid, both in conjunction with a hypocaloric diet in year 1 and a eucaloric diet in year 2. After 1 year, the average loss from initial body weight was 6.2% for orlistat-treated patients and 4.3% for placebo ($p < 0.05$). After 2 years, orlistat-treated patients had lost 6.7% of initial body weight versus 3.7% for placebo ($p < 0.05$). Of patients who had normal OGTT values at baseline, 1.3% of the placebo sub-group and none of the orlistat sub-group were classed as diabetic at the end of 104 weeks. Similarly, of patients with impaired glucose tolerance at baseline, 25% of the placebo sub-group and 4.3% of the orlistat sub-group were diabetic at the end of 104 weeks. The overall changes in fasting insulin after 104 weeks from initial values for placebo and orlistat were -8.9 and -20.3 pmol/L, respectively. There was a statistically significant difference in fasting glucose between the placebo and orlistat groups after 1 year ($p=0.001$; difference -0.07 mmol/L). Also after 1 year, oral glucose tolerance tests (OGTT) revealed there was a mean increase in incremental glucose area under the curve (AUC) level of 0.23 for placebo-treated patients compared with a mean decrease from baseline of -1.51 for orlistat treated patients ($p<0.001$). Furthermore, in year 1, insulin AUC only decreased by 18.26 in placebo recipients compared with 263.8 in the orlistat group ($p<0.001$).These results suggest that orlistat may assist in reverting impaired glucose tolerance to normal, which may delay or prevent progression to Type 2 diabetes in non-diabetic obese individuals.

774

PREDICTING CHANGE IN VISCERAL ADIPOSITY: A PROSPECTIVE STUDY IN JAPANESE AMERICANS

E.J. Boyko, L. Newell-Morris, D.L. Leonetti, and W.Y. Fujimoto. University of Washington, Seattle, USA.

We hypothesized that baseline insulin resistance and lower insulin secretion would predict change in visceral adiposity over 6 years of follow-up in third generation Japanese Americans. At baseline, 115 nondiabetic men and 115 nondiabetic women had a 75 g oral glucose tolerance test (WHO criteria for glucose tolerance); body mass index (BMI) (weight in kg/height in m2); visceral adiposity as measured by intra-abdominal fat area (IAF) at the level of the umbilicus using computed tomography; and fasting and 30 minute plasma glucose, insulin, and C-peptide levels. Insulin secretion (IS) was defined as the (30 - 0 minute insulin)/30 minute glucose. Measurement of BMI and IAF was repeated after 6 years of follow-up. The outcome was defined as change in IAF (ΔIAF) over 6 years of follow-up (6 year IAF - baseline IAF). Baseline characteristics were as follows: mean age women (W) 40.1 yr, men (M) 40.1 yr; mean BMI W 22.8, M 24.9; mean IAF W 42.6 cm2, M 74.8 cm2; IGT prevalence W 31.1%, M 19.1%. Overall and visceral fatness increased on average over 6 years (ΔBMI W 1.3, M 1.0; ΔIAF W 19.0 cm2, M 13.5 cm2). Among women, ΔIAF was positively correlated with the following baseline variables: fasting insulin (FI) (r=0.27, p=0.008), fasting C-peptide (FC) (r=0.29, p=0.004), IAF (r=0.31, p<0.001), and BMI (r=0.33, p=0.001). In a multiple linear regression model among women that adjusted for baseline age, IAF, and IGT status, both baseline FI (coefficient (B) =0.130, 95% confidence limits (CL) 0.003 to 1.257, p=0.046) and IS (B= -0.14, 95% CL -0.25 to -0.04, p=0.009) were significantly related to ΔIAF. Among men, similar weaker, nonsignificant associations were noted between ΔIAF and baseline FI, FC, and IS in univariate and multivariate analyses. We conclude that gain in visceral adiposity was related to higher fasting insulin (reflecting lower insulin sensitivity) and lower insulin secretion in women, but this effect was not observed to the same degree in men. In this population, patterns of insulin sensitivity and secretion associated with higher subsequent NIDDM risk predict gain in visceral adiposity.

775

GLUTAMATE DECARBOXYLASE ANTIBODIES IN CHINESE PATIENTS WITH NIDDM DO NOT IDENTIFY LATENT IDDM

AC Thai, WY Ng and KF Lui. Dept of Medicine, National University of Singapore.

NIDDM is a heterogeneous condition, with patients having varying age-at-onset, body weight and need for insulin treatment. It has been suggested that in Asians patients with NIDDM, a significant subset of patients may have latent or slow-onset IDDM, characterised by presence of autoantibodies to GAD, eventual loss of ß-cell function and need for insulin treatment. The objective of this study was to determine the prevalence of GADab in Chinese NIDDM patients and evaluate them with patients with classical IDDM. Autoantibodies to GAD were tested in 168 Chinese NIDDM patients (mean age 40±15.3yr, mean duration 2.3±4.3yr), and 134 IDDM patients (mean age 22.1±12.9yr, mean duration 4.6±6.6yr). GADab was measured with an ELISA (rated 83% valid, 100% specific and 75% sensitive;1st GAD Proficiency Program, USA). The prevalence of GADab was 16.1% in the NIDDM patients and 39.6% in IDDM patients (p<0.0001). GADab titre in NIDDM was similar to IDDM (31.3±29.4 vs 42.6±41.1 relative units). GADab[+] NIDDM patients compared to those GADab[-] had similar age-onset (39.3±16.5 vs 38.3±15.1yr), body weight (BMI 23.2±4.0 vs 24.6±4.0kg/m2), duration of diabetes (2.8±5.2 vs 2.2±4.3yr) and fasting C-peptide concentrations (0.62±0.30 vs 0.69±0.32 nmol/l). In contrast, GADab[+] IDDM had significantly younger age-onset (18.1±11.5yr), lower body mass index (18.1±3.3 kg/m2) and fasting C-peptide concentrations (0.20±0.1nmol/l) compared to both the GADab[+] and GADab[-] NIDDM patients.Six of 27 (22.2%) GADab[+] NIDDM patients required insulin treatment for glycaemic control compared to 26 of 141 (18.4%) GAD[-] NIDDM patients (p=NS). In conclusion, 16%of our Chinese NIDDM patients had presence of GADab compared to 1.7% reported in Koreans and 8.3% in Thais.The presence of GADab in Chinese NIDDM patients did not distinguish a sub-group who may have latent or slow-onset IDDM.

776

SICK GENES, SICK INDIVIDUALS OR SICK POPULATIONS WITH CHRONIC DISEASE? AN INTERNATIONAL EXAMPLE FROM STUDYING DIABETES.

J.K. Cruickshank[1], JC. Mbanya[2], R. Wilks[3], T. Forrester[3], B. Balkau[4]; Univs of: [2]Yaounde, Cameroon; [3]West Indies, Jamaica; [1]Manchester, UK; [4]Inserm U21, Paris

Intensive searches for genes predisposing to or "causing" chronic disease are based on a premise that familial patterns indicate gene-based inheritance. Rose's alternative, less popular with clinical scientists thinking in individuals only, is that populations give rise to their deviations and extreme values who become patients. NIDDM is an example where population-based twin registers (e.g. Denmark) show little mono-dizygotic difference, suggesting major hospital ascertainment bias in ascribing a genetic basis. Here, we examined geographically dispersed populations of West African origin of similar genetic background to test how much environmental exposures can contribute to diabetes prevalence. Careful representative samples (n=400 per site, 200 men) aged 25-74 years were drawn from local population registers at rural and urban sites in Cameroon, Jamaica and among African-Caribbean (AfC) migrants to Manchester, UK who are mainly of Jamaican birth. Standardised methods, including cross-site training, were used to ascertain blood pressure (BP) and diabetes status by 2 hour GTT, on WHO criteria. Nutritional intakes were also characterized in each site. World age-adjusted NIDDM prevalence rose considerably within Cameroon, rural (0.8%, 95% CI 0.1-3%) to urban (2, 0.4-5 %) despite younger urban mean age, was higher again in Jamaica (7.4, 4-12 %) where male body mass indices (BMI) were lower than in Yaounde perhaps related to recent economic difficulties. Results were highest in Manchester (11.2, 8-19,%) where physical activity rates were minimal. Across-site population attributable risk for known diabetes from obesity (>25kg/m^2) ranged from 20-40%. Hypertension rates also rose sharply across site (6% rural Cam.-28%,UK), closely related to BMI. Occurring on closely similar genetic backgrounds within Cameroon and between Jamaica and Manchester suggests factors affecting energy balance (intake versus expenditure) rather than gene differences determine diabetes and hypertension rates in these and likely in most populations.

777

IS INSULINOPENIA IN AFRICAN NIDDM IMPORTANT?

W J Kalk. University of the Witwatersrand, Johannesburg, South Africa.

To test the hypothesis that severe hyperglycaemia at presentation in Africans with NIDDM (**A**) is a consequence of insulinopenia, associations with plasma glucose at diagnosis were sought in 127 **A** and 74 caucasian patients (**C**) with similar BMI (±30 kg/m^2). **A** had higher glucose (**A** 18.2, IQR 13-32 mmol/l; **C** 15.0, 12-19 mmol/l, p<0.001); were more often ketonuric (**A** 35.2%; **C** 14.3%, p<0.001), acidotic (**A** 16.5%; **C** 8.5%, p=0.015), and significantly infected (**A** 29.1%; **C** 13.5%, p=0.01). Ischaemic heart disease was present in 15% of **C**, but was absent in **A**. Regression analysis showed independent associations with glucose in **A** only - with infections, p=0.003, and with BMI (neg) p=0.02). After stabilization C-peptide was 1.9 ng/ml in **A**,. vs 4.0 ng/ml in **C** (p<0.001), and was associated with BMI in both **A** (glucose 10.2 mmol/l) and **C** (glucose 10.2 mmol/l). In a parallel study, C-peptide was significantly (p<0.05) lower in **A** vs **C** in each quartile of BMI. *Conclusions*: at diagnosis of NIDDM in **A**, severe hyper-glycaemia 1) is more frequent in **C**; 2) is associated with infections and weight loss; 3) is not associated with C-peptide levels. Insulinopenia does not cause severe hyperglycaemia in **A**, who are more insulin sensitive than **C**.

778

Sequential changes in serum insulin concentration during development of non-insulin dependent diabetes in Japanese

Suzuki,S.,Chino,T.,Tsumagari,K.,Shimizu,T.,Inoue,M.,Ishihara,H. Sato,T.,Makino,H.,Gomi,Y.,Hisaoka,T.,Yoshimoto,M. and Inoue,T. Showa University Fujigaoka Hospital,Yokohama,Japan

Changes in serum insulin concentrations during deterioration of glucose tolerance were studied in 38 male Japanese workers serving in a Japanese company who changed from IGT to NIDDM according to WHO criteria. When they had IGT, they were followed at 0.5 to 1 year intervals and had an OGTT, in which venous plasma glucose and serum insulin concentration were measured after an overnight fast and 1 and 2h after ingestion of a 75 g glucose. In 23 subjects(48.0±6.5years and body mass index,BMI 23.8±2.4,means±SD) fasting and glucose-stimulated insulin concentrations decreased progressly with increased glycaemia until glucose concentrations reached the range that defines IGT. Progression from IGT to NIDDMM was associated a further decrease in fasting insulin concentrations and insulin response. On the other hand,in 8 subjects(46.9±6.4 years and BMI 28.1±3.6) the onset of IGT or NIDDM was associated with an increase in fasting and glucose-stimulated insulin concentrations. In 7 subjects(50.4±3.2 years and BMI 24.1±1.7) the onset of IGT was associated with high insulin concentrations, but progression from IGT to NIDDM was associated with a decline of insulin concentrations. In Japanese NIDDM, there is heterogeneity in the patogenesis of NIDDM. Some people destined to develop diabetes have primary defect in β-cell function, some people have primary defect in insulin sensitivity and others have diabetes because of both diminished insulin sensitivity and impaired β-cell function.

779

GLUCOSE TOLERANCE AND OTHER METABOLIC PARAMETERS IN SIBLINGS OF NIDDM PATIENTS (PRELIMINARY RESULTS)

E. Chala, P. Tsapogas, D. Perrea, V. Alevizou, E. Kitsou and N. Katsilambros 1st Dept. Propaedeutic Medicine, Athens' University Medical School, Athens, Greece.

Aim of the study was to investigate in which extent relatives of NIDDM patients present an impaired metabolic profile. 17 siblings of NIDDM patients and 16 controls, matched for sex, age and BMI, underwent oGTT (WHO criteria). Lipids and uric acid (UA) were also measured. Male siblings, as compared to controls, had higher concentrations of UA (303.35±27.58 vs. 249.82±21.44μmol/l, p=0.029). No significant differences were noted in triglycerides, total-, HDL-, LDL-cholesterol, apoA1 and apoB. Female relatives had higher waist-to-hip ratio (W/HR) and fasting c-peptide levels than respective controls (0.88±0.075 vs. 0.79±0.085, p=0.018 and 2.51±0.96 vs. 1.45±0.45ng/ml, p=0.008 respectively). Areas under glucose curves (AUGC) were significantly higher in siblings (1208.48±213.59vs. 988.82±174.86 mmol/l/120min, p=0.003). In addition, 13 out of 17 siblings but only 2 out of 16 controls had impaired glucose tolerance (IGT), (Chi-square=13.60, p=0.0002, RR=6.12). Relation between BMI and AUGC was significant in siblings (r=0.72, p=0.003) but not in controls (r=0.18, p=0.512). In addition c-peptide was positively related to age in controls (r=0.59, p=0.031) and negatively in siblings (r= -0.68, p=0.007).This was confirmed by subsequent multiple regression analysis (independent variables: age, BMI, WHR). **Conclusions:** Siblings, compared to controls, present a) higher frequency of IGT, b) greater AUGC values, c) higher UA(males), d) higher fasting c-peptide levels (females), e) similar lipid levels. Furthermore, there was a positive relationship between c-peptide and age in controls and a negative one in siblings.

780

RISK FACTORS OF NON-INSULIN DEPENDENT DIABETES MELLITUS, IMPAIRED GLUCOSE INTOLERANCE AND HYPERTRIGLYCERIDEMIA IN CHINESE

Jia Weiping,Xiang Kunsan,Din Wei,Lu Junxi,Tang Junlin and Li Jie Shanghai Sixth People Hospital, Shanghai, P.R.China

In order to ascertain whether visceral obesity is a risk factor for non-insulin dependent diabetes mellitus (NIDDM), impaired glucose intolerance (IGT) and hypertriglyceridemia in Chinese, regional adipose tissue distribution was measured by magnetic resonance imaging (MRI) in 44 patients with NIDDM, 28 with IGT, 18 with hypertriglyceridemia and 79 healthy controls.All were male with age from 40 to 70 years old.The influences of insulin-glucose homeostasis indices, body mass index (BMI), blood pressure, serum lipids and regional adipose tissue distribution indices on NIDDM, IGT and hyperglyceridemia were analyzed by logistic regression method.Results: 1.Fasting plasma insulin (P=0.0004), ratio of insulin to glucose at 30' after 75g oral glucose load(P=0.0183), fasting insulin resistance index (FIRI=fasting glucose×fasting insulin/25) (P=0.0000), molar ratio of C-peptide to insulin area under curve after glucose challenge (P=0.042), serum triglyceride (P=0.0139) and systolic blood pressure (P=0.0176) were independent variables for NIDDM. 2.C-peptide at 2h after glucose challenge (P=0.0536), FIRI (P=0.0001), molar ratio of C-peptide to insulin in fasting state (P=0.0815), systolic blood pressure (P=0.0776), BMI (P=0.0011) and visceral adipose tissue area (P=0.09) were risk factors for IGT. 3.Visceral adipose tissue area (P=0.0145) and molar ratio of C-peptide to insulin in fasting state (P=0.0575) were independent variables for hypertriglyceridemia. Our study suggested that in Chinese insulin resistance,abnormalities of insulin secretion and insulin clearance were also the common characteristics of NIDDM and IGT, while visceral adipose tissue accumulation was an important risk factor for IGT and hypertriglyceridemia.

781

ARE NUTRITIONAL FACTORS INVOLVED IN THE INCREASED PREVALENCE OF NIDDM IN JAPANESE MIGRANTS IN BRAZIL?

MB Costa, LJ Franco, M Iunes, SGA Gimeno, Chain R, SRG Ferreira and JBDSG. Federal University of Sao Paulo, Sao Paulo, Brazil.

Genetic and environmental factors may be involved on the genesis of NIDDM. We confirmed the increased prevalence of glucose intolerance in a Japanese community aged 40-79 yrs living in Brazil, using OGTT and WHO criteria. The present study aimed to evaluate the association of nutritional aspects with glucose intolerance in this population. Nutritional questionnaires (food frequency data from the 2 months) were obtained from 506 subjects and computed by specific software. 335 subjects were normals, 88 impaired glucose tolerants (IGT) and 83 were diabetics, being 51 previously and 32 newly diagnosed (ND). Nutrients intake and clinical parameters of ND and IGT subjects (intolerant group) were compared with the normals. Intolerant group showed higher BMI, waist/hip ratio, plasma cholesterol and triglyceride and higher frequency of obesity, hypertension and dyslipidemia (p<0 05). Normal and intolerant groups, respectively, did not differ concerning total energy intake (EI) (medians: 2802 and 2779 Kcal), percentages of energy derived from fat (FI) (31.9 and 31.6%), protein (14.2% for both) and carbohydrate (53.5 and 53.2%), polyunsaturated / saturated ratio (P/S) (0.53 and 0.51) and had similar acculturation scores. Intolerant group tended to have lower level of physical activity. Considering adjustments for sex, age, generation, EI, FI, P/S, hypertension, waist/hip, physical activity and acculturation, logistic regression showed that only hypertension and waist/hip remained associated with glucose intolerance and reinforce a lack of association with FI. This methodology did not differentiate the groups by food intake patterns, which could be in part due to the sample size. On the other hand, our data could be reflecting the importance of genetic factors for NIDDM, expressed by a western type diet.

782

THE PRELIMINARY EPIDEMIOLOGIC STUDY OF RISK FACTORS IN 50 CHINESE NIDDM FAMILIES

Wang Hua, Mu Lijun, Chen Jiawei Yu Hao and Zhang Zhengxian. First Affiliated Hospital of Nanjing Medical University, Nanjing, P.R.China

Diabetes has become a major public health problem for people of any age and in any country in the world. In order to estimate the environmental factors for NIDDM patients, investigation was carried out in 50 Chinese NIDDM families. There are at least two sips with NIDDM in every family. The other members of the family were divided into normal or IGT (impaired glucose tolerance) group according to the test of OGTT. Comparison of the means was done by X test using SPSS package. The results showed that ages, BMI, w/t rates and blood pressure in NIDDM patients (119 cases) have significant difference compared with those of the normal group (131 cases). We also found 41 IGT patient in those families. It is suggested that the development of NIDDM was closed associated with ages, obesity and hypertension. Further studies are proceeding, especially in screening of the candidate genes in these families.

783

EVIDENCE OF ACCULTURATION IN FIRST AND SECOND-GENERATION JAPANESE AND JAPANESE-BRAZILIANS: ASSOCIATION WITH NIDDM?

Iunes M, Kikuchi M, Wakisaka K, Ferreira SRG, Franco LJ, Iochida LC and JBDSG. Federal University of São Paulo, SP, Brazil.

Japanese migrants are more susceptible to NIDDM, that may occur in response to environmental factors, many of which reflect acculturation. We have reported increased prevalence of NIDDM in Japanese-Brazilians especially in the second-generation (IIG). The present study evaluate the acculturation process from the first (IG) to the IIG and a possible association with NIDDM. The sample comprised 238 IG and 292 IIG subjects; male/female ratios were 1.14 and 0.87, and mean ages were 66±9 years and 53±8 years, respectively. Diagnosis of NIDDM was based on oral GTT using WHO criteria. An acculturation score (0 or 1 or 2) was attributed to each subject based on a sociodemographic questionnaire, using a sociometric scale. Score 2 corresponded to those who considerably changed to western lifestyle. Higher number of subjects with score 0 was seen in the IG when compared to IIG (47% vs 26%) and higher frequency of score 2 in the IIG (20% vs 42%) ($p<0.0001$). Dividing in three groups (normals: n=349; impaired glucose intolerants (IGT): n=90 and diabetics: n=91), the same pattern of acculturation score was observed for each single group and no association with their glucose tolerance state. We conclude that our methodology was able to demonstrate the higher degree of acculturation in the IIG Japanese-Brazilians, but not to differentiate the 3 groups according to the acculturation scores. However, our results could be pointing to the importance of genetic factors, whose expression was manifested when a high risk population is exposed to an unfavorable environment.

784

BODY MASS INDEX, WAIST TO HIP RATIO AND OTHER RISK FACTORS FOR DIABETES IN CHONGQING, CHINA

Longjian LIU[1,3], Weikai SHI[2] and Xiaoyan YIN[2]. [1]Dept of Epidemiology of Chongqing University of Medical Sciences. [2]Dept of Internal Medicine of Chongqing Yangtze Navigation Hospital; Chongqing, China. [3]Dept of Community Medicine of The University of Hong Kong

Objectives: To investigate the prevalence of diabetes mellitus (DM) and its risk factors in Chinese people. **Methods**: A cross-sectional survey was conducted in 1996 in Chongqing people, aged ≥35 years old. DM was diagnosed based on 2-hour plasma glucose ≥11.1 mmol/L or DM patients on treatment. Age-adjusted mean was used in statistic test. **Results**: (1) A total of 489 subjects was randomly selected (241 in men and 248 in women). Mean (SD) age was 49 (10.3) in men and 48 (9.6) in women. (2) Prevalence of DM was 12.5% in men and 9.7% in women. (3) Age-adjusted mean (SE) for significant factors between subjects with and without DM is shows in Table 1.

Table 1 Age-adjusted mean (SE) in subjects with and without diabetes by sex

	Non-Diabetes	Diabetes	P
Males			
Body mass index (BMI)	23.98 (0.23)	26.29 (0.63)	<0.001
Waist to hip ratio (WHR)	0.88 (0.01)	0.93 (0.01)	<0.001
HDL-cholesterol (HDL)	1.20 (0.02)	0.97 (0.06)	<0.001
Triglyceride (TG)	1.40 (0.07)	2.08 (0.19)	<0.001
Females			
Waist to hip ratio (WHR)	0.81 (0.004)	0.85 (0.01)	<0.001
Systolic BP (SBP)	118.32 (1.19)	132.17 (3.73)	<0.001
Diastolic BP (DBP)	74.63 (0.71)	79.51 (2.23)	<0.05
HDL-cholesterol (HDL)	1.39 (0.02)	1.19 (0.07)	<0.01
Triglyceride (TG)	1.05 (0.04)	1.79 (0.13)	<0.01

Conclusion: The findings suggest that increased WHR, TG and decreased HDL are associated with risk of DM in both sexes. BMI in men and blood pressure in women are associated with risk of DM, respectively.

785

WESTERNIZED LIFESTYLE INCREASING INSULIN RESISTANCE DURING DEVELOPMENT OF NIDDM IN JAPANESE SUBJECTS.

G. Egusa, H. Hara, M. Okubo and M. Yamakido
Hiroshima University School of Medicine, Hiroshima, Japan

Both insulin resistance (IR) and insufficient insulin secretion play an important role in the development of NIDDM. The present study investigates how more westernized lifestyle has influenced the association between IR and NIDDM in Japanese subjects. Japanese - American originally from Hiroshima who are now living in Los Angeles (JA, N = 1,020, age 61± 8 (SD) yrs) and Japanese currently residing in Hiroshima (JH, N = 962, age 59 ± 4 yrs) were surveyed between 1980 and 1993. Serum glucose (SG), insulin (IRI) and C - peptide (CPR) levels were measured before and after a 75-g glucose load. In the 1980 study, IRI and the SG ratio were measured over the first 30 min after the glucose load (Δ I / G30) as a marker of insulin secretion. Age•sex -adjusted prevalence of diabetes (WHO criteria) was significantly higher in JA than JH (13.4% vs. 6.2%, $p < 0.01$). Waist -hip ratio, as well as fasting (F)-IRI, F-CPR, ∑-IRI and ∑-CPR were significantly higher and F-CPR / F-IRI molar ratios were significantly lower in JA than JH when age, BMI and glucose tolerance state were adjusted ($p < 0.05$ - $p < 0.001$). IR (evaluated by homeostasis model assessment) associated with increasing 2hr-SG post glucose load was significantly higher in JA ($p < 0.01$ - $p < 0.001$). The highest incidence of diabetes during the 6 ± 3 yr follow-up period was observed in the low Δ I / G30 (≤ 0.5) and high F-IRI (≥ 9 μU/ml, a marker of IR) group (36.4 per 1,000 person / year) followed by the low Δ I / G30 and low F-IRI group (16.1 per 1,000 person / year) . Thus, the hyperinsulinemia observed in JA appears to be associated with higher CPR levels, suggesting the presence of IR and compensatory excretion of insulin. Central obesity may also play an important role in IR in JA. The present results also suggest that increased IR associated with a westernized lifestyle in subjects with decreased insulin secretion play an important role in the development of diabetes in Japanese subjects. Thus, an increased westernized lifestyle appears to greatly impact the development of NIDDM through an increase in IR in Japanese subjects.

786

HYPERINSULINAEMIA AND DIABETES:
A FAMILY STUDY OF NIDDM IN NEW ZEALAND MAORI

A Daniels,M.White, C. Kyle. And J. Wong. Diabetic Clinic, Dept of Medicine, Middlemore Hospital, Auckland, N.Z.

Aim: We investigated a diabetes prone Maori family with a history of early onset diabetes to determine the prevalence of hyperinsulinaemia, niddm, and igt.
Methods: A multigenerational family was enrolled for this cross-sectional study All but one of the subjects studied had a physical examination and an oral GTT with total insulin) levels at time 0 (fasting), 30,60 and 120 minutes.
Results: 64 studied. Raised fi (fi>13μu/ml=2 SD above normal mean) was present in 34/64. 7/33 with raised fi had abnormal glucose tolerance(agt) and 5/31 of normal insulin grp. Generation 1(n=9):4 nidds, 2 igt, 3 normal oggt (ngt). Three nidds, 2 igt were newly diagnosed. Generation 2(n=31):3 nidds, 2 igt, 26 ngt. Two nidds and both igt were new. Prevalence of abnormal glucose tolerance varied from 16% (gen 2) to 67% (gen 1).Generation 3(n=26):26-ngt. Of 52 ngt: 26 (grp1) had raised fi and 26 normal fi (grp 2 controls). Relative risk for diabetes in grp 1 vs grp 2: 1.17(ci: 0.28 to 0.48). Factors associated with raised fi were: Grp 1: systolic bp (p<0 02,ci:0.1 to 0 9), Grp 2:bmi (p<0.03),age (p<0.03) and male gender. Oggt insulin levels at 30, 60 and 120 minutes but not fasting were reduced (p<0.01) in nidds and glucose levels were increased (p<0.0001) vs ngt. The area under the glucose and insulin curves were not different for grp 1 vs grp 2.
Conclusions: In this Maori pedigree,raised fi confers increased risk of diabetes and is inherited as autosomal dominant. Prevalence of agt increases by generation. Raised fi and systolic bp may be an early feature of a familial insulin resistance syndrome. Factors other than bmi, age, sex appear to determine the insulin resistance in a subgroup of this family with ngt. The high prevalence of undiagnosed diabetes suggests regular screening is required in these families.

787

MATERNAL AND PATERNAL DIABETES CONFER SIMILAR RISKS OF TYPE II DIABETES TO CHILDREN.

CF Weijnen, JH Warram, and AS Krolewski, Joslin Diabetes Center, Boston, USA.

The occurrence of Type II diabetes in siblings of 743 Type II patients (aged 42-86 years and diagnosed between ages 35-74) was ascertained by questionnaire and verified by interview. For 681 families (91.7%), the index case had knowledge of the diabetes status of both parents as well as siblings. Siblings with diabetes were reported by 222 (32.5%) index cases, giving a study group of 362 cases among 1816 siblings (20%). Life table estimates of cumulative incidence of diabetes by age 70 years in siblings (excluding index cases) was used as the measure of lifetime risk of Type II diabetes according to parental diabetes status. For 44.5 % of the families, neither parent was affected, and for 8.7% both were. For the remaining 46.8%, only one was affected; mothers accounting for 30.2% and fathers for only 16.6%. The risk of Type II diabetes among siblings was significantly higher if both parents rather than one was affected (43±5 vs. 27±2, p=0.003), and significantly lower if none rather than one was affected (16±2 vs. 27±2, p=0.0002). If one parent was affected, the parent-specific risks were:
Diabetic Father only, 23±4, vs. Diabetic Mother only, 28±2; p=0.29.
The risk was similar regardless of which parent was affected . It is an error, therefore, to interpret the prevalences of maternal vs. paternal diabetes in cross sectional studies as a measure of probabilities of transmitting diabetes. Most likely, the difference is due to more complete ascertainment of maternal than paternal status.

788

MASS SCREENING FOR NON INSULIN DEPENDENT DIABETES MELLITUS [NIDDM] AND RISK FACTORS IN THE COMMUNITY

F.Hemraj,N.Joonas,N.Gopaul,S.Hunma and C.Teeluck.
Biochemistry, Central Laboratory Candos,Mauritius.

A mass screening programme was carried out at community level to explore the relationship between NIDDM and various risk factors.A previous national survey in the Island of Mauritius had revealed a high prevalence of NIDDM (12.8%) in the adult population aged 25 and over.Adults residing in the catchment area of sixteen area health centres throughout the island were selected for the present study.Methodology included measurement of blood pressure,body mass index,and determination of fasting plasma glucose and lipids.Of the 3929 adults screened ,57% were female,43% were males and 51% were aged between 30-50.NIDDM occurred in 8% of the screenees.30% of the subjects were overweight and 13 % obese.High blood pressure was common (16%). Significant hypertriglyceridemia(25%) and hypercholesterolemia(11%) were also found. Logistic regression analysis gave an estimated risk of each factor with an NIDDM as follows:Dependence of NIDDM on age was highly significant (chi-square 128.84, p< 0.0001);no significant difference in probability of NIDDM between sexes (chi-square=0.5);weight status was significant (chi-square =19.83,p<0.001);high blood pressure was found to be significant but less so than other factors (chi-sq= 6.12,p=0.01);a strong association was found with the triglyceride level (chi-sq= 39.44, p< 0.001).The study showed that "mass screening" programme in a community with a high prevalence rate of NIDDM can provide a simple means to investigate relationship of the disease with various risk factors.

789

RISK FACTORS FOR DIABETES IN CHINESE PEOPLE

Xiao-Yan Yin. Department of Internal Medicine of Chongqing Yangtze Navigation Hospital; Chongqing, 630041, China.

Objectives: To investigate the risk factors for non-insulin-dependent diabetes mellitus (NIDDM) in Chinese people. **Methods**: A total of 48 NIDDM patients were newly diagnosed (27 in male and 21 in female). Controls (N=102) were randomly selected from healthy people and matched to cases based on the date, age at diagnosis and sex. **Results**: Mean body mass index (BMI), systolic and diastolic blood pressure and triglyceride were higher and high density lipoprotein (HDL) was lower in male cases than that in controls (P<0.05). In females, mean triglyceride was higher and HDL was lower in cases than that in controls (P<0.05). After adjustment for a wide range of covariates, multiple logistic regression analysis indicated that: (1) In males, BMI and triglyceride were independently associated with a high risk of NIDDM. (2) In females, only triglyceride showed to be an independent risk factor for NIDDM. (3) Significant interaction effects between triglyceride and total cholesterol (TC) on the risk of NIDDM were observed in both sexes. Table 1.

Table 1 Multiple logistic regression model for risk factors of NIDDM

	B (SE)	OR	OR 95%CI
Males			
Body mass index	0.31 (0.09)	1.36	1.14 - 1.63
Triglyceride	0.79 (0.28)	2.64	1.27 - 3.81
Triglyceride*TC	1.46 (0.66)	4.31	1.18 - 15.69
Females			
Triglyceride	1.38 (0.41)	3.96	1.78 - 8.89
Triglyceride*TC	1.69 (0.26)	5.43	3.26 - 9.02

Conclusion: The study suggests that BMI and triglyceride in men; and triglyceride in women are independent risk factors for NIDDM. The interaction effects between triglyceride and total cholesterol are associated with high risk of NIDDM in both sexes.

790

SCREENING FOR NIDDM IN SUBJECTS WITH FASTING PLASMA GLUCOSE OF 110-139 MG/DL

J.M. González-Clemente, G. Galdón, J. Ortiz, *J.I. Conget, *A. Costa and **M.P. Delgado. CAP Les Corts. *Endocrinology Unit. **Biochemistry Laboratory. C. Sanitària Clínic. Barcelona. Spain.

Subjects with fasting plasma glucose (FPG) of 110-139 mg/dl (SFPG) have a high prevalence of IGT and NIDDM. Screening requires oral glucose tolerance tests (OGTTs) which are time-consuming. To reduce OGTT number, tests may be performed mainly in high risk SFPG identified by other criteria. **Aim:** To find factors associated with NIDDM in SFPG. **Methods:** In 1995-96 SFPG were identified in a primary care unit of an urban area (15,000 people). NIDDM family history, physical activity, age, sex, BMI, blood pressure, ischaemic heart disease, ß blocker or thiazide treatment, FPG, lipid profile and HbA1c were recorded. All subjects underwent an OGTT not later than 3 months after FPG determination (WHO criteria). **Results:** 334 SFPG (63.4±0.7 yr, 53.0 % females) were evaluated and formed three groups: 139 (41.46%) had normal OGTT, 102 (30.5 %) IGT and 93 (27.8 %) NIDDM. NIDDM subjects were ($p<0.05$) older (59.6±1.2, 63.7±1.2, 68.5±1.2 yr, respectively), had hypertension (40.6, 43.1, 62.4 %) and were on ß blocker treatment (5.0, 4.9, 15.1 %) more frequently. They also had ($p<0.05$) higher FPG (117.9±0.5, 121.1±0.8, 125.5±0.9 mg/dl), HbA1c (5.2±0.1, 5.3±0.1, 5.8±0.1 %) and tryglicerides (128.0±6.3, 144.7±6.4, 162.1±8.9 mg/dl) and lower HDL (54.9±1.4, 51.9±1.6, 47.9±1.4 mg/dl). In the logistic regression model the presence of NIDDM was associated positively with FPG, HbA1c and ß blocker treatment; when HbA1c was excluded from the model, age (positively) and HDL (negatively) were included. **Conclusions:** NIDDM was positively associated with FPG, HBA1c, ß blocker treatment and age, and negatively with HDL.

791

FASTING PLASMA TOTAL AMYLIN CONCENTRATION PREDICTS DETERIORATION IN GLUCOSE TOLERANCE OVER 4.5 YEARS.

D.E.M. Williams[1], N.J. Wareham[1], M.S. Fineman[3], J.E. Koda[3], S.G. Anderson[1], N.E. Day[1] and C.N. Hales[2]. Departments of Community Medicine[1] and Clinical Biochemistry[2], University of Cambridge, Cambridge, UK and Amylin Pharmaceutical Inc.[3], San Diego, USA.

A strong cross-sectional association between fasting total plasma amylin concentration and glucose tolerance has been demonstrated. This prospective study was undertaken to examine whether baseline fasting total plasma amylin concentration predicts deterioration in glucose tolerance over 4.5 years. 723 volunteers who had a non-diabetic oral glucose tolerance test (OGTT) in 1990-92, were followed up at 4.5 years and their OGTT repeated. Fasting plasma amylin was measured at baseline by an assay which assessed both glycosylated and non-glycosylated amylin species.

Geometric mean fasting total amylin (and 95% confidence interval) (pmol/l) by baseline and follow-WHO category.

	Follow-WHO category		
Baseline WHO Category	Normal	IGT	NIDDM
IGT (n=129)	4.21 (3.36-5.28)	6.28 (4.68-8.41)	7.68 (5.33-11.03)
Normal (n = 594)	4.12 (3.81-4.45)	4.52 (3.27-6.24)	6.91 (4.78-9.97)

ANOVA of fasting total plasma amylin by follow-up WHO category (adjusting for baseline WHO category) was $F=4.04$, $p=0.02$. Subjects were grouped into quintiles by change in 120 min. plasma glucose, adjusted for regression to the mean. A significant association was found between baseline amylin and deterioration in glucose tolerance (odds ratio per quintile of fasting total plasma amylin concentration 1.16, 95% CI = 1.02-1.34). We conclude that baseline amylin concentration predicts change in glucose tolerance over 4.5 years. Whether this association reflects a causal relationship remains to be determined.

792

IS IMPAIRED GLUCOSE TOLERANCE A RISK FACTOR FOR DEVELOPING TYPE II DIABETES MELLITUS?

S.L.Xue, J.S.Ding and W.Wu. Lanzhou Medical College, Lanzhou, China.

53 subjects of impaired glucose tolerance (IGT) and 43 of type II diabetes mellitus (NIDDM), over 40 years of age, were detected by stratified sampling of 1800 of adult population, diagnosed by WHO's criterious with standard 75g. –OGTT, in an epidemiological surveying in Jiu–Quan County, China. Statistical evaluation of blood pressure (B.P.), waist–hip ratio (WHR) and body mass index (BMI) of the IGT in compare with the NIDDM and 63 normals by multiple linear regression analysis studied in this paper to identify whether IGT is a risk factor for developing NIDDM. The results showed: 1)There were linear relationships in the regression analysis in the inspected subjects with the 3 factors (B.P., WHR, BMI). The variance analysis $F=12.03$, $P<0.01$. 2) The standardized regression coefficiency of the WHR was the largest (0.2709) which suggested that WHR was the most important factor of the three. 3) By t test: the WHR in IGT ($\bar{X}=0.91\pm 0.07$SD) and NIDDM (0.91 ± 0.07) were significantly larger than that of the normal (0.85 ± 0.07), $P<0.01$, but no differance between IGT and NIDDM, $P>0.05$. 4) There were no significant differences of BMI in between IGT, NIDDM and normal group (24.67 ± 4.04, 24.49 ± 3.16, 23.19 ± 3.12, respectively). In conclusion: IGT is a risk factor for developing NIDDM, and WHR is a critical risk factor for NIDDM rather than BMI.

793

INSULIN RESISTANCE AND SECRETION INDEPENDENTLY PREDICT 4.5 YEAR DETERIORATION IN GLUCOSE TOLERANCE.

N.J.Wareham[1], C.D.Byrne[2], D.E.M.Williams[1], N.E.Day[1] and C.N.Hales[2]. Departments of Community Medicine[1] and Clinical Biochemistry[2], University of Cambridge, Cambridge, UK.

To study the relative roles of insulin resistance and insulin secretion in the pathogenesis of glucose intolerance, a population-based cohort of 1071 caucasian subjects who had a non-diabetic oral glucose tolerance test in 1990-92 were traced and invited to attend for a repeat test 4.5 years later. 937 volunteers attended for rescreening. The crude incidence of diabetes in this population was 6.3 per 1000 person years of follow up. The probability of changing between WHO categories is a function of baseline glucose tolerance, regression to the mean and true change. To separate these effects, we analysed the 2 hour plasma glucose as a continuous variable after adjusting for regression to the mean. Subjects were grouped into quintiles for regression to the mean adjusted change in the 2 hour plasma glucose. Subjects in the top quintile were compared with those in the middle 3 quintiles by logistic regression. The probability of deterioration was independently associated with increasing baseline age, body mass index and 2 hour plasma glucose and change in body mass index from baseline to follow up. The probability of deterioration in glucose tolerance, adjusting for these factors, was independently associated with increasing baseline fasting insulin (Odds Ratio per log unit 2.08, $p<0.0001$), a measure of insulin resistance, and with a lower 30 minute insulin incremental response (Odds Ratio 0.54, $p<0.0001$), a measure of insulin secretion. We conclude that measures of insulin resistance and insulin secretion independently predict deterioration in glucose tolerance over 4.5 years.

794

THE IMPACT OF MENOPAUSE AND AGING ON THE DEVELOPMENT OF GLUCOSE INTOLERANCE IN PERIMENOPAUSAL WOMEN

S. T. Tsai, S. I. Wu and P. Chou. Veterans General Hospital-Taipei and Institute of Public Health, National Yang-Ming University, Taipei, Taiwan, ROC

There is a sharp rise of prevalence of diabetes mellitus and impaired glucose tolerance in women aged 45-55. To investigate the possible impact of menopause and aging on the development of glucose intolerance in perimenopausal women, a community-based epidemiologic study was conducted in Kinmen. 1100 adults (56.7% postmenopausal) were screened by single fasting plasma glucose (FPG) followed by an OGTT undertaken in subjects with FPG ≥5.5 and <7.8mM. According to the WHO criteria, the overall prevalences of DM and IGT are 7.2% and 5.8% in the age group of 45-49 (n=584) and 9.9% and 4.8% in the age group of 50-54 (n=516), respectively. With multivariate analysis, in women aged 45-49, hypertension (SBP≥160mmHg and/or DBP≥95mmHg) is significantly associated with the diagnosis of IGT (vs normal glucose tolerance, odds ratio=2.83) while hypertriglyceridemia (≥2.3mM, OR=11.59), family history of diabetes (OR=11.02) and menopause (OR=2.61) are associated with the development of diabetes mellitus. On the contrary, in women aged 50-54, family history (OR=8.67), hypertriglyceridemia (OR=5.53) and regional adiposity (waist-hip ratio ≥0.89, OR=2.36) are identified as risk factors for diabetes. It is concluded that relatively early menopause is an independent risk factor for diabetes in women less than 50 years of age.

795

THE CHARACTERISTICS OF DIABETES IN THE INITIAL STAGE: CAN WE PREDICT THE EARLY GLYCEMIC STATUS FOLLOWING DETECTION?

M. A. Sayeed, M. G. Kibriya, P. A. Khanam and A. K. Azad Khan.
BIRDEM, Dhaka, Bangladesh

To determine the association of glycemia with the increasing age and obesity of newly detected non-insulin-diabetes mellitus (NIDDM) and to quantify the predictors of the risk variables for glycemic status in the initial stage we investigated 107,743 (men 71,512, women 36,231) subjects of age ≥30yr. According to WHO diagnostic criteria (1980), oral glucose tolerance test (OGTT) was done in these subjects during registration. The mean (SD) values for age (yr), blood glucose (mmol/l)), fasting (FBG) and 2h after glucose (2-hBG) of men were comparable to that of women 48.7 (10.8) vs 47.7 (10.7), 11.3 (4.7) vs 11.4 (4.5) and 18.6 (6.4) vs 18.8 (4.0), respectively. Although the men had significantly higher height (Ht, $p<0.0001$) and weight (Wt, $p<0.001$) than women the mean BMI (body mass index = kg/m sq) was significantly lower in men than women (22.4 (3.6) vs 24.4 (4.4), $p<0.001$). Glycemia was significantly associated with increasing age but only in women (FBG, <50 vs ≥50y: X^2 ,123 $p<0.0001$). Both FBG and 2-hBG showed significant negative correlation with Wt, Ht, BMI, systolic (SBP) and diastolic (DBP) blood pressure (for each variable, $p <0.001$) in either sex. These observations were further analyzed by stepwise multiple regression model which estimated these variables for the predictive values of 2-hBG and FBG as dependent variables. In men, the predictive value for log-2-hBG (mmol/l) was 57.5 + 0.090(wt, kg) + 0.026(DBP, mmHg) - 0.027(age, yr) - 0.680(BMI) - 0.038(SBP, mmHg) - 0.153(ht, cm) [Adjusted R sq = 0.09, F 1156, $p<0.0001$]. Similar observations were also noted in women. When FBG was taken as a dependent variable the results were almost the same. Regardless of sex the significant inverse relationship of glycemia with Ht, BMI and SBP may be attributed to the detection of diabetes in a very advanced stage with moderate to a very high blood glucose level in the study population. These findings suggest that the glycemic status in early stage of diabetes does not relate to obesity, particularly in developing communities, where the detection of diabetes are too late when hyperglycemia is not infrequently associated with low BMI.

796

EFFECT OF YEARLY FOLLOW-UP OF POTENTIAL DIABETICS

H.Platilova, K. Vondra and *L.Waldmannova. Institute of Endocrinology, *Diabetic Outpatient Center, Prague , Czech Republic.

In 1967, we began to follow-up the patients with "border diabetes", since 1981 only with IGT, founded with "case finding" of clinically silent diabetics in an area of Prague-West since 1961. They were as potential diabetics educated and yearly (until to onset of NIDDM) examined. In 1993, all these living 331 patients (group AB) were matched against 654 Type 2 diabetics (group C) living in the same area, in whom this diagnosis (DG) was established at their first examination. Group AB was devided into 2: subgroups: A = 142 (43%) of them, in whom this DG was already established and B = other 189 (57%) still as IGT followed-up. The main results: at inclusion, group AB was younger than C (56.6±14.4 and 60.9±10.9 yrs $p < 0.001$), had a lower BMI (29.4±5.7 and 30.4±5.0 kg/m^2 $p < 0.01$) and the same duration of follow-up: 7.9±7.4 yrs and 8.0±6.4yrs. Subgroup A was younger than subgroup B (53.8±13.9 and 58.7±14.4 yrs $p <0.01$), but had a higher BMI already in younger age (30.5±5.5 and 28.5±5.8 kg/m^2 $p < 0.01$) and longer duration of follow up: A 12.4±7.9 yrs = 6.0±5.7 before + 6.4±5.3 yrs after the DG of NIDDM, B only 4.6±4.8 yrs, $p < 0.001$. In 1993, subgroup B was already 2,4 yrs older (63.3±13.7 yrs $p < 0.05$) than group C at the DG of NIDDM, but still only with IGT. At DG. of NIDDM, age of subgroup A (59.8±12.1 yrs) and that of C did not differ. BMI of A was also the same as of C, but A reached this value of BMI already in younger age. In 1993, duration of treatment after the DG of NIDDM was in A shorter than in C ($p <0.01$). At this time, more patients of group A needed still only diet to good control (55.5% and 33.0% in C, $p < 0.001$) and less OAD (31.1% and 49.7% $p < 0.001$). No significance was found in need of insulin: 13.4% and 17.3%! A shorter time since the DG of NIDDM to indication of insulin (or insulin + OAD) in A: 5.6±3.3 yrs than in C group: 8.2±6.1 yrs ($p < 0.05$), could correspond with more of patients with the LADA Type in subgroup A.

797

DIABETIC PATIENTS ASSOCIATED WITH POSITIVE GAD-ANTIBODIES AND MITOCHONDRIAL DNA ABNORMALITY IN JAPAN

M.Kitatani, K.Yagi, A.Inazu, A.Nakagawa, K.Kajinami, J.Koizumi and H.Mabuchi. University of Kanazawa, Kanazawa, Japan.

Mitochondrial $tRNA^{Leu(UUR)}$ gene (mtDNA) mutation is one of important causes of diabetes in Japanese patients, and manifests a wide range of diabetic phenotype, from NIDDM to IDDM. Glutamic acid decarboxylase antibodies (GADab) is a useful screening test for IDDM. To study the frequency and the clinical characteristics in the diabetic patients associated with positive GADab and mtDNA mutation (A to G transition at nucleotide pair 3243), diabetic patients whose onset of the disease were under 50 years were examined. MtDNA was isolated from the peripheral leukocytes, and the mtDNA 3243 mutation was detected by Apa I digestion. GADab was measured by radioimmunoassay using Hoechst GAD kit. Four patients (3.3%) with mtDNA mutation and 10 (8.3%) GADab positive patients were found in 120 diabetic patients. There were no patients associated with both mtDNA mutation and positive GADab. The onset age and body mass index of 4 patients with mtDNA mutation were 29±6 years and 16.4±1.5 kg/m^2. The diabetic phenotype of 2 patients were clinically IDDM. The other 2 patients were NIDDM, but a patients started insulin injection at 11 years since onset of DM. Six of 10 patients with positive GADab showed IDDM phenotype and 3 patients had been considered to be NIDDM. The onset age in patients with positive GADab were 33±14 years, and 3 NIDDM patients were associated with obesity at the onset of DM. Eight of 10 patients were treated by insulin injection. In conclusion, mtDNA mutation and positive GADab account for 12% of early onset diabetes in Japan. The patients with mtDNA mutation are characterized by early onset diabetes with loss of body weight, and most of the patients with positive GADab show IDDM-like phenotype.

798

GLUCOSE TOLERANCE STATUS OF BLACK SUBJECTS WITH IMPAIRED GLUCOSE TOLERANCE AFTER 4 YEARS. WF Mollentze, JM Koning, G Joubert, GM Oosthuizen, M Steyn, TI Muller, DJV Weich. Departments of Internal Medicine, Biostatistics and Chemical Pathology, University of the Free State, Bloemfontein, South Africa.

At least in Europids IGT confers an increased risk of progression to diabetes and also to the development of coronary heart disease. The meaning and longterm implications of IGT in black populations are still unknown. The aims of the study were to determine the glucose tolerance status of a group of black subjects with IGT after 4 years. The addresses of one hundred and three blacks (72 females, 31 males) with IGT identified 4 years earlier in a survey to determine the prevalence of diabetes mellitus in the black community of Mangaung were revisited by a health care worker. Available subjects were requested to undergo another standard 75g oral glucose tolerance test. They were also once more subjected to the same research protocol as was previously followed. Death certificates of deceased subjects were obtained. Seventy eight subjects (54 females, 24 males) participated in the follow-up study. Of the remaining 24 subjects, 12 had died, 4 had left the area, 6 refused and 2 were to ill to participate. Of the 78 subjects with IGT 12 (15%, Group 1) became diabetic, 26 (33%, Group 2) remained in the IGT category and 40 (52%, Group 3) reverted back to normal glucose tolerance. Median two-hour plasma glucose levels of the respective groups were 13.76 mmol/l, 8.51 mmol/l and 6.66 mmol/l. Median fasting serum insulin levels were significantly lower after 4 years in all three groups. Median differences between present and previous fasting serum insulin levels were -7.7 uIU/ml for Group 1 (95% CI -23.9; -5), -4.7 uIU/ml for Group 2 (95% Ci - 10.6; -1.8) and -5.2 uIU/ml for Group 3 (95% CI -9; -4.5). IGT also confers an increased risk of diabetes in black subjects. No direct cause-and-effect relationship between IGT and death was evident. Irrespective of glucose tolerance status subjects became significantly more insulinopaenic as judged by fasting serum insulin levels.

799

Glucose tolerance in first degree relatives of NIDDM patients in a mediterranean area. Main determinants.

I.Conget, A.Costa, *R.Casamitjana and R.Gomis. Endocrinology and Diabetes Unit, *Hormonology Unit, Hospital Clínic. Universitat de Barcelona. Barcelona, Spain.

First degree relatives of NIDDM patients are at increased risk to developing the disease. Metabolic abnormalities have already been described in such a subjects. The aim of our study was to characterize the main determinants of glucose tolerance in subjects with family history of NIDDM. One hundred and ninety one first degree relatives (38.8±14,8 year-old, 61 % women / 39 % men) were included in the study. In all of them body mass index and blood pressure were evaluated. After 12-h fasting, an oral glucose tolerance test was performed , obtaining basal glucose and insulin (IRI) in order to calculate fasting insulin resistance index (FIRI), % B (HOMA insulin secretion) and % S (HOMA insulin sensitivity). In 32 % of subjects , an abnormal glucose tolerance was found: 22 % impaired glucose tolerance and 10 % NIDDM (WHO criteria). A stepwise regression analysis demostrated that 120' glucemia was independently related to basal glycemia, FIRI, % B and % S. When those variables calculated from IRI determination were excluded, basal glucose was the only main determinat of glucose tolerance. Conclusions: Abnormal glucose tolerance is a highly common finding in subjects with family history of NIDDM; fasting glycemia, as well as, insulin sensitivity and secretion capacity being the major determinants of it.

800

PROGRESSION OF IMPAIRED GLUCOSE TOLERANCE TO DIABETES MELLITUS IN NORTH-EASTERN PENINSULAR MALAYSIA

W.B. Wan Mohamad, A.M. Zaimah, M. Mafauzy, M. Musalmah, N. Mokhtar and B.E. Mustaffa. School of Medical Sciences, University Sains Malaysia, Kota Bharu, Malaysia.

Impaired glucose tolerance (IGT) is associated with an increased risk of atherosclerosis and of developing Non-Insulin Dependent Diabetes Mellitus (NIDDM). NIDDM has been found to occur in 10%-70% of patients with IGT followed for 14 years. In order to investigate the contributing factors and the conversion rate of IGT to NIDDM, we reexamined 79 IGT subjects diagnosed between 1991-1994 after interval of 20 months.
A total of 2284 subjects, aged more than 20 years old were chosen from 9 districts of the region by cluster sampling. 176(7.7%) patients were diagnosed to have NIDDM and 379 (16,6%) patients were IGT (using WHO criteria). Measurement of Body Mass Index (BMI), blood pressure (BP), oral glucose tolerance test (OGTT), lipid and lipoprotein levels were repeated.
After 20 months, 31(39.2%) of 79 subjects with IGT has normal glucose tolerance, 32(40.5%) maintained the IGT stage and 16(20.3%) persons developed to NIDDM. Fasting blood sugar (FBS) and BMI were positively correlated to the development of NIDDM ($p<0.007$ and $p<0.006$ respectively). However, other parameters such as age, 2h post-glucose challenge blood sugar, lipid, lipprotein levels and BP were not significantly correlated.
The result of the survey revealed a high prevalence of IGT in this region and 11.8% of these subjects developed NIDDM each year. BMI and FBS positively related to prognosis of IGT.

801

HERITABILITY ESTIMATES AND ETIOLOGICAL MODELS FOR NON-INSULIN-DEPENDENT DIABETES MELLITUS (NIDDM) AND ASSOCIATED METABOLIC PARAMETERS.

P. Poulsen, K. O. Kyvik, A. Vaag and H. Beck-Nielsen. Diabetes Research Center and Genetic Epidemiological Research Unit, Odense University Hospital, Odense, Denmark.

Non-insulin-dependent diabetes mellitus (NIDDM) is a heterogen disease with a multifactorial etiologi comprising genetical and environmental factors. Epidemiological and metabolic studies of twins and first degree relatives have indicated genetic components in the development of NIDDM. Among a population-based twin material (n=604 twins) we have estimated the heritability and best fitting models for NIDDM and indirect derivatives of glucose tolerance (0 min and 2 h OGTT plasma glucose), insulin secretion (30 min OGTT plasma insulin) and insulin resistance (0 min plasma insulin). The methodology permits models with additive genetic (A), dominance (D), shared environmental (C) or unique environmental (E) sources of variance to be fitted and the magnitude of each contributor to variance can be estimated.

Phenotype	Best model	Parameter estimates		
		a2	c2	e2
NIDDM	ACE	0.27	0.41	0.33
IGT+NIDDM	AE	0.61	-	0.39
F-glucose	AE	0.27	-	0.73
2h-glucose	AE	0.42	-	0.58
F-insulin	AE	0.53	-	0.47
30 min-insulin	AE	0.27	-	0.73

Concordance rates for NIDDM based on this population suggested a major importance of environmental factors in the etiology of NIDDM, which is supported by the estimated ACE model, in which additive genes only contribute 27% to the total variance, with 41% and 33% from common and unique environment, respectively. However, the model for IGT+NIDDM indicates a relatively greater genetical component in the etiology to abnormal glucose tolerance compared to NIDDM per se. The heritability estimates for the metabolic parameters suggest an importance of environmental factors for the phenotypes glucose (in)tolerance and insulin secretion, however for insulin resistance, the proportion of variance determined by genetic factors is greater, confirming the importance of a genetic component. In conclusion the results confirm the multifactorial etiology of NIDDM, but emphasizes the importance of environmental factors. "Susceptibility genes" for NIDDM appears to be found among genes coding for insulin resistance.

802

PREDICTORS OF IMPAIRED GLUCOSE TOLERANCE IN OFFSPRING OF PARENTS WITH CONJUGAL NIDDM.

T.Kasperska-Czyżyk, K.Jaskólska-Ładosz, K.Stępień and R.Nowaczyk.
Central Clinical Hospital, Warsaw, Poland

In the group of 56 adult normoglycaemic non-diabetic subjects, whose both parents had NIDDM, impaired glucose tolerance (World Health Organization criteria) occurred during the 5-year follow-up (1990-95) in 18 (group A), and in 38 the tolerance to glucose remained normal. At the initial examination (1990) the group A didn't differ from the group B in mean age, BMI, serum C-peptide area under curve (AUC) after oral glucose (75g), nor in fasting serum levels of triglycerides, total cholesterol, LDL-cholesterol, apolipoprotein B and A1. The former group was, however, characterized by higher glycaemia AUC [18.3±0.67 (SEM) vs 16.7±0.40 mmol · l^{-1} · h^{-1}, p=0.019] and higher serum insulin (IRI) AUC [1.18±0.10 vs 0.98±0.40 nmol · l^{-1} · h^{-1}, p=0.027], and by lower serum level of HDL-cholesterol [1.05±0.07 vs 1.28±0.06 mmol · l^{-1}, p=0.019]. The onset of impaired glucose tolerance (1995) was associated in this group with the increase in serum insulin (IRI) AUC [1.8±0.22 vs 1.18±0.10 nmol l^{-1} · h^{-1}, p=0.008) and the decrease in serum C-peptide AUC [9.43±0.57 vs 10.75±0.58, nmol · l^{-1} · h^{-1}, p=0.057], and with increase in serum apolipoprotein B [164±8.6 vs 105±6.1 mg/dl, p=0.000] and the decrease in serum apolipoprotein A1 [135±6.2 vs 150±6.5 mg/dl, p=0.04]. Conclusion: The slight elevation of blood glucose (within the normal range) and of serum insulin (IRI), and the decrease in serum HDL-cholesterol seem to be significant predictors of impaired glucose tolerance in healthy offspring of parents with conjugal NIDDM.

803

AN EPIDEMIOLOGICAL STUDY OF OBESITY AND DIABETES IN JAMAICA

D. Ragoobirsingh, E. Lewis-Fuller, and E. Morrison, University Of The West Indies Diabetes Outreach Project, and Ministry Of Health, Kingston, Jamaica.

The aim of this survey was to determine the prevalence and pattern of obesity in the Jamaican adult population and how these relate to the incidence of diabetes mellitus .This Caribbean Isle has an area of 11,460 km², with a population of over 2 million, which is predominantly of Afro origin. A two stage stratified random sampling design, in which each dwelling had an equal probability of being selected, was employed. Selected households were visited in which subjects 15 years and over, from whom informed consent was obtained, were interviewed. The control group included one person in every twenty seen. A questionnaire which included medical and family histories was administered. In addition, anthropometric and fasting capillary blood sugar (FBS) measurements were done using standard techniques. An abbreviated oral glucose tolerance test, after an overnight fast, was performed on all subjects with FBS >6.1 mmol/L. The data was analysed using Epi 5, an advanced statistical program specific for epidemiological data. Non-response was documented and factored in the final analysis of the data. The prevalence of obesity in the adult population was 36.6 %; which had the following pattern: 30.0 % with Body Mass Index(BMI) > 25 kg/m² and normal Waist Hip Ratio (WHR), 3.0% had normal BMI but WHR ≥ 1, and 3.6% with BMI > 25 kg/m² and WHR ≥ 1; of which 22.0 %, 24.9 % and 46.0 % respectively were diabetic. The data of this study show that 36.6 % of the Jamaican adult population is obese 48.5 % of which is diabetic. It is also apparent that truncal obesity is a greater(P<0.05) risk factor, and WHR perhaps a better predictor, for diabetes in Afro Caribbean people.

PS 17

Epidemiology of Cardiovascular Risk Factors in NIDDM

804

PHYSICAL ACTIVITY IN ELDERLY SUBJECTS WITH IMPAIRED GLUCOSE TOLERANCE OR NEWLY DIAGNOSED DIABETES MELLITUS

CA Baan, RP Stolk, EJM Feskens. Erasmus University Rotterdam, The Netherlands

Several studies report that physical inactivity is a risk factor for developing diabetes mellitus type II. However, these studies are based on adult populations, excluding elderly subjects. Therefore we studied the association between physical activity and diabetes mellitus in 1107 subjects, aged 55-80 years. The study was performed as part of the Rotterdam Study, a population-based cohort study in elderly subjects. The participants were classified as diabetes (known or newly diagnosed), impaired glucose tolerance and normal glucose tolerance, according to the WHO criteria. Physical activity was assessed with a self-administered questionnaire. Physical activity was expressed as hours/week as well as categories of intensity: light, moderate and heavy. For these analysis the known diabetic patients were excluded. The mean age of the study population was 66.8 years (SD 5.5), 745 subjects (68%) had normal glucose tolerance (NGT), 153 IGT (14%) and 118 newly diagnosed diabetes (11%). The mean total activity time was 22.9 hr/wk (SD 21.9) for newly diagnosed diabetes, 21.6 hr/wk (SD 18.3) for IGT and 25.5 hr/wk (SD 18.3) for NGT. Housekeeping, work (paid or volunteer), walking and bicycling together contributed 80% of the mean total activity time in all groups. Sporting activities contributed 4% to the total time spent on physical activity for NGT, 3% for IGT and 1% for newly diagnosed diabetes. The diabetic subjects (17%) and subjects with IGT (15%) spent less time on heavy activities as compared with the NGT (20%). After adjustment for age and sex, a significant trend for the three groups was shown for sporting activities (p=0.001) bicycling (p=0.03) and heavy activities (p=0.006). Preliminary results showed that physical activity in elderly subjects, newly diagnosed with diabetes, is lower as compared to subjects without diabetes, but this difference did not reach statistical significancy. However, intense physical activity was significantly less in newly diagnosed diabetes patients, which suggest that also at higher ages physical inactivity is associated with the development of diabetes mellitus.

805

AGING AND VISCERAL ADIPOSITY ACROSS TWO GENERATIONS OF JAPANESE-AMERICAN WOMEN

L. L. Newell-Morris, E.J. Boyko, J.B. Shofer and W.Y. Fujimoto. University of Washington, Seattle, USA.

Increasing age and adiposity (subcutaneous and visceral) contribute to the risk of developing NIDDM and CHD. We explored the effects of these parameters on the risk factors of fasting insulin (FI), C-peptide (FC), triglycerides (Tg), LDL-Cholesterol (LDL-C) and HDL-Cholesterol (HDL-C) among 158 second-generation (Nisei) and 95 third-generation (Sansei) Japanese-American women. Glucose tolerance status was determined by a 75g oral glucose tolerance test and WHO criteria. Subcutaneous adiposity was represented by triceps skinfold thickness (Skfld) and visceral fat by intra-abdominal fat area (IAF) at the umbilical level as measured by computed tomography. Mean age of Nisei was 62 yrs vs Sansei, 40 yrs; frequencies of IGT and NIDDM were 37% and 29% (Nisei) vs 31% and 0 (Sansei), respectively. Nisei were significantly fatter than Sansei: Skfld 24 vs 22 mm, t-test p= .03; IAF 94 vs 44 cm^2, p <.0001. The two generations did not differ in FI or HDL, but Nisei had significantly higher FC (.93 vs .79 nM, p<.0001), Tg (131 vs 109 mg/dl, p= .0008) and LDL (145 vs 121 mg/dl), p<.0001. Within generation (Gn), subjects were assigned by terciles of IAF into high (H), medium (M) and low (L) groups (Gp) for which mean values of risk variables were calculated. Mean FI (pM) for Nisei by Gp: (L) 64 (M) 100 (H) 122, Sansei: (L) 64 (M) 62 (H) 120 (ANCOVA of Gp by Gn adjusted for Skfld: Gp effect p< .0001). A similar trend was seen for FC and Tg, and a reverse trend for HDL. The two H-Gps were indistinguishable by generation. In this population of Japanese-American women, the interactive effects of older age with high levels of visceral adiposity are associated with adverse risk profiles for NIDDM and CHD. A subset of premenopausal Sansei women, identified by high visceral adiposity, present a risk profile more typical of postmenopausal Nisei, who average over 20 years older.

806

ASSOCIATION OF PHYSICAL ACTIVITY WITH GLUCOSE INTOLERANCE AMONG NATIVE HAWAIIANS IN NORTH KOHALA, HAWAII.

HK Chang, A Grandinetti, JD Curb, MK Mau, EK Kinney*, RF Arakaki, and the NHHR Consortium, RCMI Program, University of Hawaii, Honolulu, Hawaii, *Hui Malama Ola Na `Oiwi, Hilo, Hawaii, U.S.A.

Specific Aims: The Native Hawaiian Health Research (NHHR) Project characterized glucose intolerance and heart disease risk factors among 350 adult Hawaiians, ages ≥30 years old. Our clinic screening included an assessment of glucose tolerance, body mass index (BMI), waist-hip ratio (WHR) and physical activity levels. Physical activity has been associated with glucose intolerance in previous population-based studies. We report a comparison of physical activity among native Hawaiians with and without glucose intolerance. Methods: Glucose tolerance status was assessed by 2-hr OGTT using WHO criteria, or by medical history. Physical activity was estimated with the Pima Indian Questionnaire (PIQ) (Kriska, 1990), which was modified to include traditional Hawaiian activities. Modified versions of this instrument have been used in a variety of populations. Age, WHR, and BMI were regressed on metabolic equivalents (METS) for past week and past year activity calculated from the frequency and duration. Prevalence odds ratios for glucose intolerance were estimated using logistic regression. Results: WHR and BMI were not associated with either past year or past week activity. Age (mean=47.9±12.7 y.o.) was inversely and statistically associated with past week activity only (ß=-0.412,p≤0.001). Participants with glucose intolerance had significantly lower past week activity levels than participants with normal glucose tolerance (17.1±3.06 METS vs. 27.5±2.28 METS, respectively; p≤0.01). Prevalence of glucose intolerance was higher in less active participants (POR = 2.07, 95 Percent CI 1.33-3.23). The age-adjusted POR was unattenuated, and remained statistically significant (adjusted POR=1.95, 95 Percent CI 1.23-3.11). Conclusion: Prevalence of glucose intolerance was higher among adult native Hawaiians reporting lower levels of past week activity, even after adjustment for age. Lack of association between physical activity and BMI or WHR suggests that physical activity may be beneficial to glucose tolerance regardless of body mass.

807

BODY FAT CHANGES WITH DIET AND EXERCISE DIFFER BETWEEN MEN AND WOMEN

D. Leonetti, J. Shofer, E. Boyko, and W. Fujimoto, University of Washington, Seattle, WA, USA

Change (Δ) in body fat deposits and general adiposity over 2.5 y were examined in relation to diet and exercise in non-diabetic Japanese American men (n=146) and women (n=130), ages 45-74 y at baseline. Computed tomography (CT) measured subcutaneous fat for the thorax (TX), abdomen (AB) and mid-thigh (TI), and intra-abdominal fat (IAF). Weight and height provided body mass index (BMI, kg/m^2). Food frequency questionnaires estimated baseline animal fat (BAF) and plant fat (BPF) intakes. Questions at follow-up on dietary changes targeted sources of fat (dairy, red meat, oils, etc.). Questionnaires covered daily activity levels which were converted to estimates of energy expenditure at baseline (BEE) and follow-up (ΔEE). Adjusting for baseline body fat values, partial correlation coefficients were calculated. BPF was significant only in women: ΔTX (-0.27, p<0.01), ΔAB (-0.19, p<0.05), ΔBMI (-0.23, p<0.05), and Δweight (-0.23, p<0.05). ΔEE was significant only in men: ΔTX (-0.22, p<0.01), ΔAB (-0.22, p<0.05), and ΔIAF (-0.18, p<0.05). Reduction in red meat intake was also only significant in men: ΔTX (-0.31, p<0.001), ΔAB (-0.18, p<0.05), ΔIAF (-0.21, p<0.05), ΔBMI (-0.27, p<0.001), and Δweight (-0.31, p<0.001). BEE was significantly correlated with ΔTX in women (-0.19, p<0.05) and men (-0.19, p<0.05). BAF was correlated with ΔAB in women (0.30, p<0.001) and men (0.20, p<0.05) and with ΔTX in women (0.32, p<0.001). No factors were significantly related to ΔTI. In summary, baseline energy expenditure and animal fat intake were associated with gains at subcutaneous truncal fat sites in both sexes. In addition, for men exercise and reduction in red meat intake appear to be the most important avenues toward adipose tissue reduction, while for women, baseline plant fat intake appeared to be most associated with loss of adipose tissue. Thus we conclude that in both men and women avoidance of gain of truncal fat may be best attained by exercise and low animal fat intake, whereas approaches to adipose tissue reduction seem to differ between men and women.

808

RELATIONSHIP BETWEEN SPORTS ACTIVITY AND INSULIN RELEASE IN RELATIVES OF NIDDM PATIENTS

S. Dubbeldam, M.L. Zonderland and T.W. van Haeften. Department of Medical Physiology and Sports Medicine, and Internal Medicine, Utrecht University, Utrecht, The Netherlands.

The relationship between regular physical activity and insulin release after an oral glucose tolerance test (OGTT) was studied in first-degree relatives of NIDDM patients and in control subjects. Relatives (7M, 20F) and control subjects (5M, 17F) did not differ for age (45.4 ± 6.3 vs 46.2 ± 7.0 years), body mass index (BMI) (26.3 ± 3.8 vs 26.2 ± 3.3 kg/m^2), and waist-hip ratio (0.82 ± 0.07 vs 0.82 ± 0.07). Subjects underwent an OGTT (75 g) and completed a questionnaire for sports activity yielding a sports index (SI). Insulin sensitivity was assessed as glucose infusion rate (GIR) divided by mean plasma insulin (I) during the 2nd and 3rd hour of a hyperglycemic clamp (10 mmol/l, 180 minutes). All subjects had a normal glucose tolerance. There was no significant difference between relatives and controls for SI (2.5 ± 0.7 vs 2.6 ± 0.6). After the OGTT, the time-to-peak-insulin and the plasma insulin at 120 minutes were inversely correlated with the SI in relatives, but not in controls (r=-0.52, p=0.011 and r=-0.43, p=0.039; partial correlation, gender, age, and BMI as covariates). In relatives, the SI was positively related to the GIR/I during the 2nd (r=0.50, p=0.013) and 3rd (r=0.54, p=0.006) hour of the clamp. SI and GIR/I were not correlated in controls. In conclusion, in NIDDM relatives, but not in controls, regular sports participation is related to an earlier decline in insulin release after an OGTT, presumably due to an enhanced insulin sensitivity.

809

OBESITY IN JAPANESE DIABETICS AND THE IMPLICATIONS.

H.Kurahachi,M.Kajikawa,H.Kobayashi,T.Ishihara and K.Moridera
Kobe City General Hospital, Kobe, Japan.

With rapidly developed life style into modernization-westernization in Japan, NIDDM is enormously increasing. In this study, we undertook to know what resultant obesity has influenced on diabetes. 100 diabetics(male 44 and female 56, mean age 62±13 yr, mean duration 10±6 yr) without other peculiar diseases were unintentionally chosen. They included NIDDM 58, insulin requiring diabetes(N/I) 25 and IDDM 17 and were subdivided into 4 groups by the present BMI(kg/m^2), Ⅰ(BMI≦18,n=2), Ⅱ(18<BMI≦26,n=74), Ⅲ(26<BMI≦30, =20) and Ⅳ(30<BMI,n=4),respectively. Their maximum BMI in the past were Ⅰ(n=0),Ⅱ(n=53),Ⅲ(n=26) and Ⅳ(n=21). Inherent diabetic pictures in 7 subgroups classified by the combination of both BMI were investigated. Personal history of obesity was recognized in only 3/17(17.6%) of IDDM, but in 40/83(42.8%) of both NIDDM and N/I. The more marked obesity in the past was, the higher prevalence of N/I was especialliy shown even if the present BMI is within normal limits. Microangiopathic complications were frequently shown in IDDM mostly classified in Ⅱ at present, but their frequencies were the highest in both NIDDM and N/I of Ⅱ at present whose BMI reduced from Ⅲ in the past because of poor diabetic control. Complications of ischemic heart disease, hypertesion and hyperlipidemia were more frequently involved in the groups not only being obese right now, but also being overweighted solely in the past. Detailed clinical courses in some obese NIDDM followed for a long term revealed a close parallel to these findings. It was suggested that we should have a strategy to prevent positively obesity and to provide against the explosive increase of diabetes, by asking ourselves to reconsider what the changed mode of life has brought on.

810

EPIDEMIOLOGY OF NIDDM IN RELATION TO OTHER CARDIOVASCULAR RISK FACTORS IN LEBANON.

I.Salti, M.Khogali,S. Alam and Amal Masri M.P.H.,Faculty of Medicine, American University of Beirut, Beirut, Lebanon.

The aim of the study is to define the prevalence and current epidemiological features of NIDDM, impaired glucose tolerance and other cardiovascular risk factors in the adult Lebanese population. Cluster sampling technique was used in two urban settings representing low and high socioeconomic groups and one semi-rural setting.Chi square and T-test was used in order to correlate Diabetes with other risk factors.A total of 2518 Lebanese subjects aged 30 years and above were studied and showed an over-all prevalence of diabetes and impaired glucose tolerance of 13.15 % and 6.0 % respectively with no differences between males and females. The results are similar to those reported from studies reported recently from some Middle Eastern and other countries. The prevalence was very low (< 1 %) below the age of 40 and increased steadily with age. The main risk factor was obesity (especially abdominal) which probably accounts, at least in part, to the observed increased prevalence with age and amongst lower socio-economic groups.A positive family history of diabetes but not consanguinity was another risk factor. Subjects with diabetes and IGT were more likely to have heart disease, had a slightly higher mean systolic and diastolic pressure and serum triglycerides. An increase in total and LDL-cholesterol and lower HDL-cholesterol was seen only in female but not in male subjects with diabetes and IGT .

811

CARDIOVASCULAR RISK OF BODY MASS INDEX (BMI) IN ELDERLY RURAL INDIANS: A NEED TO REASSESS OBESITY CRITERIA?

K.M.Shelgikar and C.S.Yajnik. Diabetes Unit, K.E.M. Hospital and Research Centre, Pune, India.

We studied glucose tolerance, plasma lipids, blood pressure and resting ECGs in people >40 y in the village of Pimpale Jagtap near Pune (158 men: 58 y, 1.63 m, 52 kg, BMI 19.5 kg/m^2 and WHR 0.88; 163 women: 53 y, 1.50m, 45 kg, 19.8 kg/m^2 and 0.78). Four percent had diabetes and 4% IGT, only 1 had cholesterol >6.2 mmol/l, 6% had triglycerides >2.3 mmol/l and 14% were hypertensive (>140/90 mm Hg and/or treatment). 15% (16 men & 31 women) showed an 'ischaemic' ECG (coronary probable 4, possible 43; Minnesota 1982). Plasma glucose, triglycerides, cholesterol and blood pressure were all related to BMI ($p<0.01$). There was a U shaped distribution for triglycerides, IGT and 'ischaemic' ECGs, but not for diabetes, hypertension and cholesterol which showed a continuous rise with BMI. In the highest quartile of BMI (median 22.9 kg/m^2 men, 24.5 kg/m^2women) 8% had IGT, 10% diabetes, 33% hypertension and 20% 'ischaemic' ECG. Thus, the cardiovascular risk in rural Indians is related to relatively low BMI. This could be related to their past nutritional experiences.(intrauterine as well as subsequent).

812

CIGARETTE SMOKING IS THE RISK FACTOR FOR METABOLIC DISTURBANCES IN THE OBESE

Jagoda B.Jorga, M.Cutovic, D.Micic. School of Medicine , Belgrade University, Belgrade, Yugoslavia

Cigarette smoking is well known risk factor for CVD. The aim of this paper was to find out its potential role in the metabolic disturbances especially those concerning glucose metabolism in the obese. The investigation was conducted in the group (N=146) of the obese persons (BMI>30 kg/m2) aged 20 to 64 years, devided in two subgroups: smokers(S) and nonsmokers (NS). BMI was used as an index of obesity, waist circumference (W), waist to hip ratio (WHR) and Sagittal diameter (Sd) as indices of fat distribution. The following parameters of glucose metabolism were measured: fasting glucose and inslin levels as well as glucose and insulin levels during OGTT. The results obtained show no difference in BMI between smokers and nonsmokers (35.5 v.s 35.2) but smokers tend to dispose more fat in deep abdominal region and all the parameters of fat distribution were significantly higher like W,WHR and Sagittal diameter ($p<0.02$, $p<0.009$, $p<0.0001$). Fasting glucose was 5.40 mmol/L v.s 4.69 what is significantly higher ($p<0.04$) as well as glucose area under the curve (930.5 v.s 790.7 mmol/L/min) and fasting insulin: 25.4 mU/L in smokers v.s 17.2 in nonsmokers ($p<0.001$). The insulin area under the curve was higher but not significantly. Systolic blood pressure was 141.7 mmHg v.s 132.5 ($p<0.004$) and diastolic was also higher but not significantly. It can be concluded that smoking cigarette is a risk factor for metabolic distrurbances especially in obese with abdominal type of fat distribution..

813

COMPARISON OF BMI AND WHR BETWEEN JAPANESE POPULATIONS IN JAPAN AND BRAZIL

A Sekikawa, LC Iochida, H Eguchi, H Sasaki, M Tominaga, LF Marcopito, JF Franco Yamagata University School of Medicine, Yamagata Japan, and Universidade Federal de Sao Paulo, Sao Paulo Brazil

Migrant studies measure the impact of environmental factors on the development of diseases. We reported that prevalence of NIDDM in Japanese Brazilian in Bauru, Brazil is much higher than that in Funagata, Japan (17.6 % vs 10.1 %). These two Japanese populations are considered genetically identical. Both are population-based study with high participation rates (74.5% in Japan and 83.2% in Brazil). Both employed a 75 g oral glucose tolerance test as a primary test with 1985 WHO diagnostic criteria. This study compares body mass index (BMI) and waist-to-hip ratio (WHR) between these two populations in the same age group (40-79). Body height (m) and weight (kg) were measured while subjects were wearing light clothing without shoes. Waist and hip circumferences were measured at the level of the umbilicus and at the level of the greater girth, respectively. BMI was calculated as weight divided by the square of height. WHR was calculated as waist divided by hip. Student's t-test was used to compare the data. Means and standard deviations are shown in the below table.

		Japan	Brazil
BMI	Men	23.5 (3.0)	24.2 (3.5)
	Women	23.9 (3.3)	24.3 (3.6)
WHR	Men	0.89 (0.06)	0.99 (0.08)
	Women	0.88 (0.06)	0.90 (0.08)

Both BMI and WHR showed significantly higher value in Japanese Brazilian than in Japanese in Japan. Higher prevalence of NIDDM in Japanese Brazilian can probably be attributed to obesity.

814

DIABETIC CHRONIC COMPLICATIONS IN TYPE 2 DIABETES: A MULTICENTRIC STUDY. X. Mundet, JF. Cano,M. Mata, J. Franch, M. Bundó, M. Berenguer and the GedapS Group Catalan Famiy and Community Medicine Society. Barcelona (Spain)

Aims: To assess prevalence of diabetic chronic complications in type 2 diabetic patients attended in Primary Health Centres (PHC) and to know the compliance of screening measures.***Patients and methods***: Cross-sectional study carried out in 1993-94 in 76 PHC (34.1% rural and 65,9% urban) attending 1.092.532 people. Patients were selected by systematic sampling from 21,556 adults registered as type 2 diabetics. Final sample included 2,595 patients with a mean age of 66,8+/-10 years and a mean evolution time of 8,1+/-5,9 years from the diagnosis.***Results:*** Nephropathy: Screening for microalbuminuria was performed in 34% of diabetics. Microalbuminuria was confirmed in 17% (IC95%: 14-20), proteinuria in 5,3% (IC: 4-6) and renal insufficiency in 5%. Retinopathy: Fundoscopy was performed in 55% of patients, finding some kind of diabetic rethinopaty in 37% of them (IC: 34-40), blindness was present in 2%. Ischemic Heart and Cerebrovascular Disease were present in 12% (IC: 12-14) and 6% (IC: 5,3-8). Diabetic Foot was reported in 10% of cases (IC: 8,8-11,1), the acute lesions raised 7,9% (6,8-8,9) and amputations were 2,1% (IC: 1,5-2,6). Varience analysis showed a close relationship between microvascular complications and age (p: .006), diabetes average evolution time (p:.00001), current level of HbA1c (p:.0004) and systolic Blood Pressure (p:.0001). Macrovascular disease was correlated with age (p:.00001), evolution time of diabetes (p:.00001) and current level of total cholesterol (p:.0004). ***Conclusions:*** 1. The frequency of complications is similar to the found in other country studies. 2. The detections of the complications must be improved. 3. As it is already known, the age and the average evolution time of diabetes are strongly correlated to the complications. Furthermore, we found that the metabolic control, Total Cholesterol level and Systolic Pressure have an important influence in its development.

815

Accuracy and Reliability of Dual Energy X-ray Absorptiometry (DEXA) for rat body composition measurement.

E. Bertin[1], J.C. Ruiz[2], J. Mourot[3], D. Bailbé[1], B. Portha[1].
[1]Lab Physiopathol Nutrition CNRS-URA307, Paris; [2] Av Lesueur, Paris; [3]INRA, St-Gilles; France.

Rat is a current model for nutrition studies. One limitation in its use is the accurate determination of the total body fat mass which can only be determined with the tiresome chemical extraction technique (CE) which requires sacrifice of the animal. Usefulness of DEXA in human nutrition investigations suggest that it could be suitable also for rat studies. Therefore we have tested intra- and inter- assay reliabilities of the DEXA technique (coefficient of variation: CV) and its accuracy as compared to the gold standard CE procedure (linear regression analysis with correlation coefficient: r). 26 rats (18 Wistar; 8 GK) with age ranging from 2 to 24 months and body weight (bw) ranging from 130 to 500 g, were screened in triplicate after anaesthesia on a QDR 4500 absorptiometer (Hologic). After sacrifice their lipid content was determined by CE (mean of 3 determinations/sample). 1/ Comparison of the two techniques (DEXA vs CE) showed a strong linear correlation ($r=0.975$; $p<0.0001$). 2/ During intracalibration studies, CV value for boneless lean mass was found lower than 1%, except for the case of animals with bw lower than 150g (CV: $1.4 \pm 0.9\%$, n=5). CV value for % of total body fat mass CV was $6.8 \pm 3.3\%$ for bw <150g (n=5), $4.2 \pm 3\%$ for bw in the range 150-250g (n=9), and $2.6 \pm 1.1\%$ for bw beyond 200g (n=14). There was no significant difference concerning reliability between the two techniques. 3/ Intercalibration reliability was lower and induced an increase of CV values (up to 8% for the % fat mass value, in the animals with bw beyond 200g). However, this limitation can be circumvented by using a quality control, and correcting the results using a standard. Therefore, DEXA can be considered as an accurate, reliable and non aggressive technique for body composition determination in rat, as far as rigorous methodology and inter and intra-assay quality controls are taken into account.

816

DOES A CLINICAL PHENOTYPE AT RISK FOR DIABETIC COMPLICATIONS EXIST? A 20 YEAR FOLLOW UP STUDY IN A NORTH EASTERN ITALIAN REGION

G.Bax, Fagherazzi C., Cospite A., Piarulli F., Marin N., Fedele D.
Department of internal Medicine Chair of Diseases of Metabolism Padua University

To verify if clinical phenotypes prognostic for diabetic complications exist or only the good metabolic control can prevent these alterations we 100 type 2 diabetic patients 59 males (M) and 41 females (F), randomly chosen on 540 patients who were diagnosed type 2 diabetes between 1974-1984,were analyzed with a retrospective study. The multiple logistic regression verifies the Odds ratio (OR) (I.C 5-95°) of some clinical parameters (CP);: A) age at the diagnosis (AD) BMI ; Systolic and diastolic blood pressure ; fasting glucose and glycated hemoglobin (Hba1c) (evaluated three time every year) respect to ischemic heart disease (angina or myocardial infarction), retinopathy (evaluated by fundus), Lower Extremity artery disease (LEAD) (evaluated by ankle brachial index (ABI), and neuropathy (evaluated by Diabetes neuropathic index and Biotesiometer).

Clinical Parameter	IHD	Retinopathy	LEAD	Neuropathy
AD (<55/>55)	0.69(0.18-2.5)	0.61 (0.19-1.9)	0.35 (0.24-1.0)	0.39 (0.11-1.0)
SEX (F/M)	0.11(0.01-0.9)	0.84 (0.25-2.8)	0.49 (0.15-1.5)	0.34 (0.13-0.9)
BMI(>26/<26)	1.12(0.26-4.7)	1.21 (0.33-4.3)	0.30 (0.10-0.9)	0.50 (0.18-1.3)
SDP(<160/>160)	1.61 (0.36-7.1)	2.61 (0.72-9.4)	3.20 (1.02-10)	1.40(0.40-4.1)
DBP(<90/>90)	4.59 (0.86-24)	1.41 (0.25-7.9)	1.83 (0.39-8.5)	1.42 (0.31-6.4)
FG (<140/>140)	0.77 (0.20-2.8)	1.77 (0.51-6.0)	1.92 (0.65-5.6)	1.61 (0.63-4.1)
HbA_1c(<7.1/>7.1)	0.86(0.23-3.2)	0.86 (0.23-3.2)	0.79(0.26-2.37)	0.67(0.22-1.6)

We conclude that in these patients with the diabetes showed a phenotype at risk for neuropathy and Lead (male, lower weight at the diagnosis); instead the metabolic control and blood pressure increased the risk to develop ischemich heart disease and retinopathy.

817

INCREASED INCIDENCE OF HYPERTENSION AND DYSLIPIDEMIA IN MIDDLE-AGED MEN WITH HYPERINSULINEMIA OR DIABETES

J.T. Salonen, H-M. Lakka, T.A. Lakka, V-P. Valkonen, S.A. Everson and G.A. Kaplan. Research Institute of Public Health, University of Kuopio, Kuopio, Finland; Human Population Laboratory, Western Consortium for Public Health, Berkeley, California; Human Population Laboratory, California Department of Health Services, Berkeley, California.

We investigated the association of diabetes and hyperinsulinemia with the incidence of future hypertension and dyslipidemia in the Kuopio Ischemic Heart Disease Study (KIHD), a population-based study of middle-aged men from eastern Finland. Subjects were 558 unmedicated men with resting blood pressure < 165/95 mmHg, or 786 men with serum triglycerides < 2.3 mmol/l and HDL cholesterol > 1.0 mmol/l at baseline and whose hypertensive status and blood lipids were assessed at 4-year follow-up. In logistic regression models adjusting for age, resting blood pressure, obesity, weight change and other predictors, diabetic men (blood glucose of ≥ 6.7 mmol/l or clinical diagnosis of diabetes with either dietary, oral or insulin treatment) had a 6.0-fold (95% confidence interval 1.8 to 20.2, p = 0.004) risk of subsequent hypertension (≥ 165/95 mmHg) compared to non-diabetic men. Men with hyperinsulinemia (fasting insulin of ≥ 12mU/l) had 2.0-fold (p = 0.015) risk of hypertension, 2.1-fold (p = 0.002) risk of dyslipidemia and 2.8-fold (p = 0.026) risk of the combination of these two insulin-resistance-related conditions in four years. These preliminary findings demonstrate the role of hyperinsulinemia and diabetes in hypertension and dyslipidemia and suggest that both hypertension and dyslipidemia can be associated with insulin metabolism disturbance, independent of body weight and obesity.

818

MONITORING THE INCIDENCE OF LOWER EXTREMITY AMPUTATIONS: APPLICATIONS OF CAPTURE-RECAPTURE TECHNOLOGY.

Spichler, ERS., Spichler, D., Franco,LJ., Chang,Y-F.,and LaPorte,RE. Health Ministry, Health State Secretariat of Rio de Janeiro,Federal Fluminense University of Rio de Janeiro, Federal University of Sao Paulo,Brazil & University of Pittsburgh,USA.

Lower Extremity Amputations (LEAs) are a major health problem in the diabetic population.The Capture-Recapture (C-R) method was used in this report to estimate the LEAs incidence rates in the city of Rio de Janeiro, for the 1992-4 period. This amputee register (AR) is carried out in the city of Rio de Janeiro (population of ± 9,500,000 inhabitants).Diagnosis were recorded according to the WHO ICD-9.The AR data were classified into:.peripheral vascular disease (PVD), diabetes mellitus (DM) trauma, neoplasms, gangraena emphysematosa (G.Emphy) and ostheomielitys (Osteo).The LEAs reporting cases came from: Source 1 (S1)-1191 cases from records of 23 hospitals, and Source 2 (S2)-157 cases from a limb fitting center. An additional source (S3) was a larg rehabilitation center (34 cases). Log-linear models were applyed to the C-R technique when more than two sources were used. Amputee death certificates from S1 were reviewed with the identification of 257 deaths.To estimate LEAs incidence models were evaluated with 2 and 3 sources,and including or excluding deaths. Applying C-R with 2 sources (S1 and S2), excluding deaths, the results are: S1=934 cases; S2=193 cases, and common to S1 and S2=50 cases, with an estimation of 3,555 cases (95% CI: 2,748 - 4,362). Applying log-linear models for S1 (1,191 cases), S2 (157 cases) and S3 (34 cases), the estimated total number is 5,040 cases. Excluding deaths, the total number of estimated cases are 3,954, that is an annual incidence rate of 13.8/100,000. Altogether, 1,383 patients with LEAs were identified as having: DM =379 (27.4%), PVD = 804 (58,1%) G.Emphy = 36 (2.6%), Osteo =44 (3.1%), trauma=103 (7.4%), neo=16(1.1%). These findings showed a high incidence of LEAs and that DM is one of the leading causes; must of the LEAs may be preventable with the provision of adequate health care.

819

RELATIONSHIPS BETWEEN SOCIOECONOMIC STATUS AND CARDIOVASCULAR RISK FACTORS IN AFRICAN AMERICANS

T.R. Gaillard, D.P. Schuster, B. Bossetti, P. Green, and K. Osei, The Ohio State University, Columbus, Ohio, USA

The rate of diabetes mellitus (DM) in African Americans (AA) is reaching epidemic proportions. AA with type 2 DM suffer more from cardiovascular diseases (CVD) associated with diabetes than the general population. Lower socioeconomic status (SES), family history, obesity, and hyperinsulinemia are often cited as contributory factors to the premature development of DM and CVD in this population. However, we are not aware of any study that has examined the relationships between SES and CVD risk factors (i.e. Syndrome X) in a genetically-enriched AA population at high risk for type 2 DM. **METHODS:** We studied 200 healthy first degree relatives of AA patients with type 2 DM, age range 25-65 years, 42 males and 158 females. Standard OGTT, metabolic and anthropometric parameters and questionnaires on SES and demographics were obtained in each subject. SES was divided into quartiles based, on annual income, ranging from <$10,000 to >$100,000. To examine the impact of insulin on CVD risk, we examined the clinical characteristics and metabolic parameters according to quartiles of fasting insulin concentrations. **RESULTS:** There were no significant differences in any of the clinical characteristics, metabolic, lipid and lipoprotein concentrations and anthropometric parameters among our SES quartiles. When examined as insulin quartiles, body mass index (BMI), waist hip ratio (WHR), % body fat tended to be greatest in the 4th quartile when compared to the lower quartiles. Fasting serum and postprandial glucose and c-peptide levels were significantly higher in the 4th quartile when compared to the lower quartiles. We observed greater very low density lipoprotein cholesterol (VLDL-C) and triglycerides (TRIG) and lower high density lipoprotein cholesterol (HDL-C) in the 4th when compared to the lower quartiles. Serum cholesterol (CHOL) and low density lipoprotein cholesterol (LDL-C) levels were not associated with increasing insulin concentrations. **CONCLUSION:** Our present study demonstrates no SES/income effect on CV risk factors in AA at high risk for type 2 DM. Clustering of the components of Syndrome X was only seen in those individuals in the highest quartile of insulin. We conclude that, AA at high risk for type 2 DM especially those with clinical and metabolic characteristics similar to those found in subjects in the 4th quartile should be evaluated for CV risk, as well as, considered for DM and CVD prevention programs, regardless of their SES.

820

PREVALENCE OF DIABETES AND RISK FACTORS FOR CORONARY HEART DISEASE AND STROKE IN PERUVIAN MESTIZO POPULATION.

S.Seclén, A.Villena, J.Leey and 3E-NT Group, Institute of Gerontology, Peruvian University Cayetano Heredia, Lima-Perú.

Since 1994 has been designed a national epidemiologic study which aim is to examine the prevalence of the main risk factors which provides coronary heart disease (CHD) and stroke in our population.

The present pilot study was done at ingenieria urbanization, Lima which population is 26,497. A sample population of 158 people up to 18 years old was chosen by multiphase cluster through a descriptive, prospective and cross-sectional research during October-December 1995.

The chosen people was visited in their homes by a previously capacitated health team making them an epidemiologic questionnaire, anthropometric measures and determination fasting blood sample for blood glucose and lipidic profile. The statistic program STATA was used for calculated the distibution of frecuencies, Chi2, the correlation analysis and the association measures.

The prevalence of diabetes mellitus was 7.5%, hypertension 37.8%, hypercholesterolemia 21% and obesity 28.7%. 18% of subjects were smokers, 39% alcohol drinkers, 70% sedentarian life and 72% coffe drinkers.

The results explain the contribution of diabetes and associated risk factors in the elevated morbility and mortality by CHD and stroke in the peruvian mestizo population.

821

SOCIO-ECONOMIC STATUS, PREVALENCE OF DIABETES AND OTHER CARDIOVASCULAR RISK FACTORS IN CHINESE

Gary T.C. Ko, *Juliana C.N. Chan, Vincent T.F. Yeung, Chun-Chung Chow, June K.Y. Li, Wing-Yi So, Lynn L.W. Tsang and Clive S. Cockram. Departments of Medicine and *Clinical Pharmacology, The Chinese University of Hong Kong, The Prince of Wales Hospital, Shatin, N. T., Hong Kong

Low socio-economic status is associated with increased prevalence of diabetes mellitus (DM), coronary heart disease and early mortality in Caucasians. We studied 2847 Hong Kong Chinese subjects undergoing oral glucose tolerance tests (OGTT) and examined the relationships between socio-economic status, glucose intolerance and other cardiovascular risk factors. Of the 2847 subjects, 473 (16.6%) were men and 2374 (83.4%) were women. They were classified according to their education level and occupation. When analysed according to education level and after adjustment for age, women in the lowest socio-economic group had the highest body mass index (BMI), systolic and diastolic blood pressure (BP), fasting and 2-hour plasma glucose (PG), prevalence of DM and obesity. After further adjustment for BMI, alcohol and smoking, the differences in systolic BP, 2-hour PG and prevalence of DM lost their significance. Men with the lowest education level had the highest prevalence of diabetes and smoking after age adjustment. The difference in prevalence of DM in men also lost significance when BMI, alcohol and smoking were adjusted as covariates. When categorised according to occupation and after adjusting for age, women in the lowest socio-economic group had the highest fasting and 2-hour PG, glycated haemoglobin, prevalence of DM, alcohol intake and obesity. After further adjustment for BMI, alcohol and smoking, women in the lowest socio-economic group still had the highest fasting PG and prevalence of DM. Men in the lowest socio-economic group had the highest prevalence of smoking and alcohol intake after adjusting for age and BMI. In conclusion, Hong Kong Chinese in the lower socio-economic group have increased risk of glucose intolerance and cardiovascular risks. Obesity, tobacco and alcohol are important factors within these associations.

822

GLUCOSE INTOLERANCE AND PATIENTS WITH CORONARY ARTERY DISEASE: DO THE WHO CRITERIA NEED REEVALUATION?

MR Rifaie, H El Soutohi, M Abul-Magd, N Sayed-Ahmed, H Tillmans, and H Laube*. Mansoura University, Mansoura, EGYPT; and * der Justus Liebig University, Geissen, GERMANY).*

The aim of the present work was to study the role of glucose intolerance and the metabolic condition in patients with coronary artery disease (CAD). Forty four non diabetic patients with CAD, verified by coronary angiography, were screened with oral glucose tolerance testing. According to the WHO (1985) criteria, 11 (25%) patients were found to have impaired glucose tolerance (IGT group) while 33 (75%) were euglycemic (non-diabetic non-IGT group). A control group of 10 age- and sex-matched euglycemic subjects, with angiographic evidence of absent CAD, was also studied. All individuals were subjected to biochemical tests including complete lipid profile, oral glucose tolerance test and serum insulin and C-peptide levels, and anthropometric measurements including body mass index, waist/hip ratio and skin fold thickness, as well as estimation of body composition by near-infrared interactance technique to assess the percentage of total body as well as abdominal fat. The non-diabetic non-IGT CAD patients showed a significantly lower HDL ($p<0.001$) and a significantly higher glucose area ($p<0.05$) than the respective parameters of the matched control group, although both were not significantly different regarding the anthropometric measurements. This could suggest that values of glucose tolerance test lower than that of the WHO (1985) might still impose risk for developing CAD and raises the question whether the IGT figures of the WHO (1985) needs modification or a term like "pre-IGT" be considered, especially in CAD patients: A concept that still needs more work on a larger scale.

823

LIPOPROTEIN(A) LEVELS IN OBESE SUBJECTS WITH AND WITHOUT NON INSULINDEPENDENT DIABETES MELLITUS

C.Llor, C. Richart, JJ.Vendrell, C.Gutiérrez, E.Satué and M.Cots. Hospital Joan XXIII Tarragona and ABS Valls, Spain

The aim of this study is to compare lipoprotein(a) levels [Lp(a)] in obese individuals with non insulindependent diabetes mellitus with obese subjects without diabetes mellitus. We also describe if the increase in the body mass index [BMI] goes along with higher concentrations of Lp(a) in both groups. A cross-sectional survey was set out in our centre in which 224 obese subjects (BMI > 25 kg/m^2) were analyzed (56 subjects with non insulindependent diabetes mellitus and 168 without diabetes). t-tests and simple regression were performed; only p-values of less than 0.05 were reported as significant. Mean Lp(a) values were lower in obese people with non insulindependent diabetes (11.3 mg/dl versus 12.7 mg/dl). No statistical differences were observed comparing age and gender. Among people with BMI ranging from 25 to 29.9 kg/m^2, mean Lp(a) levels were 13.7 mg/dl in patients with non insulindependent diabetes and 14.9 mg/dl in those without diabetes mellitus. The results observed in subjects with BMI between 30 and 34.9 kg/m^2 were 12.4 mg/dl and 13 mg/dl and in people with BMI greater that thirty-five were 10.6 mg/dl and 11.8 mg/dl. The correlation observed comparing Lp(a) levels with BMI was the same in both groups (r:0.09). No statistical differences were achieved. Lp(a) is considered as an independent risk factor for developing ischaemic heart disease. Depending on the results observed in this survey mean Lp(a) values are not significantly modified when an increase in BMI is produced either in people with non insulindependent diabetes or without diabetes mellitus.

824

STUDY ON DIAGNOSTIC VALUES FOR ORAL GLUCOSE TOLERANCE TEST BASED ON COMPLICATIONS

C. Ito. Hiroshima Atomic Bomb Casualty Council Health Management Center, Hiroshima, Japan

To prevent DM complications, diagnostic values of GTT were investigated using long term follow-up observation. Subjects were 19,734 GTT examinees between 1965–1995. Diabetics under treatment and gastrectomy and liver dysfunction cases were excluded. Results :1) DM development rate increased with increasing 2hr-PG and reached a plateau at 2hr-PG of 180mg/dl or more. 2) Incidence of retinopathy rose with increasing 2hr-PG. In the 180–199 mg/dl 2hr-PG group the rate was 6.1/1000 PY, significantly higher than that for the 140–159mg/dl group but little different from that for the 200–239mg/dl group. 3) There was no difference with respect to incidence of hypercholesterolemia between the 180–199mg/dl 2hr-PG and the 200–239mg/dl groups. 4) Incidence of ischemic changes in ECG was significantly higher in the 180–199 mg/dl than in the normal group, but no difference was observed between the 180–199mg/dl and the 2hr-PG 200–239mg/dl groups. 5) Incidence of hypertension was higher in the 180 –199mg /dl than in the 140–159mg/dl group, but no difference was observed between the 180–199mg/dl and the 200–239mg/dl groups. 6) CHD mortality rate was higher in the 180–199 mg/dl than in the normal and 140–159mg/dl groups. Conclusion:DM diagnostic 2hr-PG value was 180mg/dl or more.

825

SERUM LIPOPROTEIN(A) CONCENTRATION IN CHINESE NIDDM PATIENTS WITH ALBUMINURIA

C.J. CHANG, J.T. KAO, F.H. LU, T.J. WU, J.S. WU and T.Y. TAI
National Cheng Kung University, Tainan, Taiwan

Our study was to determine the relationship and distribution of Lp(a) levels in NIDDM patients with different urinary albumin excretion rates (AER) compared with healthy nondiabetic subjects. Diabetic patients were grouped in normoalbuminuric, AER< 20 μ g/min (n=126), microalbuminuric, AER 20-200 μ g/min (n=56) and macroalbuminuric, AER> 200 μ g/min (n=52) categories. Within the diabetic patients' population, we examined the relationship between Lp(a) concentration and the rates of urinary albumin excretion. We measured lipids, lipoproteins, Lp(a) and blood pressure, and urinary albumin excretion in the 234 subjects with NIDDM and 100 healthy nondiabetic subjects. Non-insulin-dependent diabetic patients with normo-, micro- and macroalbuminuria were compared with healthy nondiabetic subjects. The macroalbuminuric diabetic group had significantly higher Lp(a) levels than the normoalbuminuric diabetic group and healthy nondiabetic subjects (28.0$\pm$19.5 vs 21.1$\pm$21.9 mg/dL; 28.0$\pm$19.5 vs 20.7$\pm$18.7mg/dL, respectively).($P<0.05$, $P<0.05$). The prevalence of is chemic heart disease was higher in macroalbuminuric as compared to normoalbuminuric diabetic patients ($P<0.05$). Importantly, there were positive correlations between Lp(a) and the urinary albumin excretion rate in the macroalbuminuric diabetic group ($P<0.00001$) and in all diabetic patients ($P<0.0001$). In conclusion, Lp(a) level is significantly elevated in NIDDM patients with macroalbuminuria.

826

DETERMINANTS OF CHANGE IN PLASMA TRIGLYCERIDE LEVEL OVER 4.5 YEARS IN THE ELY PROSPECTIVE STUDY

CD.Byrne[1], DEM Williams[2], NE Day[2], CN Hales[1] and NJ Wareham[2]
[1]Depts of Clinical Biochemistry and [2]Community Medicine, University of Cambridge Cambridge, UK

Increased plasma triglyceride (TG) levels are a cardinal feature of the insulin resistance syndrome (IRS) and therefore the increased risk of IHD associated with the IRS may be mediated by abnormalities of TG metabolism. To study determinants of change in plasma TG concentration with time we have undertaken analyis, stratified by gender of follow-up data from a population-based cohort, established in Ely, Cambs, UK. 1071 Caucasian subjects known to have either normal glucose tolerance or IGT in 1990-1992 were traced and invited to attend for a repeat test 4.5 years later. 937 volunteers attended for rescreening. In men the mean change in fasting plasma TG concentration was 0.026 mmol/l (range -4.6 to +10.5) and in women the mean change was 0.11 mmol/l (range -2.3 to +6.0). As the probability of change in TG concentration is affected by baseline TG concentration, regression to the mean and true change, we analysed TG concentrations as a continuous variable taking into account each of these factors separately. Subjects in the top quintile in whom plasma TG deteriorated were compared to subjects in the middle three quintiles in whom there was no change in triglyceride level. By logistic regression analysis the probability of deterioration was independently associated only with measures of obesity; baseline BMI (or WHR) and the increase in BMI (or WHR) over 4.5 years. (For baseline BMI; adjusted odds ratio 1.13 (95%CI 1.04-1.23, p=0.003 [men]; adjusted odds ratio 1.03 (95%CI 0.98-1.08, p=NS [women]. (For change in BMI with time adjusted odds ratio 1.22 (95%CI 1.02-1.46, p=0.028 [men]; adjusted odds ratio 1.17 (95%CI 1.04-1.33, p=0.01 [women]. These results show that increasing levels of obesity with time mediate adverse changes in triglyceride metabolism and suggest that a reduction in fat mass would improve the cardiovascular risk factor profile.

827

THE RISK FACTORS IN ADULT PROGENY OF PATIENTS WITH NON-INSULIN-DEPENDENT DIABETES MELLITUS

CC.Fu, JD.Chen, CJ.Chen and TY.Tai. Provincial Taoyuan Hospital, Taoyuan, Taiwan.

The major risk factors for coronary heart disease is amplified in diabetic patients and their families. To explore the occurrence of risk factors in the progeny of diabetes, 88 patients with non-insulin-dependent diabetes mellitus and 86 control subjects were recruited from a health center of northern Taiwan. Their adult progeny were invited to have the screening about the risk factors through a structured questionnaire and blood check-up to measure plasma glucose, cholesterol, triglyceride, HDL-cholesterol and HbAlC. Totally, there were 168 and 165 adult progeny in diabetic and control groups respectively. In univariate analyses, the diabetic progeny had higher percentage of parental hypertensive history than the control group. Besides, the male progeny of diabetes had higher mean BMI, blood pressure, HbAlC, serum cholesterol and triglyceride levels. Multiple regression analyses showed paternal diabetes was positively associated with HbAlC, systolic and diastolic blood pressure while maternal diabetes was associated with higher diastolic blood pressure and HbAlC in the male progeny. There was no risk factor associated with parental diabetes in the female progeny. In conclusion, our study demonstrated that the male progeny of both paternal and aternal diabetes were associated with more coronary risk factors including higher blood pressure and HbAlC.

828

PREVALENCE OF ASYMPTOMATIC BACTERIURIA IN NIDDM FEMALES AND ASSOCIATION WITH RISK FACTORS.

A.Sotiropoulos,Th.A.Peppas,D.Voutsinas,E.Tamvakos,O.Apostolou,D.Panayotu, V.Sotirchou, V.Kotsini and S.Pappas.G.Hospital of Nikaea, Piraeus, GREECE.

Aim of our study was estimating the prevalence of asymptomatic bacteriuria (AB), a well-known and described condition in NIDDM females, and associate it with any relevant parameters. We prospectively enrolled 363 patients (m.age 61.3±10.5 yrs range: 32-81, m.duration of Diabetes 10.8 yrs) followed in our Diabetes Clinic and screened them for the presence of AB and associated the results with their demographic, history, complications and glucaemic control data . Analysis was done via an IBM compatible computer using the EPI5-INFO (CDC/WHO) 1993 program. Statistical analysis was performed with Yates corrected chi square test. We found AB in 35 patients (9.7%) with *E.coli* (28), *Proteus* (3), *Klebsiella* (2) and *Citrobacter* and Enterococcus 1 each, been the isolated organisms. There was no difference found in the age and Diabetes duration of AB+ v no AB patients. (64.3 and 11.3 v 61.1 and 10.6 years respectively).or with the kind of Diabetes treatment or glycaemic control. The prevalence of AB by age group did not differ significantly, with the exception of the 70-79 yrs age group where AB was more prevalent (p=0.02). The presence of Diabetes complications was not associated with AB, including individual analysis for those with Diabetic nephropathy and neuropathy. The prevalence of AB among the sexually active women was 9/128 (7%) less than the overall percentage. The factor that was more strongly associated with AB was the history of previous urinary tract infections, whereAB was found in 73% of those with such history (p<0.001). In conclusion AB was found in a considerable percentage of NIDDM females, should be sought for in all age groups. It is also of critical importance that screening for AB must not be omitted in patients with previous urinary tract infection history.

829

SEVERE HYPERGLYCEMIA AND MACROALBUMINURIA IS MORE PREVALENT IN THE RURAL AND AMONG THE POOR DIABETICS

F. Mahtab, H. Mahtab, M. A. Sayeed and A. K. Azad Khan
BIRDEM, Dhaka, Bangladesh.

In the developing countries, compared with the urban and the rich, diabetes awareness is less in the rural people and least among the poor socio-economic class which leads to late detection of diabetes among them. To compare the glycemic status and macroalbuminuria (as one of the diabetic complications) between the rural and the urban subjects we investigated 8879 (M=5405, F=3474) non-insulin-dependent diabetes mellitus (NIDDM) subjects over 29 years of age. Among these newly registered subjects in 1995, the urban and rural diabetics were 70 and 30%, respectively. According to social class the rich, the middle and the poor were 29.9, 66.0 and 4.1%, respectively. Compared with the urban subjects, the mean (±SD) duration of hyperglycemic symptoms (typical: polyuria, polydipsia, weight loss) was significantly higher in the rural diabetics (21.6 ±15.6 vs 18.1 ±13.2 mo, p=0.03). The mean age (±SD) of rural subjects of either sex was also significantly higher (men: 50 ±11 vs 47 ±10yr, p<0.001; women: 49 ±11 vs 46 ±10, p<0.001). Rural subjects had also significantly higher fasting plasma glucose (FPG in mmol/l: men, 12.2 ±5.3 vs 11.0 ±4.3, p<0.001; women, 12.2 ±5.0 vs 10.9 ±4.2, p<0.001). Similarly, 2h after glucose load (2h-PG) was significantly higher among them (p<0.0001). In contrast, adjusting for sex, the rural subjects had significantly lower body mass index (BMI±SD) than their urban counterpart (men: 21.5 ±3.8 vs 23.3 ±3.3, p<0.001; women: 23.0 ±4.6 vs 25.2 ±4.1, p<0.001). Hyperglycemia (2h-PG) over 20.1 mmol/l was more frequent among the rural than the urban subjects (42.2 vs 34.4%: X^2 46.0, p<0.001) and also more frequent among the poor than the rich (47.3 vs 32.3%, p<0.001). In addition, compared with the urban and the rich, macroalbuminuria was significantly associated with the rural (11.4 vs 13.8%, p=0.01) and with the poor (11.5 vs 15.4%, p=0.03) diabetics. Therefore, this study suggests that regardless of diabetes prevalence in rural and urban population, severe hyperglycemia with typical symptoms and low BMI is more frequent in the rural area and among the poor social class. Similarly, macro-albuminuria, an indicator of advanced stage of diabetic nephropathy is also more prevalent in these subjects.

Low Birthweight and Gestational Diabetes

830

LOW BIRTHWEIGHT AND RAISED PLASMA CORTISOL CONCENTRATIONS IN ADULT LIFE

DIW.Phillips[a], DJP.Barker[a], CHD.Fall[a], CB.Whorwood[a], B R.Walker[b] and PJ.Wood[c]. [a]MRC Environmental Epidemiology Unit (University of Southampton) UK, [b]Department of Medicine (University of Edinburgh) UK and [c]Regional Endocrine Unit, Southampton General Hospital,UK.

Low birthweight in babies born at term is associated with insulin resistance, glucose intolerance and raised blood pressure in adult life. Because there is evidence from animal models that undernutrition in utero could lead to persisting alterations in the hypothalamic-pituitary-adrenal axis, we have investigated whether low rates of fetal growth are associated with altered plasma cortisol in adult life. In a follow-up study of 370 men born in Hertfordshire during 1920-30 whose birthweights were recorded and who attended a local clinic for oral glucose tolerance tests, fasting plasma cortisol concentrations rose with increasing age ($p<0.001$) and fell with increasing body mass index ($p=0.05$). Plasma cortisol fell progressively with increasing birthweight from 408nmol/l among those who weighed ≤2.5kg at birth to 309nmol/l among those who weighed ≥4.3kg ($p=0.007$), a trend that was independent of age, body mass and levels of cortisol binding globulin. Higher fasting plasma cortisol concentrations were associated with insulin resistance estimated by HOMA ($p=0.006$), raised systolic blood pressure ($p=0.02$), and higher 2-h plasma glucose ($p=0.04$). Low rates of fetal growth are associated with increased circulating concentrations of cortisol throughout life. This may be one mechanism underlying the association between low birthweight and diabetes and hypertension.

831

GESTATIONAL DIABETES AND NEONATAL OUTCOME: EFFECTS OF PREPREGNANCY BMI

G. Di Cianni*, L.Volpe*, P. Orsini*, I. Casadidio*, L.Marselli*, P.Bottone°, S. Murru°, G.Teti°, L.Benzi*.
*Departement of Metabolic Desease; °Departement of Obstetric-Gynecology, University of Pisa, Pisa, Italy.

This study investigates the clinical characteristics of gestational diabetes mellitus (GDM) and neonatal outcome in relaction to prepregnancy body mass index (BMI). Data were obtained using a computerized data system for all deliveries (n.4171) that occurred at the Departments of Obstetrics and Gynecology of the University of Pisa (Italy) from Jan.1, 1987 through to Dec. 31, 1992. 93 women with GDM (prevalence 2.3%) were found and divided into three groups in relation to their pre-pregnancy BMI: normalweight (Nw), overweight (Ow) and obese (Ob). 110 matched control subjects were also evaluated. GDM was diagnosed earlier in Ow and Ob than in Nw ($p<0.01$) and insulin treatment was used in 86% of Ob-GDM and 91% of Ow-GDM patients in respect to Nw-GDM women (77%, $p<0.001$). Preterm deliveries and cesarean sections resulted significantly increased in all B.M.I. categories of GDM patients in respect to normal controls. Prevalence of neonatal macrosomia was higher in GDM patients (44.6%) compared with normal controls (15.4%) and correlated ($p>0.01$) with prepregnancy BMI in both groups. The body weight increase during pregnancy was not associated with neonatal macrosomia. In conclusion, this study shows that the degree of overweight is related to an earlier diagnosis of GDM. Moreover prepregnancy BMI is more predictive of macrosomia than weight gain specially in women suffering from GDM.

832

INTRAUTERINE GROWTH RETARDATION AND PRENATAL GLU COSE INFUSIONS: RISK FACTORS FOR NIDDM AND SYNDROME X ?

S. Brand *, U. Haase, F. Pulzer, K. Hessel, Wetzig, J. Kratzsch and E. Keller. *University-Hospital Munich-Großhadern and University of Leipzig, Germany.

Recent epidemiological studies in adult populations suggest that intrauterine growth retardation (IUGR) is a risk factor for developing NIDDM and syndrome X later in life. Two groups of children and adolescents (aged 9.6 to 20.3 years) with low birthweight were compared: an IUGR group (group1, n=50) and another group of low birth weight children (group2, n=50) whose mothers received a minimum of 5 i.v. infusions of 2000 ml 10% glucose during pregnancy to compensate a suspected fetal malnutrition because of placental insufficiency. All subjects underwent an OGTT and IVGTT.

In the OGTT we observed a high prevalence of IGT according to WHO criteria. In group1 16% and in group2 22% had IGT. Subjects with IGT showed significantly higher insulin levels at 60 min ($p=0.007$), 90 min ($p=0.0001$), 120 min ($p<0.0001$) and higher proinsulin levels at 0 min ($p=0.003$), 30 min ($p=0.01$), 60 min ($p=0.0002$), 90 min ($p<0.0001$), 120 min ($p<0.0001$). The birthweight correlated inversely with the diastolic blood pressure ($r= -0.25$; $p=0.01$) and the serum uric acid ($r= -0.25$; $p=0.015$). Systolic and diastolic blood pressure were correlated with serum creatinine ($r=0.51$ and $r=0.45$; $p<0.0001$) and serum uric acid ($r=0.60$).

The early phase of IVGTT did not reveal any abnormalities in our patients.

Our results suggest a higher risk of developing diabetes and syndrome X later in life in persons with IUGR because there is an association of low birthweight and impaired glucose tolerance, insulin resistance (hyper-insulinemia and hyperproinsulinemia) and high blood pressure. There were no significant differences in the glucose metabolism of the both test groups. We conclude therefore that the prenatal glucose infusion therapy did not have an additional diabetic effect on these children and adolescents.

833

SERUM LIPID AND LIPOPROTEIN LEVELS IN WOMEN WITH GESTATIONAL IMPAIRED GLUCOSE TOLERANCE

M.M.S.Britto, J.M.D.Carreiro Pousada, S.Mengue and M.I.Schmidt. Federal University of Bahia, Federal University of Rio Grande do Sul-Brasil

A progressive increase in serum lipids and lipoproteins has been observed in pregnant women. However, variable results in pregnancies complicated by pregestational diabetes mellitus (PGDM) and gestational diabetes mellitus (GDM) had been previously reported. The purpose of this study was to investigate the effect of pregnancy on serum concentrations of lipids and lipoproteins in gestation impaired glucose tolerance (GIGT). The WHO 75g glucose tolerance protocol test and criteria were used between 24 and 28 weeks of pregnancy to diagnose GIGT. Fasting serum concentrations of lipids and lipoproteins were measured. As a result 219 consecutive laboratory tests were conducted and evaluated on women in a public prenatal care center in Salvador-Bahia. Glucose tolerance tests were normal in 200 pregnant women and GIGT was observed in another 19. The mean concentrations of lipids and lipoproteins shown in the normal glucose tolerance pregnant group (NGT) and GIGT were as follows:

	TC (mmol/l)	TG (mmol/l)	LDL (mmol/l)	HDL (mmol/l)	VLDL (mmol/l)
NGT n=200	4.63	1.27	2.95	1.09	0.25
GIGT n=19	4.08	1.19	2.40	1.13	0.24
P value	0.07	0.44	0.05	0.38	0.47

Body mass index (BMI) was significantly higher in GIGT women as compared to the NGT. Maternal age ,weight gain during pregnancy and parity were similar in the two groups. LDL levels were significantly higher in NGT than in GIGT. No hypertriglyceridemia was present in the GIGT women. Serum lipids showed a trend towards lower levels in GIGT women and were especially significant in LDL levels The absence of an increase in triglyceride levels detected thus far during pregnancy was unexpected. Additional researches are needed to assess the effect of abnormal glucose tolerance on the metabolic regulation of lipids in pregnancy.

834

Low birth weight does not predict metabolic syndrome in adult life.

P Vanhala[1], M Vanhala[1], E Kumpusalo[2], J Takala[2];[1] Pieksämäki Health Centre, [2] Department of Public Health and General Practice, University of Kuopio, Finland

It has been proposed that there is an association between low birth weight and metabolic syndrome (MBS) in adult life. In order to test this hypothesis, we screened all subjects aged 36, 41 and 46 years (N=1008) in Pieksämäki, a town in central Finland, for MBS, and collected data on birth weight, and weight and height of seven years of age . MBS was defined to be present in those subjects having simultaneously dyslipidemia (hypertriglyceridemia≥ 1.70 mmol/l and/or low high density lipoprotein cholesterol <1.00 mmol/l in men and <1.20 mmol/l in women) and insulin-resistance (impaired glucose tolerance or non-insulin-diabetes or hyperinsulinemia≥ 13.0 mU/l). We determined the occurrence of MBS in adult life according to quintiles of birth weight, and to quintiles of body-mass index (BMI) at the age of seven years. Chi-squared test was used for analysis. In all,712 (71%) subjects participated in the screening. Data on birth weight and BMI at age of seven years were obtained for 428 (42%) subjects. In these, MBS was present in 31/210 (15%) men and in 23/218 (11%) women. The prevalence of MBS was 9% in both the lowest and the highest quintile of birth weight, and ranged from 14% to 17% in three middle quintiles without there being any statistically significant difference between quintiles (p=0.32).The prevalence of MBS was 8% in the lowest quintile of BMI at seven years of age and increased up to 21% in the highest quintile. This increasing trend according to quintiles was statistically significant (p=0.026). Conclusion: we could not identify any evidence that there would be on association between low birth weight and MBS in adult life. However,a high BMI at seven years of age predicted MBS in adulthood.

835

LIPID PROFILE OF WOMEN WITH GESTATIONAL DIABETES AND IMPAIRED GLUCOSE TOLERANCE

N.Bikas, A.Hall, J.Anastasiou, A.Mermiri and S.Bousboulas. Department of Diabetic Endocrinology, "Mitera" Maternity Hospital, Athens, Greece

It is known that during pregnancy changes occur in the plasma lipid profile, in particular, increases in the levels of triglycerides (TG), cholesterol and phospholipids, with corresponding changes in the lipoproteins-mainly VLDL. The aim of this study was the evaluation of the level of lipids and lipoproteins in pregnant women with gestational diabetes or impaired glucose tolerance. A cohort of 136 women in the 28th to 32nd week of pregnancy were selected. Following a 12 hour fast and a 3-day measured intake of 150 g/day carbohydrate, each woman was subjected to a glucose tolerance test (OGTT) with 100 g glucose. Plasma glucose was measured colorimetrically at baseline and at 1, 2 and 3 hours after glucose load, and levels of CHOL, TG, HDL, LDL and VLDL were measured colorimetrically in the plasma prior to the OGTT. Using the diagnostic criteria of O'Sullivan and Mahan and according to the results of their OGTT, the women were divided into 3 categories: (i) 40 with confirmed gestational diabetes (GD). (ii) 63 with impaired glucose tolerance (IGT). (iii) 33 normal controls. Statistical analysis was by the student "t-test". It was confirmed that in relation to the normal controls, the women with GD (t=4.86, p<0.0001) and those with IGT (t=4.53, p<0.0005) had significantly increased levels of TG in their plasma, with parallel increases in the levels of VLDL, GD (t=3.72, p<0.001), IGT (t=3.72, p<0.001). Between the 2 groups of women with disturbed glucose metabolism (GD and PGT) there was not a significant difference in the levels of plasma TG and VLDL, as similary, there was not between these two groups and the normal controls when the plasma levels of CHOL, HDL and LDL were compared. In conclusion, the characteristic phenomenon of increased levels of plasma TG and VLDL in pregnant women with gestational diabetes or impaired glucose tolerance was confirmed.

836

SIZE AT BIRTH AND CORONARY HEART DISEASE MORTALITY IN FINNS BORN DURING 1924-33.

Forsén[1] T.J., Tuomilehto[1] J., Teramo[2] K., Reunanen[1] A., Nissinen[3] A., Osmond[4] C., Barker[4] D.J.P., Eriksson[1] J.G. [1]National Public Health Institute [2]Helsinki University Central Hospital [3]University of Kuopio [4]University of Southampton.

Diabetes is a major risk factor for coronary heart disease (CHD). Impaired fetal growth, as measured by low birthweight and low ponderal index (birthweight/length3, a measure of thinness at birth) has been associated with an increased risk of both NIDDM and CHD mortality. To study the impact of early life on CHD mortality we collected birth data from 11704 hospital births during 1924-33 in Helsinki. Of these 9578 subjects were identified in the population register, which was computerised in 1971. Birth weight could be measured in 9545 and ponderal index in 6987 subjects. During follow up since 1971 there have been 1463 deaths, of which 543 were due to CHD (448 male, 95 female). The impact of size at birth on CHD mortality was assessed using Cox's proportional hazards model. Risk of CHD death was 5.4 times higher in men (p=0.0001), decreased by 15.3 % (0.2%-28.1%, p=0.0479) for each additional kg of birthweight, and decreased by 3.5 % (1.2%-5.7%, p=0.003) for each additional unit (kg/m3) of ponderal index. Dividing ponderal index into equal fourths, risk of CHD death ranged from 2.0(1.4-2.9)- 1.6(1.1- 2.3) - 1.5(1.0- 2.2) -1.0(baseline) in men and from 1.3(0.6- 2.8) - 0.8(0.3- 2.0) -1.2(0.53- 2.669) -1.0(baseline) in women. Studies concerning the impact of impaired fetal growth on glucose metabolism are in preparation. Conclusion: thinness at birth predicts death from CHD in adult life.

837

THE IMPORTANCE OF A FAMILY HISTORY OF DIABETES MELLITUS IN RELATION TO THE AGE OF THE WOMAN IN THE MANIFESTATION OF GESTATIONAL DIABETES MELLITUS

N.Bikas, K.Vrionis, A.Zarkadoulias, J.Andreou, N.Spirtos and A.Kollias. Department of Diabetic Endocrinology, "Mitera" Maternity Hospital, Athens, Greece

The aim of this study was the appraisal of the importance of a family history of diabetes mellitus (DM), both independently and in correlation with age, in the manifestation of gestational diabetes mellitus (GDM). A cohort of 295 pregnant women were selected aged from 20 to 44 years, of whom 178 (60.3%) had a family history of DM, while 117 (39.7%) did not. Each woman was subjected to an OGTT using 100 g of glucose and plasma glucose was measured colorimetrically at baseline and 1, 2 and 3 hours after the load. According to the criteria of O'Sullivan and Mahan, out of the 178 women who had a family history, 21 (11.8%) had a normal OGTT, 83 (46.6%) had an impaired OGTT, while 74 (41.6%) had an abnormal OGTT. Out of the 117 women with no family history of DM, 23 (19.7%) had a normal OGTT, 52 (44.4%) had an impaired OGTT and 42 (35.9%) had an abnormal OGTT. The statistical comparison was obtained using the chi-squared test after the correction of Yates and the student "t-test" from which it was confirmed that the women with no family history of DM had a significantly increased frequency of normal OGTT (x^2=4.08, p<0.05). When this statistical exercise was applied to the ages of the women, it was found that only in this group of women (no history) was there a particularly significant correlation for the manifestation of gestational diabetes mellitus (t=2.68, p<0.01). We conclude that: 1) All pregnant women with a family history of DM, independent of age, should be subjected to an OGTT. 2) Pregnant women who have no family history of DM but are relatively advanced in years should be subjected to an OGTT.

838

MATERNAL CARBOHYDRATE METABOLISM AND REDUCED FETAL GROWTH

A.Caruso, G.Paradisi, and S.Ferrazzani. Catholic University School of Medicine, Rome, Italy.

Our purpose was to determine the impact of maternal carbohydrate metabolism and anthropometric characteristics on fetal growth in pregnancies with small for gestational age. We studied 8 women with unexplained small for gestational age and 10 with normal pregnancies using an oral glucose tolerance test and hyperinsulinemic euglycemic clamp in the third trimester of pregnancy. These data and maternal anthropometric characteristics were subsequently related to neonatal birth weight and percentile. The women with small for gestational age were relatively more insulin sensitive compared to controls ($p<0.05$) and showed a reduced insulin and glycemic area ($p<0.01$ and $p<0.04$, respectively). Insulin sensitivity had the strongest correlation with neonatal birth weight and percentile in the small for gestational age ($r=-0.77$, $p<0.03$ and $r=-0.73$ $p<0.04$ respectively). In contrast, in control women the best correlation between birth weight and birth weight percentile was seen with maternal weight gain ($r=0.83$, $p<0.01$ and $r=0.71$, $p<0.03$ respectively). Including all variables in the stepwise model we found that insulin sensitivity, insulin area and fasting insulin together explained 80% of the variability of neonatal weight in women with small for gestational age. On the contrary, in the controls the independent predictor accepted in the model was maternal weight gain and parity that explained 75% of the variability of birth weight. We conclude that insulin sensitivity seems to be a determinant factor for fetal growth in women with small for gestational age.

839

THE IMPORTANCE OF THE AGE OF THE WOMAN IN THE MANIFESTATION OF GESTATIONAL DIABETES MELLITUS

N.Bikas, A.Hall, S.Bousboulas, V.Sotiracopoulos and D.Kellaris. Department of Diabetic Endocrinology, "Mitera" Maternity Hospital, Athens, Greece

The aim of this study was the appraisal of the importance of the age of the woman in the manifestation of gestational diabetes mellitus. A cohort of 556 pregnant women, aged from 18 to 44 years were selected and subjected to an OGTT with 100 g glucose following a 3-day diet including 150 g/day carbohydrates. Plasma glucose was measured colorimetrically at baseline and 1, 2 and 3 hours after the glucose load. The assessment of the results was according to the diagnostic criteria of O'Sullivan and Mahan. Results: Nine out of 65 women (13.8%) aged up to 24 years, 29 out of 165 (17.6%) aged 25-29 years, 66 out of 203 (32.5%) aged 30-34 years, 37 out of 102 (36.3%) aged 35-39 years and 21 out of 47 (44.7%) aged 40-44 years were diagnosed as having gestational diabetes mellitus. The statistical comparison was performed using the chi-squared test after the correction of Yates. It was subsequently proven that women aged 30-34 years had a significant difference from women aged 25-29 years ($x^2=11.4$, $p<0.01$). A still greater effect on the diagnostic outcome was observed in women aged 35-39 and 40-44 years. Overall, the women who were over 30 years of age had a significantly different and pathological OGTT from women aged under 30 years ($x^2=25.2$, $p<0.001$). We conclude that for women aged over 30 years extra vigilance for the onset of gestational diabetes mellitus is required during a pregnancy.

840

MATERNAL SIZE, NUTRITION AND FOETAL GROWTH IN RURAL INDIA.

C.S.Yajnik, K.J.Coyaji,Shobha Rao, C.H.D. Fall, and D.J.P.Barker. K.E.M. Hospital Research Centre, Pune,India, Agharkar Research Institute, Pune, India and Institute of Human Nutrition,Southampton, U.K.

Recently described association between poor intrauterine growth and adult diabetes may be particularly relevant in India. We studied maternal size, nutrition and foetal growth in 6 villages near Pune. 814 pregnant women (age 21.3 y, height 1.52 m, weight 41.7 kg and haemoglobin 119 g/L; mean) delivered 771 live babies (weight 2613g, length 47.4 cms, placenta 357g). Average maternal intake was 1790 kcal, 45 gm proteins and 18 mg iron. In addition to the length of gestation and sex, birthweight was related to maternal preconceptional weight ($r=0.23$, $p<0.001$) and height ($r=0.16$, $p<0.01$), and to weight gain ($r=0.15$,$p<0.01$), haemoglobin ($r=-0.12$, $p<0.05$) and fasting plasma glucose concentration ($r=0.09$, $p<0.05$) at 28 wks and to placental weight ($r=0.61$, $p<0.001$). It was, not related to maternal intake of calories, proteins and iron. Maternal size and weight gain though significant determinants, together made a relatively small contribution to the variability of birth weight (~5%).

841

INSULIN SECRETION AND SENSITIVITY IN WOMEN WITH GESTATIONAL DIABETES MELLITUS AT FOLLOW-UP

R. Corcoy, A. García, J. Rodríguez, M. Albareda, A. Caballero and A. Leiva. Sant Pau, Barcelona

In women with gestational diabetes (GD), abnormal insulin secretion (SEC) and sensitivity (SI) have been described. We aim to assess the contribution of these factors to GD and to abnormal glucose tolerance postpartum. At postdelivery follow-up, a 75 gr oral glucose tolerance test (0'30'60'120' glucose and insulin) has been performed in 55 GD women and a control group (C) with negative GD screening. SEC has been estimated as the ratio of insulin to glucose incremental areas 0-30' and SI as the index described by Cederholm. Mann-Whitney test is used for comparison. GD women have a SI lower than controls (50.5±12.2 vs 69.0±4.1 $mg.l.l.mmol^{-1}.mU^{-1}.min^{-1}$, $p<0.05$) but a similar SEC (16.5±17.0 vs 20.7±16.4 mU/mmol, ns). According to NDDG criteria, glucose tolerance is abnormal in 12 GD women (GD_AGT) and normal in 43(GD_NGT). From C to GD_NGT to GD_AGT, there is a stepped decrement in SI (69.0±4.1 $mg.l.l.mmol^{-1}.mU^{-1}.min^{-1}$ vs 53.9±11.2 vs 38.3±6.6, C vs GD_NGT $p=0.05$, GD_NGT vs GD_AGT $p<0.001$). For SEC the only decrease is between GD_NGT and GD_AGT (20.7±16.4 mU/mmol vs 18.8±18.6 vs 8.5±3.3, C vs GD_NGT ns, GD_NGT vs GD_AGT $p<0.01$). We conclude that the main feature of GD is low SI whereas both low SI and SEC contribute to AGT in women with prior GD.

FIS 94/1538

842

ASSOCIATION BETWEEN BIRTH WEIGHT AND ADULT METABOLIC PROFILE IN THE OFFSPRING OF NIDDM SUBJECTS

T. Valle[1], C.D. Langefeld[2], E.R. Hauser[2], R.M. Watanabe[2], S. Ghosh[3], K. Kohtamäki[1], T. Forsen[1], J. Tuomilehto[1], T.A. Buchanan[4], and J.G. Eriksson[1], for the Finland-United States Investigation of NIDDM Genetics (FUSION) study. [1]National Public Health Institute, Helsinki, Finland; [2]University of Michigan, Ann Arbor, MI, USA; [3]NCHGR, Bethesda, MD, USA; [4]USC School of Medicine, Los Angeles, CA, USA.

Impaired and disproportionate fetal growth has been associated with an increased risk for NIDDM, coronary heart disease, and hypertension in large-scale epidemiological studies. To determine whether a similar risk profile occurs across a spectrum of birth weights (BWs) in individuals at high risk for NIDDM, we analyzed data from the FUSION study. 466 adult offspring of a diabetic parent who were products of singleton pregnancies delivered at term participated in a clinical examination with an oral glucose tolerance test (75 g glucose load) and a frequently-sampled intravenous glucose tolerance test (FSIGT) using the Minimal Model approach. The offspring were divided into two groups depending whether the affected parent was the mother (AFMO) (n=172) or the father (AFFA) (n=294). Birth weight did not differ between the two groups (AFMO 3606g, SD 582; AFFA 3548g, SD 442; p=0.26). The relationship between BW and systolic and diastolic blood pressure, fasting and 2-hour post-load plasma glucose and serum insulin, FSIGT measures (acute insulin response, insulin sensitivity, glucose effectiveness) and serum lipids (total and HDL-cholesterol, triglycerides) were tested using Generalized Estimating Equations, adjusting for gender and age of the offspring. In the AFMO group there was a positive nonlinear relationship between BW and acute insulin response (p=0.032). Furthermore, a negative nonlinear relationship between BW and fasting insulin was observed (p=0.0051). We found negative relationships between systolic (p=0.0010) and diastolic blood pressure (p=0.0042) and BW in the AFMO group. In the AFFA group, the study showed evidence for a positive relationship between birth weight and fasting insulin value (p=0.0234). All the other variables failed to show a significant relationship to BW. Thus, the offspring with diabetic mothers showed a stronger association between factors associated with fetal growth and adult metabolic risk factor profile than those with diabetic fathers. These findings suggest an important influence of intrauterine development on blood pressure and hyperinsulinemia in families with NIDDM.

843

PREGESTATIONAL DIABETES : INSULIN MULTIPLES DOSES AND CONTINUOUS SUBCUTANEOUS INSULIN INFUSION

J.E.Costa Gil, C.López, M.C.De los Santos. Hospital Materno Infantil de San Isidro. Centro de Reproducción y Planificación Familiar. La Plata, Argentina

OBJECTIVE. To compare the results between the usage of combination of intermediate and regular insulin multiple doses (IMD) and continuous subcutaneous insulin infusion with pumps (CSII) during pregnancy in intensified insulin therapy treated type I diabetic patients, in two medical centers of Argentina,

MATERIAL AND METHODS. From 1984 to 1996, 94 pregnancies in 68 women with IDD were evaluated. IMD was used in the course of 59 pregnancies (Mean and SD of: 1) the age at the time of pregnancy: 24.8 +/- 4.9 yr.; 2) the age at the beginning of IDD : 14.7 +/- 6.7 yr. 3) the IDD evolution time: 10.2 +/- 5.7 yr.) and CSII was used in 35 (Mean and SD of : 1) the age at the time of pregnancy: 25.8 +/- 4.1 yr., 2) the age at the beginning of IDD: 16.4 +/- 6.9 yr. and 3) the IDD evolution time : 9.3 +/- 5.6 yr.). In the study, 74.5% of the patients with IMD and 52.4% with CSII went through her first pregnancy. Statistical methods: Student, Fisher and Mantel-Haenszel Tests.

RESULTS. The mean newborn weight was 3508 +/- 562 g in the 37.4 weeks in the IMD group and 3586 +/- 401 g in the 38.4 weeks in the CSII group. Statistical difference between groups was not found to exist in the age at pregnancy, the age at the beginning of IDD, the IDD evolution time and the newborn weight, but there was difference at the moment of delivery. The following difficulties were observed:

	IMD	CSII	
Abortion or in uterus fetal death	15	3	p = 0.044
Newborn complications	18	4	p = 0.035
Congenital abnormalities	6	4	p = 0.550

CONCLUSIONS. In a study of comparable groups of pregnancies in IDD patients treated with IMD or CSII, there was not difference in the weight of the son at born, but there was a week of difference in the mean of the date of delivery. The frequency and severity of congenital abnormalities were similar in both groups, but in patients with CSII the number of abortions and in uterus fetal death and the complication of the newborn (hypoglycemia, polycythaemia,etc) were significantly less, maybe because the CSII would permit the extension of the pregnancy and would facilitate a more tightly glycemic control near the time of delivery.

844

PARENTAL GLUCOSE TOLERANCE AND FOETAL GROWTH IN RURAL INDIA.

S.D.Kale, M.Shah, D.S.Bhat, C.H.D. Fall and C.S.Yajnik. K.E.M. Hospital, Pune, India, Inst.of Human Nutrition, Southampton, U.K..

We studied glucose tolerance (75g OGTT, WHO 1985) in 597 pregnant women (mean age 21.5 y, height 1.52 m, preconceptional weight 42.0 kg, BMI 18.1 kg/m^2) at 28 wks gestation, in 6 villages near Pune. Mean fasting plasma glucose concentration was 4.0 mmol/l and 2h post glucose 4.4 mmol/l, neither were related to age, SE status, weight, BMI, waist hip ratio and weight gain. Four women (0.07%) showed IGT, none diabetes; one woman had pregestational diabetes. Fasting but not 2h plasma glucose concentration was related to birth weight (r=0.09, p<0.05). In husbands (29y, 1.65 m, 52.9 kg, 19.5 kg/m^2), fasting and 2h plasma glucose concentration was 5.0 mmol/l and 5.1 mmol/l, 13 (2.3%) showed IGT and 1 diabetes. Paternal glucose was also related to birth weight (r=0.08, p<0.05). Our findings show a very low prevalence of gestational diabetes in rural India, probably because of low caloric intake and high level of physical exercise (farming). Maternal plasma glucose though a significant relation, is not a major determinant of birth weight in this population.

845

FASTING GLUCOSE LEVELS AT DIAGNOSIS PREDICT INSULIN REQUIREMENTS IN GESTATIONAL DIABETES(GDM).

E.Wright, J.James, C.O'Meara and J.D.Wilson. School of Nursing, University of Canberra and Department of Endocrinology, The Canberra Hospital, ACT, Australia.

Data on 330 women with GDM and a singleton fetus was analysed to determine the efficacy of the fasting plasma glucose level (FPG) at diagnosis for identifying women likely to require insulin therapy during pregnancy.The diagnosis of GDM was made on a FPG ≥5.5mmol/l and/or a two hour level ≥8.0mmol/l during a 75G oral glucose tolerance test.The women had a mean age of 34 years,BMI of 25.7 and parity of 2 (R 1-9).Seventy one percent of the women were Caucasian,11% Asian, 8% Mediterranean, 8% Indian, and 2% Maori. Fifteen percent had a previous history of GDM and 50% had a family history of diabetes. Diagnosis was made at a mean of 30 weeks gestation and insulin was commenced if fasting capillary blood glucose levels were repeatedly ≥5.0mmol/l or ≥6.5mmol/l two hours postprandial in spite of dietary intervention. Seventy two of these women required insulin with a mean dose of 34 IU per day, commencing at a mean of 31 weeks gestation. Mean birthweight was 3400G. Twelve percent of the babies were >4000G. A 50% probability for requiring insulin was reached with a FPG at diagnosis of 3.5 mmol/l if tested at 10 weeks gestation,5mmol/l at 20 weeks and 5.7 mmol/l at 30 weeks (p<.001). It is concluded that the FPG level at diagnosis may identify a subgroup of women more likely to require greater intervention during the pregnancy.

846

SCREENING FOR GESTATIONAL DIABETES MELLITUS. RELATIONSHIP WITH THE GESTOSIS DEVELOPMENT. N.V.Trusova, A.S.Ametov, L.E.Mourashko Russian Academy of Advanced Med.Studies, Moscow, Russia.

Gestational Diabetes Mellitus(GDM) connected for mothers with an increased risk of subsequent overt diabetes mellitus and in addition to the well-known perinatal risk may be associated with an increased risk of childish obesity and NIDDM development in later life. That's why the early diagnostic of GDM is very important and provides not only a healthy baby, but a unique opportunity to identify individyals at high risk of NIDDM at the time when the change of lifestyle can reduce overall diabetic morbidity. But at the present time it's no international agreement regarding diagnostic criteria for GDM and its treatment. We screened 600 pregnant women with and without risk factors at 24-28 weeks of gestation. Our programme includes 50gGCT, 100g OGTT, self-monitoring blood glucose(glucometer One Touch II (LifeScan)). Another problem is that women with GDM have an increased rate of gestosis cases. The mechanism underlying the association is not comletely understood. We obtained all women undergoing glucose challenge test to determine connection between plasma glucose level in screening and frequency of gestosis development. Our study defines the importance of uniformity in screening, diagnosis and management programme. Also we marked increase of the GDM rate in Russia and developed the programme of this disease management adapted to our conditions.

847

DIABETIC KETOACIDOSIS IN GESTATIONAL DIABETICS

Arguedas C., Jiménez F., Palma O., Fuchs J. Intern Medicine Hospital México, San José, Costa Rica

The diabetic ketoacidosis (DKA) is an uncommon complication of the pregestational diabetic (less than 1.5%) and is almost anecdotal in gestational diabetic mellitus (GDM). In a period of 3 years we had 4 cases of DKA in GDM. The principal data was:

	A	B	C	D
Age	19	17	22	29
Glycemia (mg/dl)	810	765	778	857
Arterial $_{p}H$	7.10	7.01	7.28	7.27
Bicarbonate mmol/l	7.4	2.0	9.0	8.0
I.C.A's	(-)	(-)	(-)	(-)
O.G.T.T.	(-)	(+)	(+)	(+)
Preeclampsia	(+)	(-)	(+)	(+)
B.M.I.	23	24	21	30

I.C.A's: Islet cell antibody; **O.G.T.T.:** Oral Glucose Tolerance Test; **B.I.M.:** Body Mass Intex

Because of ICA's were negative aloud us to classify these patients as NIDDM. After 6 month of delivery, 3 patients remain with diabetic OGTT according with the OMS criteria (1985), and are on insulin therapy. Only 1 patient is been treated for hypertension. One of them is prenant again (8^{th} month). Four patients had infection as the cause of diabetic derrangemet and have the DKA after week 28^{th} of pregnancy. Two had fetal death. The diagnosis of GDM is very easy to do and must be established in any health system. We do not have an explanation why these patients developed DKA. The DKA in GDM is a very important cause of fetal death and very dangerous for the mothers.

848

SCREENING AND INTERVENTION IN GESTATIONAL DIABETES MELLITUS

I.Pavlić Renar, M. Tomić, B. Horvat, Ž. Metelko
"Vuk Vrhovac" University Clinic for diabetes, endocrinology and metabolic diseases, Medical faculty University of Zagreb
Dugi dol 4a, 10 000 Zagreb, Croatia

Referred incidence of gestational diabetes (GDM) in the country is lower than 1%. Current practice of screening for GDM is OGTT (WHO criteria) in 24-28 week in women with risk factors. The aim of the study is an evaluation of this approach.

Data from 60 of total 122 women with GDM or impaired glucose tolerance (IGT) in 24-28 pregnancy week was compared with a group of 60 randomly selected from 2000 referred in the same period with normal OGTT. Fifty percent of women were less than 24 weeks pregnant. Women with IGT or GDM were older (95%ci: 31-32 years) and heavier (prepregnancy body mass index (BMI): 95% ci 26-28) than controls (95% ci age: 22,9-25,1 years, 95% ci BMI: 29-32). There were no differences in family history or history of stillbirth and miscarriages. All women with abnormal OGTT were treated targeting mean blood glucose <6,1 mM. Birth weight was insignificantly higher in IGT and GDM group. There were more caesarean sections (14) and maternal complications (6) than in controls (3 and 2 res.). There were no stillbirths, one major malformation was present in IGT and GDM group.

Even with intervention, pregnancy outcome in GDM differs from controls. By the present approach around four- fold reduction in number of screened women is expected. However, a large number of gestational diabetes is missed and it seems better to screen all the pregnancies.

849

GLOMERULAR AND TUBULAR DYSFUNCTION IN WOMEN WITH PREVIOUS GESTATIONAL DIABETES MELLITUS

Gy.Bíbok, Gy.Tamás, Á.Tabák, Á.Nádasdi*, P.Stella* and Zs.Kerényi*.1st.Dept.of Medicine, Semmelweis University and Szent Imre Hospital*, Budapest, Hungary

Our aim was to study the occurrence of late diabetic renal complications in two groups of women with previous gestational diabetes mellitus (GDM) after reclassifying their carbohydrate metabolism. Women first insulinized during pregnancy (GDM-I [n=75]; mean age 38 [range: 24-52]yrs, time elapsed since diagnosing GDM: 7.1 [3-14]yrs) were investigated. Patients on diet during gestation served as controls (GDM-D [n=29]: age 37 [26-52]yrs, follow up 6.9 [4-10]yrs). Serum creatinine, beta-2-microglobulin [b2m]; urinary albumin, creatinine and b2m were measured. To increase the sensitivity of microalbumin and urinary b2m measurements albumin/creatinine [UA/CR] and b2m/creatinine [B2M/CR] ratio were also calculated. None of the cases had elevated serum creatinine (mean [range]: GDM-I 81 [51-112]µmol/l; GDM-D 82 [69-93]). Microalbuminuria (MAU) [30-300 mg/day] was found in 15 GDM-I cases (one macroalbuminuria too): in 10/45 of verified diabetic patients (22.2%), 4/23 (17.4%) in non-diabetic persons (P=0.2, NS.) and in 1/6 IGT; in 2 GDM-D cases (1/6 diabetes, 1/6 IGT). UA/CR and B2M/CR ratio was significantly higher in GDM-I (average 6.8 ± 14.1 mg/mmol; and 0.014±0.018mg/mmol) than in GDM-D (1.9 ± 2.9 mg/mmol; and 0.007±0.004, resp); (P<0.05). However, the ratio of UA/CR and B2M/CR did not provide further information than measuring their concentration only, if the data were analized one by one. Urinary b2m concentration was significantly elevated but still in normal range in diabetic patients of GDM-I (0.068±0.07) compared to GDM-D (0.035±0.016) group; (P<0.05). One patient had pathological urinary b2m in GDM-I. Based on these data we suggest that similar prevalence of MAU in both diabetic and non diabetic patients with high frequency of hypertension may indicate that MAU could be an early cardiovascular risk marker rather than the sign of early renal impairment. On the other hand, slightly elevated urinary b2m among diabetic patients may reflect an early tubular dysfunction.

SCREENING OF GESTATIONAL DIABETES MELLITUS

Tofail A*, Rahman H*, Mahtab H*, Karim A**, Kabir T**

*Bangladesh Institute of Research and Rehabilitation in Diabetes, Endocrine and Metabolic Disorders, Dhaka
**Dhaka Medical College Hospital, Dhaka.

To know the incidence of ***Gestational Diabetes Mellitus (GDM)*** in our population, 1000 pregnant women were screened for glucose intolerance by a ***Glucose Challenge Test (GCT)*** and ***Oral Glucose Tolerance Test (OGTT)***. Of them 67 (6.7%) were found to have GDM. The GDM mothers were significantly elderly ($p < 0.001$) and overweight ($p < 0.001$) than the non-diabetics. Family history of diabetes was significantly more among the GDM group. They also belong to comparatively higher socio-economic class than the non-diabetic group ($p < 0.001$). ***Bad Obstetric History (BOH)*** was more among GDM ($P < 0.01$) but the two groups did not differ by parity. Analysis documented overweight, diabetic family and BOH as individual risk factor for GDM. Mothers without any of these three risk factors had lowest rate of GDM (1.68%). Underweight or younger age were not protective for GDM; combination of risk factors increase the rate. A diabetic family history plus other risk factor(s) showed significant susceptibility than any other combination. After delivery 4.5% (n=3) became diabetic, 16.4% (n=11) IGT and rest 79% (n=53) normal.

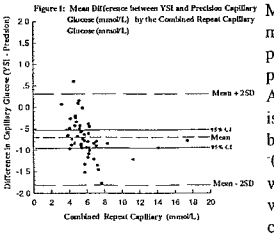
Key Words: GDM, IGT, GCT, OGTT, Diabetic family, BOH.

851

ACCURACY OF THE MEDISENSE PRECISION BLOOD GLUCOSE METER IN GESTATIONAL DIABETES MELLITUS (GDM)

L. Molyneaux, J Overland, K Willey, R Zilkens, D.K. Yue. Royal Prince Alfred Hospital, Sydney, Australia

The accuracy of blood glucose meters used in GDM is of prime importance, especially when haematocrit changes in pregnancy may be a source of error. The aim of this study was to measure agreement of the Medisense Precision meter(MPM) versus the Yellow Spring Instrument (YSI) in women with GDM. Due to the controversy regarding whether whole blood or plasma glucose should be used to monitor GDM, this study also compared the MPM, which used whole blood, with plasma glucose derived from the YSI after adjustment for haematocrit [calculated plasma glucose = (capillary whole blood result)/[1.0-(2.4×10^{-3} x haematocrit%)]]. 200 μL of capillary blood was collected into a lithium heparin microlette CB 1000 from 50 women with GDM (gestation 10-39 weeks). Repeat blood glucose readings were obtained on both the MPM and YSI. Mean haematocrit was 36% (range 31-42%). The mean capillary blood glucose using the MPM and Microflo test strip was 6.5 ± 2.5 mmol/L compared to 5.8 ± 2.4 mmol/L ($r=0.98$; $p<0.0001$) or 6.3 ± 2.6 mmol/L for calculated plasma glucose ($r=0.98$; $p<0.0001$). Agreement/difference between the MPM and YSI is shown in Figure 1. The mean difference between the instruments was -0.7 (95% CI: -0.6 - -0.9) mmol/ L for whole blood. This difference was reduced to -0.2 (95% CI: -0.05-0.3) mmol/L when MPM whole blood was compared with calculated plasma glucose. This study showed a strong agreement between the MPM and YSI over a wide haematocrit range. The agreement was even stronger with calculated plasma glucose after adjustment for haematocrit, indicating that the MPM is an accurate instrument with which to monitor diabetic control in women with GDM.



852

DIAGNOSTIC VALUE OF THE MULTIPLICATION OF THE FASTING LEVELS OF GLUCOSE AND TRIGLYCERIDE IN WOMEN WITH GESTATIONAL DIABETES

N.Bikas, A.Hall, S.Bousboulas, J.Anastasiou and K.Kanellopoulou. Department of Diabetic Endocrinology, "MITERA" Hospital, Athens, Greece

In a previous paper we proved that the concentration of the fasting blood glucose (FBG) upto a level of 105 mg% does not confirm or exclude the diagnosis of gestational diabetes mellitus (GDM). In another research project we found that increased levels of triglyceride (TG) are a characteristic finding in gestational diabetes mellitus. Therefore the aim of this work was the evaluation of the diagnostic value of multiplying the FBG with the TG (mg/dl) in cases of GDM. To this end, 191 women in the 28th to 32nd week of pregnancy and without a family history of hypertriglycemia were subjected to an oral glucose tolerance test (OGTT) using 100 g of glucose after three days of carbohydrate intake (150g daily) and a 12 hour fast immediately prior to the test. Glucose by the glucose oxidase methods and triglyceride by a colorimetric method were measured in the plasma of the fasting blood with further samples for the OGTT being taken at 1, 2 and 3 hours after the administration of the glucose load. Using the diagnostic criteria of O'Sullivan and Mahan, the women were categorised into 3 groups: 1) 66 with overt GDM, 2) 84 with impaired glucose tolerance (IGT), 3) 41 with normal OGTT. For each woman the FBG X TG was calculated and a statistical relationship was determined using the student "t-test". It was found that in comparison with the women who had a normal OGTT, women with GDM had a significantly increased value when the FBG was multiplied by the TG ($t=5.77$, $p<0.0001$) and women with poor glucose control also had an increased value but to a slightly lesser extent ($t=4.7$, $p<0.0005$). Furthermore, betwen the women with GDM and those with IGT the values for FBG X TG were significantly different ($t=2.1$, $p<0.05$). Conclusion: The multiplication of the FBG by the TG in pregnant women has a high diagnostic value for gestational diabetes mellitus.

853

SPECIFIC INSULIN ASSAY TO MEASURE INSULIN RESISTANCE AND GLUCOSE EFFECTIVENESS IN GESTATIONAL DIABETES MELLITUS (GDM)

J. Castro-Soares, C. Hensen[1], O. Jones[1], V. Anyaoku, C Kong[1], C. Prendergast, S. Batty[1], J. Higham, R.W. Beard, R.S Elkeles[1], D.G. Johnston and S. Robinson[1]. Department of Obstetrics and Unit of Metabolic Medicine[1] St Mary's Hospital, London.

Insulin insensitivity and hyperinsulinaemia are recognised features of normal pregnancy and GDM. The proportion of biologically inactive insulins, detected by RAI, is increased in GDM. We therefore aimed to measure insulin secretion and insulin action in women with GDM using a specific insulin assay after performing an insulin modified frequent-sampling intravenous glucose tolerance test. Eight women with GDM were compared with 8 control pregnant women and 8 non-pregnant controls; body mass index was similar in the pregnant groups but lower in controls (median[IQR]) (non-preg 23.6[20.4-29.6] vs preg 28.0 (25.1-31.1] vs GDM 32.9 [26.4-35.2] kg $\cdot m^{-1}$, $p<0.05$), gestational age was similar in the pregnant groups (preg 32[30-34] v GDM 33[30-3]). A specific insulin ELISA and minimal modelling were used to assess insulin sensitivity (S_I) and glucose effectiveness (S_G). Fasting plasma glucose concentrations were similar in the three groups (non-preg 4.9 [4.7-5.2] vs, preg 4.7 [3.9-5.4], GDM 4.5 [3.9-4.7]mmol.l^{-1}). Fasting plasma insulin was raised in GDM compared to non-pregnant women (non-preg 3.4[1.1-5.6], preg 13.6 [10.1-30.4], GDM 13.5 [7.0-21.9]pmol/l), as was insulin area under the curve 2-24 minutes (non-preg 97[53-444], preg 393[237-885], GDM 394 [172-614] pmol per 24 min, $p<0.05$). Glucose tolerance (K_d) was decreased in pregnancy and further decreased in GDM (non-preg 2.4 [1.5-3.0], preg 1.8 [1.5-2.2], GDM 1.1 [0.7-1.3]%, $p<0.05$). S_I was decreased in pregnancy and further decreased in GDM (non-preg 18.3 [6.2-26.6], preg 4.2 [2.5-5.2], GDM 2.2 [1.3-3.3]$10^{-4} \cdot m^{-1}$ per $pM.l^{-1}$, $p<0.05$). S_G was decreased in GDM (non-preg 2.5 [1.7-3.0], preg 3.1 [2.1-4.6], GDM 1.4 [0.4-2.1]$10^{-2} \cdot min^{-1}$, $p<0.01$). Triglyceride concentrations were increased in pregnancy and further increased in GDM (non-preg 0.63 [0.57-0.67], preg 1.46 [1.14-2.16], GDM 2.21 [1.98-3.00]$mM.l^{-1}$,$p<0.01$). The use of a specific insulin assay with minimal modelling has demonstrated insulin resistance and reduced glucose effectiveness in women with gestational diabetes.

854

PROGNOSTIC VALUE OF FASTING BLOOD GLUCOSE FOR GESTATIONAL DIABETES MELLITUS

N.Bikas, S.Bousboulas, A.Hall, P.Valsamopoulos and N.Linardos. Department of Diabetic Endocrinology, "Mitera" Maternity Hospital, Athens, Greece

The aim of this study was the appraisal of the prognostic value of a fasting blood glucose (FBG) <130 mg% in the diagnosis of gestational diabetes mellitus, given that two separate measurements above this threshold is regarded as being diagnostic for the condition. A cohort of 728 pregnant women were studied aged from 20 to 42 years. Following 3 days of carbohydrate intake of 150 g/day, each woman was subjected to an OGTT using 100 g of glucose and measuring plasma glucose at baseline and 1, 2, and 3 hours after the load. According to the criteria of O'Sullivan and Mahan the results of the women were divided into the following categories: (i) 159 women (21.8%) with normal OGTT. (ii) 347 (47.7%) with impaired glucose tolerance. (iii) 222 (30.5%) with gestational diabetes mellitus. Also, the women were divided into groups according to their fasting blood glucose: (i) up to 89 mg%. (ii) 90-105 mg%. (iii) 106-130 mg%. Each group was then divided into 3 sub-groups depending on whether the OGTT was normal, impaired or abnormal. Results: There were 67 women (17.7%) with confirmed GDM in group 1, 84 women (32%) in group 2 and 71 (81.6%) in group 3. Statistical comparison was obtained using the chi-squared test after the correction of Yates. The women in group 3 had a statistically significant difference in the effect of confirmed GDM on their FBC from the women in group 2 (x^2=66.97, p<0.005) and an even greater difference from the women in group 1 (x^2=141.83, p<0.0001). Also, the results of the women in group 2 were statistically different from those of the women in group 1 (x^2=18.60, p<0.005). We conclude that: 1) A fasting blood glucose (FBG) of 106-130 mg% in a pregnant woman is indicative in a relatively high percentage of cases of gestational diabetes mellitus (GDM). 2) A FBG of 90-105% conceals the incidence of 1 in 3 cases of GDM. 3) A FBG less than 90 mg% does not exclude GDM, and for this reason, if it is to be aided by other tests for the diagnosis of impaired glucose tolerance, then an OGTT is the test of choice.

855

SPECIFIC INSULIN ASSAY DEMONSTRATES INSULIN RESISTANCE IN WOMEN WHO HAVE HAD GESTATIONAL DIABETES MELLITUS

E. Kousta, V. Anyaoku, D.G. Goulis, S. Batty, C. Kong, D.G. Johnston, M. McCarthy and S. Robinson. *Unit of Metabolic Medicine, Imperial College School of Medicine at St Mary's, London, UK.*

NIDDM in women is often preceded by gestational diabetes (GDM). We investigated insulin action and secretion in healthy women with previous GDM (median months after pregnancy 17 (IQR 38)). An insulin-modified frequent-sampling intravenous glucose tolerance test was performed in 8 women with previous GDM and 9 control women with similar BMI (median 26.4 (IQR 7.9) vs 26.0 (8.1) kg $\cdot m^{-2}$) and age (35.5 (3.5) vs 40.0 (9.8) yrs). Specific insulin was measured by ELISA as opposed to the more conventional but less specific insulin RIA; minimal modelling was used to measure insulin sensitivity (Si) and glucose effectiveness (Sg). Fasting triglycerides were higher (1.1 (0.5) vs 0.7 (0.1) mM $\cdot L^{-1}$, p=0.0008) and HDL cholesterol lower (1.1 (0.3) vs 1.5 (0.3) mM $\cdot L^{-1}$, p=0.01) in previous GDM. Fasting insulin was also higher (14.0 (11.0) vs 4.8 (5.2) pM $\cdot L^{-1}$, p=0.008). The lower Si in women with previous GDM (4.2 (6.5) vs 14.7 (18.3) $10^{-4} \cdot min^{-1}$ per pM $\cdot L^{-1}$) was not statistically significant (p=0.07). Glucose tolerance (K_d) was not significantly decreased in previous GDM (1.4 (0.9) vs 2.4 (1.1) %, p=0.07). There was no difference in Sg (1.9 (1.0) vs 2.3 (1.1) $10^{-2} \cdot min^{-1}$) nor in the area under the curve for insulin. In conclusion women who have had gestational diabetes have fasting hyperinsulinaemia and suggest insulin resistance, using the specific insulin ELISA.

856

GESTATIONAL DIABETES MELLITUS IN KOREA: PREDICTION OF SUBSEQUENT GLUCOSE INTOLERNACE AT EARLY POSTPARTUM

H. Jang, H. Jung, I. Han, and H. Min, Samsung Cheil Hospital, Seoul, Korea

To determine the prevalence of impaired glucose tolerance and diabetes, and identify clinical and metabolic parameters that can predict the risk of glucose intolerance at early postpartum in women with gestational diabetes mellitus (GDM), we performed 75 g oral glucose tolerance test between 6 and 8 weeks postpartum in 149 women with GDM. The recommendations from International Workshop-Conference on GDM were used for screening, diagnosing, and subclassifying GDM. National Diabetes Data Group criteria were used for classification of glucose tolerance postpartum. Among 149 women with GDM, 109 were GDM class A_1, 27 were GDM class A_2, 13 were GDM class B_1 in antepartum oral glucose tolerance test.

Thirty-eight (25.5%) of the patients had abnormal glucose tolerance in the early postpartum period; 16 (10.7%) had impaired glucose tolerance (IGT) and 22 (14.8%) had diabetes. Those who had IGT or diabetes at early postpartum had significantly higher antepartum glucose levels at 0, 1, 2, and 3 h compared with those who had normal glucose tolerance at postpartum. They had also significantly lower insulin levels at 1, 2, and 3 h than those with normal glucose tolerance at postpartum. However fasting insulin levels were not different between women with normal glucose tolerance and women with abnormal glucose tolerance at postpartum. The gestational age at diagnosis of GDM in women with diabetes postpartum was significantly lower than those with normal glucose tolerance at postpartum. Logistic regression analysis showed that abnormal glucose tolerance at early postpartum testing was independently associated with prepregnant BMI (P<.05), gestational age at diagnosis of GDM (P<.05), and 2 h glucose and 1 and 2 h insulin levels at antepartum glucose tolerance test (P<.05, P<.001, P< 5, respectively). Our results demonstrated that impaired β-cell function and obesity at diagnosis of GDM were associated with the abnormal glucose tolerance at early postpartum.

857

MATERNAL AUTOIMMUNE THYROIDITIS DOES NOT ELEVATE STREPTOZOTOCIN SENSIBILITY IN OFFSPRING

J.Lementa, V.Poltorack. Ukrainian Scientific Research Institute of Endocrine Diseases Pharmacotherapy, Kharkov, Ukraine

In order to evaluate the impact of autoimmune thyroiditis (AT) during gestation on streptozotocin (STZ)-reactivity in offspring the maternal (CBA/J x C57Bl/KsJ)F_1 mice with AT, gestational diabetes (GD), AT+GD, or controls and their progeny were used. AT was induced by s.c. injection of human thyroid antigen with Freund's adjuvant, the maternal mice were rendered diabetic by an i.p. injection of STZ (50 mg/kg) on the first day of pregnancy. To characterise the sensibility to STZ in offspring the i.p. GTT (2 g glucose/kg) was performed at 2 and 3 months of age (before - and a month after a single injection a nondiabetogenic dose STZ-35 mg/kg i.p.). The used dose of STZ did not induce any alterations of basal blood glucose levels (BGL) and tolerance to glucose 1 month after STZ-injection in control mothers offspring (n=7) compared to vehicle-injected ones (n=8). In offspring of diabetic mice (n=11) this dose of STZ resulted in an increase of BGL (8.3±0.2 mmol/l vs 5.7±0.1 mmol/l in controls, p<0.001) and a decrease of tolerance to glucose (integral glycemia during i.p.GTT at 0, 30, 60 and 120 min was 39.8±3.2 vs 25.6±1.6 mmol/l in controls, p<0.01). The single maternal AT did not increase offspring sensibility to STZ: integral glycemia in offspring of AT-mothers was like to controls (28.2±1.2mmol/l). Moreover, it was revealed significant decrease both basal and integral glycemia in offspring of (AT+GD) mothers (n=9) as compared with GD-mothers offspring (respectively, 7.3±0.4 mmol/l, p<0.05; 30.9±1.7 mmol/l, p<0.05). Thus the maternal AT during gestation does not enhance reactivity to STZ in offspring of mice with -and without GD.

858

GLUCOSE TOLERANCE AFTER GESTATIONAL DIABETES IN SRI LANKAN WOMEN

D.J.S. Fernando, S.H. Siribaddana , University of Colombo Sri Lanka

Gestational diabetes mellitus (GDM) has long term implications for the health of the mother. We assessed the rate of recurrence in GDM and the subsequent development of diabetes mellitus (DM) in a cohort of 220 women with GDM (group A) who were followed up for a period of 5 years and a cohort of 220 women who had no GDM in the index pregnancy (group B) matched for age and parity.

75g oral glucose tolerance tests were performed at 5 years. A second pregnancy occurred in 116 of A and 121 in B. GDM recurred in 31.8% in A and occured in 9% in B. (p=0.01). DM was diagnosed in 72 (32.7%) in A and14(6.3%) in B (p= 0.01) An increase in weight of 2.3Kg between pregnancies. maternal age 30 yrs and a higher parity were associated with a higher rate of recurrence in GDM weight gain =1.5Kg. age=30 were associated with a higher risk of developing DM.

GDM recurrs in one third of Sri Lankan Women and one third develop DM within 5 years of GDM in an index pregnancy.

859

LEVELS OF IGF-1, IGFBP-1,INSULIN C-PEPTIDE IN UMBILICAL CORD SERUM: CORRELATION WITH BIRTH WEIGHT

L. Volpe*, G. Di Cianni*, L. Benzi*, I. Casadidio*, L.Marselli*, M.Fantoni°, ^A.Perutelli,^P.Bottone, S.Murru^, G.Teti^, M. Ferdeghini>, R.Navalesi. *Department of Metabolic Disease; ^Department of Obstetric and Gynecology^; ° Departement of Neonatology; Institute of Nuclear Medicine,University of Pisa, Pisa, Italy

Our purpose was to the determine the correlation between birth weight , insulin, insulin-like growth factor-1 (IGF-1) and its binding protein (IGFBP-1) in neonates from 49 normal pregnancies (NW) and 21 complicated by pregestational (n.5) and gestational (n.16) diabetes (DW) . The two groups were similar as for age, BMI, weight gain during pregnancy and gestational age. Immediately after delivery umbilical venous blood was taken from clamped cord. Samples were collected for insulin, C-peptide, IGF-1 and IGFBP-1. DW showed higher glucose (104.4±29 vs NW 77.5±9.7 mg/dl, p<0.001) and higher HbA1 (5.58±1.6 % vs NW 4.5±0.38%, p<0.001) levels by 36-38 weeks. The neonatal weight was similar in DW (3448±485 gr.) and NW (3392±542 gr.), as the prevalence of macrosomia (LGA) (DW: 38.09% vs NW: 30.6%). Levels of insulin and C-peptide were higher in newborns from DW than in NW (28.8±60 vs 10.6±12.9 µU/ml, p<0.04;1.37±1.25 vs 0.9±0.3ng/ml, p<0.02, respectively). There were no differences in IGF-1 and IGFBP-1 concentrations in both groups. LGA newborns (n. 23) had higher levels of IGF-1 than normal size babies (79.5±22.9 vs 60.9±37.1 ng/ml, p<0.03). LGA newborns from DW had higher insulin levels (LGA-DW 19.3±8.6 vs LGA-NW 9.5±5.5 µU/ml, p< 0.005). Birth weight was positively correlated with cord serum IGF-1 (r=0.38, p>0.001), but negatively with IGFBP-1 (r=-0.28, p<0.01). Serum levels of IGFBP-1 in umbilical cords from all neonates were negatively correlated with cord serum IGF-1 (r=-0.55, p<0.0001), but no correlation was found with insulin.We conclude that cord serum IGF-1 is related to fetal growth in newborns from both NW and DW, while cord serum insulin is mainly related to diabetic macrosomia. Cord serum IGFBP-1 may be a growth inhibitor in the fetus and it seems to be insulin-independent in fetal life.

GESTATIONAL DIABETES DETECTION PROGRAM - RAMOS MEJIA HOSPITAL

P.Tesone, N.Del Hoyo, A.Dunaiewsky, E.Fiora, F.Castelli, A.Hakim, S.Righi, K.Glase and H.Valli. Ramos Mejia Hospital, Buenos Aires, Argentina.

Objective: to assess prevalence of Gestational Diabetes (GD) among pregnant women who attend the ambulatory consultation of Ramos Mejía Hospital and to relate it to the presence of Risk Factors (RF). Design and Method: from July 26, 1995 to September 9, 1996, 269 pregnant women were studied according to an algorhythm recommended by the Argentine Diabetes Society. Pregestational diabetic women were excluded from this study. Initial screening test (ST) (weeks 24-28) was considered positive if, 1 hour after an oral load of 50g glucose, glycemia was ≥140 mg/dl. Negative ST with positive history of RF was repeated at week 32. A 100g oral glucose tolerance test (OGTT) was done in all cases with positive ST. Results were considered positive when 2 or more values exceeded the following: basal 105, 1h: 190, 2hs: 165, 3hs: 145 mg/dl (O´Sullivan and Mahan). When initial ST was positive and OGTT negative, a second OGTT was done at week 32. All positive OGTT were considered as diagnostic of GD. Results: 218 women completed the full algorhythm. Out of 55 women with RF, 35 had positive ST; some patients showed 2 or more RF; these were: age ≥30 (26); body mass index (BMI) ≥26 (26); 1st. degree relatives with diabetes (25); personal history: macrosomic faetus (9), perinatal mortality (3), GD (2), gestosis (11). GD was diagnosed in 5 of 218 (2.29 %). Conclusion: in our Country it is difficult to perform an OGTT in all pregnant women; this is a major cause of motivation for doing the ST, which we consider an efficient method in programs of collective detection of GD applied to the general population of pregnant women, since searching for GD only in women with RF considerably decreases its efficacy. The ST is simple, cheap and useful in relation to a population study. Prevalence found in our initial program agrees with data published in our Country and abroad, thus encouraging us to proceed with this Program.

861

CORD BLOOD C-PEPTIDE LEVEL IN NEWBORNS OF DIABETIC MOTHERS.

E.Wender-Ożegowska,M.Pietryga, W. Meissner, K.Hansz and R. Biczysko,. Institute of Obstetrics and Gynecology, Karol Marcinkowski University School of Medical Sciencies, Poznań, Poland

Purpose of our study was to determine the correlation between mothers' glycemia and newborns weight and cord blood C-peptide level. 116 cord serum samples, taken from 80 patients with GDM and 36 with PGDM, were analyzed for C-peptide level and correlated with mothers' glycemia (MBG, HbA_{1C}, FA), pregnancy trimester at which the intensive care was started and newborns weight.

In the two analyzed subgroups (GDM and PGDM) the results of mother's metabolic control pertaining to all trimesters were as follows: GDM group-HbA_{1C} (normal range < 6,3%) in I trimester-5,08%, II- 5,5%, III-6,1%, FA (normal range < 2,7 mmol/l) in I trimester-2,8 mmol/l, II- 2,2 mmol/l, III 192 mmol/l. In the PGDM group HbA_{1C} concentration was: I trim. - 7,1%, II- 6,6%, III-6,9%, FA -in I trim.-2,5 mmol/l, II-2,5 mmol/l, III- 2,3 mmol/l. Mean mothers' diurnal glycemia in III trimester reached 86,5 mg%in the GDM group, but in the PGDM as much as 103,9 mg%. All intergroup differences were statistically significant. Newborns' body weight in the GDM group amounted to 3300g and in PGDM to 3380g (difference n.s.), but the newborns' glycemia in GDM-43 mg% and PGDM-34 mg% respectively differed significantly. C-peptide levels ranged from 0,79±o,54ng/ml in newborns with IUGR, over 1,06±1,38ng/ml in the AGA newborns, up to 1,41±1,87 in the LGA newborns. In newborns of the GDM group presenting with IUGR, c-peptide levels were 0,6±0,26 ng/ml, in those from AGA group 0,81±0,47ng/ml and in those from the LGA group 0,59±0,22 ng/ml. In the PGDM group c-peptide in IUGR newborns amounted to 1,09±0,8ng/ml, in those of the AGA group to 1,95±2,67ng/ml, and in those belonging to the LGA group to 1,87±2,27ng/ml. The analysis of results pertaining to C-peptide in cord blood in dependence of the onset and or duration of the mothers' treatment has shown a negative correlation between these parameters.

C-peptide in cord blood is a parameter correlating with diabetic mother's metabolic control and fetal birth weight but is mainly related to fetal IUGR.

862

Reevaluation of Diabetes Mellitus or glucose tolerance in Women after gestacional diabetes.

Schirmer, J.
São Paulo/Brasil

A study with (39) women who had diabetes mellitus (DM) during pregnancy, who were attended at a State Hospital in São Paulo City from 1983 to 1993, and reevaluated on average at a seven year time interval, allowed the conclusion that 53,8 of those who developed DM or impaired glucose tolerance (IGT) were over 35 years old, overweight or obese, and had a higher birthrate than the women from the control group, and higher number of caesarean operations, only the OGTT-2h and not the glicemia on fasting allowed the identification of the alterations in both instances; the family history of diabetes did not constitute a significant risk factor for the later development of diabetes did not constitute a significant risk factor for the later development of alterations of glucose tolerance (AGT), unlike insuline therapy during pregnancy; the values of the anti-insulin antibodies did not exceed the limits of normality, but were greater in the group with diabetes in repeated pregnancies with current AGT in relation to those with a single pregnancy and AGT. The HbA1 values were altered in all women with AGT on re-evaluation, whilst the insulin dosage did not differ from that of the control group. The recurrency of diabetes during pregnancy did not appear as a risk factor int the prevalence of the DM or IGT during the average seven year time interval.

863

AMNIOTIC FLUID GLUCOSE AT 14-16 WEEKS PREDICTS SUBSEQUENT GESTATIONAL DIABETES

W.Ricart, C.Bach, JM.Fernández-Real, D.Cabrero, M.Obón and J.Cebrià. Hospital Universitario Doctor Josep Trueta. Girona. Spain.

Glucose, insulin and C-peptide have often been measured in amniotic fluid (AF) during late gestation, but little is known about their concentrations during early pregnancy. We examined the predictive value of amniotic fluid glucose (AFG) and maternal serum glucose (MSG) at 14-16 weeks gestation for subsequent gestational diabetes (NDDG criteria) and macrosomia in unselected 336 gravidas (mean age 34.5±4.7 years) with chromosomopathy risk. In a randomized subgroup of 73 cases amniotic fluid insulin (AFI) and maternal serum insulin (MSI) were also analyzed. They were classified as normal glucose tolerance (group-I, n=148), 1 abnormal value (g-II, n=120) and >1 abnormal value (g-III, n=68). Birth weight (BW) was expressed as % of the 50th percentile adjusted by sex and gestational age. Large for age (LGA) was defined when BW above 90th percentile for sex and gestational age. There was a significant correlation between AFG and glucemia post 50 g glucose test (r=0.32, p=0.0001) and between AFG and MSG (r=0.45, p=0,0001). The correlation between AFI and MSG and MSI was also signifcant (r=0.46, p=0.0001 and r=0.42, p=0.001 respectively), but not with AFG (r=0.19). The AFG and MSG values (95 Pct Con) between groups were progresively higher (AFG: g-I:44.6 to 47.6, g-II:47.2 to 50.7 and g-III:53.7 to 62.7 mg/dl, p=0.00001; MSG: g-I:74 to 80, g-II:79 to 88 and g-III:83 to 101 mg/dl, p=0.0004). BW was similar between groups (101.1%, 101,1% and 101.2%). LGA were detected in 41 cases (12%). No significant differences in AFG, AFI, MSG and MSI between LGA neonates and normal BW neonates were found. In summary, gestational diabetes is associated with increased AFG at 14-16 weeks, suggesting that altered glucose metabolism is present in early fetal period.

864

PREVALENCE OF RISK FACTORS FOR GESTATIONAL DIABETES IN ZAIREAN WOMEN. EK. Sinamuli, N.F. Tandu-Umba and K. Kandjingu, University of Kinshasa, Kinshasa, Zaïre.

Gestational Diabetes Mellitus is still a worrying among pregnant women in Zaïre. To determine the prevalence of diabetic features in the high-risk population, a study has been realized from January 1984 to December 1993 at the Department of Obstetrics and Gynecology of University Clinics of Kinshasa. 58 gestational diabetic women have been compared with 32 insulino-dependent diabetes pregnant women and 84 normo-glycaemic pregnant ones with diabetic risk factors. Family and obstetrical stories and perinatal complications have been checked out. Statistical analysis (chi- square and Pearson tests) shows very significant differences of predictive values of family obesity, high blood pressure, perinatal mortality(p<0,005 respectively) and macrosomia (p<0,025) during previous pregnancies on the one hand and hydramnios, glycosuria, excessive weight gain and fasting glucose level (p< 0,005 respectively) on the other hand.

This finding suggests the possibility of intervention in high-risk groups.

865

INSULIN-LIKE GROWTH FACTOR-1 IN AMNIOTIC FLUID OF WOMEN WITH AND WITHOUT GESTATIONAL DIABETES.

D. Romann, I. Schadek, U. Lang, H. Laube and T. Linn. Justus-Liebig-University of Gießen, Gießen, Germany.

Insulin-like growth factor-1 (IGF-1) is known as a potent mediator and regulator of cell growth and development, whereas diabetes and gestational diabetes are characterized by an increased incidence of intrauterine growth alterations. Thus the aim of this study was to examine IGF-1 in the amniotic fluid (reflecting fetal situation) of 20 women with gestational diabetes (GD) and compare them with 96 healthy control women (no pathological serological or cytogenetical screening results) representing different gestational ages (subgroups: 15/16.(C1); 17/18. (C2); 19/20. (C3); 21-25.wk (C4)). Both groups were matched in BMI before pregnancy (24.3±0.8(GD) vs. 23.0±0.4(C) kg/m^2; mean ± SE; p=0.36), parity (1,1±0.2 vs. 1,0±0.1 (C)), age (36.3±0.6 vs. 34.0±0.4 (C); p=0.06) and delivery on term (38-42 wk). IGF-1 was determined by a RIA method (Fa. Nichols, Cal., USA) after acid-ethanol-extraction. Results: We found an increase in amniotic IGF-1-content depending on gestational age (83.6(C1); 121.2(C2); 291.2 (C3); 355.4(C4) ng/mL; geometric means; p<0.0001), confirmed by regression analysis which showed a log-log-linear relationship (p<0.0001; r=0.61). Women with GDM showed also this time-dependent increase, but on a much lower level (30.5(GD1); 77.6(GD2) ng/mL; log-log-regression p=0.0082; GD1 vs. C1 p=0.019). Further analysis of obstetrical data showed similar mean values for birthweight (3690(GD) vs. 3411 g(C); p=0.25) and height of the infants with a higher incidence for SGA- and LGA-babies in the GD-group, whereas regression analysis could not show a relationship between IGF-1 content and obstetric measurements. Thus the impact of decreased IGF-1 in GDM remains unclear and further investigations are necessary to determine the role of IGF-1 in intrauterine growth alteration.

866

PREVALENCE OF GESTATIONAL DIABETES MELLITUS: IMPACT ON FETAL MACROSSOMIA IN A BRAZILIAN POPULATION.

Spichler, ERS., Martins,CSF., Guerra,F., Carvalho,NV.,and Franco,LJ. Health Ministry, Health State Secretariat of Rio de Janeiro, Fernandes Figueira Institute, Federal University of Sao Paulo, Brazil.

Gestational Diabetes Mellitus (GDM) is defined as carbohidrate intolerance of variable severity first diagnosed during pregnancy. There is no agreement to the most appropriate way to diagnose GDM. This study (Brazilian Gestational Diabetes Study Group - BGDSG - Rio de Janeiro) considered the WHO criteria (oral glucose tolerance test - OGTT - 2h, 75g) for both GDM and gestational impaired glucose tolerance (GIGT). The purpose of this study was to evaluate the prevalence of GDM and GIGT, the influence of maternal age, obesity and alcohol intake to the severity of the disease, and the consequence of GDM and GIGT on birth weigth. The BGDSG - Rio de Janeiro enrolled a sample of 508 pregnant women (December 1992 to August 1994), aged 20 years or older, followed at the prenatal clinic amongst 1314 women. The selected women were tested with a 75g OGTT between the 24 th and 28 th gestational weeks. Prepregnancy body mass index (BMI) as ≥ 25 Kg/m² was used to define obesity. 450 deliveries during this study were analyzed for perinatal morbity, specially macrossomia. Fetal macrossomia was considered as a birth weight ≥ 4000 g. Significant differences were detected with Mann Whitney test, t-test, and Fisher test. Prevalence of gestational glucose abnormalities was 12.0% (CI 95%= 9.4%- 15,2%) (GDM = 0.4% and GIGT=11.6%) maternal age strongly influenced prevalence (12.5% to 31.8%, for 30-34 yrs and ≥ 40 yrs). Alcohol intake and pre pregnancy obesity also influenced prevalence significantly($p < 0.005$). All 450 pregancies delivered 24 macrossomic newborns. Prevalence of macrossomia was 5.3% (CI 95%= 3.5% - 7.9%). GIGT influenced the prevalence of macrossomia (11.4%) when compared with control group (4.3%) $p< 0.005$.These data support the importance of diagnose GDM and GIGT. These findings suggest that, given contemporary antenatal medical care, GDM and GIGT do not adversely affect their outcomes.

867

Is There a Genetic Link between MODY and Gestational Diabetes Mellitus ?.

R.R.Irving[i], A. Mullings[ii] , S. Kulkarni[ii] , E.Choo-Kang[iii], E.Y.St.A. Morrison[i] Departments of Biochemistry[i], Obstetrics ,Gynaccology and Child Health[ii] and Pathology, University of the West Indies, Mona.

MODY is defined as adult onset diabetes of the young ,associated with autosomal dominance inheritance and detected before age 25 years; Gestational Diabetes Mellitus (GDM) is usually detected in pregnant women older than 25years .MODY and GDM are classified as subtypes of NIDDM.

While screening patients for gestational diabetes at The Antenatal Clinic,University Hospital of the West Indies it was noticed that some patients who were diagnosed with gestational diabetes mellitus had unexplained hyperglycemia but not diabetes in previous pregnancies. The hyperglycemia was detected before age 25 years and treated by diet alone. All had family history of diabetes consecutive in three generations. Most of these patients fulfilled the criteria for MODY.

The patients with previous hyperglycemia later diagnosed as gestational diabetes showed varied heterogeneity; some had high fasting glucose and normal postprandial values ,others had both high fasting and high postprandial values.The insulin and c-peptide values ranged from subnormal to supranormal.Three patients had hypoinsulinemia with a 1 hour mean insulin value of 20±9 uUml which when compared with normal pregnant women (140±24 uU/ml)was statistically significant ($p< 0.0005$). Four patients showed marked hyperinsulinemia with mean insulin value of 325uU/ml ($p<0.002$). Regression analysis confirmed the heterogeneity of the metabolic response.

The genetic heterogeneity of MODY could possibly explain the metabolic heterogeneity of these patients with GDM as they fit the criteria for MODY.It has been shown that polymorphisms in the glucokinase(GCK) gene on chromosome 7 are tightly linked with hyperglycemia in a panel of French MODY family. MODY Patients with mutation in the GCK gene demonstrated a milder insulin secretory defect than MODY associated with polymorphic DNA markers on chromosome 20 which causes an inability to increase insulin secretion as the plasma glucose value rises above 7-8mmol/l.

Determining the genetic makeup of these special patients could help us in understanding the possible relationship between these two subtypes of NIDDM .

868

RISK FACTORS ASSOCIATED WITH THE USE OF ORAL CONTRACEPTION AND VASCULAR EVENTS IN WOMEN WITH IDDM.

R.Linkeschova and R.Kimmerle, Heinrich-Heine-University, Düsseldorf, Germany

Oral contraception (OC) ("pill") is rarely recommended for type I diabetic women (D). In D with microvascular complications, smoking and poor metabolic control OC are even considered to be contraindicated because in such women they are presumed to be associated with an excess risk of vascular events. However, so far, this assumption is not based upon valid data. The aim of our study was to assess for type I diabetic women actual and previous use of contraceptive methods, risk factors and their association with vascular events. 1028 consecutive diabetic women (age 16-46 yrs) attending a structured treatment programme for intensified insulin therapy from 1989-92 were mailed a multiple choice questionaire in 1993. 409 non-diabetic women served as a control group. 808 D (79%) answered the questionaire (age 31.5(7.2)yrs., duration of diabetes 14.4(8.2) yrs). Of all women who used any contraception in either group OC were used by 44% in the diabetic group and by 57 % in the control group. Of 202 diabetic OC-using women (age 27(5)yrs) 65% had at least one "contraindication" to OC-use (proteinuria, hypertension, retinopathy, smoking, poor metabolic control). During a total of 3945 diabetic women-years of OC-use (in 301 previous and 202 actual users) there had been 5 cases of deep vein thrombosis, i.e. a risk comparable to non-diabetic OC-users. 12 diabetic women had a history of major vascular events (7 myocardial infarctions, 5 cerebrovascular events), 11 of which had occured without actual OC-use. One event (thromboembolic stroke) had occured during actual OC-use in a 21 yr old smoker with nephropathy. In Germany, OC are a popular method of contraception in type I diabetic women paying little attention to traditional "contraindications" other than age. The data suggest that OC-use in young diabetic women without nephropathy is not associated with an excess rate of vascular events.

869

GESTATIONAL DIABETES MELLITUS: AN IMMUNOLOGICAL AND METABOLIC FOLLOW UP FOUR YEARS AFTER PREGNANCY.

C. Betterle[o], A. Lapolla*, M. Sanzari, R. Zanchetta, S. Marini*, F. Floriani, D. Fedele* Dpt of Laboratory Medicine, *Dpt of Internal Medicine-Metabolic Disease, °Institute of Semeiotica Medica, Padova University (Italy)

Many studies have been performed to identify the presence of serological markers of pancreatic autoimmunity in gestational diabetes mellitus (GDM), but the results obtained are quite variable. We want to verify in GDM the presence of serological markers of pancreatic autoimmunity and HLA fenotype in an italian population. Islet cell antibodies (ICA), complement fixing-ICA (CF-ICA), insulin autoantibodies (IAA), other organ-and non organ specific autoantibodies, circulating lymphocyte subpopulations and HLA fenotype were evaluated in 68 women with GDM at 37th week of gestation and compared to 38 matched controls. ICA-IgG were found in 2/68 (2.9%) and IAA in 1/68 (1.5%) GDM patients. Other organ and non organ specific autoantibodies, lymphocyte subpopulations and HLA fenotype were not significantly different when compared to matched controls. 38 patients (the 3 with pancreatic autoimmunity and 35 negative) were followed up for 4 yrs after delivery by re-evaluating their immunological status and OGTT. During follow up, 8/38 patients (21%) became diabetics: 6/8 (75%) developed diabetes 1 year after pregnancy, 1/8 (12.5%) 2 years and 1/8 (12.5%) 3 years after pregnancy. Four of them required insulin therapy (basal C-peptide 0.8-1ng/ml), 1 was treated with oral hypoglycemic agents and 3 were on diet (basal C-peptide 2.3-3ng/ml); all patients were in fair good metabolic control. Furthermore 6/38 (16%) patients showed an impaired glucose tolerance (IGT) and 24/38 (63%) a normal glucose tolerance. During follow up all patients maintained unchanged their serological reactivity, but one of the two ICA-positive patients became diabetic (50%). In the 14 patients who developed IGT or diabetes the mean values of activated T-lymphocytes (HLA-Dr+CD3+) during pregnancy were significantly higher than those of pregnant control pregnant women (8.5+3.3 vs 2.4+0.5%; $p<0.05$). Moreover four years after delivery no significant differences were found in the number of activated T-lymphocytes. So GDM lacks of both immunological and genetic markers of type 1 diabetes, but progression to IDDM is more frequent in patients with serological signs of pancreatic autoimmunity. The high frequency of diabetes one year after pregnancy strongly support importance the importance of a "strict" post partum follow up in GDM patients.

870

THE INCIDENCE OF GESTATIONAL DIABETES USING TWO DIFFERENT CRITERIA

John MF Adam. Diabetes and Endocrinology Section. Faculty of Medicine, Hasanuddin University, Ujung Pandang Indonesia.

Until now there is no universally accepted criteria for the diagnosis of gestational diabetes.The mostly used screening procedures and criteria are the NDDG and the WHO. When we started our first screening we used the NDDG criteria and later on we changed to more simple criteria. We report the results of these two different methods.

Glucose challenged test with 50 gram glucose were performed in both methods.Those with challenged test positive were followed by OGTT. The NDDG used 3-hour OGTT and our criteria only 2-hour OGTT. The NDDG criteria needs two abnormal values for the diagnosis of gestational diabetes. In our new criteria , as a normal value for fasting < 100 mg/dl, 1-hour < 170 mg/dl and 2-hour < 140 mg/dl. Gestational diabetes is diagnosed if there is one abnormal value.

2074 pregnant women were screened using NDDG procedure, 42 women were positive for gestational diabetes or an incidence of 2,0%. Using our new criteria, from 1041 pregnant women , 27 were gestational diabetes or an incidence of 2,6%.. In the NDDG group cessarian section was 17,7%, and perinatal mortality 7,1%. From our new criteria, cessarian section was 22,2% and perinatal mortality 7,4%.

In conclusions, the incidence of gestational diabetes as well as perinatal mortality were not different between these two different methods of screening for the diagnosis of gestational diabetes.

871

HLA-DR/DQ-HAPLOTYPES AND AUTOANTIBODIES IN PORTUGUESE GESTATIONAL DIABETIC WOMEN

M Carvalheiro[1], A Martinho[2], RL Humbel[6], IFaguihel, L Gomes[1], A Faguihe[1], S Paiva[1], E Maria[4], E Sobral[4] A Coelho[5], MC Almeida[5], J Couceiro[5], O Simões[3], P Santos[2], F Cardoso[7], V Alves[7], H Breda-Coimbra[2], M Santos-Rosa[7], J Faguihe[4], MMA Rues[1].[1]Dept of Endocrinology and[4]Obstetric Clinic, University Hospital Coimbra,[2]Histocompatibility Center of Coimbra,[3]Hospital Center of Luxemburg,[5]Dept. of Internal Medicine and[6]Obstetric Clinic of Coimbra Hospital Center ,[7]Immunology Center, Coimbra Medical School. Coimbra, Portugal

Aim: to assess HLA-DR/DQ-haplotypes and autoantibodies (AAs) ICA, IAA, GAD 65 and correlate them in GDM women. Material and Methods: a Caucasian population of 111 GDM, 240 healthy controls (C) for HLA-analysis and 54 for AAs and 32 IDDM, were studied. HLA-analysis was performed by PCR-Oligotyping, ICA by indirect immunofluorescence, IAA by RIA and GAD by IRMA-RSR. Results: GDM is strongly associated with DR8 *vs* C *vs* IDDM ($p<0.05$) and DR7 with C vs IDDM ($p<0.02$). A positive association of DQA1*0401-DQB1*0402 and DQA1*0501-DQB1*0201, was found in GDM *vs* C vs IDDM ($p<0.05$) and of DQA1*0101-DQB1*0501, DQA1*0201-DQB1*0201 and DQA1*0501-DQB1*0301 in GDM and C vs IDDM ($p<0.05$), being the DQA1*0300-DQB1*0302 the most common in IDDM *vs* GDM and C ($p<0.05$). The haplotype DR8-DQA1*0401-DQB1*0402 (DR8/DQ4) was present and positively associated only in GDM vs C and IDDM ($p<0.05$), DR11-DQA1*0501-DQB1*0301 (DR11-DQ7) was the more prevalent in GDM (20%) and C (28%) *vs* IDDM (1.8%) ($p<0.05$) and DR14-DQA1*0101-DQB1*0503 (DR14-DQ5) in C vs GDM and IDDM ($p<0.05$). DR4-DQA1*0300-DQB*0302 (DR4-DQ8) was the most frequent in IDDM (40%) vs GDM (14%) and C (15%) ($p<0.05$). Heterozigotia DR4-DQ8/DR17-DQ2 was found in GDM and C only in 4.5% and 3.9% *vs* 36% in IDDM ($p<0.02$). Susceptibility to IDDM determined by non-Asp57 and Arg52 in DQ molecules was weakly present in GDM and C and strongly associated with IDDM. The frequency of autoantibodies positive (AAs+) in GDM was 4.5 % and in C 1.8%: ICA 3.6 and 0%, GAD 1.8% and 1.8% and IAA 0/0%, respectively. One GDM with ICA and GAD+ was DR4-DQ8/DR9-DQ9. The others ICA+ were DR16-DQ5/DR17-DQ2, DR17-DQ2/DR4-DQ8 and DR7-DQ9/DR12-DQ7. The other GAD+ was DR16-DQ5/DR4-DQ8. At least one susceptibility factor was present in the phenotype Conclusion: GDM was similar to healthy controls in terms of immunogenetic markers except for the haplotype DR8/DQ4 that was significantly increased only in GDM. The susceptibility genes and haplotypes as well as AAs+ for IDDM were found in GDM in a small percentage of cases, what makes the disease as a whole heterogenic but not immunogenetic. In spite of the results these studies are very important to select the GDM women more prone to insulin needs during pregnancy and later IDDM.

872

RISK FACTORS FOR GESTATIONAL GLUCOSE INTOLERANCE. THE BRAZILIAN STUDY OF GESTATIONAL DIABETES (EBDG).

M.I. Schmidt, L. Branchtein, J.M.D.C. Pousada, E.R. Stambovsky, A. Costa e Forti and B.B. Duncan for the EBDG Study Group. UFRGS, Porto Alegre, Brazil.

Risk factors for gestational glucose intolerance (GGI), as defined by WHO criteria, have been little investigated using multivariable techniques. To do so, we studied consecutive pregnant women, age 20 years or more, without history of diabetes mellitus outside pregnancy, in selected clinics of 6 major Brazilian cities, analyzing here the 4909 with complete data. Interview and anthropometric data were obtained and a standardized 75g oral glucose tolerance test was uniformly applied between gestational weeks 24 and 28. GGI was defined as a 2h plasma glucose $\geq$ 7.8 mmol/L, and obesity as the sum of 4 skinfold thicknesses. Odds ratios (OR) were obtained through multiple logistic regression. Independent positive associations ($p<0.05$) were found for increased age (4th vs. 1st quartile OR=3.3), increased skinfold thickness (4th vs. 1st quartile OR=2.7), a positive history of gestational diabetes (OR=2.9), and a positive family history of diabetes (OR=1.6). Independent protective associations were found for those with 4 or more previous pregnancies (compared to none: OR=0.61), for those with black skin color (OR=0.50), and for those with greater maternal height (4th vs. 1st quartile OR=0.66). In conclusion, greater maternal height, black skin color and greater gravidity were important independent factors associated with lesser prevalences of GGI in Brazilian women. The traditional risk factors of age, obesity, a family history of diabetes, and a personal history of previous gestational diabetes, were associated with increased GGI prevalences. This pattern of associations is similar to that seen for NIDDM in Brazil, highlighting the similar nature of these two conditions.

873

MORPHOMETRIC EVALUATION OF THE ISLETS OF LANGERHANS IN AN EXPERIMENTAL MODEL OF GESTATIONAL DIABETES.

L. Aerts, L. Vercruysse and F.A. Van Assche. Katholieke Universiteit Leuven, Leuven, Belgium.

Diabetes during pregnancy induces alterations in the fetus with persisting consequences for the glucose tolerance in the offspring, including gestational diabetes. The aim of the present study is to quantitate the mass and composition of the islets of Langerhans in adult offspring of streptozotocin-diabetic rats in order to look for a morphological origin for these alterations. Pancreatic biopsies were collected from non-pregnant and term-pregnant youngsters of mildly (MD) and severely (SD) diabetic mothers, stained immunologically for insulin, glucagon, somatostatin and pancreatic polypeptide, and examined morphometrically with an automatic image-analyzer. Total islet mass and islet size distribution were evaluated and related to islet neogenesis and replication of differentiated cells. The contribution of the different endocrine celltypes was measured and related to the metabolic condition of the animals. In the MD-offspring the amount of islet and B-cell mass and the islet size distribution are normal, and can not explain the deficiency in stimulated insulin output, which must be related to alterations in the islet composition: more glucagon cells (18% versus 13% in controls, $P = 0.004$) and less pancreatic polypeptide cells (2,1% versus 4,6%, $P = 0.0002$). In the SD-offspring the excessive insulin output is associated with an increase in total islet and B-cell mass (438.644 μ^2 versus 267.150 μ^2 for the islets, $P = 0.006$; 367.082 μ^2 versus 142.835 μ^2 for the B-cells, $P = 0.004$), mainly due to islet neogenesis (preponderance of small islets). During normal pregnancy islet and B-cell mass double theire size (550.230 μ^2 versus 267.150 μ^2 for the islets, $P = 0.001$; 301.060 μ^2 versus 142.835 μ^2 for the B-cells, $P = 0.001$), by a combination of islet neogenesis and replication of differentiated cells. Also the glucagon and somatostation-positive tissues increase in the same proportion, while the PP-cell mass does not change. In both MD- and SD-youngsters, the occurrence of gestational diabetes can not be attributed to a deficiency of these adaptations since islet size and composition are normal, but must be related to the factors that induce the increased B-cell function of pregnancy.

874

COMPARISON OF SOMATIC DEVELOPMENT IN THE FIRST YEAR OF LIFE IN THE CHILDREN OF MOTHERS WITH EITHER GESTIATIONAL (GDM) OR INSULIN DEPENDENT (IDDM) DIABETES MELLITUS

M .Zawodniak-Szałapska, K. Cypryk, E. Jędrzejewska, J. Wilczyński,
Department of Diabetology, Polish Mother's Memorial Hospital, Łódź, Poland

SUMMARY

The somatic development was assesed in the first year of life in the children of (GDM) and (IDDM) mothers. For each group , 26 children were assesed. All the children were full-term infants and norme suffered from illnesses with effects on somatic development. The social and economic conditions did not differ between groups. The BMI, assesed before pregnancy was higher for GDM mothers. The BMI for fathers did not differ significantly. The following somatic values were measured in the 1st, 6th and 12th month of the child's life: body mass, length, head circumference and chest circumference. For both groups the harmonic development and state of nutrition were assesed. 21 children (40.3%) were born with a birth mass above 90 centile (c) and this was disproportionately weighted towards children of GDM mothers. In the 12th month, 6 children (11.5%) were obesqe and they were all LGA children. The body lenght above 90c was more often observed for children of GDM mothers. The head circumference below 10c was statistically more often observed for children of IDDM mothers.

Basing on this study the fillowing conclusions were drawn:

1. For both GDM and IDDM children somatic development for the majority of children below the 12th month was within the broad range of the norme medical standard.
2. All the children showed a harmonic development.
3. In the 12th month 11.5% of the children were obesqe and the obesity was more often present in children born with macrosomatic features ($p<0.05$).
4. The type of mother's diabetes seems to have a significant influence on somatic development.

CONCLUSIONS

1. For both GDM and IDDM children somatic development for the majority of children below the 12th month was within the broad range of the norme medical standard.
2. All the children showed a harmonic development.
3. In the 12th month 11.5% of the children were obesqe and the obesity was more often present in children born with macrosomatic features ($p<0.05$).
4. The type of mother's diabetes seems to have a significant influence on somatic development.

PREGNANCY OUTCOMES OF WOMEN WITH PREGESTATIONAL DIABETES IN NORWAY AND NORTHRHINE (GERMANY) AND ORGANISATION OF CARE

R. Kimmerle[1], R. von Kries[2] and L. Irgens[3]. [1]Dept. of Metabolic Diseases and Nutr., Heinrich-Heine-University, Düsseldorf; [2]Inst.. Soc. Paediatrics and Adolescent Medicine, Ludwig-Maximilian-University, Munich, Germany; [3]Medical Birth Registry of Norway, University of Bergen, Norway.

To eliminate excess perinatal complications of mothers with pregestational diabetes (PD) is feasible and a WHO target for diabetes care (St. Vincent declaration). The aim of our study was to compare the outcome of these pregnancies to nondiabetic (ND) mothers in two European countries and to identify factors in the health care systems that may explain differences. Data of the Perinatatalerhebung Northrhine (NRPE) and the Medical Birth Registry of Norway (MBRN) from 1987-1992 were analysed. NRPE and MBRN are quality assurance programmes of pre- and perinatal care covering 93-100% of all births (annual birthrate ≈100.000 (Northrhine) and ≈59.000 (Norway)). Both countries have similar, highly structured, free-of-charge standard prenatal care systems, but different systems of diabetes care (in Norway centralized (14 centres) and in Germany mostly with local physicians). PD was present in 0.41 (0.35-0.57) % (mean (range)) of all births in Norway, and in 0.39 (0.35-0.45) % in Northrhine. In Northrhine, perinatal mortality rate in births of PD mothers was twice as high as in Norway (2.4 vs. 1.2 %); in the ND it was only slightly higher (0.7 vs. 0.6 %) . The higher perinatal mortality in PD in Northrhine was mainly due to stillbirths. The rates of prematurity, macrosomia and caesarian section in Norway and Northrhine were similar (18 vs. 19 %, 25 vs 24 % and 45 vs 40 %) and 2-3 times higher than the respective rates in the ND. Only 40 % of PD in Northrhine but 90 % of those in Norway attended specialized diabetes and pregnancy centres. In Germany and Norway 1 of 200 to 250 births is complicated by PD. In Norway, the excess perinatal mortality has nearly been eliminated, probably due to centralisation of diabetes care and reaching out to noncompliant patients. Reduction of other perinatal complications will require further sophistication of specialized care.

C-PEPTIDE AND INSULIN LEVEL IN WOMEN IN LABOUR AND UMBILICAL VEIN DEPENDING ON BIRTH WEIGHT AND LABOR PARITY.

N.Beridze, R.Kurashvili, M.Japaridze and M.Dundua. Diabetes Center of Georgia, Tbilisi Georgia.

To study insulin secretion in non-diabetic women in labour and their infants in relation to the body weight of the newborns, fasting IRI and C- peptide levels were measured in 415 healthy non - diabetic women in labour aged 18-36 years (161-first delivary, 254 - repeated delivery; physiologic gestation 38-40 weeks). Umbilical vein blood of 192 normal weight (NW) neonates and 223 overweight newborns were tested immediately after birth. Body weight of 4000g and more we considered excessive. Infants of primapara were overweight in 30% of cases, while in repeated delivery this number increased to 66 %. Not depending on the delivery parity women with large newborns had apparently more excessive weight gain during the given pregnancy ($p<0.05$). IRI blood level in women in birth never exceeded that of the nonpregnant group (0.75 ± 0.04 ng/ml). C - peptide level, C- peptide/IRI ratio in primapara with NW infants were 2 - fold higher comparing to controls and to women with large newborns (4.4 ± 3.2 ng/ml;5.5+0.18; respectively $p<0.05$) IRI and C-peptide levels and IRI/C- peptide ratio were apparently higher in the umbilical blood of the large infants than in NW ones (0.47 ± 0.08 ng/mg; 5.3 ± 0.09ng/ml, respectively). Thus, pregnant women, especially those with repeated parity, showing considerable body gain during given pregnancy and lack of the fasting compensatory insulin hypersecretion, comprise the risk group of gestational DM, and in their healthy newborns together with excessive body weight, insulin hypersecretion, as in macrosomic infants of diabetic mothers, is observed.

877

THE OUTCOME OF PREGNANCY IN A GROUP OF DIABETIC PATIENTS IN A RURAL HOSPITAL IN JAMAICA, 1993-96
C.BURREL, R.PARKES AND B.DIXON, Cornwall Regional Hospital and University Hospital of the West Indies
The aim of the study was to determine the outcome of pregnancy in a group of 60 diabetic patients admitted to the Obstetric Ward at the Cornwall Regional Hospital, 1993 - 1996. Patients were chosen randomly and followed through to delivery. They were matched with non-diabetic pregnant patients admitted to the Obstetric Ward with an acute episode of urinary tract infection. Controls were matched for race, same clinic attendance and time of admission. The mean age and gravidity in the diabetic group was 32.20 yrs. and 4.25 respectively while that in the control group was 23.70 yrs. and 3.02. There was a significant difference ($p < 0.01$) between the mean birth weights for the diabetic population (mean 3.85 kg ± 0.64 SD) and the control group (mean 2.92 kg ± 0.37 SD). In the diabetic group, 46.7% had lower segment caesarean section. Indications included macrosomia (57.14%) and previous caesarean section (14.29%). In the control group, 15% had lower segment caesarean section. Indications included fetal distress (44.44%) and previous caesarean section (33.33%). In the diabetic group, post partum haemorrhage was the only maternal complication (13.3%). Seventy-eight per cent of infants of diabetic mothers had complications; macrosomia 42.60%, hypoglycemia 27.66% and intrauterine death 14.89%.

878

INSULIN RESPONSE TO GLUCOSE IS SELECTIVELY MAGNIFIED BY PARITY IN WOMEN WITH NORMAL GLUCOSE TOLERANCE.
R.Anichini, M.C.Breschi, S. Sani, A.Gironi, and G.Seghieri. Diabetes Unit and Dpt. of Obstetrics and Gynaecology, Spedali Riuniti, Pistoia and Dpt. of Internal Medicine, Hospital of Viareggio, Italy.
The importance of parity in modifying both glucose tolerance and insulin secretion during the pregnancy is a matter of debate. This longitudinal study was aimed to verify the hypothesis that parity leads to a progressive modification in glucose tolerance and/or insulin secretion or sensitivity in non diabetic women. In a cohort of 45 mothers without gestational diabetes, glucose tolerance, as well as basal and post-load plasma insulin and C peptide were tested by means after a 100-g OGTT in two consecutive pregnancies between the 24th and the 28th gestational week. On the second pregnancy (40±17(SD) months on average from the previous) the women had higher pre-pregnancy (61±11 *vs* 59±8 Kg, mean±SD) and final body weight (71±10 *vs* 69±9 Kg, p=.06 for both), and delivered larger babies (3,486±473 *vs* 3,242±506 g; p=.002). As compared to the previous pregnancy, there was a significant increase in basal plasma C peptide (1.6±0.7 *vs* 1.3±0.4 ng/ml; p=.004) and in the area under curve for insulin : AUCI, (52±13 *vs* 48±8 nmol l^{-1}2h; p=.04), but no significant change in the area under curve for glucose AUCG (0.78±0.18 *vs* 0.77±0.16 mol l^{-1} 2h). The percent increase in AUCI was not related to either maternal or neonatal weight, and was independent from difference in age, AUCG, increment in maternal weight, or parity. This finding is compatible with the concept that each additional pregnancy in mothers with normal glucose tolerance amplifies the insulin response after an oral glucose load by about the 8%, likewise inducing an additive stress to beta-cells. Furthermore, the parity-induced increment in neonatal weight appears unrelated to both modifications in glucose tolerance and to insulin response to a standardised oral glucose load.

879

DIABETIC PREGNANCY: PREPREGNANCY CARE AND PREGNANCY OUTCOME
A. García, R. Corcoy, M. Albareda, A. Caballero, J. Adelantado, O. Altirriba, X. Demestre and A. Leiva. Hospital de Sant Pau, Barcelona, Spain.
In diabetic pregnancy, preconceptional clinics (PC) have shown a great impact in reducing the rate of congenital malformations (CM). Our aim is to summarize our experience in PC since its initiation in 1986. Up to 195 pregnancies of women with pregestational diabetes have been attended with 74 (37.9%) having enrolled in PC. Attenders had a longer diabetes duration (11.2±7.1 vs 8.6±6.6 years, $p<0.05$) and non-attenders had a higher first pregnancy HbA1c (in SD around the mean) (4.0±3.2 vs 2.7±2.6, $p<0.01$). The final HbA1c was in the normal range in both groups. Pregnancy outcome (abortion 14.9%, caesarean section 59.7%, preterm delivery 24%, hypertension 21.8%, perinatal mortality 1.8%, 1 min Apgar <7 15.7%, birthweight >P90 27.2%, obstetric trauma 5.6%, hypoglycemia 23.5%, hypocalcemia 0.6%, respiratory distress 11.1%, neonatal jaundice 19.8%, polycythemia 9.0%) was similar in both groups. The rate of CM was 8.9% in non-attenders vs 3.3% in attenders (OR 2.89, 95% CI 0.60-13.8). We conclude that: 1) A similarly fair glycemic control at the end of pregnancy allows for a similar outcome in terms of diabetic fetopathy 2) Even in women in moderate glycemic control at the beginning of pregnancy, PC seems to lower the rate of CM

880

ALIMENTATION AND OBESITY DURING PREGNANCY AND MATERNAL INSULIN SECRETION
G.Pudar, S. Janosevich and G. Gregorich
University Hospital , Dept. of Endocrinology, Beograd, Jugoslavia

The alimentation during pregnancy may be very important for the development of maternal metabolic abnormalities, including impaired secretion of insulin. The role of insulin in fetal development remains uncetain. The aim of this study is to evaluate the importance of obesity in development of insulin resistance and hyperinsulinemia during pregnancy. The study included 51 healthy pregnant women, mean age 27/5.2yr (22-37yr). Depending on increase in body weight (+ w) in pregnancy, all examined women were divided in three groups: A - n=18, +w<15 kg; B - n=19; +w 15-25kg; C - n=14, +w>25kg. Insulin levels (by RIA) in the sera of pregnant women and newborns (umbilical venous) were determined post partum. For statistical analysis Mann-Whitney, Spearman's rho i ANOVA tests were used. We found a significantly higher insulin levels in pregnant women in B i C groups than in group A (48.02/27.65 and 51.59/18.7 vs 36.87/15.27;p<0.05). Insulin levels were similar in all newborns (groups: A - 16.59/7.52; B - 15.05/6.92; C-17.00/8.57; p>0.05), but were not correlated with maternal insulin concentration. Birth weight (F=4.56;p<0.05) and lenght(F=4.95;p<0.05) were significantly increased in newborns of mothers from group C. We found the relationship between fetal insulin levels and: a) birth weight(R=0.73;p<0.05) and birth lenght(R=0.65;p<0.05) in these babies. Also, neonates with birth weight greater than 4000g were significantly higher in group C(50%) than in A(21%) and B(21%) groups of pregnant women. We conclude that obesity inrease insulin resistance and secretion in pregnant women.

881

OUTCOME OF PREGNANCY WITH DIABETES IN A DEVELOPING COUNTRY. C. Munichoodappa and Ashok Gurudas The Bangalore Hospital, Bangalore, India.

We reviewed 253 patients having impaired gestational glucose tolerance (IGGT) 18, gestational diabetes mellitus (GDM) 112, pregestational diabetes (PGDM) - White Class A 66, Class B 46 and Class C (Insulin dependent) 11 having 270 pregnancy and 273 fetuses (3 had twins). Age ranged from 19 to 38 years. None had microangiopathy or macrovascular disease. Two with IGGT were on diet alone. One GDM chose to continue sulphoylurea (SU) throughout gestation. The rest were continued or switched over to mostly purified insulin. Glycemic control was excellent to good in 197 pregnancies (73%) and was unsatisfactory in 73 (27%) mainly PGDM, 250 fetuses survived and 23 (8.5%)were wasted. The latter due to 11 abortion, 3 congenital heart disease, cardiomyopathy and premature birth and death 2 each, respiratory distress, intrautrine infection and hypocalcemia, intrautrine death, still birth and multiple congenital anamoly one each. Despite good control there was a tendency to macrosomia in IGGT and GDM. Associated hypertension in 3 PGDM resulted in small for gestational age infants. Twenty eight with previous bad obstetrical events had successful outcome. The use of SU at conception in 22 and till term in one had no adverse effects. Delayed detection of IGGT and GDM, unplanned pregnancy in PGDM and late referals appear to have caused 8.5% fetal mortality

882

SERUM LEPTIN CONCENTRATION IN WOMEN WITH NORMAL PREGNANCY AND PREGNANCY COMPLICATED WITH GDM.

K. Lukaszuk, E. Kusiak, J. Drużyńska, Cz. Wójcikowski, Department of Endocrinology Institute of Obstetrics and Gynecology, Medical University, Gdańsk, Poland.

The aim of the study was to examine serum leptin levels in III trimester of normal pregnancy and pregnancy complicated with gestational diabetes mellitus (GDM) and compare them with normal non-pregnant women. We examined 19 healthy non-pregnant women (the blood samples were taken twice - in follicular and luteal phase), 25 healthy pregnant women (III trimester) and 14 women with GDM. Serum leptin and progesterone concentrations were measured with RIA. The mean serum leptin concentrations in non-pregnant women was 11.9 ± 5.8 and 16.6 ± 9.1 ng/ml in follicular and luteal phase, respectively. Pregnant women had serum leptin levels 25.1 ± 11.9 ng/ml. The mean serum leptin levels in women with GDM were slightly higher, 27.8 ± 11.4 ng/ml. The serum leptin concentration was positively correlated with plasma progesterone level.

In conclusion, results of the present study suggest the possible role of steroids in the regulation of leptin release.

883

OUTCOME OF DIABETIC PREGNANCY IN MAURITIUS 1993-1996. S.Ramtoola ,B.H.Damry . Dr A.G.Jeetoo Hospital , Port-Louis, Mauritius.

Mauritius has prevalences of NIDDM and impaired glucose tolerance of 13.2% and 15.6% respectively. To evaluate the effect of such diabetes and IGT on pregnancy outcome , prospective data has been collected on all ongoing and new diabetic pregnancies since 01.10.93 at Dr A.G.Jeetoo Hospital, one of the four regional hospitals of Mauritius . 293 pregnancies were registered at 30.09.96. Outcome was analysed in 266 pregnancies , excluding patients not yet delivered and those lost to follow-up . 93 cases were of pregestational onset , including 5 women with IDDM. 85 of the 173 patients diagnosed during pregnancy had diabetes by classical WHO criteria . 17 pregnancies resulted in 1st or 2nd trimester abortion , including one therapeutic termination for anencephaly. There was one maternal death at 32 weeks' gestation preceded by intrauterine fetal death. Perinatal mortality rates in the remaining 248 pregnancies were 141.0/1000 for pregestational diabetes and 117.6/1000 for gestational diabetes , compared to whole island background rates of 26.8/1000 for 1995. There was no excess perinatal mortality in gestational IGT at 23.5/1000 . Intrauterine death in untreated or poorly controlled DM accounted for a significant part of the excess perinatal mortality in the 2 diabetes groups , with stillbirth rates of 76.9/1000 and 82.3/ 1000 for pregestational and gestational diabetes compared to 14.8/1000 background population rates . Prematurity with its complications was the commonest cause of neonatal mortality (50%) and congenital malformation accounted for 14.3% of the perinatal mortality . In conclusion , the exceedingly high perinatal mortality rate in pregestational and gestational diabetic pregnancy at 4.8 times the background rate calls for review of antenatal booking practices and referral patterns , and suggests the need for early screening for diabetes to ensure earlier institution of appropriate treatment .

884

SERUM LEPTIN IN WOMEN AND *ob* GENE EXPRESSION IN RATS IN RELATION WITH INSULIN LEVELS DURING PREGNANCY.

M.-Th. Sutter-Dub* , S. Samec^{+}, D. Dallay^{o}, J. Seydoux^{+}, A.-L. Sutter^{x} and B.Ch.J. Sutter*. *Université Bordeaux I, Talence (France) $^{+}$Centre Médical Universitaire, Genève (Switzerland), ^{o}Maternité C, CHR Pellegrin, Bordeaux, ^{x} CH Charles Perrens, Bordeaux (France).

A long-term effect of insulin was demonstrated on serum leptin production and on *ob* gene expression in humans and in rodents. Furthermore, it has been suggested that insulin regulates *ob* gene expression and leptin production indirectly, probably through its trophic effect on adipocytes. Since the size of adipocytes during pregnancy is increased, this study was undertaken to further investigate the relationship between insulin and leptin levels.This was done under conditions of hyperinsulinemia, as it occurs during pregnancy, by measuring serum leptin levels in women and *ob* gene expression in female rats. In pregnant women (35-40 weeks) serum insulin levels were increased as previously shown: 2.17 ± 0.23 ng/ml (n = 80) versus 0.65 ± 0.07 (n = 10) ($p<0.02$) with no change in glycemia, and serum leptin levels were also found to be increased : 24.65 ± 1.82 ng/ml (n = 82) versus 13.21 ± 1.75 in controls (n = 12) ($p<0.02$). No correlation was observed between leptin and insulin levels. Compared to control female rats, at day 20 of gestation serum insulin was increased : 5.66 ± 1.01 ng/ml (n = 13) versus control rats : 3.3 ± 0.22 (n = 13) ($p<0.05$), and serum glucose was decreased: 0.94 ± 0.04 $g.l^{-1}$ versus 1.22 ± 0.03 ($p<0.001$), due to the increased uptake of glucose by the fetuses. However there was no significant change in *ob* mRNA levels in parametrial adipose tissue. These data suggest that the increased levels of insulin during pregnancy may regulate, probably indirectly, human leptin production but this increase had no effect on the expression of *ob* mRNA at day 20 of gestation in the rat.

885

CONGENITAL MALFORMATIONS IN NEWBORNS OF PRE-PREGNANCY NON INSULIN-DEPENDENT DIABETIC MOTHERS.

R.M.Botta, G.Pagano, F.Cammilleri, B.Di Giovanni and B.Todaro. University of Palermo, Palermo, Italy.

The aim was to determine if the use of sulphonylureas and/or biguanides during early pregnancy is associated with an increased risk of congenital anomalies in newborns of non insulin-dependent diabetic mothers before pregnancy. From 1980 to 1995 we followed prospectively 110 pregnancies in non insulin-dependent diabetic women before conception. Of these, 41 women were taking during early pregnancy oral hypoglycemic agents (21 sulphonylureas, 4 biguanides and 16 sulphonylureas+biguanides) and stopped these drugs at 8.89 ± 5.57 weeks of pregnancy. 69 non insulin-dependent pregnant women were treated with insulin or diet alone. At first examination all the patients started the diet and the insulin therapy and they were monitored by means of blood glycemic self-monitoring. Their newborns were examined at birth. At first examination glycosylated hemoglobin was 7.11 ± 1.66% and 8.0 ± 2.1% in oral hypoglycemic drugs treated patients and in insulin or diet treated patients respectively. In these series we observed 7 congenital anomalies: talipes equinovarus, syndactyly, microcephaly and microphtalmy in insulin/diet treated patients; right tibia agenesis, right diaphragm agenesis and pulmonar hypoplasia, and 2 interatrial defect in sulphonylureas+biguanides treated patients (interruption week range: 5th-21th week of gestation). Univariate logistic regression analysis and chi-square test were used for statistical analysis. The percentage of congenital malformations was 5% in offspring of non insulin-dependent diabetic mothers treated with insulin or diet, 0% in patients treated with sulphonylureas and 20% in patients treated with sulphonylureas+biguanides ($p< 0.01$). The higher percentage of congenital malformations in newborns of non insulin-dependent diabetic women treated with sulphonylureas+biguanides can be attributed partly to biguanides influence on embryogenesis period.

886

TRIGLYCERIDEMIA IN DIABETIC PREGNANT WOMEN AND NEW BORN WEIGHT

S BLOUZA , A ABID, W HAMOI, I. KHEDHER and K NAGATI.
NATIONAL INSTITUTE OF NUTRITION
TUNIS TUNISIA

Uncontrolled metabolic situation and hyperglycemia in Diabetic pregnant women are considered for a long time a predominant factor of new born macrosomie. However, in spite of perfect metabolic control and normoglycemia, macrosomia is still observed in 25 % in our study. There by, other factors are incrimined in pathogenesis of macrosomia (genetic, dietetic factors and recently hypertriglyceridemia in pregnant women). Our prospective study suggest to know if macrosomia was correlated with hypertriglyceridemia in perfect metabolic control in pregnant diabetic patients. We have studied new born weight in tow perfect metabolic control pregnant diabetic patient groups : one group (n = 67) with hypertriglyceridemia , and the second group (n = 42) with normal triglyceridemia in 3rd trimester. Our results show that third trimester hypertriglyceridemia is not correlated with new born weight. Maternal triglyceridemia is not a determinant factor of new born macrosomia in diabetic women.

887

FETAL MACROSOMIA IS ASSOCIATED WITH HIGH MATERNAL INSULIN SENSITIVITY AND GESTATIONAL WEIGHT GAIN.

O. Giampietro, M. Ferdeghini*, P. Bay°, C. Bertoni, E. Boldrini, and E. Matteucci. Clin. Med. II, Med. Nucl.*, Clin. Ostet.°, Pisa, Italy.

Increased perinatal morbidity-mortality are associated with gestational diabetes (GDM). We investigated glucose tolerance over the course of 69 pregnancies (by oral glucose tolerance test, OGTT, and hemoglobin A1c, HbA1c) as well as fetal intrauterine growth (by ultrasound) and pregnancy outcome.

In the 3rd trimester, 7 women had abnormal OGTT, but none of the 12 mothers of large babies (>3.9 kg) had GDM. Among fifteen pregnants with basal BMI>25 kg/m^2, 2 developed GDM, 5 had babies>3.9 kg, 8 had normal birthweight babies. In normal pregnancies (n=42), area under glycemic curve (AUGC, g min/dl) changed from 4.8±2.7 (1st trim) to 6.9±2.4 (3rd trim), area under insulinemic curve (AUIC, mU min/ml) from 6.6±3.8 to 9.3±4.9; in mothers of large babies (n=12), AUGC changed from 3.6±3.4 to 5.4±1.9, AUIC from 5.5±1.5 to 8.9±3.7; in mothers with GDM (n=7), AUGC increased from 6.6±3.4 to 12.3±1.6, AUIC from 8.3±5.3 to 9.7±5.5; in obese mothers of normal birthweight infants (n=8), AUGC changed from 6.0±3.1 to 7.3±3.0, AUIC from 8.1±2.7 to 10.6±2.5. Neonatal body weight was correlated ($p<0.001$) with maternal gestational weight gain, placental weight, 3rd trimester AUIC/AUGC ratio and 1st-2nd trimester HbA1c. Fetal growth indices (femur length, biparietal diameter and abdominal circumference) were correlated with both HbA1c and 2h OGTT glycemia.

Fetal growth rate is confirmed to be associated with maternal glycemic equilibrium, but one of the main determinants of high infant birthweight seems to be an enhanced maternal insulin sensitivity, accompanied with remarkable gestational weight gain, apart from glucose tolerance or the absolute level of serum insulin.

888

PLASMA α-TOCOPHEROL LEVELS IN DIABETIC WOMEN DURING PREGNANCY.

M.Sanaka, S.Minei, K.Yanagisawa and Y.Omori. Diabetes Center, Tokyo Women's Medical College, Tokyo, Japan.

It has been clarified that administration of Vitamin E decreases the rate of embryo malformations in animal studies. To investigate the changes of α-Tocopherol in pregnancy which is a main component of Vitamin E, and elucidate the correlation between fetal anomaly and plasma α-Tocopherol level, we measured plasma α-Tocopherol levels in 52 diabetic pregnant women in the first, the second and the third trimester by using HPLC. Their glycemic controls were good (average level of HbA1c was 6.2% in the first, 5.1% in the second and 5.7% in the third trimester). The control group comprised 20 healthy non-pregnant women, 40 normal pregnant women and 239 diabetic non-pregnant women.

Non-pregnant state : The average level of plasma α-Tocopherol in 20 healthy non-pregnant controls was 0.7±0.1mg/dl. The average level of plasma α-Tocopherol in diabetic non-pregnant women was 0.9±0.3mg/dl ($p<0.005$ vs healthy non-pregnant controls).

Pregnant state : In the first trimester α-Tocopherol level was 0.8± 0.1mg/dl in normal pregnant women and 0.8±0.2mg/dl in diabetic pregnant women. No difference in plasma α-Tocopherol level was found in diabetic pregnant women when compared to normal pregnant women in the first, the second and the third trimester. There was a significant cooperative correlation between plasma α-Tocopherol level and gestational week in both normal and diabetic pregnant women. Two diabetic pregnant women had the baby with cardiovascular defects, but their plasma α-Tocopherol level was within normal range in the first trimester which is important period of organogenesis.

To elucidate the protective effect of Vitamin E against anomaly in human diabetic pregnancies, we have to establish α-Tocopherol level in the fetus.

889

MATERNAL DIABETES AND FETAL MACROSOMIA IN MAURITIUS.

J Balls, S Ramtoola and S Robinson[1]. Dr AG Jeetoo Hospital, Port Louis, Mauritius and Unit of Metabolic Medicine[1], St Mary's Hospital Paddington, London.

Maternal diabetes and maternal obesity are associated with fetal macrosomia. There is evidence that all babies of diabetic mothers are macrosomic in that their weight is greater than predicted. We hypothesised that maternal obesity and triglyceride concentrations would predict macrosomia in Mauritius. Absolute weight and neonatal skinfolds were used to assess macrosomia. Nineteen diabetic pregnancies (11Asian Indian: 8 Europid) were compared with 67 control non-diabetic (43 Asian Indian: 24 Europid). Mothers with diabetes were older (dm31.0±7.2 v control 24.7±5.2 years, $p<0.05$) and more obese (BMI dm30.5±3.3 v control 27.3±4.1kg.m^{-2}, $p<0.05$). Birthweight was similar in the two groups (dm 3089±141 vs. control 3082±226 gm, NS) but mean 4 point neonatal skinfold was increased in infants of diabetic mothers (dm 5.71±1.14 vs. control 4.92±0.93mm, $p<0.001$). Models were constructed to predict birthweight or neonatal skinfold thickness on the basis of the presence of maternal diabetes, maternal age, maternal body mass index, glucose and triglyceride concentrations. Birthweight correlated with these variables ($r=0.48$ $p<0.01$); maternal BMI ($p<0.01$) and gestational age ($p<0.05$) contributed significantly. Likewise neonatal skinfold correlated with these variables ($r=0.44$ $p<0.01$) with maternal BMI ($p<0.05$) and maternal diabetes ($p<0.05$) contributing significantly. Maternal obesity therefore influeneces both birthweight and neonatal subcutaneous fat whereas maternal diabetes influences predominately subcutaneous fat in this population.

890

ANTITHROMBIN III ACTIVITY IN IDDM AND NIDDM PREGNANTS

A.Bronisz, D.Rość, M.Kotschy, A.Graczykowska-Koczorowska and E.Wiśniewska University School of Medical Science in Bygoszcz, Poland

The antithrombin III (AT III) - very important inhibitor of blood that inhibits thrombin, factor Xa, XIa, IXa, XIIa and VIIa. Data about AT III activity in diabetic pregnants are controversial. The aim of our study was to compare AT III activity in pregnants with IDDM and NIDDM. The study was carried out in: 31 pregnants with IDDM (17 without microangiopathy - mean age: 26.9±5.5 and 14 with it - mean age: 28.0±7.0); 10 with NIDDM (mean age:36.5±5.5) and in 24 healthy pregnants (mean age: 25.6±4.5). Blood was obtained in the first, second and third trimester, post-partum and after puerperium. Chromogenic substrats of Behring were used for determinations of AT III activity. The values of AT III activity during pregnancy, post-partum and after puerperium in healthy pregnants were in normal range (112.8-120.2%). The pattern of AT III activity in IDDM patients (without regerding vascular complications) was similar to that of healthy pregnants (115.5-127.5%). The AT III activity in IDDM diabetics without microangiopathy in the first trimester was significantly lower than in pregnants with microangiopathy (107.8±32.0vs142.9±35.2%, $p<0.05$). It increased in the second and third trimester of pregnancy and decraesd post-partum. AT III activity in IDDM diabetics with microangiopathic complications was very high in the first trimester and it was significantly decraesd in the second one (142.9±35.2 vs 101.0±23.4%, $p<0.05$). The level of AT III activity in the second trimester in group without microangiopathy was 139.2±52.1 and it was 101.0±23.4% in the group with microangiopathy. The difference was significant ($p<0.05$). AT III activity in NIDDM pregnants in the first and second trimester was significantly lower than in healthy and IDDM pregnants. In the first trimester: NIDDM-98.2±23.3 vs healthy-120.0±24.9%, $p<0.05$ and NIDDM-98.2±23.3 vs IDDM-123.4±37.1%, $p<0.05$; in the second trimester: NIDDM-97.4±18.0 vs healthy-115.4±28.1%, $p<0.05$ and NIDDM-97.4±18.0 vs IDDM-122.0±45.2%, $p<0.05$. AT III activity in IDDM pregnants with microangiopathy decreased in the second trimester and in NIDDM pregnants in the first and second trimester. It could indicat its consumption during increased fibrin formation in pregnancy.

891

PERINATAL AND INFANT MORTALITY IN CHILDREN OF FINNISH WOMEN WITH TYPE I DIABETES.

G. Nikolakaros*, A. Reunanen**, K. Teramo***.
*University of Turku, Turku, **National Public Health Institute, Helsinki, ***University Central Hospital, Helsinki, Finland.

Perinatal mortality is increased in diabetic pregnancy but little is known on survival of the children later in life. From the Diabetes Drug Registrer of the Finnish Social Insurance Institution we identified all Finnish women born after 1940 that were diagnosed until the end of 1993 with insulin-treated diabetes when under 30 years of age. From the Finnish Population Register and the Finnish Central Statistical Office we identified all liveborn children and all stillbirths of these women from 1987 until 1994. We ascertained all deaths among these children until the age of one year. During the study period there were 1630 live births and 26 stillbirths in women with Type I diabetes diagnosed before pregnancy. Perinatal mortality was 2,2% (n=36). The relative risk (RR) compared to non-diabetic pregnancies was 2,9 (95% CI 2-4). Late neonatal mortality was 0,25% (n=4), RR=3,4 (95% CI 0,93-8,7). Post-neonatal infant mortality was 0,43% (n=7), RR=2,5 (95% CI 1,02-5,2). Perinantal mortality is elevated in pregnancies of women with pregestational diabetes and the children are at increased risk of dying also during infancy.

892

PAI-1 ACTIVITY IN PREGNANTS WITH TYPE 1 AND TYPE 2 DIABETES.

A.Bronisz, D.Rość, M.Kotschy and A.Graczykowska - Koczorowska; University School of Medical Science in Bygoszcz, Poland

Plasminogen activator inhibitor type 1 (PAI-1) inhibits tissue plasminogen activator (tPA) and urokinase plasminogen activator (uPA). In the last decade it became evident that PAI-1 plays an important role in inhibition of fibrinolytic system. There are few data about the PAI-1 in diabetic pregnants. The aim of the study was the estimation of PAI-1 activity in type 1 and type 2 diabetics during pregnancy, post-partum and after puerperium. The study was carried out in: 31 pregnants with IDDM (17 without microangiopathy - mean age: 26.9±5.5 years and 14 with microangiopathy - mean age: 28.0±7.0 years); 10 with NIDDM (mean age:36.5±5.5 years) and in 24 healthy pregnants (mean age: 25.6±4.5 years). The patients were normoglycaemic ($HbA_{1c}<6.5\%$).

PAI-1 activity was determined in blood plasma at the end of the first, second and third trimester of pregnancy, post-partum and after puerperium. To determine of PAI-1 activity the amidolytic method of Bioopol (Sweden) was used. PAI-1 activity in healthy pregnants from the first trimester (5.1±4.7 IU/ml) significantly increased in second (12.0±11.6 IU/ml) and third ones (17.6±9.4 IU/ml), it decreased post-partum (7.9±7.6 IU/ml) and reached values of the first trimester after puerperium (6.5±6.7 IU/ml). PAI-1 activity in NIDDM patients at all time points of investigation except of values detected in the third trimester was significantly higher than in healthy group (10.0±4.4, 12.9±3.4, 22.2±8.2, 14.0±2.8, 13.6±4.0 IU/ml respectively) and in IDDM pregnants (4.0±3.9, 7.6±5.7, 15.9±11.4, 6,1±9.4, 7.6±8.7 IU/ml respectively). The PAI-1 activity in IDDM pregnants without microangiopathy was lower than in patients with microangiopathy, but the differences were not significant. *Conclusions* 1.The highest values of PAI-1 activity were observed in NIDDM pregnants. 2.In both healthy and diabetics pregnants the highest PAI-1 activity was found in the third trimester of pregnancy. 3.No significant differences of PAI-1 activity between IDDM pregnants without and with microangiopathy were observed.

893

PREGNANCY OUTCOME IN WOMEN WITH GDM TREATED ACCORDING TO *STAGED DIABETES MANAGEMENT* IN ŁÓDŹ AND RADOM (POLAND).

K.Cypryk*, G.Penza**, J.Wilczyński*, B.Cyranowicz*, L.Czupryniak***, M.Zawodniak-Szałapska* and M.Sobczak* - Polish Mother's Memorial Hospital, Łódź*, Regional Hospital, Radom**, Gastroenterology and Diabetology Dept., Medical Academy of Łódź*** - Poland

Aim: To compare the pregnancy outcome before and after *Staged Diabetes Management* (SDM) implementation. Research design and methods: In 1995-96 the SDM was introduced to screen pregnant women for gestational diabetes mellitus (GDM). It is based on a two-step diagnosis: 50 g GCT performed between the 24-28th gestation week (with the threshold 140 mg/dl) and - on GCT being positive - 75 g OGTT, according to WHO criteria. Previously the same criteria were recommended in Poland, but they were not widely used. Upon diagnosis of GDM all women were treated according to SDM protocol in two centers in Łódź and Radom. The study subjects were divided into three groups: I - non-screened GDM women (n=67, mean age 30±6.8); II - women with GDM found in active screening performed at our centers (n=205; mean age 30±4.7); and III - healthy pregnant women (n=104, mean age 29±4.6). Results: Mean (±SD) pregnancy time before GDM diagnosis was: I - 33.0±1.6; II - 30.1±5.2 wks (p<0.05). Insulin treatment was more frequently used in group I than in II (43.6% and 22%, respectively; p<0.05). There was no difference in pregnancy duration between the groups: I - 39.0±1.0; II - 39.2±1.1; III - 39.3±1.3 wks (p>0.05). Neonatal birth weight was significantly lower in groups II and III than in I: I - 3788±449; II - 3467±461; III - 3368±383 g (p<0.05). LGA features were found in 29.6% of children born in group I, in 12.5% of II, and 4.8% of III (p<0.05). Neonatal hypoglycemia occurred most frequently in group I: I - 48.1%; II - 20.8%; III - 1.9% (p<0.05). Conclusions: Upon SDM implementation, GDM was diagnosed earlier in pregnancy and the number of insulin-treated women decreased significantly. Both birth weight and macrosomia rate were lower in the GDM group, which had been screened, than in the non-screened population. The routine screening of pregnant women for GDM and proper treatment results in lowering pregnancy and neonatal complication rates.

894

CHANGES IN SODIUM-HYDROGEN EXCHANGE ACTIVITY DURING NORMO-TENSIVE NON-DIABETIC PREGNANCY.

C. Bertoni, E. Matteucci, P. Bay*, E. Biasci, F. Piazza, F. Ruberti, and O. Giampietro. Clinica Medica II, Clinica Ostetrica*, Pisa, Italy.

Pregnancy is associated with a 30-50% rise in cardiac output and 50% increase in blood volume: the contribution of changes in the activity of primary and secondary active transporters to these hemodynamic adaptations remains unknown. For the first time, we measured sodium-hydrogen exchange activity over the course of normal pregnancy. Eighteen healthy pregnant women were studied at 14, 24 and 33 weeks of gestation and compared with 18 nonpregnant healthy women. No pregnancy was complicated by hypertension. At each antenatal visit, body weight and blood pressure were recorded; blood and 24 h-urine samples were taken to control renal function and metabolic equilibrium; maternal glucose tolerance was evaluated by oral glucose test and HbA1c; erythrocyte sodium-hydrogen antiport was also measured.

Erythrocyte antiport activity resulted 10.0±3.0, 9.6±2.9 and 8.4±3.5 mmol/L cells h in the three gestational trimesters, respectively, significantly higher at each trimester than in control women (6.8±2.5). The clearances of urea and creatinine were constantly elevated in pregnant women; at each trimester, their serum concentrations were lower than in nonpregnant women. Serum potassium significantly decreased during pregnancy. Serum total cholesterol and triglycerides, already above the normal range from the first trimester, further increased until the third one. Area under glycemic curve became larger during pregnancy, the area under insulinemic curve increased to a lesser extent. There was a significant association of antiport activity with serum triglycerides.

The observed hyperactivity of the transporter, peaking at the 14th week of gestation, may be a contributing factor to the hemodynamic adjustments attending upon normal pregnancy.

895

OUTCOMES OF IDDM PREGNANCIES : SIGNIFICANT BENEFITS ASSOCIATED WITH CONCEPTION PLANNING.

E. Renard, M.T. Baccara, P. Boulot*, P. Lefebvre, J. Bringer and C. Jaffiol, Endocrinology and Obstetrics* Depts, University Hospital, Montpellier, France.

Whereas good metabolic control during early IDDM pregnancy is recommended to prevent congenital anomalies, utility of specific pre-pregnancy care to reduce perinatal morbidity has been poorly investigated. To assess the effects of conception planning of IDDM pregnancies on overall pathological pregnancy outcomes (PPO), we analyzed the cumulated occurrence of spontaneous/therapeutical abortions (S/TAB), perinatal and neonatal mortality (PN/NNMORT), congenital anomalies (CONAN), and perinatal morbidity (PNMORB) among 61 IDDM pregnancies. Group A included 21 planned pregnancies and group B, 40 unplanned pregnancies, with similar distribution of cases according to White's classification. Group A was characterized by earlier booking (6.7 ± 1.8 vs 11.1 ± 5.3 wks, p<0.01), lower GlyHb at conception (2.4 ± 2.6 vs 4.7 ± 4.2 SD above normal mean, p<0.05) and at 24th wk (1.0 ± 1.1 vs 1.9 ± 2.1 SD, p<0.05) and later delivery (36.8 ± 1.1 vs 35.8 ± 1.5 wks, p<0.05). Cumulated PPO were less frequent in group A : 7/21 (2 SAB and 5 cases of PNMORB) vs 25/40 (4 SAB, 1 TAB, 3 severe CON, 2 cases of PN/NNMORT, 19 cases of PNMORB) (p<0.05). Moreover, the comparison between the subgroups of group A (A', n=15) and B (B', n=16), both characterized by GlyHb<3SD above normal mean at conception, showed less frequent PPO in A' (1 SAB, 5 cases of PNMORB) than in B' (2 SAB, 1 case of PNMORT, 9 cases of PNMORB) (p<0.05). Lower occurrence of obstetrical complications (hypertension, premature labor, hydramnios) in group A (vs B, p<0.05) and A' (vs B', p<0.05) might be involved in the corresponding reduction of PNMORB. These data suggest that significant reductions of PPO, mainly related to PNMORB, can be expected from conception planning. Thus, providing specific pre-conceptional counseling to IDDM women can result in additional benefits to those obtained by good metabolic control in conceptional period and prenatal care.

896

TRIMESTER-RELATED RANGES FOR FRUCTOSAMINE AND GLYCATED HAEMOGLOBIN IN CAUCASIAN NON-DIABETIC PREGNANT WOMEN

A.J.Hartland[ac] , J.Webber [ab] , P.M.S.Clark [c], J.M.Smith [c], T.Chowdhury[ab] and F.Dunne[ab] . Diabetes Unit[a] and Department of Clinical Biochemistry [c], University Hospital Birmingham NHS Trust (Selly Oak) , Birmingham , UK and Department of Obstetrics , Birmingham Womens Hospital , Birmingham ,UK[b]

This study was designed to determine trimester-related reference ranges for fructosamine and glycated haemoglobin (HbA1c) for a Caucasian non-diabetic population.The importance of strict glycaemic control during diabetic pregnancy is well recognised . Fructosamine and glycated haemoglobin are used as markers of control but quoted reference ranges are generally determined using a non-pregnant population . Between September - November 1996 , fructosamine and HbA1c was measured in 259 non-diabetic pregnant women attending routine ante-natal clinics.Of these 96 were < 12 weeks (T1) , 100 were 12-24 weeks (T2) and 63 were 25weeks-term (T3) . Only normally progressing singleton pregnancies were included.Women with known or suspected renal , cardiac ,liver or other metabolic diseases were excluded.Fructosamnine was determined colorimetrically . A latex enhanced turbidometric immunoassay (Roche Unimate 3) was used to measure HbA1c .In TI and T2 mean HbA1c was 5.1% (range 4.6-5.6 %). In T3 mean HbA1c was significantly higher at 5.3% (range 4.4-6.1%). These ranges are lower than the reference range presently quoted (range 3.5-6.5 %) , being that for a general non-diabetic population.Fructosamine levels decreased throughout pregnancy . In T1 , mean = 220 umol/lL(range 185-255 umol/L) , T2 mean = 212umol/L (range 172-251umol/L) and T3 mean = 188umol (range 158-218 umol/l). T1 versus T2 p<0.001 and T2 v T3 p<0.001 .These ranges are also lower than the quoted reference range (210-280umol/L). This study suggests that trimester-specific reference ranges should be established to enable truer monitoring of diabetic control throughout pregnancy.

DIABETES AND PREGNANCY PROJECT IMPLEMENTATION IN GEORGIA.

N.Asatiani, R.Kurashvili, M.Natsvlishvili, K.Johtaberidze and L.Shelestova. Diabetes Center of Georgia, Tbilisi, Georgia.

In 1996 a Project Diabetes and Pregnancy was started in Georgia. The Project is sponsored by Novo - Nordisk and is realized in accordance with the Izrael - Georgian Twinning Program. The aim of the Project is to develope a completely new conception, as during last 70 years young women with diabetes were discriminated. Treatment and education in pre-gesational DM were organized.14 women with IDDM (aged 21-32 yrs) were supervised. All of them were educated at the Diabetes School, and intensive preconception treatment for minimum 2 months prior to a planned pregnancy was carried out. Patients received multiple insulin injections (4 - 6 daily) to achieve fasting, preprandial and postprandial euglycaemia (<105mg/dl and <120mg/dl, respectively). HbA1c levels prior to the planned pregnancy were 7.5±0,3%. Throughout the pregnancy all women were examined once a week at the Center. HbA1c, blood pressure, body weight and renal parameters were determined, and insulin doses were adjusted. Insulin doses were based on home blood glucose monitoring data. The fetus was assessed by serial iltrasound imaging, fetal growth and anomalies. Target metabic control was achieved in12 out of 14 women (12%) Sever hypoglycaemia occured in 3 patients. The gestational age at delivary was 38,0±1.6 weeks, with an average birth weight of 3.200 ± 660g (2.600-3.800g) No cases of respiratory distress were observed. Cesarean section was used in one case. Thus, the Project, including patient education, preconceptional treatmen and care throughout the pregnancy gave positive results. The project is being continued.

THYROID PEROXIDASE AUTOANTIBODIES :METABOLIC CONTROL AND NEED FOR THYROID TREATMENT IN PREGNANT IDDM WOMEN

ML Fernandez-Soto, A. Gonzalez, JA Lobón, JA Lopez, CM Peterson*, F. Escobar-Jiménez.Endocrine and Metabolic Unit. Department of Medicine. Universitary Hospital. Granada, Spain. *Sansum Medical Research Foundation. Santa Barbara, CA

OBJETIVE: To study whether the presence of antithyroid peroxidase antibody (TPO-Ab) before gestation in IDDM affects thyroid function and metabolic control during pregnancy and early pospartum as well as neonatal outcome.

RESEARCH DESIGN AND METHODS: A prospective study at an outpatient Endocrine-Obstetric Unit was carried out in twenty pregnant IDDM women. Free T4, TSH, TPO-Ab and HbA_{1c} were assayed before gestation, during the first, second and third trimester of pregnancy and 3 months postpartum.

RESULTS: HbA_{1c} was significantly higher in TPO-Ab positive women than in those who were TPO-Ab negative during the second ($p<0.01$) and third trimesters ($p<0.05$). HbA_{1c} levels significantly decreased in TPO-Ab negative patients when the second ($p<0.01$) and the third trimester ($p<0.05$) were compared with before pregnancy and the first trimester. There was a significant increase in the dosage of insulin for TPO-Ab positive vs negative patients during the second ($p<0.05$) and third trimester ($p<0.01$) and three months postpartum ($p<0.05$). TSH was significantly increased in the second ($p<0.001$) and third trimester ($p<0.05$) and 3 months postpartum ($p<0.01$) when compared to TPO-Ab negative patients. 7.6% of the TPO-Ab negative group and 29% in the TPO-Ab positive group presented postpartum thyroid dysfunction and 42% of the TPO-Ab positive women required thyroid treatment.CONCLUSIONS: Pregnant women with IDDM who have a positive test for TPO-Ab before gestation have poorer glucose control and a high prevalence of hypothyroidism. Therefore we recommend that pre-pregnant IDDM be screened for anti TPO-Ab. Those with a positive result should be followed with serial monitoring of free T4 and TSH levels during each trimester as well as the postpartum period.

899

RESULTS OF IMPROVED CARE FOR PREGNANT DIABETIC WOMEN IN YEARS 1970-94 IN A DISTRICT OF SLOVAKIA

M.Korecová,F.Tarina,V.Vicianová.IDF President W. Mayes Jr.Diabetes Dept.and Gyneco-Obstetrical Dept. A.Dubček's Hospital in Trenčín,Slovakia

Aims:A proof of effectivity of intensive care for pregnant diabetic women on neonatal mortality in accordance with aims of SVD in comparison with older methods.In yeers 1970-94 we followed 164 diabetic mothers with Type I and II diabetes who gave birth in single or repeated pregnancies to 197 newborns.In 1970-74 19 diabetic mothers delivered 19 newborns with 15.7% perinatal mortality(PM).In1975-1980,with increased care,32 diabetic mothers delivered 33 newborns and PM dropped to 9%.In years 1980-84 from 59 newborns died two only,i.e.3.4%.In 1985-94,due to education,preconception care,screening of GDM,intensified MC-HM insulin therapy and coperation between diabetologist and gyneco-obstetrician we have lost only one from 86 newborns,1.15%. Moreover,there was also improvement with respect of P.White classification,because mothers classified as C and D,and even with moderate diabetic complications gave birth to normal newborns with low PM. Conclusion:Our 25 years lasting well documented study proves that a good education beginning with preconception and intrapregnancy care for diabetic mother complying with diabetologist and gyneco-obstetrician can assure to-day normal pregnancy and delivery,newborn with normal birthweight and nearly normal perinatal mortality of newborns of diabetic mothers-even with moderate complications in accordance with aims of SVD.

GLUTATHIONE-DEPENDENT ANTIOXIDANT SYSTEM IN DIABETES-INDUCED EMBRYOPATHY

S. Akazawa, H. Sakamaki, M. Ishibashi, K. Izumino, N. Abiru, H. Kondo, H. Takino, H. Yamasaki, Y. Yamaguchi, T. Kondo,S. Nagataki, NAGASAKI, JAPAN

We have recently shown that the mechanisms of hyperglycemia-induced embryonic malformations are mediated through increased free radical formation and depletion of intracellular glutathione (GSH) in embryonic tissues during organogenesis(Diabetes 44:992,1995). In this study, we investigated the role of glutathione-dependent antioxidant system and GSH on diabetes-related embryonic malformations. Embryos from streptozotocin-induced diabetic rats on gestational days 11 showed a significantly high frequency of embryonic malformations (neural lesions 21.5 vs. 2.8%, $P<0.001$) and growth retardation compared with those of normal mothers. The formation of intracellular free oxygen radical species increased in isolated embryonic cells of diabetic rats on days11. The concentration of intracellular GSH in embryonic tissues of diabetic pregnant rats on day 11 was significantly low compared with those of normal rats. The activity of γ-glutamylcysteine synthetase (γ-GCS), the rate limiting GSH synthesizing enzyme, in embryos of diabetic rat was significantly low, associated with reduced expression of γ-GCS mRNA. Administration of buthionine sulfoxamine (BSO), a specific inhibitor of γ-GCS, during the period of maximal teratogenic susceptibility (6 to 11 day of gestation) to diabetic rats reduced GSH by 46.7% and increased the frequency of neural lesions (62.1 vs. 21.5%, $P<0.01$). Administration of GSH ester to diabetic rats restored GSH concentration in the embryos and reduced the formation of free oxygen radicals leading to normalization of dysmorphogenesis (1.9 vs.21.5%) and improvement in growth retardation. Administration of insulin in another group of pregnant rats during the same period resulted in complete normalization of dysmorphogenesis (4.3 vs.21.5%) and growth retardation. Our results indicate that GSH depletion and impaired responsiveness of GSH-synthesizing enzyme to oxidative stress during organogenesis, are critical in development of embryonic malformations in diabetes.

901

FIRST TRIMESTER METABOLIC CONTROL AND PERINATAL OUTCOME IN WOMEN WITH IDDM

N. Dozio, E. Sarugeri, S. Rosa, G. Lo Popolo, P. D'Ambrosio, F. Bombelli, A. Ferrari, A. Beretta, G. Pozza and M.Castiglioni - H. San Raffaele Scientific Institute - University of Milan - Milan Italy

Metabolic control in IDDM women during pregnancy has greatly lowered maternal and perinatal mortality. Increasing evidence has strengthened the importance of metabolic control for adequate foetal development. Aim of the study was to evaluate foetal outcome in 93 consecutive pregnancies in women with IDDM referring to our Institute within 12 weeks after last menstrual period. Four patients were excluded because of nephropathy. Patients were allocated into 3 groups with 1) HbA1c ≤ 6% (n=24), 2) HbA1c >6.1≤7 (n=30), 3) HbA1c >7 (n=35) (normal <6%) determined at 12 week corresponding to the organogenic period. Mean HbA1c decreased in all groups by the third trimester to 5.5%±0.7, 6.0%±0.6 and 6.6%±0.9 in groups 1, 2 and 3 respectively but remained statistically different in the 3 groups. Age and diabetes duration did not differ among groups whereas BMI was higher in group 3. Patients of group 2 and 3 delivered earlier than those of group 1 and % of delivery before week 35 was 0% in group 1 vs 15.3% in groups 2 and 3 ($p<0.05$). The % of macrosomia was 16.7%, 36.7% and 51.4% in group 1, 2 and 3 respectively, $p=0.025$). Similarly the rate of caesarean sections was increased in group 2 and 3 (55% vs 29% in group 1 $p<0.05$). Pathological NST where more frequent in group 2 and 3 than in 1 (24.6% vs 4.2%, $p<0.05$) and hypertension or preeclampsia were observed only in groups 2 and 3. This data suggest that metabolic control early during gestation is associated with increased rate of macrosomia, earlier and preterm delivery, increased rate of caesarean sections and gestational hypertension/preeclampsia also in the group of patients in whom a value below 7% is reached by the 12th week.

902

SELF-MONITORING BLOOD KETONE WITH PAPERSTRIPS AND REFLECTANCE METER IN DIABETIC PREGNANCY AND GESTATIONAL DIABETES MELLITUS.

Honda M., Mogi M., Takano Y., Amemiya T, Ko C., Yokosuka K., Aiba S. and Nakabayashi M.* Siseikai Daini Hospital and Maternal and Perinatal Center of Tokyo Woman's Medical College *

Controlled diet is important in the management of pregnancy with impaired glucose tolerance. However, such calorie restriction during pregnancy could produce maternal ketonemia that cause central nervous function depression and endangers the fetal well-being. Recently, a paper-strip sheet (ketofilm) and reflectance meter (ketometer) for blood ketone (3-OHBA) have been developed . In this study, we have evaluated the clinical usefulness of paper strips and reflectance meter in monitoring the blood ketone levels in diabetic pregnancy and GDM. Ten pregnant diabetic woman and three GDM, 8 of them were obese (BMI>25) and 5 were non-obese were the subjects of this study. All the subjects followed a strict diet of 1200-1600 kcal/day. The blood ketone, measured using the ketofilm/ketometer system, and the urinacy ketone were measured at the same time.

The normal blood ketone level is less than 100μmol/L. Before breakfast, the 5 non-obese diabetic subjects showed blood ketone levels of less than 100μmol/L and negative for urinary ketone body, whereas the 8 obese patients showed higher blood ketone levels (150-380μmol/L), 4 of them were negative for urinary ketone body. Addition of 160-240 kcal to the basic meal maintain the normal blood ketone level and negative urinacy ketone. Our results also showed that daily profile lowered the blood ketone level.

Our findings suggest that self-monitoring of blood ketone levels would motivate the patients to maintain the normal range and control their diet, especially the obese, thus reducing fetal risks in diabetic pregnancy and GDM.

903

PROBLEMS OF PREMATURE DELIVERY IN DIABETIC PREGNANCY

E.Wender-Ożegowska, M. Pietryga, W. Meissner, E. Biegańska and R. Biczysko, Institute of Obstetrics and Gynecology , Karol Marcinkowski University School of Medical Sciences, Poznań, Poland

A population of 535 diabetic pregnancies treated in our department over a period ranging from 1.01.1990 to 29.02.1996, was analyzed with respect to the incidence, reasons and consequences for the newborns of premature deliveries. The analyzed group consisted of: 205 (38,3%) pregnat women classified as G_1DM (treated with diet), 116 (21,6%)- as G_2DM (treated with nsulin), 90 (16,8%)- as cl. B, 61 (11,4%) - as cl. C, 28 (5,2%) - as cl. D and 35 (5,5%)- as cl. R/F. Premature deliveries occurred in 89 instances, that is in 16,6% of the analyzed diabetic pregnancies. In classes G_1- C, the percentage of premature deliveries ranged from 12,2% - 14,7%, in class D it amounted to 25%, while in cl. R/F to as much as 54%. Spontaneous premature deliveries occurred in 25 (27%) cases and 65 (73%) had to be delivered by cesarean section. Fetal distress was the most frequent indication for operative delivery. The mortality rate in the premature group of newborns reached 7,9% and that in the mature group of newborns rated 3,2%. We want to stress our findings that malformations (3 cases) and RDS (3 cases) were the most frequent reasons for the death of prematurely delivered newborns.

Pregnancy in diabetic women is still a high risk for premature delivery, especially in the group with vascular complications.

904

Blood Pressure Monitoring in Diabetic Women: Their Pregnancy Outcome

Napoli A., Sabbatini A., La Torre R.*, Di Biase N., Fallucca F.
Cattedra di Diabetologia, II Clinica Medica, * Istituto II Clinica Ostetrica

Pregnancy induced hypertension (PIH) which is more frequently found in pregnancies complicated by diabetes mellitus, still worsens the pregnancy outcome. Our previous observations in 124 diabetic pregnant women, showed a relationship between the blood pressure (conventionally investigated) and microalbuminuria. Prospectively, we observed the blood pressure (ABP) profile for a 24-hour period (by using an automatic blood pressure monitoring system: TAKEDA Medical TM2421) in 54 out-patients (age 30.4±5.2) (WC: 7GDM, 19B, 10C, 18 D/R) (Type: 7GDM, 13 type 2, 34 type 1) consecutively enrolled, during pregnancy (<13, 20-22, 33-35 week of gestation). We investigated the mean of 24hour Systolic and Diastolic BP as well as Day/Night BP. A slight decrease of blood pressure was observed at the second trimester of pregnancy both in diabetic and non diabetic women (n=40), followed by an increase at the third trimester when the values reached those recorded in early gestation. In diabetic pregnant women we recorded higher ABP levels than in non diabetic women, even if they did not reach the level of significance. Among the diabetic patients, significantly higher values were observed in type 1 in comparison with gestational (GDM) or GD+type 2 diabetic women (III trim Diastolic ABP: 67; 4±2 vs 58; 1±2; 7 or 60; 3±2; 1 mmHg). In type 1 diabetic women a strong correlation was found with the diabetes duration whereas, in type 2 diabetic women with patients'age. Furthermore, several significant increases of ABP (Systo/Diastolic) were seen throughout the pregnancy, in the women whose diabetic duration had lasted for over 10 years as opposed to the patients of less than 10 year duration (1st Trim Total ABP: 115.5±4.6/73.2±2.5 vs 103.8±4.1/64.9±2.4 mmHg; 3rd Trim Total ABP: 115.9±3.2/70.9±1.9 vs 104.1±2.2/64.6±1.4 mmHg). Finally, early in pregnancy (<13 week of gestation), we noticed higher ABP values in those subjects who developed PIH. This finding could have a prognostic clinical meaning also because it was associated with an evident alteration of BP circadian biorhythm.

905

SOCIAL STRESS DURING EARLY PREGNANCY INDUCES CHANGE OF GLUCOSE TOLERANCE AND SEXUAL BEHAVIOUR IN MALE OFFSPRING

G. Brizgalova, L. Sergienko, I. Sidorova, T. Bondarenko, Y. Gunchenko and O. Kartavceva. Ukrainian Research Institute of Endocrine Diseases Pharmacotherapy, Kharkov, Ukraine.

The aim of the study was to assay the influence of social stress during early pregnancy on glucose tolerance and sexual behaviour in male offspring. Pregnant Wistar rats were exposed social stress – every day rat was placed in another rat's association during the first 7 days of pregnancy. In 3-month-old offspring the i.p. GTT and sexual behaviour were examined. Then, the offspring were decapitated and blood plasma corticosterone levels were measured by fluorimetric method. After i.p. GTT the offspring have been divided into 2 groups. Group 1 had fasting plasma glucose levels and glycaemic pattern like to control rats (from intact mothers). Group 2 showed higher fasting plasma glucose levels (6.2±0.3 vs 3.9±0.2 mmol/l in control, $p<0.001$) and "plane" glycaemic pattern. Sexual behaviour was evaluated on the results of the 4th test. Group 1 had sexual activity, but number of mountings was elevated by 3-fold ($p<0.001$ vs control). Latency of intromissions and ejaculations was significantly lengthened ($p<0.001$ vs control), that resulted in the decrease of ejaculation frequency ($p<0.001$ vs control). Group 2 showed a loss of sexual activity during test. Maternal stress provoked the increase of corticosterone content both Group 1 and Group 2 (1.19±0.06 and 1.84±0.05 mmol/l, respectively vs 0.64±0.04 mmol/l in control, $p<0.001$). We conclude, that social stress during early pregnancy induces of glucose tolerance modification and sexual behaviour suppression in offspring and corticosterone may be one of the possible factors mediating these disorders.

906

EFFECT OF STRICT DIETARY CONTROL OF DIABETES MELLITUS IN PREGNANCY.

M.S. El-Nasr; N. Shoukry and A. Amin, Al-Azhar University, Cairo, Egypt.

Seventy diabetic pregnant women were followed during pregnancy with strict dietary control (1800 - 2500 KCal/day according to ideal body weight). All received human insulin in a mixture of short and intermediate acting forms in morning and evening doses. Measurement of plasma glucose was done every two weeks by glucose oxidase method. During the last three months of pregnancy, the mean plasma glucose averaged 5.21 mmol/l. Patients were allowed to go as close to term as possible, with 50% being delivered at or beyond 38 weeks. 21.4% were delivered by C.S., Forceps or vacuum extraction deliveries were performed in 11.4% of cases. Perinatal mortality rate was 1.28%. Only 2 babies (2.8%) were delivered because of deterioration of feto-placental function tests. 17.9% of live born babies had neonatal hypoglycemia. 71.4% of live born babies had congenital anomalies mainly renal, cardiac or caudal regression syndrome. Our results suggested that strict metabolic control during pregnancy may decreases the incidence of perinatal morbidity and mortality, fetoplacental function abnormalities and neonatal hypoglycemia.

907

FACTORS WHICH INFLUENCE ATTENDANCE AT A PREPREGNANCY CLINIC

D.W.M. Pearson, G.D. Lang and H.W. Sutherland. Combined Obstetric Diabetic Clinic, Aberdeen Maternity Hospital, Aberdeen Royal Hospitals NHS Trust, Aberdeen, Scotland.

Because optimal glycaemic control in early pregnancy is of proven benefit to improve outcome in diabetes, educational strategies should be developed to encourage attendance at prepregnancy clinics. Methods: In a single geographic region 325 consecutive pregnancies in 194 women with established IDDM were investigated to assess registration at a well advertised pre pregnancy clinic(PPC). Availability of this clinic was emphasized in the educational program for newly diagnosed women with IDDM, teenage girls transferring to adult clinics and at the post natal multidisciplinary clinic. Results: Out of 325 pregnancies, 121(37.2%) were preceded by registration at the PPC. No significant relationships were found between registration and age at diagnosis(16.3±7.5vs15.2±7.3 yr), parity, pregnancy number , previous adverse outcome or prepregnancy weight (65.9±8.6 vs 64.6±8.9kg). Registrants were older (28.2±3.4 vs 26.4±4.4yr. $p<0.0001$) and had fewer smokers (20% vs30% $p<0.002$). Few women with advanced complications attended (Class F 0%,R 23%). Conclusion: Women of reproductive age with complications of diabetes should be particularly targeted for prepregnancy care.

908

THE IMPACT OF PRECONCEPTUAL CARE IN WOMEN WITH INSULIN DEPENDENT DIABETES MELLITUS (IDDM)?

F.Dunne F[ab] J.Webber [ab] T. Smith [ab] M. Essex [ab]A. Hartland [c] T.Chowdhury [ab]and H.Nicholson [b]. Diabetes Unit[a] and Department of Clinical Chemistry[c], University Hospital Birmingham NHS Trust and Department of Obstetrics[b] Birmingham Womens Hospital, Birmingham UK.

Between April 1994-96, 47 women with IDDM attended our antenatal clinic, 12(26%) of whom attended the preconceptual clinic(PC). We analysed the latter by comparing pregnancy outcomes between the 12 attenders (PC) and the 35 non attenders (NA).The groups were similar for age, ethnicity, duration and complications of diabetes. Marital status was different between groups (100% (PC) v 54%(NA) married. There were less smokers (8% v 28%) and mean booking HbA_1C was lower (8.1% v 10%) in the PC group. 58% of babies were delivered at term (≥37weeks) and 42% preterm (30-36 weeks)(PC group) compared to 57% and 43% respectively (NA group), although 17% of the latter were between 26-30 weeks. The incidence of macrosomic babies was lower in the PC group (25% v 39%) and there were no major congenital anomalies.There were no neonatal deaths and 17% required neonatal unit care (NNU)(PC group) compared with two neonatal deaths and 30% requiring NNU care (NA group). This clinical service has improved periconceptual control (HbA_1C 8.1% v 10%), reduced neonatal morbidity(17% v 30%)(NNU) and mortality (0% v 5.7%) and decreased the number of macrosomic infants (25% v 39%) and deliveries before 30 weeks (0% v 17%). In view of these beneficial effects all women with IDDM should be encouraged to attend.

909

GLYCAEMIC RESPONSE TO A STANDARDISED TEST MEAL IN PREGNANCY

DWM Pearson, GD Lang and HW Sutherland,Aberdeen Royal Hospitals NHS Trust, Aberdeen, Scotland.

Two groups of pregnant women with (Group A n=982) and without (Group B n=192) risk factors for gestational diabetes mellitus had timed post prandial glycaemic responses measured following a standardised test meal. The meal(453kcal, cho 61.3%, prot 15.6%, fat 17.8%) was well tolerated. Dietary advice was given to group A when fasting or 120min glucose was >97%ile of group B. When dietary management failed to normalise blood glucose insulin was prescribed. Results:The differences between mean fasting and mean 120min glucose were A 1.0mmol/l and B 0.7mmol/l. Group B were younger (27.3±3.9 vs 28.6±5.1yr), had a lower BMI (23.0±3.4 vs 26.8±6.6), fasting (4.3±0.37 vs 4.7±0.66mmol/l) and post prandial glucose(5.0±0.5 vs 5.7±1.1mmol/l) than group A. 49%(451) of women in group A had dietary advice and 4%(37) insulin. Offspring of mothers in group A were heavier (3602.3 ±586 vs 3365± 410g, centile 53.9±29.1 vs 44.3±25.5), had more neonatal hypoglycaemia (7% vs 3%) and were more often admitted to the SCBU.

Conclusion: This novel approach to the detection of hyperglycaemia in pregnancy provides a physiological basis for intervention.

910

THE COMPARISON OF THE THERAPEUTIC PROCEDURES IN DIABETIC CARE OF PREGNANT WOMEN IN THE LAST DECADE.

Cz. Wójcikowski, A. Szczurowicz, K. Łukaszuk, M. Kowalczyk and J. Liss. Department of Endocrinology Institute of Obstetrics and Gynecology, Medical University, Gdańsk, Poland.

The aim of the work was the comparison of the procedures used in diabetic and obstetric care of pregnant women in the last decade. Study was performed on the group of 246 patients (127 with diabetes mellitus type I [DM] and 119 with gestational diabetes mellitus [GDM]). Pregnant women were divided into 3 groups depending on the date of delivery. To group I - 30 patients were included (who delivered within period 1985-88) - before establishing the central system of obstetric and diabetic care and intensive insulin therapy. To group II - 129 patients were included (who delivered within 1989-93). It was a transitory period when centralization of care and intensive monitoring (NST, Doppler test, profile of glycemia, HbA_{1c}) were successively included. Group III - 87 patients delivering within 1994-95. At this time our regional center was totally organized. During the period of our investigations we achieved decrease in the mean fasting blood glucose concentration between groups I and III in I^{st}, II^{nd} and III^{rd} trimester from 200.3 to 122.0 mg/dl, from 173.9 to 110.0 mg/dl and from 157.3 to 95.7 mg/dl respectively. The rate of preterm deliveries decreased from 54% to 21%; macrosomia from 50% to 20%. The mean duration of gestation increased from 35.5 to 38.7 weeks. The amount of neonates with Apgar score higher than 7 increased from 46% to 90%.

Hospitalization in specialized center with adequate equipment and with experienced staff improved prognosis and results in treatment of gestation complicated with DM and GDM.

911

Determinants of Glucose Intolerance during Pregnancy in Barbadian Women.

A.Hennis[1,2], P.Doyle[1], P.Shetty[1] N.Maconochie[1] and H.Fraser[1]. [1]London School of Hygiene & Tropical Medicine,UK. [2]Faculty of Medical Sciences, University of the West Indies, Barbados.

A cohort of 342 pregnant Barbadian women was studied to evaluate determinants of glucose intolerance.Nutritional status of participants was assessed by measurement of plasma glucose and serum insulin in response to a 75 gm oral glucose load at 18 and 28 weeks gestation.Multivariate analyses indicated that age ($p< 0.0001$) and body mass index (BMI)($p= 0.0034$)were independent determinants of glycaemic status at 18 weeks gestation.Similar associations were evident at 28 weeks gestation for both age ($p< 0.0001$) and BMI($p= 0.0067$).Change in glucose curve area between 18 and 28 weeks gestation was independently determined by weight change adjusted for age,BMI and parity ($p= 0.028$).Fat mass gain over this period did not predict hyperglycaemia,but independently predicted increased insulin secretion($p= 0.016$).Thus age and BMI were determinants of hyperglycaemia.Weight change determined changes in glycaemic status between visits whereas changes in fat mass determined changes in insulin secretion.

912

EMBRYONIC CONCENTRATION OF PHOSPHATIDYLINOSITOL IS NOT ALTERED BY MATERNAL DIABETES.

C. M. Simán, and U. J. Eriksson, Department of Medical Cell Biology, Uppsala University, Uppsala, Sweden

Children of mothers with diabetes are at risk of being born with malformations. Embryos cultured in high glucose concentration have a decreased *myo*-inositol uptake into the lipid fraction and are protected by *myo*-inositol supplementation. Hence, an involvement of decreased concentration of phosphatidylinositol (PI) in the etiology of congenital malformation have been suggested. This study aimed to test the validity of this hypothesis by direct measurements of PI in offspring of diabetic rats.

Phosphatidylcholin, phosphatidylethanolamin+sphingomyelin and PI were measured with HPLC in rat embryos on gestational day 11 and in fetal liver, brain and placenta on gestational day 20. The fraction of PI was calculated as a percentage of all phospholipids.

In general, embryos had less phospholipids per wet weight than fetal tissue, and these levels were not affected by maternal diabetes. Furthermore, embryonic tissue had the highest fraction of PI (11.7±0.5%) compared to fetal liver (6.7±0.6%), fetal brain (5.6±0.9%) and placenta (0.7±0.%). Diabetes in the mother slightly decreased the PI fraction in fetal liver (5.4±0.3%) but not in embryos (12.3±0.2) or any other of the tissues examined.

In conclusion, embryos have a higher concentration of PI compared to fetal tissue. The data suggest that diabetes does not reduce the concentration of PI in embryonic tissue. Therefore, maternal diabetes probably interferes with inositol metabolism rather than the absolute concentration of PI in embryos of diabetic rats.

913

CONTRACEPTIVE PRACTICE IN 93 INSULIN DEPENDENT DIABETES MELLITUS WOMEN.

A. Muller, K. Boireau, S. Fieuzal, S. Fradet and R. Marechaud.
Endocrinologie et Maladies Metaboliques, CHU Poitiers, France.

The aim of this study was to determine the contraceptive practice of IDDM women. From december 1995 to august 1996, we consecutively interwiewed 104 IDDM women 15-50 year-old. Four of them have had hysterectomy and 7 were pregnant. Among the 93 remaining patients, 17 did not use any contraceptive method (18%) and 76 used a contraceptive method (82%): hormonal compounds (HC) in 39 cases (51.3%), Intra-Uterin Device (IUD) in 19 cases (25%), sterilization in 11 cases(14.5%), and local contraception in 7 cases (9.2%). The 39 HC users took low dose progestogen only pills (POP) in 25 cases (64%), Oral Combined Pills (OCP) in 9 cases (23%), and high dose progestogen pills in 5 cases (12.8%). Age of patients and duration of IDDM were significantly higher in patients using non hormonal contraceptives methods, compared to those using HC (age: 36.8 +/- 9.52 vs 28.2 +/- 8.41 years, $p<0,0003$; duration of diabetes: 16.8 +/- 10.82 vs 10.4 +/- 7.17 years, $p<0,003$). HbA1c, BMI, daily insulin requirement were similar between these two groups. All of the women using IUD or who were sterilizated had >1 child, whereas 46% of the HC users had > 1 child. Microangiopathy was present in 10/39 HC users and in 18/37 non hormonal contraceptive users. Macroangiopathy was present in 2 patients (one using IUD, one sterilizated woman). Among the 9 OCP users, 1 had a diabetic retinopathy, and 5 had 1 or 2 other cardiovascular risk factor(s) associated with IDDM. A variable cycle length was present in 30/76 patients, more frequently in POP users ($p<0,05$). In this study, 58 patients were satisfied with their contraceptive method (63%), OCP administration was unadapted in 5 patients, and POP was the less comfortable contraceptive method. These results confirm that the contraceptive practice of IDDM women must be frequently reevaluated according to its safety, efficacy and acceptability.

914

DISTURBED PROSTAGLANDIN METABOLISM IN RAT EMBRYOS CULTURED IN A DIABETIC ENVIRONMENT

P. Wentzel and U. J. Eriksson, University of Uppsala, Uppsala, Sweden.

Previous studies have suggested that disturbed arachidonic acid metabolism may be associated with embryonic dysmorphogenesis in diabetic pregnancy. The aim of this study was to investigate the relationship between morphologic development and prostaglandin metabolism in day-9 embryos subjected *in vitro* to high concentration of glucose, arachidonic acid, PGE2, or cyclooxygenase inhibitors for 48 hours. Increasing the glucose concentration from 10 to 30 mmol/l caused embryonic dysmorphogenesis (from 2 % to 86 % major malformation). Addition of either 20 µmol/l arachidonic acid or 28 nmol/l PGE2 protected from the glucose-induced maldevelopment (12 % or 21 % major malformation). Culture in the presence of the cyclooxygenase inhibitors indomethacin (100 µmol/l) or acetylsalicylic acid (1 mmol/l) in low glucose yielded embryonic dysmorphogenesis of a comparable degree to that caused by high glucose alone (82 % or 100 % major malformation). Addition of either arachidonic acid or PGE2 to the low glucose culture medium with cyclooxygenase inhibitors normalized the embryonic development (0-6 % major malformation). In contrast, only PGE2 addition could normalize the development of embryos cultured in high glucose with cyclooxygenase inhibitors (4-21 % with PGE2, 93-100 % major malformation with arachidonic acid).

In conclusion, a diabetic environment disturbs both embryonic development and arachidonic acid metabolism *in vitro*. The results suggest a causal relationship, and that the prostaglandin disturbance includes an inhibition of the enzymatic activity of embryonic cyclooxygenase.

915

FETAL INSULINISATION IN RELATION TO MATERNAL ANTHROPOMETRY AND BODY COMPOSITION

H.Soltani-K., C.Bruce and R.B.Fraser. University of Sheffield, Sheffield, England.

Insulin functions as the major anabolic factor in the regulation of intrauterine growth. Factors affecting fetal insulinisation are not fully characterised. This prospective study was designed to examine the relationship of maternal body composition on fetal metabolism. Cord blood samples were collected from 60 infants of non-diabetic, healthy women. The samples were centrifuged and the plasma was pipetted and stored at -20°C. Where haemolysis had occurred only C-peptide was measured. In non-haemolysed specimens (n=48) both C-peptide and insulin were measured. Maternal weight, height and body composition (by Skinfold thickness measurements and Bio-electrical Impedance) were assessed at 13-15 weeks gestation. A positive correlation was observed with both cord insulin and/or C-peptide levels and maternal early pregnancy body mass index ($r=0.44$, $p=0.002$ and $r=0.33$, $p=0.008$ respectively). The result of multiple regression analysis (forward method) revealed that maternal fat mass in early pregnancy would explain the variation in cord insulin (0.002) and C-peptide levels (0.02) rather than the lean mass. We did not see a positive correlation between cord insulin/C-peptide levels and birth weight or birth centile. However, dividing the infants to three groups of SGA, AGA and LGA (small, average and large for gestational age) based on birth centiles, a significantly higher values of insulin was observed in LGA infants than the second group ((mean; µU/l): 4.46 >1.31, $p<0.05$). In conclusion, reducing maternal BMI (in particular maternal fat mass) at prepregnancy, might have an impact on the care of overweight diabetic women, in the sense that it might reduce the risk of fetal hyperinsulinemia and macrosomia. Further investigation on this specific group is required.

916

HIGH 3-DEOXYGLUCOSONE (3-DG) CONCENTRATION IN MALFORMED RAT EMBRYOS *IN VITRO*

U. J. Eriksson, P. Wentzel, H. S. Minhas* and P. J. Thornalley,* University of Uppsala, Uppsala, Sweden and University of Essex,* Colchester, UK.

Diabetic pregnancy is associated with increased risk of fetal malformation. High ambient glucose concentration has been identified as a teratologic agent in experimental studies, but possible effects of embryonic protein glycation have not been investigated. We measured the concentration of the glycating agent 3-deoxyglucosone (3-DG) in rat embryos after 48 h *in vitro* culture in 10, 30 or 50 mM glucose. These glucose concentrations produce a graded response of embryonic dysmorphogenesis. 3-DG is formed from the degradation of fructosamines and fructose-3-phosphate and reacts with proteins to form cysteinyl hemithioacetal adducts and advanced glycation endproducts. After *in vitro* culture, the embryonic content of 3-DG was: 0.3 nmol (10 mM glucose), 1.7 nmol (30 mM glucose), and 5.5 nmol (50 mM glucose). Furthermore, addition of 3-DG to culture medium with 10 mM glucose caused disturbed development. Embryos cultured in 10 mM glucose with no 3-DG had 29.6 somites and a malformation score (MS) of 0.1. (None or major malformation scored MS 0 or MS 10, respectively, therefore $0 \leq MS \leq 10$). Addition of 100 µM 3-DG yielded embryos with 24.3 somites and MS 4.0, addition of 500 µM 3-DG gave 23.1 somites and MS 6.2 whereas 1 mM 3-DG produced embryos with 18.8 somites and MS 7.7.

In conclusion, we have shown that increased ambient glucose concentration leads to increased embryonic concentration of the glycating agent, 3-DG. We also find 3-DG to be teratogenic *in vitro*, and suggest that protein glycation may have an important role in diabetic embryopathy.

917

HYPERANDROGENISM AND HYPERINSULINEMIA AFTER PRE-ECLAMPTIC PREGNANCY

R. Kaaja, H. Laivuori and O. Ylikorkala. Department of Obstetrics and Gynecology, Helsinki University Hospital, Helsinki, Finland.

Pre-eclampsia is known to be accompanied by metabolic changes similar to those in insulin resistance syndrome. We have recently demonstrated that some of the changes such as hyperinsulinemia is detectable 17 years after pre-eclamptic pregnancy. As hyperandrogenism is often related to insulin resistance we studied further this same study population and examined the serum concentrations of testosterone, estradiol (E2), dehydroepiandrosterone sulfate (DHEAS),androstenedione (ADIONI), calculated serum free testosterone and free androgen index (FAI), sex hormone binding glubulin (SHBG), insulin-like growth factor binding protein 1 (IGFBP), plasma endothelin-1 , insulin related binding proteins as well as the production of vasoactive endothelin.
Twenty-one women who had had previous pre-eclamptic first pregnancy and 20 BMI matched control women were studied. Women with prior pre-eclampsia had significantly elevated fasting serum insulin (7.1±0.6 vs 5.3±0.4 mU/l, mean ±SE, P=0.02) free testosterone levels (20.1±2.2 vs 15.1±1.2 pmol/l, P=0.03) and FAI (3.1 ±0.5 vs 2.0±0.2, P=0.04) whereas other parameters did not differ between the study groups. We conclude that a history of pre-eclampsia is associated with hyperadrogenism and hyperinsulinemia.

918

INSULIN SENSITIVITY OF MUSCLE GLYCOGEN SYNTHASE DURING LATE PREGNANCY IN THE RAT

M.C. Sugden, L.G.D. Fryer and M.J. Holness. Biochemistry Department, Queen Mary & Westfield College, London, U.K.

During late pregnancy, maternal metabolism adapts to maintain an optimum fuel mix for presentation to the developing foetus, and a major adaptation involves the development of maternal insulin resistance in skeletal muscle with respect to glucose transport and phosphorylation. The present study examined the effects of pregnancy on skeletal-muscle glycogen synthase (GS) activation by insulin in vivo. The aim was to evaluate whether maternal glycogen storage is, or is not, resistant to the action of insulin in pregnancy through effects at the level of muscle GS. GS activity was measured in the absence (GSa) or presence (GSa+b) of 10 mM glucose 6-phosphate (G6P). Results are expressed as activity ratios (±G6P). The euglycaemic-hyperinsulinaemic clamp technique was used to produce a sustained elevation of the insulin concentration in the absence of any change in glycaemia. Muscles were sampled at 15 min after steady state had been reached. GSa and GSa+b activities were measured in three skeletal muscles containing predominantly fast-twitch fibres and in two skeletal muscles containing predominantly slow-twitch fibres. At 130-170 μU/ml insulin, mean %GSa for the three fast-twitch skeletal muscles were 46.7 ± 2.5 (n=15) for unmated rats and 51.0 ± 2.5 (n=18) for pregnant rats (n.s). The trend towards higher %GSa activities after insulin stimulation in the pregnant group achieved statistical significance for the slow-twitch muscles (unmated rats, 33.7 ± 2.9 [n=10]; pregnant rats, 55.7 ± 3.3 [n=12]; P<0.001). Insulin resistance at the level of GS activation is therefore not a feature of skeletal-muscle metabolism in late pregnancy at insulin concentrations in the high-physiological range. The findings are consistent with a lower EC50 for activation of GS than for stimulation of glucose transport by insulin. The possibility is raised that GS activation may play a role in carbohydrate homeostasis even when insulin concentrations are suboptimal for glucose clearance, possibly through limiting net glycogenolysis. By giving priority to maternal glycogen storage, loss of carbon is minimised and, under conditions where the carbohydrate supply is restricted and glucose oxidation suppressed, lactate and alanine derived from muscle glycogenolysis will be made available for gluconeogenesis.

919

EVIDENCE AGAINST A ROLE FOR HYPERINSULINAEMIA IN THE GENESIS OF GESTATIONAL INSULIN RESISTANCE

A.G. Nieuwenhuizen[1], A. Bonen[2], A.M.J. Paans[3], W. Vaalburg[3], G.A. Schuiling[1] and T.R. Koiter[1]
[1]Dept. of Obstetrics & Gynaecology and [3]PET center, Univ. Hospital Groningen, the Netherlands, and [2]Dept. of Kinesiology, Univ. of Waterloo, Canada.

During pregnancy hyperinsulinaemia is associated with diminished insulin action. It has often been suggested that hyperinsulinaemia may cause insulin resistance. This hypothesis was tested in pregnant rats, which were treated with insulin (4.8 IU/day) from day 8 to 14 of gestation while normoglycaemia (5.0 mmol/l) was maintained by i.v. infusion of D-glucose. Despite constant elevated plasma insulin levels, the amount of glucose infused daily to maintain normoglycaemia increased from 12 ± 1 g/day on day 8 to 20 ± 1 g/day on day 14, suggesting improvement of insulin action. Saline-infused controls showed increased insulin responses to an i.v. glucose load (0.5 g/kg body weight; area under curve [AUC]: 243 ± 29 vs 57 ± 10 ng/ml min, $p<0.05$) accompanied by unchanged glucose disappearance on day 15 of pregnancy compared to virgin controls, suggesting decreased insulin action. This was associated with reduced 2-^{18}Fluor-2-deoxy-D-glucose (FDG) uptake, as measured by PET scanning, in heart (0.48 ± 0.10 vs 1.81 ± 0.20 mmol/l min, $p<0.05$) and brown adipose tissue (BAT: 0.11 ± 0.02 vs 0.30 ± 0.08 mmol/l min, $p<0.05$), but not in liver, brain and skeletal muscle. Furthermore, the relative GLUT4-protein content was diminished in heart (112 ± 23 vs 209 ± 25 %, $p<0.05$), BAT (114 ± 11 vs 175 ± 6 %, $p<0.05$) and white adipose tissue (WAT: 10 ± 4 vs 56 ± 21 %, $p<0.05$), but not in white gastrocnemius, red gastrocnemius and soleus muscle. 24 h after cessation of the combined insulin/glucose treatment, glucose-stimulated insulin secretion (AUC: 158 ± 16 vs 243 ± 29 ng/ml min, $p<0.05$) was diminished while glucose disappearance remained unaffected when compared to saline-infused day 15-pregnant controls, suggesting improved insulin action. This was associated with increased FDG uptake in BAT (0.28 ± 0.03 vs 0.11 ± 0.02 mmol/l min, $p<0.05$), and increased GLUT4 content of WAT (54 ± 10 vs 10 ± 4 %, $p<0.05$). Thus, prolonged hyperinsulinaemia exerts beneficial effects on glucose uptake and insulin action during pregnancy, presumably mediated by actions on (brown and white) adipose tissue. This argues against a causative role of hyperinsulinaemia in the impairment of insulin action during pregnancy.

920

VITAMIN E TREATMENT INCREASE CuZn-DISMUTHASE ACTIVITY IN DIABETIC RAT PREGNANCY.

B. Wysocka-Sołowiej, M. Kinalski*, W. Zarzycki, J. Górski** and I. Kinalska
Institut of Obstetrics and Gynecology* Department of Endocrinology and Department of Physiology**, University Medical School Białystok, Poland

The damage of antioxidant system in diabetic pregnancy is postulated as one of the main mechanisms that play an important role in the disturbances of embryonic development in human pathology as well as in the experimental animal models of the diabetic pregnancy. Tocopherol in a dose of 40 mg/kg/day acts as prophylaxis providing the metabolis changes in the experimental diabetic pregnancy. The aim of the study was to establish, if moderate, physiological doses of vitamin E could play a role in the prevention of antioxidant system disturbances in a rat diabetic pregnancy. In 30 female Wistar rats, diabetes were induced 7-12 days before conception using streptozootocin in one dose 40 mg/kg. The mean plasma glucose level in this group was 16 +- 8 mmol/l. These animals were divided into two gruops of 15 each. The first group was treated with vitamine E oil solution orally in a dose of 3 mg/kg of chow, and the second group was given only standard diet. Control groups consisted of 10 healthy pregnant animals treated with the same dose of vitamin E, 10 pregnant rats fed standard diet as well as 10 non pregnant rats. In both experimental and control groups the activity. of CuZn-dismuthase was estimated according to Misra and Fridovitch in tissues of uterus and liver in mother rats and in liver and lungs in neonates in the first day of live. The mean weight of neonates in diabetic pregnancy was found to be higher in comparison to control groups. The activity of dismuthase in animals treated with vitamin E was significantly higher in comparison to diabetic pregnancy without vitamin E - in the mothers liver 1.11 +- o.45 ng/mg of protein vs 1.90 +- 0.39 ng/mg of protein ($p<0.01$); mothers uterus 0.59 +- 0.21 ng/mg of protein vs 0.93 +- 0.21 ng/mg of protein ($p<0.05$); neonatal liver 0.74 ng/mg of protein vs 0.96 +- 0.14 ng/mg of protein ($p<0.05$); neonatal lungs 0.50 +- 0.09 ng/mg of protein vs 0.74 +- 0.13 ng/mg of protein ($p<0.05$). In both groups of diabetic animals, activity of estimated enzymes was lower in comparison to the control groups. In conclusion, the study shows that administration of moderate doses of vitamin E to the diet of diabetic pregnant rats elevated the activity of antioxidant system and diminished the complications of diabetic pregnancy - the fetal macrosomia and hypoglycemia in the rats neonates.

921

INCREASE IN SERUM PROINSULIN CONCENTRATION AND PROINSULIN/INSULIN RATIO IN PREGNANT WOMEN

R. Kanamuro, Y. Iwamoto, K. Yanagisawa, T. Nagashima, N. Suzuki, M. Sanaka and Y.Omori. Tokyo Women's Medical College,Tokyo, Japan

Serum proinsulin is disproportionately elevated both at fasting and after an oral glucose load in non-insulin dependent diabetes mellitus. We investigated the effect of pregnancy on serum proinsulin level and the proinsulin/insulin ratio (PI/IRI) during an oral glucose tolerance test in pregnant women. Forty-six pregnant women with normal glucose tolerance (NGT), 60 pregnant women with borderline glucose intolerance (BGI), and 10 nonpregnant healthy controls were examined by 75g-oral glucose tolerance test(OGTT). Serum proinsulin was measured by radioimmunoassay using specific antiserum for human proinsulin. Fasting proinsulin levels in nonpregnant controls, NGT in early gestational period, NGT in late gestational, BGI in early gestational and BGI in late gestational were 5.2±1.2, 6.1±5.9, 8.9± 4.5, 8.6±5.5 and 10.9±4.4 pmol/l(mean±SD), respectively. Fasting PI/IRI ratios in these groups were 0.12±0.04, 0.12±0.09, 0.19±0.10, 0.19±0.13 and 0.27±0.14, respectively. In both NGT and BGI, fasting proinsulin levels and the PI/IRI ratio in late gestational period were significantly higher than those in early period. In 27 cases with BGI , OGTT was repeated in the late gestational period. Amelioration of glucose tolerance was observed in 6 cases (group A), but not in 21 cases (group B). Summed values of the serum PI/IRI ratio during OGTT in early gestational period in group A was lower than group B (0.08±0.02 vs 0.15±0.07, $p<0.05$). The results suggest that serum PI/IRI increases during pregnancy and that serum PI/IRI in early gestational period in BGI case serve as a predictor of glucose tolerance in late gestational period.

922

INFLUENCE OF VITAMINE E TREATMENT ON ANTIOXIDANTS SYSTEM ACTIVITY IN THE RAT DIABETIC PREGNANCY.

M. Kinalski*, W. Zarzycki, B. Wysocka-Sołowiej, J. Górski** and I. Kinalska
Department of Endocrinology, Institut of Obstetrics and Gynecology* and Department of Physiology**, Medical University, Faculity of Medicine, Białystok, Poland

Diabetes mellitus decreases the activity of antioxidant systems in both, human and experimental diabetes animals. It is concomitant with dysmorphogenesis observed in diabetic pregnancy. The aim of the study was to estimate the influence of the vitamin E treatment on the antioxidant systems in the rats diabetic pregnancy. 30 pregnant Wistar rats were divided into two different groups of 15 each. The first group was treated with vitamine E oil solution orally in a dose of 40 mg/kg /day. The second group of animals was given only oil with the stanndard diet. On the 7th day of pregnancy streptozootocin in a dose of 40 mg/kg/day was given to induce diabetic conditions. The mean plasma glucose level in this group of animals in the day of delivery was 15 mmol/l +- 4 mmol/l and there was no difference between diabetic rats recived vitamin E and that not recived it. A control group consisting of 10 healthy pregnant animals treated with this same dose of vitamin E, 10 pregnant rats fed with standard diet and 10 non pregnant female rats. In all groups of animals the activity of glutatione peroxidase was estimated accdording to Paglia and Valentine and CuZn-dismuthase was estimated according to Misra and Fridovitch in tissues of mother and neonatal liver, mothers liver and neonatal lungs. The mean weight of neonates born to diabetic mother was higher then the control group. The mean activity of dismuthase and glutathione-peroxidase in animals treated with vitamin E was significantly higher. For example in the mother liver 1.55 +- 0.31 IU/mg of protein in comparison to diabetic pregnancy without vitamin E treatment 1.82+-0.33 IU/mg of protein ($p<0.05$) and adequately glutathione peroxidase 9.34 +- 2.21 ng/mg of protein vs 12.12 +- 2.12 ng/mg of protein ($p<0.05$). In both groups of diabetic animals, the activity of estimated enzymes was lower in comparison to control groups. We conclude, that the administration of vitamin E to the rats with diabetic pregnancy is effective and increase the activity of antioxidant enzyme system and decreased the complication of diabetic pregnancy.

Hypoglycemia

923

EFFECT OF DURATION OF RECENT, ANTECEDENT HYPOGLYCAEMIA ON RESPONSES TO SUBSEQUENT HYPOGLYCAEMIA IN HUMANS.

C.Fanelli, S.Pampanelli, M.Ciofetta, C.Lalli, P.Del Sindaco, M.Lepore, P.Brunetti and G.B.Bolli. University of Perugia, Perugia, Italy.

It is generally accepted that recurrent hypoglycaemia (hypo) may induce hypo unawareness, but the number and/or duration of antecedent hypo required to exert the effect are not known. To assess the effect of duration of recent, antecedent hypo on responses of counterregulatory hormones (CR-H) and symptoms (Symp) to, and onset of cognitive dysfunction (CogDys) during, hypo, 8 normal volunteers were studied with the hyperinsulinaemic-hypo clamp (plasma glucose, PG, was decreased stepwise from 5.0 to 2.2 mmol/l) on 4 different occasions at 1 month intervals (Studies 1-4). On the day prior to studies, either euglycaemia (S1), or 1 insulin-induced hypo (PG 2.7 mmol/l, 21.00-23.00 h) (S2), or 2 hypo (13.00-15.00 h and 21.00-23.00 h) (S3), or 3 hypo (08.00-10.00, 13.00-15.00 and 21.00-2300 h) (S4) were performed. In S2, increase in CR-H initiated at lower PG (i.e. thresholds were higher) and maximal responses of adrenaline, glucagon, growth hormone and cortisol were all lower ($p<0.05$), but neither autonomic nor neuroglycopenic Symp and CogDys (battery of 12 different tests) were affected vs S1 (p=NS). In S3, and to larger extent in S4, not only CR-H, but also Symp (both autonomic and neuroglycopenic) and CogDys had thresholds greater and maximal responses lower than in S1 and S2 ($p<0.05$). Conclusions: the duration of recent, antecedent hypo (i.e. the number of hypo multiplied the duration of single hypo) is the main determinant of loss of responses of CR-H, Symp and CogDys to subsequent hypo. A single episode of hypo does not induce hypo unawareness, but only mild impairment in CR-H responses. Multiple, recent episodes are required to induce hypo unawareness. There is a hierarchy of loss of responses to hypo after multiple episodes of recent, antecedent hypo, i.e. responses of CR-H are lost first, and responses of Symp and CogDys second.

924

SYMPATHETIC AND PARASYMPATHETIC ACTIVITY DURING HYPOGLYCAEMIA IN OBESE AND LEAN SUBJECTS

C. Macor, E. Rella, M. De Marco*, F. Novo, P. Bondiolotti §, I. Balzani*, De Masi G.*, M. Carruba §, F. Bellavere* and R. Vettor
*Institute of Semeiotica Medica-Patologia Medica III, University of Padua, * Autonomic Nervous System Physiopathology Unit, 1st Medicine Dep., S. Antonio City Hospital, Padua, § Pharmacology Dep., University of Milan, Italy*

Abnormalities of the sympathetic nervous system has been hypothesized in the aetiology or maintenance of obesity. However conflicting results, describing either a reduced or an increased sympathetic activity, are reported in obesity. Since hypoglycaemia is a powerful stimulus of both sympathetic and parasympathetic nervous systems, our study was designed to examine the effects of insulin-induced two-stepped hypoglycaemia on norepinephrine (NA), epinephrine (A) plasma levels and on the neuroautonomic function, evaluated by power spectral analysis (PSA) of heart rate variability in obese subjects and healthy lean controls. PSA comprised two frequency domain components: high (HF) and low (LF) frequency power, reflecting respectively parasympathetic and sympathetic activity; the LF:HF ratio reflects the sympatho-vagal balance. A modified glucose clamp technique (insulin infusion rate 40mU/min/m^2bs) was used to produce a standardized fall in glycaemia in 10 obese and 8 lean subjects. NA and A response and PSA were collected at baseline and during the two steps of hypoglycemia. Obese patients had a decreased response to hypoglycaemia regarding plasma NA and, in particular, A in respect to controls. In the lean group an increase in heart rate was showed ($p < 0.005$), but this finding was not observed in the obese group. The LF:HF ratio was increased in both groups ($p< 0.01$), in particular in the controls. While HF values decreased at the same extent (b= - 8.9 vs b= - 8.7, p=0.02 vs 0.04), LF values increased only in normal subjects ($p<0.05$). In conclusion, obese subjects seem to have a similar vagal withdrawal, but a decreased sympatho-adrenal function and a depressed cardiac sympathetic responsiveness to insulin-induced hypoglycaemia.

925

EFFECTS OF LACTATE INFUSION ON HEPATIC AND MUSCLE GLUCOSE METABOLISM UNDER HYPOGLYCAEMIA.

Pagano C., Granzotto M., Sagrillo E., Federspil G., Vettor R.
Endocrine-metabolic lab., Inst. of Semeiotica Medica, via Ospedale 105, 35100 Padova, Italy

Hypoglycaemia is characterized by several metabolic alterations involving glucose metabolism in skeletal muscle and liver. Moreover several hormonal and cognitive responses to hypoglycaemia are reduced by administration of lactate in humans and animals. Little is known about the metabolic interactions between lactate and glucose under hypoglycaemia. In order to clarify the effect of hypoglycaemia and lactate on glucose metabolism we studied anesthetized normal rats under euglycaemic and hypoglycaemic clamp and infused with either sodium lactate or buffer solution. 3 experimental designs were carried out: 1) euglycaemic hyperinsulinemic clamp combined with the 3-^{3}H-glucose technique. 2) hypoglycaemic hyperinsulinemic clamp combined with the 3-^{3}H-glucose technique. 3) hypoglycaemic hyperinsulinemic clamp combined with the 2-deoxyglucose technique. In study 1 and 2 we calculated glucose rate of disappearance, hepatic glucose release, glucolytic flux and glycogen storage. In study 3 glucose utilization index was evaluated in individual skeletal muscles.
Results from our experiments show that hypoglycaemia per se reduced glucose rate of disappearance (24.5±0.5 vs 12.4±0.9 mg•min^{-1}•kg^{-1}; p<0.01) reducing to a similar extent both the glycolytic flux and glycogen storage. Also muscle glycogen content was reduced at the end of hypoglycaemic compared to euglycaemic clamp. Lactate infusion under hypoglycaemia did not alter overall glucose rate of disappearance (12.4±0.9 vs 13.9±0.8 mg•min^{-1}•kg^{-1}) while inhibited the suppression of hepatic glucose release by hyperinsulinemia (-1.0±0.9 vs 9.3±1.6 mg•min^{-1}•kg^{-1}; p<0.01). No differences were observed in glucose utilization index neither in individual skeletal muscles.
In conclusion our results show that hypoglycaemia inhibits both glycolysis and glycogen storage in skeletal muscle. Moreover lactate may influence hepatic glucose metabolism under insulin-induced hypoglycaemia by enhancing glucose release without affecting overall glucose disposal. We speculate that lactate may potentially be a protective mechanism against hypoglycaemia providing 3 carbons substrates for hepatic gluconeogenesis thus enhancing hepatic glucose production.

926

EFFECT OF HYPOGLYCAEMIA ON BETA ADRENERGIC SENSITIVITY

A. Fritsche*, M. Stumvoll*, M. Grüb*, S. Sieslack*, R.M. Schmülling*, H.U. Häring and J.E. Gerich° *Med. Klinik IV, Universität Tübingen, Germany; °University of Rochester, USA

Reduced peripheral tissue sensitivity to catecholamines is suggested to be one of the mechanisms contributing to hypoglycaemia unawareness. It has been shown that a single episode of hypoglycaemia reduces awareness of hypoglycaemia. Therefore we tested the hypothesis that a single episode of hypoglycaemia reduces hypoglycaemia awareness by reducing beta adrenergic sensitivity. 10 healthy subjects (7 male, 25±4 years old) were studied twice using an isoproterenol test (IT) (0.25, 0.5, 0.75, 1.0, 1.5, 2.0 and 2,5 µg isoproterenol i.v. every 20 minutes) at 7:00: once after a hyperinsulinaemic, euglycaemic clamp (E) and once after a hyperinsulinaemic, hypoglycaemic (blood glucose 3 mmol/l) clamp (H) with 1 mU/kg/min insulin performed between 19:00 and 22:00. Heart rate and blood pressure were recorded continuously with computerized devices, blood glucose and free fatty acids were measured 5 minutes before and after isoproterenol injection. Increment of heart rate during IT was significantly higher after H (p=0.002, MANOVA), the dose required to increase heart rate by 25 beats per minute was 0.83±0.22µg after H and 1.13±0.21µg after E (p= 0.036). Systolic and diastolic blood pressure during IT increased (p=0.02) but showed no difference concerning preceeding H or E. Blood glucose levels didn't change during IT and showed no difference between H and E whereas overall fatty acids during IT were higher after H (0.054±0.02mmol/l) compared to E (0.45±0.01 mmol/l, p<0.001). We conclude that in normal subjects antecedent hypoglycaemia does not impair but increases sensitivity to catecholamines of heart and adipose tissue. This positive feedback is probably one factor preventing hypoglycaemia unawareness in normal subjects.

927

LACTATE AND HYPOGLYCAEMIA INHIBIT INSULIN-MEDIATED GLUCOSE UTILIZATION BY HEART MUSCLE.

Ferretti E., Pagano C., Granzotto M., Fabris R., Sagrillo E., Lombardi AM., Marzolo M., Federspil G., Vettor R. -- *Endocrine-metabolic lab., Inst. of Semeiotica Medica, via Ospedale 105, 35100 Padova, Italy*

Heart muscle can oxidize different energy-providing substrates to meet energy requirements. Several pathological conditions including diabetes, are characterized by an increased concentration of plasma lactate. The aim of this study was to investigate the role of increased lactate availability on glucose utilization in heart muscle under different plasma glucose concentrations ranging from mild hypoglycaemia (2.8 mmol/l) to hyperglycaemia (13 mmol/l). Sodium lactate or sodium bicarbonate were infused in anesthetized rats and animals underwent a euglycaemic, hypoglycaemic or hyperglycaemic clamp study. At steady state glucose concentration, a bolus of 2-deoxy-(1-^{3}H)-glucose was administered accumulation in of 2-deoxy-(1-^{3}H)-glucose-6-phosphate in heart muscle was measured. Results show that lactate inhibits glucose uptake in all the three conditions studied (euglycaemia: 17.5±4.5 vs 45.9±6.5 ng•mg^{-1}•min^{-1}, p<0.01, hypoglycaemia: 11.2±2.6 vs 32.6±3.0 ng•mg^{-1}•min^{-1}, p<0.01, hyperglycaemia: 15.7±1.6 vs 30.6±3.6 ng•mg^{-1}•min^{-1}, p<0.01). Moreover hypoglycaemia *per se* significantly reduced glucose utilization by 30% compared to euglycaemia. These results show that lactate may reduce heart glucose utilization regardless of glucose concentration and support the role of lactate as the preferred substrate for myocardial metabolism. Moreover they show that glucose utilization by heart muscle is reduced under hypoglycaemia. Taken together these results suggest that competition between lactate and glucose may reduce insulin sensitivity in heart muscle and may possibly play a pathogenetic role in the impaired glucose utilization in the diabetic heart.

928

The effect of nocturnal hypoglycaemia on susceptibility to fatigue the following day

P. King,[a] H. Parkin,[b] M-F. Kong,[a] IA Macdonald,[b] and RB Tattersall[a]. [a] Diabetes Unit, University Hospital, [b]Department of Physiology and Pharmacology, University of Nottingham, Nottingham, UK

This study assessed the effect of nocturnal hypoglycaemia on physical fatigue the next day using 10 subjects with Insulin Dependent diabetes. After an initial visit to determine workloads corresponding to 30 and 60% V_{O2} max (estimated from heart rate using bicycle ergometry), subjects were studied twice 4 weeks apart. One night blood glucose was lowered to 2.3-2.7mmol/l for 1 hour and during the other hypoglycaemia was avoided. Subjects underwent bicycle ergometry the next day initially for 30 minutes at the predetermined workload corresponding to 30% V_{O2} max, and then at 60% V_{O2} max until exhaustion. Fatigue was assessed every 10 minutes using the Borg scale. Although there was no difference in exercise capacity between visits (mean time 35.3±1.2min hypoglycaemic vs 38.2±1.8min control night, p>0.05), higher Borg scores were obtained after the hypoglycaemic night (p<0.05, ANOVA). There was no difference in glucose, potassium or catecholamine concentrations between visits either before exercise (mean glucose 14.9±0.84mmol/l vs 14.31±1.0mmol/l; potassium 4.5±0.14mmol/l vs 4.2±0.13mmol/l; adrenaline 0.17±0.04nmol/l vs 0.3± 0.03nmol/l; noradrenaline 1.7±0.26nmol/l vs 1.46±0.25nmol/l for hypoglycaemic and control nights respectively, all p>0.05) or at any point during exercise (p>0.05 ANOVA). Thus although 1 hour of nocturnal hypoglycaemia has no effect on exercise capacity, subjects feel more fatigued. This cannot be explained by differences in glucose, potassium or catecholamine concentrations.

929

FATTY ACID UTILIZATION INFLUENCES THE COUNTERREGULATORY RESPONSE TO INSULIN-INDUCED HYPOGLYCEMIA IN RATS.

S.D. Bouman, J.E. Bruggink, A.J.W. Scheurink, J.H. Strubbe and A.B. Steffens; Department of Animal Physiology, University of Groningen, Haren, The Netherlands.

Changes in the availability of energy substrates such as glucose and fatty acids (NEFA) lead to counterregulatory responses (CRs) to maintain energy homeostasis. The aim of the present study was 1) to characterize the counterregulatory response to insulin-induced hypoglycemia, and 2) to investigate the effects of changes in NEFA utilization on this CR. In the first set of experiments, four different concentrations of insulin (0.25, 0.5, 1.0 and 2.0 IU/h Velosulin® respectively) were infused for 90 minutes. In the second set of experiments, NEFA utilization was reduced by injection of the NEFA oxydation blocker mercaptoacetate (600 μmol/kg) during insulin-induced hypoglycemia (0.5 IU/h insulin). In control studies saline was administered. All studies were performed in permanently cannulated rats. Blood samples were withdrawn for determination of glucose, insulin, glucagon, adrenaline, noradrenaline and corticosterone levels. Hypoglycemia induced a dose-dependent increase in glucagon and adrenaline (peak values of glucagon 89 ± 7, 73 ± 9, 110 ± 13 and 151 ± 18 pg/ml and of adrenaline 38 ± 16, 5 ± 4, 105 ± 64 and 400 ± 134 pg/ml respectively (average ± SEM; Mann-Whitney U p-values all < 0.05)). Glucose levels were not different for the different concentrations of insulin (nadir levels 3.4 ± 0.2, 3.4 ± 0.1, 3.2 ± 0.2 and 3.0 ± 0.1 mmol/l, $p > 0.05$). Blockade of NEFA utilization during hypoglycemia significantly increased the glucagon response (peak values 93 ± 9 vs. 182 ± 13 pg/ml, $p < 0.05$) and the adrenaline response (peak values 5 ± 4 vs. 756 ± 108 pg/ml, $p < 0.05$). Blood glucose levels were slightly higher than in the control experiment. The data reveal that the counterregulatory response to insulin-induced hypoglycemia depends on the availability not only of glucose but also of fatty acids as energy substrates.

930

HIGH PREVALENCE OF NOCTURNAL HYPOGLYCAEMIA IN CHILDREN WITH TYPE 1 DIABETES : ANALYSIS OF SLEEP PHYSIOLOGY

K Matyka[1], C Crawford[2], L Wiggs[2], G Stores[2] and D B Dunger[1]. University Departments of Paediatrics[1] and Psychiatry[2], Oxford, UK.

Nocturnal hypoglycaemia in young children with IDDM may disturb sleep and subsequent cognitive function. In order to determine the prevalence of hypoglycaemia in prepubertal children and to examine its effects on sleep physiology and cognitive function two metabolic profiles were performed at home, 20:00 - 08:00 hours, in children aged 8.7 (5 9-12.9) years, duration of diabetes of 4.1(1.2-10.2) years. Blood was taken for glucose every 15minutes, every 60 minutes for insulin and metabolites and sleep EEG was recorded during the profile. Uncooked cornstarch was administered to those hypoglycaemic on night 1 to avoid hypoglycaemia on night 2 17 out of 23 were hypoglycaemic on one night (70%) The hypoglycaemic episodes were both profound, median glucose nadir 2 2(1.1-3.4) mmol/l and of long duration, median duration 210(15-630) minutes, despite waning insulin levels. Sleep recordings were analysed in 12 subjects (8 hypoglycaemic on night 1 and 4 on night 2). There were no significant differences, using Wilcoxon matched-pairs signed rank test (two-tailed), in total sleep time, 8.4(7.1 - 9.2) vs 8.6(6 8 - 9.7)hours, $p=0.784$ [median (10th -90th centile), hypoglycaemic vs non-hypoglycaemic nights, respectively]. There was a trend for reduced percentage of REM sleep, 11.6 (5.7 - 26.3) vs 15.2 (8.9 - 27.5)%, $p=0.158$, and increased number of arousals 6.5 (2 - 12.8) vs 3 (0 - 10.1)%, $p=0$ 136, on the night of hypoglycaemia. There were no associations between severity of the hypoglycaemic episodes and any of the sleep variables, perhaps reflecting apparent loss of adequate glucose counterregulation. However, overall the diabetic children had altered distribution of sleep with increased slow wave sleep ($p<0$ 0001) and increased number of arousals ($p<0.005$) compared to laboratory controls which could relate to recovery from previous hypoglycaemia This is being verified with controls undergoing home recordings.

931

EFFECT OF HIGH GLUCOSE ON COUNTER_REGULATION HORMONE RESPONSE IN NIDDM VERSUS DMID.

F.Arrieta,N.Pulido,A.Suarez,P.Saavedra,A.Rovira,I.Valverde, J.L. Herrera. Fundación Jiménez Díaz.Madrid.

Diabetes mellitus induces defects in counterregulatory responses to reductions in glucose plasma levels.The important of these response has only been recently appreciated. We have study in 13 DMNID with BMI 38.7±7% (mean±ds) age 49.7±10 years and 8 DMID with BMI 23.6±5.1 age 31±10 years the response of glucagon,GH and cortisol to the infusion of 0.1 U/Kg insulin bolus after an overnight fast, basal glucose level DMNID vs DMID (226±65 vs 273 ± 67mg/dl, pns).We extraction sample at - 15 ,0,15,30,45,60,90 and 120 min. Basal plasma insulin level was higher in DMNID vs DID (33±16 vs 8±6.5, $p<0.05$), after insulin infusion insulin increased in DMNID vs DID to (563±158 vs 446±22, pns) at 15 min. and declined to basal level at 90 min.The lowering of blood glucose were not significantly between both group. During the hypoglycemic period glucagon level lower from the basal level (187±96 vs 163±80 pg/ml, pns) and was significantly lower at 120 min DID vs DMNID (102±69 vs 168±70 ,$p<0.05$). An absence of increase of cortisol and GH levels from basal levels was observed in both group DMNID and DID.In conclusion: insulin in hyperglycemic patients led to a decrease of glucose and glucagon with absence of cortisol and GH response.This observation provide new insights in the counter-regulatory response to hypoglycemia in diabetic patients.

932

A POSITIVE CORRELATION BETWEEN THE MAGNITUDE OF THE SOMOGYI EFFECT AND THE DOSAGE OF INTERMEDIATE ACTING INSULIN.

O.K. Hejlesen[1], S. Andreassen[1], R. Hovorka[2], D. Meeking[3] and D.A. Cavan[3] Dept. of Medical Informatics[1], Aalborg University, Denmark. Dept. of Systems Science[2], City University, London, UK. Dept. of Endocrinology[3], St. Thomas' Hospital, London, UK.

Somogyi suggested that insulin-induced hypoglycaemia can lead to hyperglycaemia in insulin-dependent diabetes, and the main aim of our study was to analyse the temporal relation between spontaneous episodes of hypoglycaemia and hyperglycaemia. There is little support, however, from clinical studies for significant hyperglycaemic 'counter-regulations' following hypoglycaemia. Using a physiologically based compartment model of the carbohydrate metabolism, we have analysed data on measured blood glucose, insulin injections, and meals from 20 inpatients with insulin-dependent diabetes and found evidence to support the occurrence of counter-regulations typically beginning 6-8 hours following hypoglycaemia and lasting for 16-18 hours with a magnitude of 4-10 mmol/l above expected blood glucose levels. We found a significant correlation between the dose of intermediate-acting insulin (as a fraction of total daily dose, F) and the magnitude of the counter-regulations (C, in mmol/l) according to the equation $C = 0.73 + 9.79 \times F$ ($r = 0.67$, $p < 0.001$). Other studies have suggested that elevated blood glucose levels following hypoglycaemia could be explained by reduced insulin absorption from subcutaneous depots in patients with insulin-dependent diabetes. Our data indicate that counter-regulations are related to the type of insulin treatment. We suggest that reduced absorption or subcutaneous inactivation of injected intermediate-acting insulin, rather than a direct effect of counter-regulatory hormones, may be a cause for the post-hypoglycaemic counter-regulatory response of elevated blood glucose concentrations.

933

DIVERSITY OF HYPOGLYCEMIC THRESHOLDS FOR EPINEPHRINE SECRETION IN VARIOUSLY CONTROLLED DIABETES

K.Nonaka,Y.Imamura,S.Kohno,S.Shouji,N.Tomari and K.Yamada
Kurume University School of Medicine, Kurume, Japan.

In daily diabetes practice, we often observe hypoglycemic symptoms due to epinephrine secretion to occur at wide hypoglycemic ranges. Some patients may perceive them at 90 mg/dl, while others don't at even as low as 40 mg/dl. To elucidate this diversity, we determined glycemic thresholds for counterregulatory hormone(epinephrine, GH, cortisol, glucagon) secretion, autonomic and neuroglycopenic symptoms by using artificial pancreas. Nineteen diabetics, aged 17–58 y.o., were analyzed. They were divided into 3 groups; high(H),low(L) and ordinary(O) threshold groups for epinephrine secretion. H was defined as having thresholds more than mean+2 S.D.(61.6 mg/dl) of normal controls, L less than mean−2 S.D.(40.6 mg/dl) and O in between H and L. H had significantly higher HbA1c level, 12.0 ± 3.5%, than O, 8.2 ± 0.6%. The HbA1c of L, 7.8 ± 1.5%,was not different from that of H, however had more hypoglycemic episodes(less than 40mg/dl in SMBG, 6.2 ± 2.9 times/month) than H, 0.5 ± 1.2 times/month. In general glycemic thresholds for epinephrine secretion pararell glycemic control, hypoglycemic episodes change this tendency. Therefore, those with poorly controlled diabetes usually having high thresholds could have normal or lowered thresholds for epinephrine secretion if they experienced recent hypoglycemia attacks. By knowing these facts we could develope better therapeutic means to avoid excess epinephrine secretion to minimize worsenig of diabetic angiopathies.

934

THE BLOOD GLUCOSE ESTIMATION ACCURACY TRIAL PROVIDES A RELEVANT MEASURE OF HYPOGLYCAEMIA UNAWARENESS

M.M.J. Janssen, F.J. Snoek, R.J.Heine. Research Institute for Endocrinology, Reproduction and Metabolism. Vrije Universiteit. P.O. Box 7057, 1007 MB Amsterdam.

In several studies hypoglycaemia unawareness (HU) has been identified as the main cause of severe hypoglycaemia (SH). Investigation of HU is complicated by the wide range of definitions and assessment methods used. Often patient self-reports are used, providing a subjective measure of HU. Possibly a more reliable measure of HU can be derived from the "blood glucose estimation accuracy trial" (BGET), developed by Cox et al. The aim of this study was to determine the relationship of the BGET-derived measure of HU and of the self-reported degree of HU with the number of SH in the preceding year (as a clinically important consequence of HU) and with the level of fear of hypoglycaemia. So far we studied 11 insulin-dependent diabetes mellitus patients (6 men, 5 women, age (average) 32.5 (SD: 7.5) years, duration of diabetes 15.6 (6.1) years, HbA1c 7.8 (0.6) %, number of SH 1.8 (2.3), range 0-7) .For the BGET patients estimate and subsequently measure their blood glucose level 4 to 5 times a day during a period of 2 to 3 weeks. Both estimate and measurement are entered in a hand-held computer. The percentage of accurately estimated hypoglycaemic readings (% A-zone hypos) are used as a measure of hypoglycaemia awareness. During the initial visit patients filled in the worry scale of the HFS-95 and were asked to rate their ability to recognize hypoglycaemia on a scale from 0 to 5. They were given instructions for the BGET and made 70 estimates during the following 2 to 3 weeks. Data from two patients could not be analyzed because of early drop-out and lack of hypoglycaemic readings. A preliminary data analysis shows a highly significant correlation between % A-zone hypos and number of SH ($r = -.9$, $p < 0.0001$), but no significant correlation between self-reported hypo awareness and number of SH. Furthermore, a significant correlation was found between the HFS-95 worry score and self-reported hypo unawareness ($r = .9$, $p = 0.001$). The worry score did not correlate significantly with % A-zone hypos. These data suggest that the BGET may provide a clinically more relevant measure of HU than patient self-reporting. Furthermore, results so far suggest that BGET is applicable in clinical practice.

935

COUNTERREGULATORY HORMONE AND SYMPTOM RESPONSES TO HYPOGLYCAEMIA IN DIABETIC CHILDREN

M.Bjørgaas[1], T.Vik[1], T.Sand[1], G.Sager[2], H.Vea[2], K.Birkeland[3] and R.Jorde[2], University of Trondheim[1], Tromsø[2] and Oslo[3], Norway

We investigated hormonal and symptom responses to hypoglycaemia in 19 diabetic (age 14.2±1.4 years; mean±SD) and 16 nondiabetic children (14.4±1.0 years) with the glucose clamp technique. The hypoglycaemic thresholds for adrenaline, and for autonomic and total symptoms, were similar in the diabetic and nondiabetic groups, and were found at plasma glucose levels between 3.4 and 3.7 mmol/l. An increase of cortisol, growth hormone and glucagon was triggered at lower ($p<0.01$) glucose levels in the diabetic than in the nondiabetic children. Adrenaline, cortisol and glucagon increased less in the diabetic than in the nondiabetic group. In the diabetic children, BMI was positively correlated with the glycaemic thresholds for autonomic and total symptoms ($r=0.64$, $p<0.01$ and $r=0.72$, $p=0.001$, respectively). We conclude that hormone responses to hypoglycaemia are attenuated in diabetic as compared to nondiabetic children, whereas symptom recognition mainly is unaffected in the diabetic group. Diabetic children with a high BMI seem to have increased awareness of a declining plasma glucose level.

936

EFFECT OF BLOOD GLUCOSE AWARENESS TRAINING ON EPINEPHRINE RESPONSES TO HYPOGLYCEMIA IN INTENSIVELY TREATED DIABETES

M. Bajaj, BT. Kinsley, K. Weinger, CJ. Levy, M. Waters, DC. Simonson, D. Cox, and AM. Jacobson. Joslin Diabetes Center, Brigham and Women's Hospital, Boston and University of Virginia, Charlottesville, USA.

To determine the effect of Blood Glucose Awareness Training (BGAT) on epinephrine (EPI) responses to hypoglycemia (HYPO) in IDDM during Intensive Diabetes Therapy (IDT), 36 subjects with uncomplicated IDDM (duration 3-15 yr; HbA1c = 9.02±0.22) were enrolled in a 4 month outpatient IDT program. Subjects were randomized to classes in BGAT or cholesterol awareness (CONTROL). All subjects underwent stepped hypoglycemic clamp studies prior to (Clamp 1) and at completion of IDT (Clamp 2). BG was lowered from 6.7 mmol/L (baseline) to 4.4, 3.9, 3.3, 2.8 and 2.2 mmol/L over 190 minutes. 18 subjects reduced their HbA1c by ≥ 1% with IDT. In this subgroup the mean HbA1c fell from 9.44 ± 0.49 to 7.50 ± 0.23 ($p<0.001$) for BGAT (n=9) and 9.73 ± 0.48 to 7.7 ± 0.38 ($p<0.001$) for CONTROLS (n=9) (p=NS between groups). EPI responses to HYPO were lower in the CONTROL group following IDT and this difference was most marked at the 3.3 mmol/L level ($p=0.05$). EPI responses to HYPO did not differ in the BGAT group.

Epinephrine pmol/L

Glucose	Clamp 1	Clamp 2	
	Controls		
3.3 mmol/L	1334 ± 538	787 ± 349	p=0.05
2.8 mmol/L	1512 ± 421	922 ± 210	p=0.08
2.2 mmol/L	3012 ± 670	2073± 395	p=0.2
	BGAT		
3.3 mmol/L	840 ± 218	802 ± 143	p=0.8
2.8 mmol/L	2075 ± 607	1890± 454	p=0.7
2.2 mmol/L	2367 ± 437	2923± 702	p=0.3

BGAT is associated with preservation of the EPI response to HYPO in IDDM subjects who achieved substantial improvement in glycemic control with IDT. BGAT may be useful in reducing the risk of iatrogenic hypoglycemia and blunted counterregulatory responses associated with strict glycemic control of IDDM.

937

GLUCOSE INTOLERANCE IN HAMSTERS IS ASSOCIATED WITH INCREASED TURNOVER OF SEROTONIN AND NORADRENALINE IN THE VENTROMEDIAL HYPOTHALAMUS (VMH).

S. Luo, J. Luo, A. Meier and A. Cincotta. Ergoscience, Boston, USA

The VMH is known to have a role in regulation of feeding, and of carbohydrate and lipid metabolism. Increases in noradrenergic activity within the VMH have been associated with increased hepatic glucose output and increased lipolysis, which may potentiate increased insulin resistance. Moreover, increases in central serotonergic activity has been shown to increase substantially both hypothalamic noradrenaline turnover and blood glucose concentrations. The present study employed in vivo microdialysis to investigate whether there are differences between the monoamine profiles in the VMH of freely moving naturally glucose-tolerant and glucose-intolerant Syrian hamsters. Male Syrian hamsters (ave BW 190 ± 10g) held on 14 hr daily photoperiods were divided into these two groups based on the results of glucose tolerance tests. Microdialysis cannula were implanted in the right VMH of each hamster. Dialysate samples were collected every hour for 24 hr through the microdialysis probe (perfused with Ringer's solution at 0.12 ul/min), and analyzed by HPLC with electrochemical detection. In glucose intolerant hamsters, the VMH extracellular levels of the metabolites of serotonin (5-hydroxyindolacetic acid) and noradrenaline (3-methoxy-4-hydroxy-phenylglycol) were 43% and 25% higher, respectively, than in glucose tolerant hamsters ($p<0.05$). There was no significant difference in VMH extracellular levels of a metabolite of dopamine (homovanillic acid). These findings demonstrate that increases in both serotonergic and noradrenergic activity within the VMH are associated with and may promote glucose intolerance. This conclusion is further substantiated by our recent study wherein treatment with bromocriptine, a dopamine agonist, improved glucose tolerance in obese hamsters while also reducing VMH serotonin and noradrenaline turnover.

938

INSULIN INDUCED HYPOGLYCEMIA IN IDDM PATIENTS ADMITTED TO AN EMERGENY ROOM

A. Hvidberg, N.J. Christensen and J. Hilsted Hvidovre University Hospital and Herlev University Hospital, Copenhagen, Denmark.

The aim was (1) to describe hormone responses in iatrogenic hypoglycemia and (2) to investigate if a combined treatment of insulin induced hypoglycemia with intravenous dextrose and intramuscular glucagon (A) would improve glucose recovery as compared to treatment with intravenous dextrose alone (B). Twenty adult patients with IDDM (age 47±4 y, BMI 23±1, diabetes duration 20±4 y, Hemoglobin A1c 7.8±0.5) admitted to the Emergency Room were randomized to one of the above treatments and plasma glucose and counterregulatory hormones were measured before and 30-120 min after treatment. Plasma glucose was 1.18±0.03 mmol/l on admission. Pretreatment counterregulatory hormone concentrations were significantly lower than concentrations during hypoglycemia in healthy control subjects (age 30±3 y, BMI 22±1) yet pre-treatment counterregulatory hormone concentrations were significantly above fasting concentrations in healthy control subjects for plasma epinephrine ($p=0.00024$), glucagon ($p=0.0012$), growth hormone ($p=0.00052$) and for cortisol ($p<0.00001$). Thirty min after treatment A plasma glucose had risen to 5.44±1.02 mmol/l and after treatment B 8.12±1.12 mmol/l ($p=0.042$). Despite access to food two of six patients in group A and one of five patients in group B had plasma glucose below 4.0 mmol/l after 120 min. In conclusion (1) the present study confirms low, yet significantly elevated concentrations of epinephrine and glucagon in diabetic patients admitted with hypoglycemia to an emergency room. (2) Plasma glucose concentrations were higher 30 min after a combined treatment of insulin induced hypoglycemia with both intramuscular glucagon and intravenous dextrose as compared to treatment with intravenous dextrose alone. (3) Regardless the initial treatment regimen a strict food regimen must be advised to prevent late recurrent hypoglycemia.

939

EFFECT OF NICOTINOYL-GABA ON BRAIN METABOLIC STATE AND NEUROTRANSMISSION IN STREPTOZOTOCIN-INDUCED DIABETES

T.Kuchmerovskaya, G.Donchenko, N.Kuchmerovsky, I.Obrosova, A. Yefimov and A. Klimenko. Institute of Biochemistry, Kiev,Ukraine

We previously reported that serotonin-, dopamine- and GABAergic system functions deranged by diabetes. The aim of the study was to assess the mechanism of neurotropic action of nicotinoyl-GABA(pycamilon,P) in CNS-disfunction in diabetes.Four rat groups were studied: control and three groups of rats 1 month after induction of diabetes by STZ(70 mg/kg of body weight), two treated by P (20 and 200 mg/kg daily, 14 days) the forth untreated. The blood glucose level of diabetic rats was 312 mg/dl. The findings showed that both low- and high-dose P administration was accompanied by restoration of [U-^{14}C]GABA release by brain cortex synaptosomes, while for dopamine-and-serotoninergic systems his effect was absent. It was demonstrated that as a result of 6 hours injections of NA, GABA and P in low-dose brain NAD level increased to 0.204±0.014, 0.181±0.013, 0.220±0,015 vs 0.170±0.012 μmol/g, $p<0.05$ in diabetes respectively,while GABA level was almost unchanged. Brain ATP level in control was 2.07±0.07μmol/g. The P increasead this level to 1.62± 0.05 vs. 1.41±0.02 μmol/g, $p<0.05$ in diabetes. However, the P effect on cytosolic redox imbalance free NAD(P)-couples was negligible. It was shown that P inhibited NAD specific binding by diabetic synaptic membranes by 27%, besides NAD(1mM) inhibited P specific binding by 32%, as compared with diabetes. These results suggest that P was able to increase the NAD permeability into synaptosomes of diabetic rats. Our study suppouse that P plays an important role in improving the GABA-release mechanism and brain functional state in diabetic rats. Thus P is involved in the regulation of the processes in the brain streptozotocin-induced diabetes.

940

DRUG INDUCED HYPOGLYCAEMIA IN DIABETIC PATIENTS-A REVIEW OF 114 HOSPITALISED PATIENTS

W.Y.So, V.T.F.Yeung, C.C.Chow, G.T.C. Ko, J.K.Y.Li and C.S.Cockram.Diabetes and Endocrine Centre, Department of Medicine, Prince of Wales Hospital, Hong Kong.

We retrospectively evaluated 114 diabetic patients admitted to hospital with hypoglycaemia during the period Jan 95 to Mar 96 as defined by plasma glucose concentration ≤ 3.0mmol/l together with hypoglycaemic symptoms. It accounts for 0.5% of all admissions to the department of Medicine of Prince of Wales Hospital. All data were expressed as mean±SEM. The laboratory glucose on admission was 1.94±0.07mmol/l compared to 1.91±0.08mmol/l for capillary blood testing using a reagent strip. Sixteen patients wwere recieving OHA-insulin combination therapy. The remaining were divided into two groups for analysis-62 on oral hypoglycaemic agents (sulphonylurea± metformin,OHA) and 36 on insulin(INS). In the OHA group, 37 were on sulphonylurea alone and 25 on sulphonylurea plus metformin. These patients were older(71.4±1.56 vs 63.0±2.39years,$p<0.001$), mostly female(67.8%), and had a poorer premorbid state with multiple complications. Contrary to previous experience, the newer agents, gliclazide(n=13) and glipizide(n=10) accounted for 39% of hypoglycaemic episodes among the OHA group, while the remainder were receiving glibenclamide. These shorter-acting sulphonylureas were believed to be safer and hence selected for patients who were older and more complicated. Nevertheless, considerable hypoglycaemia still occurred. Restricted carbohydrate intake(64.04%), concurrent infection(32.2%), and other illness(45.7%) were commonly found predisposing factors. More severe clinical presentation in terms of duration of dextrose infusion was associated with plasma creatinine > 150μmol/l($p=0.06$), low albumin < 30g/dl($p=0.03$) and dependent premorbid state($p=0.01$). Drug interactions were not common, but ACEI therapy coexisted in 10%. We conclude that short acting sulphonylureas carry a significant risk of severe hypoglycaemia especially when used in elderly or complicated patients.

941

FUNCTIONAL MRI CHANGES IN THE HYPOTHALAMUS OF STREPTOZOTOCIN-TREATED RATS AFTER GLUCOSE LOADING

K. Torii, T. Kondoh and M. Mori. Torii Nutrient-Stasis Project, ERATO,JRDC, Yokohama and Ajinomoto Co. Inc.,Kawasaki, Japan

Functional MRI changes in the brain of streptozotocin(STZ)-treated diabetic rats was reported as follows; the hippocampus 20min. the paraventricular nucleus 40min., the dorso-medial hypothalamus(H). 60min. and the ventromedial H 100min. after insulin i.p. Overnight fasted male Sprague-Dawley strain rats, weighing 150g, treated with or without STZ(30 and 60mg/kgBW) i.p., were used, settled in a functional MRI(4.7 T). The metabolic change of each particular brain area was visualized chronologically by the magnetization, prepared rapid gradient echo pulse sequence method, following 2ml isotonic glucose solution injected, i.p., through the catheter. From 20 to 30min after glucose treatment, quite vivid metabolic change as the decrease of intensity was observed at the area between the hypothalamus and thalamus, especially the subfornical organ in case of rats injected with low dose or without STZ(control). These changes were recovered at 45min after glucose treatment. When rats were treated with high dose STZ, glucose treatment never caused any metabolic change in the same area of brain. These data suggested that fasted rats with glucose hunger could elicit certain metabolic change in the hypothalamus during glucose uptake into the brain and the neuronal activity of nuclei in these areas were declined due to recognition of sufficient glucose intake concurrently with insulin release, but STZ-induced diabetic rats never did because of insufficient glucose utilization peripherally.

942

LONG-TERM ADMINISTRATION OF THEOPHYLLINE AND GLUCOSE RECOVERY AFTER HYPOGLYCEMIA IN IDDM.

A. Hvidberg, A. Rosenfalck, N.J. Christensen and J. Hilsted, Hvidovre University Hospital and Herlev University Hospital, Copenhagen, Denmark.

We tested the hypothesis that long term administration of theophylline augments glucose recovery after insulin induced hypoglycemia. The metylxanthine theophylline increases intrahepatic c-AMP. The major glucose counterregulatory hormones epinephrine and glucagon use c-AMP as second messenger when increasing hepatic glucose production. We have previously demonstrated an increase in glucose recovery when intravenous theophylline was administered during insulin induced hypoglycemia. Eleven healthy subjects (mean (range): BMI 24 (20-27), age 28 (22-34) y) and eight insulin dependent diabetes patients (BMI 24 (21-30) age 31 (22-37) y duration of diabetes 3 (1-10) y hemoglobin A1c 8.2 (5.8-12.1)) participated in two hypoglycemia experiments (intravenous insulin infusion for 60 min) preceeded by (in a randomized, placebo controlled double blinded design) the ingestion of theophylline or placebo for two weeks. The dose of Teophylline was adjusted to maintain serum levels of 55-85microM. We found an increase in plasma glucose area under the curve (calculated from the start of the insulin infusion to 150 min thereafter) after theophylline treatment ($p=0.03$ and $p=0.02$, healthy subjects and diabetes patients respectively). However, there were no significant concomitant increases in incremental area under the curve for plasma c-AMP ($p=0.60$ and $p=0.32$), for glucose production rate ($p=0.16$ and $p=0.71$) or for glucose disappearance rate ($p=0.20$ and $p=0.21$). As regards counterregulatory hormones no significant changes were observed except for a decrease in incremental area under the curve for plasma glucagon after theophylline in healthy subjects ($p=0.0007$). In conclusion: the biological significance of long term phosphodiesterase inhibition is limited in the counterregulation of hypoglycemia. Thus theophylline is not suitable for the prevention of insulin induced hypoglycemia.

943

HYPOGLYCAEMIA DETECTION BY ECG RECORDING: REPRODUCIBLE EFFECTS ON T AND R WAVES

J. Meinhold, T. Heise and L. Heinemann; Dept. of Metabolic Diseases and Nutrition, Heinrich-Heine-University of Düsseldorf, Germany

ECG changes induced by hypoglycaemia might be used for hypoglycaemia detection. We compared reproducibility and magnitude of these changes between the 12 leads of a conventional ECG. On two study days 8 healthy volunteers (age 23±3 years, BMI 21.6±1.4 kg/m^2) received a s.c. injection of 0.15 U/kg regular insulin. During the subsequent 60 min blood glucose, insulin, potassium, and ECG changes (CS 3000, Picker-Schwarzer, Munich, Germany; amplitudes of R- and T-waves and QT-interval) were measured in 15 min intervalls. 60 min after insulin injection, blood glucose had declined from baseline values of 4.5 to 2.8 mmol/l, insulinaemia had increased from 41 to 193 pmol/l, while potassium levels fell from 3.9 to 3.7 mmol/l (all $p<0.05$). The ratio of R/T amplitudes showed a significant increase predominantly in the left precordial leads: 58 % in lead I ($p<0.01$), 55 % in lead V3 ($p<0.02$) and 63% in lead V5 ($p<0.005$). Repetition of the hypoglycaemic episode on study day 2 resulted in comparable changes in all measured parameters (R/T amplitude changes: 27 % in lead I, 70% in lead V3 and 135% in lead V5 ($p<0.05$)). The frequency-corrected QTc-intervals did not change in comparison to the initial values during the hypoglycaemic epsiodes. In conclusion, insulin-induced hypoglycaemic episodes resulted in reproducible ECG-changes in healthy subjects. These changes may be useful for a hypoglycaemia detection system.

944

RESPONSE DIFFERENCES FOR RECOMBINANT GLUCAGON IN DOGS.

R. Bowsher, J. Woodworth, A. Wilke, W. Smith, R. Yordy, and R. Lynch. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, USA.

A study of recombinant DNA-derived (rDNA) glucagon was conducted in beagle dogs for 2 weeks. This study was a placebo-controlled dose-ranging trial, with 3 dogs of each gender receiving daily subcutaneous doses of 0, 0.02, 0.06, and 0.2 mg/kg. Blood samples were collected for 2 hours after dosing for determination of serum glucose concentrations on study days 0 and 13. We calculated the maximum absolute blood glucose excursion from baseline (MAE), time to MAE (T_{MAE}), and the glucose excursion area under the curve (AUC_{ex}). Statistical comparisons were made across dose, gender, and day of measurement. Mean data are summarized below:

		Day 0			Day 13		
Dose, mg/kg	Sex	MAE, mg/dL	T_{MAE}, min	AUC_{ex}, mg•min/dL	MAE, mg/dL	T_{MAE}, min	AUC_{ex}, mg•min/dL
0	F	-3.0±19	50±61	-17±334	26±7	90±30	---
0.02	F	50±22	13±6	1038±966	109±16	23±12	5721±1578
0.06	F	44±4	10±0	593±208	76±6	10±0	2926±2001
0.2	F	103±34	23±12	5281±1145	115±28	27±6	8127±2669
0	M	-9.3±19	38±26	-144±301	8.3±20	87±58	---
0.02	M	40±18	10±0	542±219	41±13	17±6	1663±1151
0.06	M	58±4	10±0	627±214	76±9	10±0	2972±2028
0.2	M	74±25	37±21	971±613	82±4	10±0	3108±1010

Serum glucose concentrations peaked rapidly after subcutaneous injection of rDNA glucagon. Even though the glucodynamic response lasted for up to 2 hours, the response was greater on study day 13. A gender difference was detected with a greater response in females. In conclusion, rDNA glucagon is active and exhibits a dose-response in beagle dogs following a single subcutaneous injection.

945

Well being and cerebral function the day after nocturnal hypoglycaemia

P. King,[a] H. Parkin,[b] M-F Kong, IA Macdonald,[b] and RB Tattersall [a]
[a] Diabetes Unit, University Hospital and [b]Department of Physiology / Pharmacology, University of Nottingham Medical School, Nottingham, UK.

This study assessed the effect of nocturnal hypoglycaemia on well being and cerebral function the next day. Ten subjects with Insulin Dependent Diabetes were studied twice 4 weeks apart. One night blood glucose was lowered to 2.3-2.7mmol/l for one hour, and at the control visit, hypoglycaemia was avoided. The following morning, well being was assessed using the Minor Symptom Evaluation Profile (MSEP) and cerebral function with PASAT, Digit Symbol Substitution Test (DSST), Trail Making B, Four Choice Reaction Time (RT) and Auditory P_{300} latency. All 3 components of the MSEP scored higher after the hypoglycaemic compared with the control night (mean scores 226±37.8 vs 168±24.7 contentment, $p<0.01$; 182±26.2 vs 126±18.9 vitality, $p<0.001$; 183±14.7 vs 135±24.4 sleep, $p<0.05$ for hypoglycaemic and control nights respectively). None of the cerebral function tests performed the next day were affected by nocturnal hypoglycaemia (mean Trail Making 55.9±6s vs 54.9±7.5s; DSST score 66.5±3.4 vs 69.2±4; PASAT 2.56±0.1s vs 2.57±0.19s; RT 414±17.7ms and 411±15.6ms ; P_{300} 309±5.34ms and 321±9.1ms for hypoglycaemic and control nights repectively, all $p>0.05$). Thus 1 hour of hypoglycaemia at night affects well being but not cerebral function the next day.

946

INTRA-NASAL AND INTRA-MUSCULAR GLUCAGON IN HYPOGLYCAEMIC INSULIN-DEPENDENT DIABETIC SUBJECTS

E. Bell, P. Chester, K.R. Paterson, Diabetes Centre, Royal Infirmary, Glasgow, Scotland and Novo-Nordisk Pharmaceuticals Ltd, Crawley, England.

Glucagon treatment of severe hypoglycaemia could be facilitated if injection were obviated. Intra-nasal insufflation of a dry powder human glucagon (2.5 mg) formulation (NG) was compared to intra-muscular (IM) human glucagon (1 mg) in an open-label, random sequence study in 10 adult subjects with IDDM. Subjects were made hypoglycaemic (median glucose nadir 2.0 mmol/l (NG), 2.4 mmol/l (IM), NS (Wilcoxon)) by continuous intravenous insulin infusion, discontinued at the time of glucagon administration. A rise in plasma glucose was seen after glucagon in all subjects (median increment 1.5 mmol/l (NG), 1.2 mmol/l (IM), NS), the peak glucose occurring after 30 minutes in both groups. Peak plasma glucagon levels (median 1626 mg/l (NG), 1753 mg/l (IM), NS) occurred 15-20 minutes after administration by both routes. Mild-moderate nasal irritation of short duration was noted by 8 subjects immediately after nasal administration with mild erythema at rhinoscopy in 3 subjects. Intra-nasal and intra-muscular glucagon show equivalent metabolic responses and patient acceptability in hypoglycaemic adults. Easier administration by intra-nasal insufflation could extend the availability of this treatment option.

947

MILD HYPOGLYCEMIA-INDUCED COGNITIVE DYSFUNCTION IS INDEPENDENT OF ANXIETY AND IS LIMITED TO DIABETIC SUBJECTS.

DJ becker, C Suprasongsin, I Jarjour, S. Arslanian and C Ryan
University of Pittsburgh, Pittsburgh, USA

To examine the relationship between anxiety, autonomic nervous system (ANS) responsivity and cognitive functioning during mild hypoglycemiain in adolescents and adults, we studied in 25 individuals with IDDM (age = 18.6±5.4 yrs (range 12-28yrs); duration = 8.9±9.5 yrs; M ± SD) and 16 age-matched nondiabetic controls. Each subject participated in a euglycemic (Eu) and a Hypoglycemic (Hypo) clamp, in random order, 2 months apart. During the Hypo, serum glucose was clamped at 5.6mm/L for 90 mins, dropped to 3.3mm/L and maintained for 60 min. Plasma epinephrine (Epi), norepinephrine(Nor) and pancreatic polypeptide (HPP) were measured every 15 min. A battery of cognitive function tests including Letter Rotation Reaction Time Test (LR), Digit Vigilance (DV) and Trail making B (Trail B) and self-reported anxiety (Spielberger State Anxiety Inventory) were performed during the last 30 mins of both hypo and eu clamps. The increment in anxiety levels during hypo was significant in both groups, but greater in controls. However significant declines on cognitive function were limited to IDDM subjects. In neither group was cognitive change correlated with age or anxiety. The mean nor during this time was significantly correlated with anxiety levels in both groups. Cognitive function deterioration correlated with ANS hormones only within the control group.

The table represents correlations with mean epi, nor and HPP levels during the 30min testing period.

	HPP : r (p)		EPI : r (p)		NOR: r (p)	
	control	IDDM	control	IDDM	control	IDDM
Anxiety	.2(.2)	-.2(.2)	.3(.1)	.1(.4)	6(.004)	.2(.2)
LR	.5 (.02)	.2(.2)	6 (.008)	.1(.4)	.5 (.02)	-1(.4)
DV	-.7 (.001)	-.1(.3)	-.1(.3)	-.1(.3)	-.3(.1)	-.03(5)
Trail B	.5 (.03)	-.2(.2)	.3 (.1)	-.04(4)	3 (.1)	.1(.3)

Conclusion: Only IDDM subjects showed significant cognitive deterioration which was independent of their level of anxiety and age.We speculate that the differences in cognitive function during hypoglycemia between subjects with and without IDDM may relate to differences in adaptation of glucose transport into the brain.

948

HELICOBACTER PYLORI-INDUCED GASRITIS MAY CONTRIBUTE TO THE OCCURRENCE OF POSTPRANDIAL SYMPTOMATIC HYPOGLYCEMIA

Ö. Açbay, A. F. Çelik and S. Gündoğdu. Department of Internal Medicine, Division of Endocrinology, Division of Gastroenterology, Cerrahpaşa Medical Faculty of İstanbul University, İstanbul, Turkey.

We have previously shown that *Helicobacter pylori* (*HP*) gastritis enhances glucose and meal-stimulated insulin release. Furthermore, in our clinical experience, postprandial symptomatic hypoglycemic (PSH) patients with *HP* gastritis showed a substantial improvement in their hypoglycemic symptoms after the eradication of *HP*. Therefore, in this study we have investigated whether *HP* gastritis may contribute to the occurrence of PSH. For this purpose, we have evaluated below parameters in 10 PSH patients with *HP* gastritis before and one month after the eradication therapy: a) the number of PSH attacks occurred in a one month period using 30 day diary, b) the total symptom score following a mixed meal using visuel scale analogue questionnaire (VSAQ), and c) the glucose and insulin responses to the mixed-meal. Before the eradication, all the patients had repetitive symptoms, 2-4 hours after their regular meals, consistent with chemical hypoglycemia (glucose values less than 60 mg/dL in at least three different symptomatic periods). After the eradication of *HP*, the areas under the curve for serum insulin decreased by 14.2% ($p<0.001$) whereas for plasma glucose increased by 9.4% ($p<0.001$) following the mixed meal. The mean±SD number of PSH attacks occurred in one month period decreased significantly from 35.6±7 to 16.5±3.8 ($p<0.0001$) and the mean±SD of the total symptom score in VSAQ decreased significantly from 5.8±1.7 to 2.9±1.2 ($p<0.0001$). In conclusion, our data suggest that *HP* gastritis may contribute to the occurrence of PSH.

949

Plasma endothelin response to acute hypoglycaemia in insulin-dependent diabetes mellitus (IDDM).

MacLeod K.M.[a], Perros P.[b], Webb D.J.[c], Frier B.M.[b].
a. Department of Vascular Medicine, University of Exeter.
b. Department of Diabetes, Royal Infirmary, Edinburgh
c. Clinical Pharmacology Unit and Research Centre, University of Edinburgh

Acute hyypoglycaemia induces major haemodynamic changes mediated principally through activation of the sympatho-adrenal system and secretion of catecholamines and vasopressin. The endothelins are the most potent vasoconstrictor agents known, and have a central role in cardiovascular regulation.

The aim of the study was to determine whether acute insulin-induced hypoglycaemic provokes detectable alterations in peripheral plasma endothelin concentrations (ET) in patients with IDDM.

Plasma immunoreactive ET concentrations were determined in 20 patients with IDDM during insulin-induced hypoglycaemia, at baseline, at the onset of the autonomic reaction to hypoglycaemia (R) and at 15, 30, and 60 minutes thereafter. A significant increase in plasma ET concentrations was observed : from 3.81 ± 0.32 pg ml^{-1} at baseline to 6.72 ± 1.47 pg ml^{-1} at 60 minutes after the onset of the hypoglycaemic reaction ($p<0.05$).

Acute insulin-induced hypoglycaemia induced a rise in plasma ET concentrations in patients with IDDM occurring after the onset of the acute autonomic activation. This finding is consistent with the hypothesis of a putative role for ET in the mediation of hypoglycaemia-induced vasoconstriction, and possible precipitation of macrovascular or microvascular events.

950

COMPLEX CARBOHYDRATES CAN PREVENT NOCTURNAL HYPOGLYCEMIA IN DIABETIC CHILDREN AND ADOLESCENTS.

A.Verrotti, M.Magrì, B.Angelozzi, G.Morgese* and F.Chiarelli.
Paediatric Departments, Universities of Chieti and *Siena, Italy.

Common risks for hypoglycemia in children with type 1 diabetes mellitus are exercise, decreased food intake or excess insulin administration. In order to prevent nocturnal hypoglycemia in patients with type 1 diabetes mellitus with complex carbohydrates, a pilot-study was designed with 8 children 9.1-17.4 years old; the patients were selected from a group of diabetics with personal history of frequent symptomatic nocturnal hypoglycemia. We studied the patients twice, once for test and once for control study. On the test day the standard evening snack, was replaced by a test "snack" not containing mono- or disaccharides. Both the snacks, standard and test, were equivalent in energy and total carbohydrate content was similar. Blood samples were collected and when the patient had blood glucose < 60 mg/dl or symptoms of impending hypoglycemia, intervention with extra carbohydrates occurred. Six out of 8 children needed intervention after the standard snack. After the test snack this intervention was necessary in 3 out of 8 children. The time of intervention ranged from 11 p.m. to 4 a.m. and 10 p.m. to 12 a.m., respectively, on the day of the standard and test snack. Raw cornstark, as a source of complex carbohydrates, can be useful in the prevention of nocturnal hypoglycemia; moreover, blood glucose levels dropped more slowly than those after the standard snack. A combination of complex and semi-complex carbohydrates in the last evening snack or meal might be effective for the prevention of nocturnal hypoglycemia.

951

MICROCIRCULATION DURING INSULIN INDUCED HYPOGLYCEMIA - THE IMPACT OF ENDOTHELIN

T. Haak, E. Haak, K. Kusterer, C. Nickel, M. Engel and K H. Usadel, Med. Department I, University-Hospital, Frankfurt am Main, Germany

In order to investigate whether hypoglycemia might influence microcirculation, and if so, whether the endothelium derived vasoconstrictor endothelin [ET] might participate in these mechanisms 8 male healthy volunteers (age 21 - 34, mean 25 $\pm$ 4 years, body mass index 22.4 $\pm$ 0.6 kg x m^{-2}) were studied. Subjects received in random order either 0.1 IU/kg body weight regular insulin (hypoglycemia) or 0.1 IU/kg body weight regular insulin plus glucose 10 % (glucose clamp) or 1 ml sodium chloride 0,9 % (placebo) intravenously on three separate days according to a double-blind, randomized study protocol. For the following 60 minutes we determinined in 10-minutes intervals blood glucose, adrenocorticotropin [ACTH], cortisol and ET as well as heart rate and blood pressure. Microcirculation was assessed at the same time points by measuring capillary blood cell velocity at rest using nailfold capillaroscopy of the left hand. Thirty minutes after insulin injection ischemia (200 mmHg for 2 minutes using a cuff around the hand ankle) was performed as a provocative test in which the time to peak capillary blood cell velocity [tpCBV] during reperfusion was measured. Hypoglycemia (blood glucose 38 $\pm$ 4 mg/dl, $p < 0.001$ vs placebo and glucose clamp) resulted in a significant increase in the tpCBV as compared to glucose clamp or placebo (23 $\pm$ 4 s vs 8 $\pm$ 2 and 10 $\pm$ 2 s respectively, both $p < 0.01$) as a parameter of an impaired capillary perfusion. In the hypoglycemia experiments only there was a subsequent rise in ET [$p < 0.05$ vs before insulin injection] as well as ACTH and cortisol [both $p < 0.01$ vs before insulin injection] as a sign of an activated pituitary-adrenal axis. Capillary blood cell velocity at rest as well as blood pressure and heart rate remained unchanged in all experiments. These results demonstrate that not insulin per se but the hormonal response to hypoglycemia is the cause for the impaired microcirculation. An increased release of the potent vasoconstrictor ET might participate in the mechanisms of the decreased capillary perfusion.

THE HYPOGLYCEMIC / HYPERGLYCEMIC EFFECTS OF ANACARDIUM OCCIDENTALE (CASHEW)

R.L.Lindo,E.Y.St.A.Morrison and M.Nair. University of the West Indies, Mona, Jamaica and Michigan State University, East Lansing, Michigan.

The use of herbal medicines in diabetes treatment is still an ongoing practice in Third World Countries. The Bark of the Cashew tree is widely used as an oral hypoglycemic agent. Preliminary studies by a group at the University of the West Indies , showed that a crude extract from the bark of the Cashew plant exhibited the hypogycemic principle. This investigation sought to isolate, purify and elucidate the structures of compounds found to show activity. Three compounds have been isolated with hypo/hypergycemic activities and the identity of these will be discussed. The isolation method involved solvent extraction while purification was performed using various chromatographic techniques. The structures will be confirmed by spectral and chemical methods, using High Resolution Fourier Transformation (FT-NMR), Heteronuclear Multiple Bond Correlation (HMBC), Heteronuclear Multiple Quantum Coherence (HMQC) and Total Correlation Spectroscopy (TOCSY) etc. The activities were assayed by the use of Oral Glucose Tolerance Test, using the glucose oxidase method to determine the blood sugar concentrations. The compounds were administered intravenously in dimethyl sulfoxide to the dogs (n=10) in a concentration of 1.0-3.5mg/kg body weight. In all experiments,each dog was used as its own control where only dimethyl sulfoxide was administered intravenously. When compared to the controls, two compounds showed significant blood sugar lowering effects where all the values obtained for the extract curve , from FBS II to 2 hours inclusive are significantly less ($p < 0.05$ at 95% confidence limit). However, the third compound displayed significant increase in blood sugar ($p < 0.01$) at FBS I. The combined effect of the two hypoactive compounds thus produced an overall hypoglycemic effect.

953

REGULATION OF PRO- AND CONTRAINFLAMMATORY CYTOKINES DURING HYPOGLYCEMIA.

I. Koop; P. Preuss, S. Will, C. Loefler, S. Schreiber, S. Nikolaus, and P. Jehle*. Depts. of Internal Medicine, *University Ulm, and University Hospital Charité, Berlin, FRG.

Hypoglycemia can be regarded as a situation of stress inducing several humoral rescue mechanisms to prevent damage from the organism. We were interested whether hypoglycemia causes activation of the immune system. Methods: Ten healthy volunteers (6m, 4f, age:22-25, BMI: 21±0.6) were studied by means of a stepwise hypoglycemic hyperinsulinemic (1mU/kg/min) clamp. In 7 volunteers, a euglycemic hyperinsulinemic clamp (5mM serum glucose) of the same duration was performed as control. Plasma cytokine and cortisol levels were determined by ELISA, epinephrine was measured by HPLC. Results: During hypoglycemia, leukocyte count increased nearly 3-fold with a relative rise of granulocytes. IL-10 concentrations increased significantly, whereas TNF-α, IL1-ß and IL-6 concentrations remained

hypoglycemic clamp	*5mM glucose*	*2.3mM glucose*
Leukocytes, GPT/l	*6.8 ±0.4*	*14.4±0.8***
IL-10, pg/ml	*<7.8*	*14.6±3 2**
Epinephrine, pM	*0.2 ±0.01*	*6.1±0.2***
Cortisol, nM	*0.39±0.01*	*1.1±0.05***

[*:p<0.01, **:p<0.001] unchanged. During euglycemia, leucocyte count and cytokine levels remained constant. Discussion: Hypoglycemia causes secretion of the contrainflammatory cytokine IL-10. As IL-10 is a potent downregulator of adhesion molecules this cytokine may be involved in the release of leukocytes from vessel walls or bone marrow.Whether counterregulatory hormones directly induce IL-10 secretion under hypoglycemic conditions is subject to future studies. This study shows that modulation of blood glucose levels can substantially alter immunoregulation.

954

In vivo Studies Of The Effects Of Capsaicin On Blood Glucose Levels And Insulin Binding Using Dog Models.

I.A. Tolan , D. Ragoobirsingh and E. Y. St. A. Morrison ;Biochemistry, University of theWest Indies, Kingston, Jamaica

A number of plants have been used in Jamaica to treat diabetes by traditional healers .One of them is Capsicum *frutences* whose active agent, capsaicin is already being used to treat Diabetic Neuropathy. This study was designed to determine if capsaicin has any effect(s) on blood sugar, insulin levels,as well as insulin binding using leucocytes. A capsaicin fraction which was isolated from Capsicum *frutences* when fed to dogs (n = 13) caused hypoglycemia that is stastically significant when compared to a control, at the 2.5 hr time interval of an Oral GlucoseTolerance Test. (5.38 mol/dl ± 0.49 versus 6.79 mol/dl ± 0.34, $p < 0.05$ for the control). These results were comfirmed by using a capsaicin standard (4.53 mol/dl ± 0.45 versus 6.6 mol/dl ± 0.46, n = 11, $p < 0.05$ for the control). Blood Sugar was measured by the Glucose oxidase method. Insulin concentration measured by the Coat a Count method at the same time showed an increase of insulin levels when compared to the control (18.83 µl/mol ± 3.6, versus 6.9µl/mol ± 1.25, n = 11, $p > 0.05$ for the control). Insulin binding was done by the Gambir *et al* method in which isolated, washed leucocytes were incubated with varying concentration of non-radioactively labeled insulin and a fixed quantity of radioactive labelled insulin. After the 3 hr incubation, cells were washed with buffer and radioactivity determined in a autogamma counter. The results showed that there was a stastically significant decrease in insulin binding of theleucocytes of the dogs injected with the capsaicin fraction when compared to the control. Binding for the capsaicin fraction was 27% ± 2.69 compared with 8% ± 1.25 (n = 10, $p>0.05$) for the control. In conclusion, it is apparent that capsaicin has a hypoglycemic effect which is mediated by a comcominant increase in blood insulin levels. The decreased insulin receptor binding may be compensatory mechanism in response to the latter and serves to prevent rapid depletion of blood glucose level which could result in a hypoglycemic coma.

Endogenous Glucose Production

955

GLUCONEOGENESIS IS NOT INCREASED IN MILDLY HYPERGLYCEMIC NON-INSULIN-DEPENDANT DIABETIC PATIENTS.

F. DIRAISON, V. LARGE, H. BRUNENGRABER, M. BEYLOT. Laboratoire de physiopathologie métabolique et rénale, LYON, FRANCE and the Case Western Reserve University, Cleveland, USA.

The enhanced endogenous glucose production (EGP) of non insulin dependent diabetic subjects (NIDDM) is generally considered to result from an increased gluconeogenesis (GNG). We infused (post-absorptive state) 5 normal subjects and 5 NIDDM (glycemia 11,1 ± 1,0 mM) with [6,6-$^2H_2$] glucose (150 min) and [3-^{13}C] lactate (6 hours). Liver glutamine was non invasively sampled with phenylacetate and its labeling pattern determined (mass spectrometry) after purification of the glutamine part of urinary phenylacetylglutamine. After correction for labeled CO_2 reincorporation by pyruvate carboxylase (PC) (control test with $NaH^{13}CO_3$ infusion) this labeling pattern was used to calculate a correction factor for isotopic exchange in the oxaloacetate pool and flux through liver Krebs cycle. NIDDM had increased lactate Rt (15,3 ± 0,7 vs 10,0 ± 0,7 µmol/kg/min, $p<0,01$) and EGP (15,22 ± 0,90 vs 12,52 ± 0,33 µmol/kg/min, $p<0,05$). Uncorrected contribution of GNG to EGP were 28 ± 3 % (control) and 19 ± 4 % (NIDDM). Correction factor were comparable in controls (1,34 ± 0,02) and NIDDM (1,46 ± 0,04) and the correted relative and absolute contribution of GNG to EGP were not increased in NIDDM (27 ± 5 % and 4,1 ±0,5 µmol/kg/min) compared to controls (38 ± 3 % and 5,0 ± 0,6 µmol/kg/min). The calculated PC over pyruvate dehydrogenase activity ratio, were comparable (12,1 ± 0,6 vs 13,0 ± 1,3). Lastly hepatic fatty acid oxidation, as estimated by this model, was not increased in NIDDM. Conclusion, despite an increased lactate Rt we found no increase of GNG in the diabetic patients studied.

956

RELEASE OF GLYCEROL FROM MUSCLE TISSUE IS ONLY MINOR IN OBESE AND NORMAL SUBJECTS.

M. Sjöstrand, Lena Strindberg, A. Holmäng and P. Lönnroth. Lundberg Laboratory for Diabetes Research, Department of Internal Medicine, Gothenburg, Sweden

Recently, a microdialysis study reported molar concentrations of glycerol in adipose as well as muscle tissue. Since this should result in non-physiological plasma concentrations of glycerol we performed calibrated microdialysis measurements in three subject groups. In six normal weight non-diabetic subjects fasted over night arterial glycerol and abdominal adipose tissue interstitial glycerol was 39±1 and 176±25µmol·l^{-1}, respectively($p<0.001$). Interstitial glycerol in medial femoral muscle (50±6 µmol·l^{-1}) was significantly ($p<0.05$) higher than in arterial plasma but lower (0.01) than in adipose tissue. Also, we measured muscle interstitial glycerol during a euglycemic hyperinsulinemic clamp in obese (BMI:33±4, n=10) and normal weight (BMI:23±1, n=10) subjects. At steady state obese subjects had p-glucose 5.8±0.2mmol·l^{-1}, p-insulin 480±52 mU·l^{-1}, arterial glycerol 31±3µmol·l^{-1} and muscle interstitial glycerol 54±10µmol·l^{-1}, (arterial vs interstitial $p<0.01$). Normal weight subjects: p-glucose 5.7±0.1, p-insulin 297±29, arterial glycerol 16±1 and interstitial glycerol 64±20 (arterial vs interstitial $p<0.05$). The data conclude that glycerol is released only to a minor extent from muscle tissue in normal weight and obese subjects. The data do not confirm molar interstitial glycerol levels in either adipose or muscle tissue.

957

EVALUATION OF THE DYNAMIC RELATIONSHIP BETWEEN FFA AND ENDOGENOUS GLUCOSE PRODUCTION IN NORMAL AND OBESE SUBJECTS. L.D. Monti, P.M. Piatti, A. Caumo, G. Valsecchi, C. Stangalini, F. Magni, S. Costa, M. Galli-Kienle, A.E. Pontiroli and G. Pozza. Istituto Scientifico H. San Raffaele, Milano, Italy.

Recent studies have suggested that free fatty acids (FFA) are the link in the suppression of endogenous glucose output (EGP) by insulin. However, the dynamic relationship between the time courses of FFA and EGP has not been fully investigated. To clarify this issue we studied FFA decline and EGP inhibition during a low-dose (0.4 mU/kg/min) hyperinsulinaemic euglycaemic clamp in normal (n=6; age=34±2 yrs; BMI=25.0±1.4 kg/m^2) and in obese subjects (n=5; age=42±4 yrs; BMI=35.7±1.1 kg/m^2). Dideuterated glucose was infused to trace glucose turnover and the hot-GINF technique was employed to obtain a reliable assessment of EGP. FFA and EGP measurements were available at 5,10,15,20,25,30,45,60,75,90,105, and 120 min. A kinetic model was used to relate FFA decline to EGP inhibition during the nonsteady state. It provided metabolic indices such as the sensitivity of EGP to FFA, S_{FFA}, and the time delay between FFA and EGP changes, τ_{FFA}. In the fasting state, FFA levels were lower in normal subjects (0.46±0.04 vs 0.64±0.06 mmol/l;$p<0.05$) while EGP (1.95±0.18 vs 1.61±0.11 mg/kg/min) was similar in the two groups. At 120 minutes, no differences in the percentages of inhibition either of FFA (66.0±6.9 vs 75.5±6.6 %) or of EGP (83.1±5.2 vs 71.5±4.1%) were found. When the nonsteady-state period was considered, differences in the FFA vs EGP relationships of the two groups emerged. In normal subjects the model fit was good and the metabolic indices were precisely estimated: S_{FFA} was 6.2±1.1 mg/kg min per mmol/l and τ_{FFA} was 11.5±5.6 min. In contrast, in four out of five obese subjects FFA decline did not account accurately for EGP inhibition. In fact the model fit was poor, especially during the first 30 min of the clamp when FFA decrease was slower than EGP inhibition. We conclude that during a hyperinsulinaemic euglycaemic clamp FFA decrease is tightly related to EGP inhibition in normal subjects. In obese subjects some other factor is likely to be involved in the suppression of EGP.

958

IN SITU LIPOLYTIC RESPONSE TO PHYSIOLOGIC STRESSORS AND ISOPROTERENOL IN PIMA INDIANS AND CAUCASIANS.
S Snitker, J Hellmér*, M Boschmann*, OE Odeleye, MB Monroe, E Ravussin. CDNS/NIDDK/NIH, Phoenix, AZ, USA. *Rockefeller Univ. New York, NY, USA

Pima Indians have a high prevalence of obesity and NIDDM. We hypothesized that lipolytic responses to stimuli would be lower in Pima Indians than in sex-, age-, and body composition-matched Caucasians. Lipolysis was measured by microdialysis *in situ* in non-diabetic Pima Indians (12 M/15 F, 30±7y, 85±18kg, 38±10% body fat; means±SD) and Caucasians (11 M/10 F, 34±7y, 105±26kg, 41±12% body fat). Glycerol concentration was measured in the dialysate of a probe inserted in the abdominal subcutaneous adipose tissue during a 30 min baseline and 1) 30 min exercise at 41±12% VO2max, 2) 30 min mental stress (color-word test), and 3) 40 min local infusion of isoproterenol added to the perfusate (10μM). Plasma epinephrine and norepinephrine were measured during baseline and in response to exercise and mental stress. Baseline dialysate concentrations of glycerol were similar in the two groups.

Relative change in dialysate glycerol concentration over baseline (%)

	Pima Indians	Caucasians	*t*-test
Exercise	38±38	41±41	NS
Mental stress	-2±11	-1±12	NS
Local isoproterenol	66±31	72±31	NS

The groups were also similar after correction for changes in local blood flow (n=44). Plasma catecholamines increased similarly in the 2 groups in response to exercise and mental stress. In conclusion, a lower lipolytic response to stimuli does not seem to explain the high susceptibility of Pima Indians to weight gain.

959

ROLE OF FFA IN THE REGULATION OF BASAL GLUCOSE METABOLISM IN CONTROL AND DIABETIC RATS.
L. Morviducci, L. Pastore, §D. Zorretta, §A. Buongiorno, G. Tamburrano and *A. Giaccari. Endocrinology, II Inst. of Medicine, Univ. "La Sapienza"; §Ist. Superiore di Sanità and *Div. of Endocrinology, Catholic University; Rome, Italy.

Increased FFA concentration, experimentally induced during an hyperinsulinemic clamp, is able to inhibit glycolysis and reduce glucose uptake, finally determining insulin resistance. Hyperinsulinemia, however, markedly lowers FFA concentration. The aim of this study was to clarify the effects of high plasma FFA on glucose uptake (GU), hepatic glucose production (HGP), and gluconeogenesis (GN) in control (C) and diabetic (90% pancreatectomy) rats (D) in presence of identical basal insulin and euglycemia. In order to acutely reach euglycemia without insulin, D rats received an infusion of phloridzin (inhibitor of glucose reabsorption in the kidney: glycosuria). After a 6h fast, all rats were infused for 120 min with [3-^{3}H]-glucose, [U-^{14}C]-lactate plus a concomitant infusion of triglyceride emulsion (Intralipid plus heparin) or saline. At tracer/tracee steady state, GU was calculated as the rate of disappearance of glucose minus glycosuria. The minimal estimation of GN was calculated as the ratio between plasma ^{14}C-glucose and 2 · plasma ^{14}C-lactate multiplied HGP (glucose rate of appearance). Saline infused D rats, as expected, showed reduced GU (D: 37.1±3.3 vs. C: 66.8±3.9 μmol·kg^{-1}·min^{-1}). Elevated FFA did not modify GU in both groups (D: 32.2±2.2; C: 62.3±1.7 μmol·kg^{-1}·min^{-1}). HGP was markedly increased in D rats compared with C (D: 89.5±3.8 vs. C: 61.8±3.9 μmol·kg^{-1}·min^{-1}) and remained unaffected by FFA infusion in both groups (D: 78.9±4.4; C: 60.1±2.8 μmol·kg^{-1}·min^{-1}). GN relative contribution to HGP was almost doubled by increased FFA in C (from 18.7±6 to 34.5±8 %, or from 11.7±1.7 to 20.6±2.2 μmol·kg^{-1}·min^{-1}); it was already increased in saline infused D rats (either relatively: 54.4±4 %, or as absolute flux: 21.1±1.7 μmol·kg^{-1}·min^{-1}) but remained unaffected in FFA infused D rats (52.3±5 %, 18.7±2.2 μmol·kg^{-1}·min^{-1}). In conclusion, this results suggest that, in presence of basal insulin and euglycemia, an acute elevation of FFA concentration: 1. is not able to modify GU and overall HGP, either in diabetic or control rats and 2. increases GN in control rats, but not in D rats, where it is already elevated. In perspective, other mechanism(s) than just increased FFA and GN are responsible for augmented HGP, at least in this model of diabetes.

960

FREE FATTY ACIDS METABOLISM IN HUMANS : CONTRIBUTION OF OXIDATION, INTRAHEPATIC AND EXTRAHEPATIC REESTERIFICATION.
F. DIRAISON, C. PACHIAUDI, M. BEYLOT, Laboratoire de physiopathologie métabolique et rénale, et C.R.N.H. de LYON, FRANCE.

Plasma FFA can be either oxidized or reesterified into triglycerides (TG). This reesterification can take place in liver (the TG being then secreted as VLDL-TG) or in extrahepatic tissues. To measure these metabolic pathways five normal subjects drank deuterated water (for measurement of lipogenesis) in the evening and were infused the following morning in the post-absorptive state with [1-^{13}C] palmitate (4 hours). We determined : 1) FFA turnover rate (from the enrichment of plasma palmitate), 2) FFA oxidation rate (from the excretion rate in expired gas of $^{13}CO_2$), 3) total lipid oxidation (by indirect calorimetry, corrected for the measured lipogenesis), 4) intrahepatic reesterification (from the kinetic of ^{13}C palmitate incorporation into TG during [1-^{13}C] palmitate infusion), 5) TG turnover rate (from the kinetic of ^{13}C palmitate disappearance in TG after the end of [1-^{13}C] palmitate infusion). FFA oxidation rate (calculated using the acetate correction factor of Sidossis) was 2,76 ± 0,65 μmol/kg/min, accounting for 45% of FFA R_t (6,04 ± 1,04 μmol/kg/min) and 90 % of total lipid oxidation (3,02 ± 0,5 μmol/kg/min). Total FFA reesterification was therefore 3,27 ± 0,54 μmol/kg/min). TG turnover rate was 0,11 ± 0,05 μmol/kg/min). Lipogenesis accounted only for 4% of TG secretion rate whereas hepatic FFA reesterification accounted for about 50% representing only 0,16 ± 0,02 μmol/kg/min of plasma FFA utilisation. Extrahepatic reesterification was therefore 3,11 ± 0,53 μmol/kg/min. Conclusion : 1) FFA oxidation account for near the totality of lipid oxidation. 2) oxidation and reesterification contribute each about one half to FFA utilization. 3) lipogenesis and reesterification account for only 50-55% of TG secretion. 4) most of FFA reesterification takes place in extrahepatic tissues.

961

NITRIC OXIDE INHIBITS HEPATOCYTE GLUCOSE METABOLISM.

F. Sprangers, A.J. Meijer, J.A. Romijn and H.P. Sauerwein; Metabolic Research Unit and Dept. of Biochemistry, Academic Medical Center, Amsterdam, The Netherlands.

There is increasing evidence in literature for the existence of intrahepatic regulation of glucose production by Kupffercell products as cytokines and prostaglandins. The role of nitric oxide (NO), another Kupffercell product, is less well studied. NO has been described to influence gluconeogenesis from lactate by inhibiting rate-limiting gluconeogenic enzyme fluxes of PEPck and PC. It is not known whether NO influences other pathways of intrahepatic glucose metabolism. We aimed to study the influence of NO on gluconeogenesis from dihydroxyacetone (DHA) and on glycogen synthesis from either DHA or glucose by adding a low dose of the chemical NO-donor S-Nitroso-Acetyl Penicillamine (SNAP) to fasted, isolated rat hepatocytes. Cells were incubated for 1 hour with mentioned substrates and with or without proline or glutamine to stimulate glycogen synthesis. For results see the table:

substrate	SNAP mM addition	GLUCONEOGENESIS isotonic	glutamine	proline	GLYCOGEN SYNTHESIS glutamine	proline
DHA 10 mM	0	259 (± 57)	280 (± 33)	317 (± 39)	77,1 (±7,2)	81,7 (±1)
	0,25	264 (± 49)	273 (± 45)	307 (± 41)	15,7 (±14,6)*	11,5 (±19,9)*
glucose 20 mM	0	All expressed as umol/gdw			113 (±15,1)	120 (±15,6)
	0,25	* P < 0,05			17,9 (±21)*	39,6 (±30)*

We found that: **1.)** Gluconeogenesis from DHA was not affected by SNAP. **2.)** Glycogen synthesis from DHA and glucose was 80-90% inhibited by SNAP. **3.)** Total cell ATP levels were not affected by SNAP.
Conclusion: SNAP-derived NO causes inhibition between glucose-6-phosphate and glycogen, presumably by inhibiting glycogen synthase.

962

REGULATION OF LIPOLYSIS STUDIED BY MICRODIALYSIS IN NORMAL AND SPINAL CORD INJURED SUBJECTS.

AK Karlsson, M. Elam, P. Friberg, L. Sullivan and P. Lönnroth. Departments of Clin. Neuroscience, Clin. Physiology and Medicine, Univ. of Göteborg, Sweden

Stress reactions with increased sympathetic activity may cause insulin resistance whereas reduced lipolytic rates due to an inherent reduced adrenergic sensitivity has been proposed to cause obesity. To elucidate the role of the sympathetic nervous system (SNS) we studied a spinal cord injured (SCI) group with decentralised SNS and a weight and age-matched control group. Subcutaneous microdialysis and blood flow measurements (^{133}Xe-clearance) were performed in umbilical and clavicular region during centrally mediated sympathoexcitation. The SCI group showed an increased fat mass (26.8 kg vs 16.1 kg, $p<0.01$), higher p-glycerol (82±7 vs 61±4, $p<0.05$), p-insulin (9.0±2 vs 5.0±0.7 mU/l, $p<0.05$) and lower p-noradrenaline (NA) (0.78±0.2 vs 1.23±0.14 nmol/l $p<0.05$) concentrations. Sympathoexcitation increased blood flow and glycerol release (rest:98±41, excit:167±43 nmol/min/100g, $p<0.05$) in umbilical region among controls, whereas no reaction was found in the decentralised region in the SCI group. P-glycerol, -FFA, -insulin, -NA and -adrenaline increased in control subjects. In spite of this, lipolysis rate was similar in both groups in both regions. In conclusion: The insulin resistance and increased adipose tissue mass found in SCI seem not to be caused by the decentralisation of the SNS.

963

EVIDENCE, IN ISOLATED MICROSOMES, FOR THE INHIBITION OF GLUCOSE-6 PHOSPHATASE AFTER REFEEDING.

N. Danièle, C. Zitoun and G. Mithieux. Institut National de la Santé et de la Recherche Médicale (U.449), Lyon, France.

It has been recently shown that the activity of liver glucose-6 phosphatase (Glc6Pase), the final enzyme of gluconeogenesis and glycogenolysis, was inhibited (Vmax) after refeeding. The inhibition was observable in homogenate and not in isolated microsomes, suggesting it was either labile or due to a metabolite lost during the isolation process. To distinguish between both hypotheses, we designed a very rapid microsome isolation procedure (less than 1 hour), from a small amount (≈1g) of fresh liver sampled in anesthetized rats. Microsomal Glc6Pase Vmax in 48h-fasted rats (0.35±0.01 µmol/min/mg prot., mean±S.E.M. n=12) was inhibited after 7h-refeeding (0.27±0.01 µmol/min/mg, n=12, $p<0.01$). The inhibition was also observable after detergent-treatment of microsomes (0.6±0.03 vs 0.45±0.2 µmol/min/mg prot., before and after refeeding, respectively, n=12, $p<0.01$). The Km of Glc6Pase (≈2.5 mM in intact membranes, 1 mM in detergent-treated membranes) was not affected by refeeding. Once they had been rapidly isolated, microsomes could be further washed, inhibition was retained. Glc6Pase inhibition was not removed upon incubation in the presence of BSA (1 mg/ml), ruling out that it could be mediated by unsaturated fatty acids or fatty acyl-CoA esters (known inhibitors of the enzyme) bound to the membrane. Our results strongly suggest that the inhibition of Glc6Pase after refeeding is not dependent on a metabolite present in homogenate and lost in microsomes. This inhibition, which might involve a covalent modification of the enzyme, is stable after rapid removal of microsomes from homogenates.

964

CAN INSULIN MEDIATED SUPPRESSION of FFA AND GLYCEROL BE USED TO EVALUATE THE LIPOLYTIC ACTIVITY DURING I.V. INSULIN TOLERANCE TEST ?

Ü.Korugan[1], Y. Altuntaş[1], N. Hekim[2]
[1] University of İstanbul, Medical Faculty of Cerrahpaşa, Department of Endocrinology and Metabolism, [2] Pakize Tarzi Laboratuary, Istanbul -TURKEY

NIDDM and obesity are also characterized by resistance to the antilipolytic effects of insulin. To determine whether the insulin mediated suppression of FFA and glycerol are an indicator of the degree of insulin sensitivity, we measured FFA, Glycerol, Plasma glucose disappearance rate (K_{ITT}) during I.V. insulin tolerance test (IVITT) non-diabetic obese young women (Age:41±3 yr, BMI: 28±3.3 kg/m^2, WHR: 84±0.05). Insulin sensitivity was measured with IVITT (Regular insulin 0.05 IU/kg) The glucose levels were determined at 3 min intervals for 15 min before and after insulin administration. The FFA and glycerol levels were determined at 15 min intervals for 60 min before and after insulin administration. K_{ITT} was 4.11±1.6 %.min^{-1} .FFA were 590±254, 460±245, 260±133, 292±147, 350±190 µEq/L, Glycerol were 8.57±2.6; 5.9±1.5; 5.67±2.1; 5.76±2.3; 6.1±1.8 mg/L at 0, 15, 30, 45, 60min respectively. Suppression of FFA were 24±22 %, 54±20 %, 45±26 %, 10±4 % and suppression of glycerol were 27±19 %, 33±26 %, 31±25 %, 8±3 % at 15, 30, 45, 60 min, respectively K_{ITT} correlated only with 30 min -FFA level ($r= -0.72$, $p=0.012$) not correlated any glycerol levels. As a conclusion, levels of glycerol are insufficiently suppressed according to FFA levels during IVITT. At least 50 % decrease in FFA level at 30 min during IVTTT may reflect insulin sensitivity in android obesity.

965

SMALL AMOUNTS OF FRUCTOSE AUGMENT NET HEPATIC GLUCOSE UPTAKE DURING HYPERGLYCEMIA IN INSULIN DEFICIENCY.

M. Shiota, P. Galassetti, M. Monohan, D. W. Neal, and A. D. Cherrington.
Vanderbilt University School of Medicine, Nashville, U.S.A.

Fructose activates glucokinase by releasing the enzyme from its inhibitory protein in the liver. We showed previously that intraportal infusion of small amounts of fructose markedly augmented net hepatic glucose uptake during hyperglycemic hyperinsulinemia. In this study we examined whether small amounts of fructose augment net hepatic glucose uptake during hyperglycemia with normoinsulinemia in conscious 42 h-fasted dogs. Isotopic and A-V difference methods were used. Each study consisted of an equilibration period (-140 to -40 min), a control period (-40 to 0 min), and a test period (0 to 240 min). During the latter glucose (6.5 $mg \cdot kg^{-1} \cdot min^{-1}$) was continuously given intraportally with (0.4 $mg \cdot kg^{-1} \cdot min^{-1}$) (+F) or without fructose (-F). During the study, somatostatin (0.8 $\mu g \cdot kg^{-1} \cdot min^{-1}$) was given along with basal insulin (0.25 $mU \cdot kg^{-1} \cdot min^{-1}$) and glucagon (0.6 $ng \cdot kg^{-1} \cdot min^{-1}$) intraportally. In the +F group, fructose increased the sinusoidal blood fructose level (nmol/ml) from <16 to 139 ± 11. The average rate of net hepatic fructose uptake and fractional extraction during the test period were 2.1 ± 0.2 $\mu mol \cdot kg^{-1} \cdot min^{-1}$ and 46 ± 2 %. The infusion of glucose alone elevated arterial blood glucose (μmol/ml) from 4.3 ± 0.3 to 11.2 ± 0.6 during the first 2 h after which it remained at 11.6 ± 0.8. In the presence of fructose glucose infusion elevated arterial blood glucose (μmol/ml) from 4.3 ± 0.2 to 7.4 ± 0.6 during the first 1 h after which it decreased to 6.1 ± 0.4 (3 h). With glucose infusion, net hepatic glucose balance ($\mu mol \cdot kg^{-1} \cdot min^{-1}$) switched from output (8.9 ± 1.7 and 13.3 ± 2.8) to uptake (12.2 ± 4.4 and 29.4 ± 6.7) in -F and +F, respectively. Average net hepatic glucose uptake ($\mu mol \cdot kg^{-1} \cdot min^{-1}$) and fractional extraction (%) (last 3 h of the test period) were higher in +F (30.6 ± 3.3 and 14.5 ± 1.4) than in -F (15.0 ± 4.4 and 5.9 ± 1.8). In conclusion, small amount of fructose markedly reduces hyperglycemia during intraportal glucose infusion by increasing net hepatic glucose uptake even when plasma insulin levels remain at the basal.

966

RELATIONSHIP BETWEEN FREE-TESTOSTERONE LEVELS AND GLUCOSE EFFECTIVENESS AFTER AN ACUTE DECREASE IN FFA LEVELS IN OBESE WOMEN.

M. Conti, P.M. Piatti, A. Caumo, L.D. Monti, B. Guazzini, B. Dallagrassa, E. Fochesato, A. Pizzini, A.E. Pontiroli and G. Pozza. Istituto Scientifico San Raffaele, Milano, Italy

Androgen hormones (i.e. free testosterone: FT) seem to decrease insulin sensitivity with an effect probably mediated by an increase in FFA levels. To evaluate whether an acute decrease in FFA levels may induce a reduction in FT levels and in turn increase insulin sensitivity, 21 women affected by obesity (age 41±2 yrs, BMI 37.3±0.9 kg/m^2, waist/hip range between 0.76 and 0.91) underwent two IVGTT studies separated by a one week interval. Placebo or acipimox (to inhibit lipolysis) were administered orally before the beginning of the IVGTT. Glucose and insulin concentration profiles obtained during the IVGTT, were analyzed with the minimal model of glucose disappearance which provides indices of both insulin sensitivity (SI) and glucose effect *per se* or glucose effectiveness (SG). After placebo, basal FFA were 0.8±0.5 mM and decreased to 0.2±0.03 mM after acipimox p<0.0001). Basal insulin (I) levels were 13.4±1.1 μU/ml after placebo and decreased to 11.0±1.2 μU/ml after acipimox (p<0.05). basal FT levels were 1.0±0.1 ng/ml after placebo and significantly decreased to 0.73±0.09 ng/ml after acipimox (p<0.05). During IVGTT and placebo, SI and SG were 2.26±0.36 10^{-4} $min^{-1}/\mu U/ml$ and 0.013±0.001 min^{-1}, respectively. After acipimox, SI increased to 2.92±0.40 10^{-4} $min^{-1}/\mu U/ml$ (p=0.058) and SG to 0.018±0.002 min^{-1} (p<0.01). Interestingly, the increment in SG significantly correlated with the decrement of basal FT levels (r=0.45, p<0.05). In conclusion: 1) fasting FFA concentrations seem to modulate fasting FT and insulin levels; 2) an acute decrease in FFA increase both SI and SG; 3) the increase in SG after an acute decrease in FFA levels seems related to a simultaneous reduction in FT levels.

967

HUMAN SYSTEMIC, HEPATIC AND RENAL GLUCOSE, GLUTAMINE AND ALANINE METABOLISM: EFFECTS OF EPINEPHRINE.

M. Stumvoll, C. Meyer, G. Perriello, M. Kreider, S. Welle and J. Gerich. Tübingen, Germany, and Rochester, NY, USA.

Glutamine (GLN) and alanine (ALA) are the most important gluconeogenic amino acids. Recent studies indicate that in humans liver and kidney are equally gluconeogenic organs. It has been proposed that epinephrine stimulates gluconeogenesis (GN) by increasing substrate availability. To test this concept we used a combination of isotope ([6-^{3}H] glucose, [U-^{14}C] glutamine, [3-^{13}C] alanine) and renal balance techniques before and during infusion of epinephrine (E) in 9 normal postabsorptive volunteers.

Tbl. 1. Systemic (syst), hepatic (hep) and renal (ren) rates ($\mu mol \cdot kg^{-1} \cdot min^{-1}$).

* p<0 05	Glucose Release			Glutamine GN			Alanine GN		
	syst	hep	ren	syst	hep	ren	syst	hep	ren
Basal	11.8	9.0	2.8	.48	.13	.35	72	.69	.03
Epinephrine	15.8*	10.3*	5.5*	.69*	.06	.64*	1.70*	1.62*	.08*

Tbl. 2. Renal net balance (NB), uptake (UPT), release (REL) ($\mu mol \cdot kg^{-1} \cdot min$) and fractional extraction (FX) (%):

* p<0.05	Glutamine				Alanine			
	NB	FX	UPT	REL	NB	FX	UPT	REL
Basal	49	9.2	.73	.24	.16	8.4	.55	.44
Epinephrine	.80*	15.1*	1.29*	.49	.01	15.0*	.81*	1.01*

Summary and conclusions: GLN GN is predominantly renal (73 ± 3 % basal, 90 ± 4 % with E) whereas ALA GN is almost exclusively hepatic (96 ± 1 % basal, 95 ± 2 % with E). E increased fractional extraction of both amino acids. The resultant increase in uptake completely accounted for the increase in renal GN from ALA and GLN. Contrary to current opinion, these results demonstrate that E increases GLN and ALA GN by increasing their transport. Isotopic use of these gluconeogenic precursors permits individual assessment of hepatic and renal GN.

968

The Correlation between Insulin Resistance and the Visceral Fat vs. Skeletal Muscle Ratio (VFSMR) in Middle-Aged Women

Huh KB, Cha BS, Song YD, Lee JH, Lim SK, Kim KR, and Lee HC, Korea

In addition to visceral fat accumulation, bulk of skeletal muscle mass may influence insulin sensitivity via its capacity to store glucose load. We evaluated 129 non-diabetic middle-aged women to investigate the relationships between VFSMR and metabolic variables representing insulin resistance.

Visceral and subcutaneous fat areas at the umbilical area and skeletal muscle areas at the mid-thigh were measured by computed tomogram and VFSMRs and visceral fat vs. subcutaneous fat area ratios (VSR) were calculated. 75gm oral glucose tolerance tests were performed with measuring plasma glucose, insulin and free fatty acid(FFA) levels, and areas under the curve of glucose (Glu-AUC), insulin (Ins-AUC), FFA (FFA-AUC) and glucose/insulin ratio (GIR=Glu-AUC/Ins-AUC), were calculated.

Mean age of the subjects was 50.1±5.2 years and mean VSR and VFSMR were 0.38±0.15 and 0.57±0.26, respectively. Among the metabolic variables, Glu-AUC, FFA-AUC, total cholesterol (TC) and triglyceride (TG) levels were more significantly correlated with VSR than VFSMR, but Ins-AUC, GIR and sex hormone-binding globulin (SHBG) levels were more significantly correlated with VFSMR than VSR. After multiple linear regression analysis with adjustment of age and BMI, VFSMR was the most important anthropometric parameter in Ins-AUC, GIR and SHBG level and VSR in FFA-AUC and TG level. In subjects with VFSMR more than 0.6, age and Ins-AUC were significantly increased(p<0.001) and GIR and SHBG levels were significantly decreased (p<0.001, p<0.01) than in subjects with lower VFSMR. Regardless of the magnitude of VSR, subjects with VFSMR higher than 0.6, were older and showed higher Ins-AUC, GIR and SHBG levels than in subjects with lower VFSMR.

In conclusion, VFSMR may be a better anthropometric parameter indicative of insulin resistance than VSR in middle-aged women.

969

A DEFECT OF SUPPRESSION OF ENDOGENOUS GLUCOSE PRODUCTION CONTRIBUTES TO LIPID-INDUCED GLUCOSE INTOLERANCE.

Rigalleau V, Beylot M, Pacciaudi C, Guillot C, Deleris G, Gin H. Service de Nutrition et Diabétologie, Hopital Haut-lévêque, Pessac, and Centre de Recherche en Nutrition Humaine de Lyon, France.

In normal subjects, a lipid infusion does not greatly impair glucose tolerance, because the inhibitory effect on glucose oxidation seems matched by a rise of non oxidative disposal. But an influence of lipids on Endogenous Glucose Production (EGP) has not been examined during an Oral Glucose Tolerance Test (OGTT). In 6 normal subjects (age 23±2 y; Body Mass Index 21.5±0.4), we performed doubly labelled OGTT (1g.kg-1 maïze glucose, naturally enriched in ^{13}C, to measure exogenous glucose appearance RaE), with a primed-continuous dideuterated glucose infusion to measure total glucose appearance RaT; EGP was calculated as RaT-RaE. Each subject underwent 2 OGTTs, first during a saline (Sa), second during an "Ivélip 20%" (Iv) infusion ($0.015ml.kg^{-1}.min^{-1}$, started 90 minutes before oral glucose charge). The lipid infusion produced a marginal (NS) rise in glucose and insulin levels, but EGP was less suppressed at time 90 min (Sa:0.94±0.38 $mg.kg^{-1}.min^{-1}$, Iv:1.77±0.53; $p<0.05$), and 330 min cumulation of EGP suppression was lower (Sa: -409±24 $mg.kg^{-1}$, Iv: -298±43; $p<0.05$). Despite identical oral charges, RaE was higher under "Ivélip" (330 min cumulation: Sa:872±53 $mg.kg^{-1}$,Iv:1025±82; $p<0.05$), suggesting an increased recycling of ^{13}C. Increased gluconeogenesis may therefore be the cause of the impaired suppression of EGP under lipid infusion.

970

LIPOPROTEIN LIPASE IN MUSCLE OF hHTg RAT IS RELATED TO FATTY ACID COMPOSITION OF MUSCLE PHOSPHOLIPIDS

E. Šeböková, D. Gašperíková, P. Bohov, P. Langer, M.T. Clandinin[1] and I. Klimeš
Institute of Experimental Endocrinology SAS, Bratislava, Slovak Republic and [1]Nutrition& Metabolism Research Group, Alberta University, Edmonton, Canada

Hypertriglyceridemia is closely linked to insulin resistance. Indeed, raised dietary intake of omega-3 (n-3) polyunsaturated fatty acids (PUFA) which leads to lower plasma triglyceride (TG) levels is associated with improvement in insulin action. In order to evaluate the role of lipoprotein lipase (LPL) in the hypotriglyceridemic effect of long chain n-3 FA, the expression of LPL has been measured in skeletal muscle of hereditary hypertriglyceridemic (hHTg) rats which underwent an euglycemic hyperinsulinemic clamp. Before the clamp, groups of animals were fed a basal or a high (63%) sucrose diet with or without fish oil supplement for two weeks. Results were compared to data obtained from control animals subjected to an identical protocol. The expression of LPL was increased in the soleus muscle when the n-3 FA acids were included into the basal or high sucrose diet [B: 6.6±1.1 AU; FO: 24.2±1.8 AU $p< 0.001$; HS+FO: 46.2±2.5 AU, $p< 0.001$]. In addition, similar stimulation of LPL mRNA levels by n-3 FA was found also in hHTg rats [B: 7.9±0.7 AU; FO: 26.2±2.5 AU $p< 0.001$; HS+FO: 24.4±1.5 AU $p< 0.001$]. mRNA levels correlated negatively with plasma TG levels ($r= -0.60$, $n= 16$, $p<0.01$). Moreover, we have found a very significant positive correlation ($r= 0.87$, $n= 32$, $p< 0.001$) between the muscle LPL expression and the GIR (= glucose infusion rate) as a measure of insulin sensitivity. In addition, when the LPL expression was correlated with the content of long chain PUFAs, a highly significant positive correlation between the LPL mRNA and the total percentage of Σ20-22 PUFA in skeletal muscle phospholipids ($r= 0.85$, $n= 32$, $p< 0.001$) was obtained. On the other hand, the LPL mRNA correlated negatively ($r= -0.86$, $n= 32$, $p< 0.001$) with the ratio of n-6/n-3 FAS in muscle phospholipids. Thus, our results indicate that a) increased removal of triglyceride by muscle through the activation of LPL may contribute to the TG lowering effect of fish oil, and the b) incorporation of long chain PUFAs into muscle phospholipids could be an important long-term modulator of the skeletal muscle LPL.

971

UNDETECTABLE CONTRIBUTION BY KIDNEY TO GLUCOSE PRODUCTION IN POSTABSORPTIVE AND 60 H FASTED STATES.

K. Ekberg, B. R. Landau, S. Efendic, A. Wajngot and J. Wahren. Depts of Clinical Physiology and Endocrinology, Karolinska Hospital Stockholm, Sweden.

A-V net balance of glucose across kidney and liver and ^3H uptake after 3 h infusion of (6-^3H)glucose or (3-^3H)glucose were determined in healthy men (n=16), age 28±1 yrs, BMI 23.2±0.4 kg/m^2 after 12 and 60 h of fasting. Individual means were calculated from 9 determinations between 115 and 180 min. Net renal and splanchnic balance were calculated as A-V blood glucose differences times regional blood flow. Glucose uptakes were calculated as A-V difference of ^3H-activity in plasma glucose, divided by the ^3H-activity in arterial plasma glucose, multiplied by arterial concentration of glucose and regional flow. Results (µmol/kg/min):

	12 h		60 h	
Glucose	6-^3H	3-^3H	6-^3H	3-^3H
n	4	6	7	3
Glucose Ra	11.3±1.3	9.3±0.9	8.1±0.2	7.2±0.4
Spl ^3H-uptake	1.9±0.2		0.3±0.4	
Spl Net Balance	-9.6±1.4		-6.7±0.8	
Renal ^3H-uptake	-0.5±0.5	1.0±0.9	-0.1±0.2	0.6±0.9
Renal Net Balance	-0.2±0.3	1.0±1.8	-0.8±0.7	-1.0±0.3

Postabsorptive net balance across splanchnic bed was 9.6 and glucose uptake 1.9, equal to Ra glucose. In accord negligible net production and fractional extraction of glucose across kidney were found. In the 60 h fast 6.7 net balance across splanchnic bed, and 0.3 uptake, accounted for 92 % of total glucose production. Glucose production by kidney was not demonstrated. It is concluded that, postabsorptive contribution of renal glucose production to whole body glucose turnover is negligible; after 60 h of fasting it is about 10 % of total glucose production.

972

TRIGLYCERIDE INDUCED DIABETES MELLITUS DUE TO LIPOPROTEIN LIPASE DEFICIENCY.

G.Mingrone, [‡]F.L.Henriksen, [‡] L.N.Krogh, E.Capristo, G.Benedetti, M.Castagneto, G.Gasbarrini, A.V.Greco and [#]H.Beck-Nielsen. Dept. Internal Medicine & CNR-Dept. Surgery, Catholic University, Rome-Italy; [‡]Dept. Clinical Biochemistry & Genetics and [#]Dept. Endocrinology, Odense University Hospital, Odense, Denmark.

The complete reversal of diabetes mellitus (DM) in two sisters with familial lipoprotein lipase (LPL) deficit and normal apolipoprotein CII levels is reported. All the family members, father aged 48, mother 44, and 3 sisters (Sib1 18, Sib2 16, Sib3 11) were studied. Postheparin plasma LPL was 76.0 mU/ml in Sib1, 117.1 in Sib2, 205.7 in Sib3, 145.0 in the father and 101.7 in the mother. GC-clamped PCR-amplified DNA from the promotor region and 1 to 10 LPL gene exons were screened for nucleotide substitution by denaturing gradient gel electrophoresis. Two polymorphies were found in father's exon 4 (GAG to GAA) both coding for Glu^{118} and in mother's exon 8 (ACC to ACA) both for Thr^{361} while a stop mutation was in mother's exon 9 (TCA to TGA) coding for termination instead of Ser^{447}. The polymorphies in exon 4 and 8 were inherited by Sib 1 and 2. HDL_3 and HDL_2 were lower than normal in the whole family, but particularly in the father and Sib 1 and 2. One to 2 years after development of severe chylomicronemia with diffuse skin lesions, insulin-resistant DM ensued in Sib 1 and 2. Current medical therapy failed normalize triglycerides (TG) and glycemia; thus a modified bilio-pancreatic diversion operation was employed to induce lipid malabsorption. Within three weeks after surgery, plasma TG and cholesterol levels decreased from 56 mM and 12.9 (with dietary restrictions) to <6.2 and 2.84 mM (on free diet) respectively. Fasting glycemia decreased from >16.6 (under daily doses of insulin ≥150 IU) to 4.4-4.5 mM (without any therapy). Body weight and fat-free mass were maintained in Sibs after surgery. Glucose uptake (M) by euglycemic hyperinsulinemic clamp (EHC) and end-clamp glucose oxidation (ECGO) were significantly lower than normal before (M=Sib1;5.61 and Sib2;12.5 µmoles/kgbw/min; ECGO = Sib1; 5.08 and Sib2; 9.24) and not significantly different from normal after surgery (M=Sib1;16.7 and Sib2;20.7 µmoles/kgbw/ min; ECGO = Sib1; 16.3 and Sib2; 19.2). In conclusion our data provide, for the first time, a direct evidence that insulin-resistant DM is determined by high levels of TG and that it can be reversed by decreasing circulating lipid concentration through a lipid malabsorption.

973

Feeding suppresses gluconeogenesis significantly less in Mexican-Americans than in European-Americans: a mass isotopomer analysis study.

A.Balasubramanyam, P.Nadkarni, A.Garza, V.Pavlik, J.A. Herd, A.Rajan, F.Jahoor and P.J.Reeds. Baylor College of Medicine, Houston, TX, USA.

In a previous study we used mass isotopomer analysis to measure gluconeogenesis in healthy Mexican-American men and found that gluconeogenesis was suppressed only modestly after feeding. The aim of this study was to compare the effect of feeding on gluconeogenesis in Mexican-Americans vs. Caucasians. Five Mexican-American men (age 33-63 years, BMI 26-30) and six European-American men (age 35-64, BMI 24-28) were infused intravenously for 6 h with U^{13}C-glucose on two occasions, in the fasting and fed states. All were normoglycemic and normoinsulinemic, with negative history of NIDDM in the immediate family. The infusion rates were 12.5 μmole/kg/h for the "fasting" study, and 20 μmole/kg/h for the "fed" study (when the subject consumed each hour a balanced enteral formula supplying 15 μmole of carbohydrate/kg/min). Mass isotopomer analysis of the pentaacetate derivative of plasma glucose was carried out following positive chemical ionization gas chromatography mass spectrometry. Glucose flux was calculated from the isotopic enrichment of the [M+6]-isotopomer. The enrichments of the [M+1]-[M+3] isotopomers were used with the equations of Katz et al to estimate gluconeogenesis. In the Mexican-Americans, the rate of gluconeogenesis via pyruvate in the fasting state was 5.81 ± 1.51 μmole/kg/min [mean ± SD] and contributed 60% of glucose flux; in the fed state the absolute rate of gluconeogenesis did not change (6.01 ± 0.63 μmole/kg/min) and its contribution to total glucose flux decreased to 37%. In the European-Americans, the rate of gluconeogenesis via pyruvate in the fasting state was 7.08 ± 1.5 μmole/kg/min and contributed 76% of glucose flux; in the fed state the absolute rate of gluconeogenesis decreased significantly (4.29 ± 0.95 μmole/kg/min) and its contribution to total glucose flux decreased to 27%. The effect of feeding on suppression of gluconeogenesis was therefore significantly greater in the European-Americans than in the Mexican-Americans. There were no significant differences between the two groups in plasma insulin levels. The results suggest that ethnic differences exist in the ability to regulate gluconeogenesis in response to feeding. The underlying factors may involve differential hormonal regulation of gluconeogenesis, or variable delivery of enteral glucose to the metabolic pool in the form of 3-carbon precursors.

974

IMPORTANCE OF ALCOHOL FOR THE TRIGLYCERIDE RESPONSE AFTER INGESTION OF AN ORAL METABOLIC TOLERANCE TEST (oMTT)

S. Fenselau, A. Moers, Ch. Laue, W. Stürmer, W. Bauer, J. Schrezenmeir, Inst. of Physiology & Biochemistry of Nutrition, Federal Research Center, Kiel, Germany

The metabolic syndrome is characterized by a cluster of diseases which often coexists: impaired glucose tolerance, NIDDM, dyslipidemia, hypertension and obesity. To prevent these diseases an early detection of predisposition is desired. After ingestion of a liquid formula which contains 4221 KJ energy, 58g mainly saturated fat, 75g carbohydrates, 30g protein and 10g alcohol in a volume of 500 ml (oMTT), in a group of 25 year old men without family history 15% of subjects (High Responders, HR) showed higher pp triglycerides (TG), higher insulin, proinsulin and glucose values which indicates an early state of the metabolic syndrome. This risk profile could be confirmed by a study in sons of parents with complete metabolic syndrome. The oMTT seems to detect the metabolic syndrome at a stage where the oGTT is not yet impaired and might be helpful to early diagnose patients high of risk. To differentiate the impact of its alcohol content we studied 15 Normal Responders (NR) and 8 HR after the ingestion of oMTT with 10g alcohol (wA) and without alcohol (oA). Blood for determination of TG was drawn before, 0.5h and 1h-9h pp.The pp TG values were lower in all subjects in the test without alcohol (AUC ΔTG oA: 372±47 mg/dl vs. ΔTG wA 438±68 mg/dl). HR showed significant higher pp TG after oMTT with alcohol (AUC ΔTG wA: 726±148 vs. ΔTG oA: 387±72 mg/dl, p=0.05). So is was only possible to discriminate NR and HR significantly in the test with alcohol (wA: AUC ΔTG NR: 353±43 vs HR: 726±148 mg/dl; p=0.006 - oA: AUC Δ TG NR: 364±63 vs HR 387±72 mg/dl, p= 0.82). Addition of alcohol to fat seems to be essential for discovering the phenomenon of TG High Response. This may indicate a crucial role of the metabolic response to alcohol (and fat) in the pathogenesis of the metabolic syndrome.

975

ASSESSMENT OF HEPATIC SENSITIVITY TO GLUCAGON IN NIDDM

Michael Nielsen, Steven Wise, Sean Dinneen, W. Frederick Schwenk, Ananada Basu, and Robert Rizza, Mayo Clinic, Rochester, MN

NIDDM is associated with increased rates of endogenous glucose production (EGP) in both the postabsorptive and postprandial states. In order to determine whether these excessive rates of EGP are due to increased hepatic sensitivity to glucagon, 9 NIDDM and 10 nondiabetics (ND) were studied on three occasions. Endogenous hormone secretion was inhibited with somatostatin and replacement infusions of glucagon and growth hormone were given. Constant "basal" insulin infusions (defined as that necessary to maintain glucose at ~ 5 mM) were established in each individual. On one occasion, the glucagon infusion was maintained at 0.65 ng/kg/min (~100 pg/ml). On two different occasions the glucagon infusion was increased to 1.5 and 3.0 ng/kg/min for four hours elevating the glucagon concentrations to ~ 150 and 300 pg/ml, respectively. [6,6-$^2H_2$] glucose and $H^{14}CO_3$ were infused systematically to trace EGP and CO_2 incorporation into glucose (an index of gluconeogenesis). Glycogen was labeled via the direct pathway by having subjects ingest [6-^{3} H] galactose the evening prior to study. Each increase in glucagon resulted in a concomitant but transient (0-120 min) increase in EGP in both groups. The integrated increase in glucose concentration, EGP and CO_2 incorporation into glucose did not differ between groups implying comparable stimulation of EGP and gluconeogenesis. However the ratio of the release of [6-^{3}H] glucose to EGP was lower in the NIDDM than nondiabetic subjects indicating that a smaller portion of glucose released from glycogen was derived from the direct pathway. Glucagon did not alter carbohydrate or lipid oxidation in either group. We conclude that a) glucagon stimulation of glucose production, gluconeogenesis and by implication glycogenolysis, is equivalent in NIDDM and nondiabetic humans and b) a lesser portion of glycogen is derived from the direct pathway in NIDDM. These data indicate that the excessive rates of hepatic glucose release in NIDDM are unlikely to be due to enhanced sensitivity to glucagon.

976

FREE FATTY ACIDS IN DIABETIC KETOACIDOSIS AND DIFFERENT CONTROL OF TYPE II DIABETES MELLITUS

A. Protopopova, L. Koeva and V. Mihova. Medical University, Varna, Bulgaria

The relationship between insulin resistance, glycemia, free fatty acids (FFA) and ketogenesis substantiates a following-up the changes of total and main FFA such as C14:0, C16:0, C16:1, C18:0, C18:1, C18:2, and C20:4 using the gas-liquid chromatography during diabetic ketoacidosis (DKA) 2 days after its coping and 2 months later on after achieving a good control of diabetes mellitus (DM). The study covered 39 patients (21 females and 18 males) with type II DM (mean age of 59±3.1 years, BMI of 26.5±0.8, and ideal body weight of 113.4±0.8%). Ten age, gender and BMI-matched controls were used. During DKA (BGL of 15.32±1.38 mmol/l; HbA/C of 11.3±0.5%, pH of 7.120±0.09; BE of -8.362±4.62; K of 4.093±0.59 mmol/l, and Na of 141.25±1.75), total FFA increased up to 1131.1±170.4 μmol/l. Two days after DKA they reduced down to 826.63±133.98 μmol/l (mean daily fasting Blood Glucose Level (BGL) of 12.0±1.2 mmol/l and postprandial BGL of 19.1±2.7 mmol/l). After 2 months at mean daily fasting BGL of 6.9±0.8 mmol/l, postprandial one of 8.3±1.4 mmol/l and HbA/C of 6.9±0.33%, the total FFA decreased down to 627.036±144.3 μmol/l remaining, however, by 16.1% higher than control values of 539.8±72.5 μmol/l. In DKA and poor control of DM, the elevation of oleic, linolic and palmitic acids and the reduction of arachidonic acid (down to 18.6±2.9 μmol/l) was most outlined. It increased 2 days after DKA up to 20.42±8.8 μmol /l and at improved control up to 25.8±13.8 μmol/l without reaching the control levels of 36.0±20.1 μmol/l. There was no essential dynamics in the percentage ratio of single FFA, of saturated and unsaturated FFA, and of monoenic and polyenic FFA. The changed ratio between the linolic and arachidonic acid was well manifested being 11.6 with DKA, 5.5 with good control, and 2.7 in healthy subjects. The significant changes of FFA in different DM control states confirm metabolism lability.

977

NICOTINE IMPAIRS INSULIN-MEDIATED HEPATIC GLUCOSE HANDLING IN CONSCIOUS DOGS.

M. Matsuhisa, T. Tomita, I. Nakahara, M. Iida, Y. Shiba, M. Wada*, M. Motomura*, T. Kanda*, M. Kubota, and Y. Yamasaki , M. Hori
Osaka University School of Medcine, and *Osaka Prefectural General Hospital, Osaka, Japan

To determine the acute effect of nicotine on insulin-mediated glucose metabolism, we investigated hepatic and peripheral glucose disposal during portal glucose infusion with euglycemic hyperinsulinemic clamp in seven healthy beagle dogs. These dogs were canulated into the femoral artery, portal, hepatic, splenic, and jejunal veins and, were implanted Doppler flow probes around the hepatic artery and portal vein ten days before the experiment. During experiments, insulin was infused intraportally (13.5 pmol/kg/min) and exogenous glucose was administered peripherally to maintain arterial euglycemia. After 120-min metabolic equilibration period and 30-min basal period (period B), glucose (38.9 μmol/kg/min) was administered into the portal vein for 180 min. During portal glucose infusion, nicotine (0.3 μg/kg/min) was administered peripherally for last 90 minutes (period PN(+)) after 90-min of period PN(-). Arterial plasma glucose and insulin levels were comparable among three periods (5.2±0.04 mM, 170±7 pM, respectively). In period PN(+), plasma nicotine concentration was 5.7±0.4 ng/ml and equal to that observed after smoking. Hepatic plasma flow was stable throughout the experiment (B, 18.2±1.8; PN(-), 19.1±2.0; PN(+), 19.8±2.4 ml/kg/min). Peripheral glucose disposal rates were comparable among three periods (B, 70.6±7.8; P, 60.6±5.0; N, 76.7±6.7 μmol/kg/min). Net hepatic glucose uptake was 4.4±1.7 in basal period, and increased to 15.6±1.1 μmol/kg/min by portal glucose delivery in period PN(-). Nicotine administration decreased net hepatic glucose uptake to 8.9±1.7 μmol/kg/min in period PN(+). In conclusion, increase in plasma nicotine levels induces insulin resistance in the liver rather than in the peripheral tissues.

978

THE EFFECT OF 48 HOUR STARVATION ON MUSCLE CARBOHYDRATE AND LIPID METABOLISM IN RAT MODEL OF NIDDM.

I.Kowalska, M.Strączkowski, J.Górski* and I.Kinalska. Department of Endocrinology, Department of Physiology*, Medical School, Białystok, Poland

NIDDM is heterogenous disorder characterised by defect in insulin action and secretion, affecting carbohydrate and lipid metabolism. A rat model of NIDDM can be produced by neonatal injection of a low dose of streptozotocin(STZ) combined with later introduction of a high fat-diet. The aim of the present study was to estimate whether the 48-h starvation influence the glycogen and triacylglycerol (TG) concentrations in muscle and liver in rats with experimental NIDDM. To test this, the glycogen and TG concentration was estimated in the liver and red and white part of the gastrocnemius muscle in basal conditions and after 48-h fasting.Experiments were carried out on male Wistar rats fed from 8 to 11 week of age with isocaloric standard or high - fat diet (59% calories as fat) with previous injection of low dose of STZ (45mg/kg) or vehicle at 2 days of age (I - control group: vehicle + standard diet, II - STZ + standard diet -STZ, III - vehicle + high-fat diet-HFD, IV-STZ+high-fat diet-STZ/HFD). In all groups fasting plasma glucose, insulin, NEFA and TG were measured. Marked hyperglycemia was observed in STZ/HFD group ($p<0.05$). 48-h fasting decreased significantly glucose level in all studied groups. The highest insulin concentration was observed in HFD group, but the difference was not significant. Insulin level decreased after starvation in all studied groups, but statistical difference was observed only in HFD group ($p<0.05$). After starvation glycogen concentration fell significantly in both parts of gastrocnemius muscle in all studied groups vs starved control rats. Basal liver glycogen was markedly lower in HFD ($p<0.05$) and STZ/HFD group($p<0.05$) than in the control. Fasting caused significant decrease in liver glycogen concentrations in all studied groups vs basal conditions. A significant TG accumulation in examined tissues was observed in all studied groups in comparison to control. 48-h starvation decreased TG concentrations in white and red part of gastrocnemius muscle and liver in STZ group and STZ/HFD group. Plasma TG decreased markedly after starvation in control and STZ group ($p<0.01$, $p<0.01$). 48-h starvation did not affect plasma NEFA level in studied groups. We conclude that 48-h starvation increase TG utilization in rat model of NIDDM.

979

INSULIN EFFECTS ON HEPATIC GLUCOSE PRODUCTION: EXTENT AND PATHWAYS. J. Radziuk and Z. Zhang Ottawa Civic Hospital, Ottawa, Canada

The extent to which insulin affects hepatic glucose production (HGP) and the pathways by which this occurs were assessed using dose response determinations during a 120 min recirculating perfusion of livers from twenty-five, 20h fasted rats. The perfusion medium consisted of donor rat erythrocytes in a BSA Krebs Ringer buffer. Initial concentrations of glucose were 100 mg/dl and lactate 40 mg/dl. Lactate was infused at 1 mg/min together with [U-14C]-lactate. Insulin was infused to maintain levels of 0, 70, 175 and 1050 pmol/L. Inflow and outflow concentrations of labelled and unlabelled metabolites were measured. A mathematical model relating lactate, glucose and glycogen fluxes indicated an unchanged fractional flux from lactate to glucose and an insulin dose-dependent increase in the corresponding glycolytic flux (12±4, 17±1, 21±2 and 42±6 $X10^{-3}min^{-1}$) and glycogen synthesis (1.7±0.5, 1.6±0.1, 4.4±0.6 and 6.6±2.3 $X10^{-3}min^{-1}$). This was corroborated in dispersion-corrected estimates of net glucose production: 0.89±0.07, 0.93±0.04, 0.49±0.08 and 0.33±0.08 μmol; mean lactate extraction: 38±2, 42±5, 37±3 and 38±3% and glycogen formation: 0.14±0.04, 0.12±0.02, 0.23±0.04 and 0.32±0.06 μmol glucosyl units. These data indicate, that in the fasting rat liver perfused with lactate as the principal substrate, insulin decreases net HGP by ~ 60%. It does this in the face of an unchanged gluconeogenetic flux from lactate by increasing net glycogen synthesis as well as glycolysis.

980

ALTERED RATIOS OF GLYCOLYTIC TO OXIDATIVE MUSCLE ENZYME ACTIVITIES IN OBESITY

D. Kelley, J.-A. Simoneau, B. Goodpaster, L. Thaete, and N. Mazzei. University of Pittsburgh, Pittsburgh, Pennsylvania, USA

Reduced enzymatic capacity for substrate utilization by skeletal muscle could contribute to the pathogenesis of obesity. To examine this hypothesis, the relationship between glycolytic (Gly) and oxidative (Ox) enzyme activities within skeletal muscle were determined and the proportionality of Gly to Ox was calculated. Enzyme activities were compared to patterns of fat deposition by regression analysis and adjusted for important co-variables. Vmax for hexokinase (HK), citrate synthase (CS), phosphofructokinase (PFK), glyceraldehyde phosphate dehydrogenase (GAPDH) were determined in 50 glucose-tolerant adults (24 M, 26 F), ranging from lean to obese (BMI = 19 to 41 $kg \cdot m^{-2}$). Visceral fat (VFat) was determined by CT and overall adiposity by DEXA. Insulin sensitivity (Rd) was measured using euglycemic clamps (40 $mU \cdot m^{-2} \cdot min^{-1}$) and VO_2max by cycle ergometry. PFK/CS, HK/CS, and GADPH/CS were positively correlated with VFat ($r=0.32$ to 0.38, $p<0.05$), and total adiposity ($r=0.25$ to 0.39, $p<0.05$). Glycolytic capacities were correlated with VFat, though not as strongly as the Gly/Ox ratios. Correlations between Gly/Ox ratios and VFat remained after adjusting for oxidative capacity of muscle, i.e. CS activity. Gly/Ox ratios were also correlated with VO_2max, yet significant correlations with VFat remained after adjusting for this parameter. Gly/Ox ratios were negatively correlated with insulin sensitivity; the relationship of Gly/Ox with VFat was not independent of insulin resistance. In summary, the Gly/Ox enzyme ratios are altered in visceral obesity, reinforcing the concept that perturbations in the capacity of skeletal muscle to oxidize substrates, especially in proportion to its capacity for glycolysis, may have an important role in obesity and its metabolic complications.

981

LOSS OF FUNCTIONAL ZONATION IN HEPATIC ACINUS IN DIABETIC BB RATS.

K. Yamatani, Y. Ikezawa, K. Hama, H. Yamaguchi, M. Daimon, H. Manaka and H. Sasaki

Third Dept. of Internal Medicine, Yamagata Univ., Yamagata, Japan

In the normal rat liver, gluconeogenesis is predominat in the periportal hepatocytes (PPH), whereas gycolysis predominant in the perivenous hepatocytes (PVH) of the hepatic acinus. To know if a diabetic state modify this functional zonation in the hepatic acinus, PPH or PVH was isolated selectively by a digitonin-collagenase method from IDDM model-BB rats, and cultured in 35 mm dishes for 1 h.

Gluconeogenesis from 5 mM lactate, 0.5 mM pyruvate and 5 mM alanine was greater in PPH than PVH (50.3±5.8 vs 33.2±4.1 nmol/mg prot/30 min without glucagon, $p<0.05$, and 66.6±6.0 vs 43.3±4.7 with 100 nM glucagon, $p<0.05$) from non-diabetic BB rats, but was not different between PPH and PVH (56.8±6.9 vs 51.6±5.7 without glucagon, NS, and 98.5±7.6 vs 93.9±6.1 with 100 nM glucagon, NS) from diabetic BB rats.

Lactate release by the addition of 20 mM glucose into the medium was greater in PVH than PPH (21.3±2.0 vs 10.5±1.7 μg/mg prot/60 min, $p<0.05$) from non-diabetic BB rats, but was not different between PPH and PVH (10.1±3.6 vs 9.1±3.0, NS) from diabetic BB rats.

Gycogen content when 20 mM glucose was added into the medium was not different between PPH and PVH from non-diabetic BB rats (33.5±2.1 vs 34.7±2.4 μg/mg prot, NS), or from diabetic BB rats (24.9±10.6 vs 18.2±5.8, NS), respectively.

In conclusion, the functional zonation in the hepatic acinus was lost in diabetic BB rats. This might be responsible for hepatic glucose overproduction in diabetes mellitus.

982

THE ROLE OF LONG CHAIN POLYUNSATURATED FATTY ACID IN THE MODULATION OF INSULIN ACTION IN hHTg RAT

D. Gašperíková, E. Šeböková, P. Bohov, P. Langer, M.T. Clandinin[1] and I. Klimeš

Institute of Experimental Endocrinology, Slovak Academy of Sciences, Bratislava, Slovak Republic and [1]University of Alberta, Edmonton, Canada

We have shown previously that the *in vivo* insulin action in muscles of hereditary hypertriglyceridemic (hHTg) rats correlated negatively with the concentration of circulating triglycerides (Tg). Raised dietary intake of n-3 polyunsaturated fatty acid (PUFA) had been accompanied by increased insulin sensitivity of hHTg rats. The aim of this study was to test the role of long chain PUFA in muscle phospholipids for the modulation of *in vivo* insulin action and glucose transport under conditions of hereditary fixed and diet-induced hypertriglyceridemia. Groups of hHTG rats were fed for 2 weeks 4 types of diets: a) basal diet /BD/, b) BD with marine fish oil (BD+FO), c) high sucrose /= HS; 63 cal%/ and d) HS+FO. Then, euglycemic hyperinsulinemic (6.4 mU/kg/min) clamps were carried out in conscious rats equipped with permanent cannulas in the carotid artery and jugular vein. Skeletal muscles and the heart (collected after the clamp) were used for analyses of FA composition (gas chromatography) of skeletal muscle phospholipids (thin layer chromatography) and GLUT4 gene expression (Northern blot). Correlation analysis of fatty acid composition of skeletal muscle phospholipids with the *in vivo* insulin action of hHTg rats showed a tight positive relationship between the percentage of long-chain PUFAs (C20-22 PUFAs) and the glucose infusion rate (GIR) ($n= 16$, $r= 0.93$, $p<0.001$), and a negative correlation between the ratio of n-6/n-3 PUFA and GIR ($n= 16$ $r= -0.89$, $p<0.001$). HS feeding decreased the GLUT4 mRNA levels of hHTg rat in soleus muscle [HS: 6.9±0.2 arbitrary units (AU); BD: 13.0±1.0 AU; $p< 0.05$] and heart [HS: 1.8±0.3 AU; BD: 3.2±0.3 AU; $p< 0.05$]. Supplementation of HS diet with FO increased GLUT4 mRNA in both tissues [Soleus: 15.6±1.4 AU, $p< 0.05$; Heart: 3.4±0.2 AU, $p<0.05$]. The GLUT4 gene expression correlated positively with the long chain FA content in skeletal muscles ($n= 16$, $r= 0.55$, $p <0.05$) and in the heart ($n= 16$, $r= 0.68$, $p <0.01$). In summary: 1) the *in vivo* insulin resistance of the hHTg rats decreases with increasing proportion of the long-chain PUFAs in muscle phospholipids. 2) Data on GLUT4 mRNA tissue levels point also to a regulatory effect of C20-22 PUFAs on the gene expression for GLUT4.

METABOLIC CONTROL OF MUSCLE GLUCOSE DISPOSAL: MAGNETIC RESONANCE SPECTROSCOPY STUDY IN HUMANS

G. Velho, R. Roussel, P. G. Carlier, C. Wary, G. Bloch. INSERM U-358, Hôpital Saint-Louis, Paris; SHFJ, CEA, Orsay, France

Although the absence of muscle intracellular free glucose (ICG) in euglycemic conditions is direct evidence of glucose transport being the rate-limiting step for glucose disposal, post-transport steps might be involved in the metabolic control of muscle glucose disposal during hyperglycemia. We have previously shown a significant accumulation of ICG (≈0.8 mmol/l) in human muscle during hyperglycemia (≈22 mM) at basal insulinemia. The present study was designed to evaluate muscle ICG accumulation during hyperglycemic hyperinsulinemia in the physiological range. Five healthy men were studied during a hyperglycemic (≈10mM) hyperinsulinemic (≈60mU/l) clamp, with an infusion of somatostatin and ^{13}C-glucose. Extracellular glucose, ICG, and glycogen were measured by ^{13}C Magnetic Resonance Spectroscopy (SMR) of the leg muscles. ICG concentration was calculated from the SMR signal, and from the plasma glucose concentration and ^{13}C enrichment. No significant ICG accumulation was observed: muscle concentration was 0.09±0.07 mmol/l during the second hour of the clamp. Over the same time period, muscle glycogen synthesis rate was 0.26±0.03 mmol/min.l reflecting a rapid glucose uptake. The finding that ICG does not accumulate in conditions mimicking the hyperglycemic hyperinsulinemic situation occuring after a large carbohydrate oral load, strongly supports the predominant role of glucose transport in controlling the overall rate of muscle glucose disposal, not only at euglycemia but also during physiological hyperglycemia.

984

EFFECTS OF SHORT-TERM AEROBIC EXERCISE ON SERUM LIPID LEVELS AND LDL PARTICLE SIZE IN YOUNG MEN.

T. Kazumi, A. Kawaguchi, T. Hozumi, Y. Ishida and G. Yoshino, Hyogo Rehabilitation Center Hospital, Hyogo Medical Center, Kobe University of Mercantile Marine, Toho University School of Medicine, Kobe, Akashi, Tokyo, Japan.

To determine the effects of short-term aerobic exercise on serum levels of lipids, lipoproteins and apolipoproteins (apo), and LDL particle size, 31 nonobese men (mean ± SE body mass index; 22.1 ± 0.6 kg/m^2) aged 18 to 20 years had blood samples obtained just prior to and within 20 min of completion of 3 days of swimming exercise (4h/day). They consumed same diets (4300 kcal/day) during the entire study period. With exercise, they lost their weight from 66.3 ± 1.8 to 65.7 ± 1.8 kg ($P < .001$) and plasma glucose decreased from 4.83 ± 0.06 to 4.17 ± 0.17 mM ($P < .0001$) whereas nonesterified fatty acids increased from 463 ± 37 to 1078 ± 64 μM ($P < .0001$). Levels of total cholesterol decreased 9% from 4.44 ± 0.16 to 4.06 ± 0.10 mM ($P < .001$), LDL cholesterol decreased 14% from 2.74 ± 0.13 to 2.35 ± 0.10 mM ($P < .001$), apoB decreased 17% from 90 ± 4 to 75 ± 3 mg/dl ($P < .001$). Although LDL particle size decreased, postexcercise peak LDL diameter averaged 26.6 ± 0.4 nm, a figure that was shown to be less susceptibility to oxidative modification (pre-exercise, 27.1 ± 0.3 nm). Levels of triglyceride decreased 13% from 0.81 ± 0.05 to 0.71 ± 0.05 mM ($P < .1$), apoCII decreased 40% from 2.5 ± 0.2 to 1.5 ± 0.1 mg/dl ($P < .001$), apoCIII decreased 30% from 8.8 ± 0.4 to 6.2 ± 0.4 mg/dl ($P < .0001$), apoE decreased 14% from 5.0 ± 0.2 to 4.3 ± 0.2 mg/dl ($P < .01$). However, serum levels of insulin, HDL cholesterol and apoAI did not change significantly. Lp(a) levels decreased from 55 ± 10 to 46 ± 8 mg/dl ($P < .005$) in a top-tertile group whereas they did not change in the other two groups. These observations may explain in part the reduced risk of developing vascular disease in individuals who are physically active.

985

MODELS TO MEASURE FLUORODEOXYGLUCOSE TRANSPORT AND PHOSPHORYLATION IN HUMAN SKELETAL MUSCLE FROM PET DATA

S. Lovisatti, P. Nuutila, T. Utriainen, H. Yki-Järvinen and C. Cobelli. University of Padova, Padova, Italy; Turku Medical PET Center, Turku, Finland; University of Helsinki, Helsinki, Finland.

Measuring glucose transport and phosphorylation in skeletal muscle is crucial for understanding of diabetes. Dynamic PET [^{18}F] fluorodeoxyglucose ([^{18}F]FDG) data contain information on transport and phosphorylation of glucose analogue FDG, but a model is required. Several FDG models and numerical identification approaches have been proposed in brain and heart. However these models have never been evaluated in human muscle tissue [^{18}F]FDG data. Here we assess the performance of two of these models. DATA. 5 normal subjects in the basal state received 8 mCi [^{18}F]FDG and dynamic scanning and plasma sampling were performed for 40 min. MODELS. Sokoloff et al. model parameters are 3 (3K model): transport in (ml/min-gram muscle) out (k2, min^{-1}), phosphorylation (k3,min^{1}). Phelphs et al. model assumes that phosphorylation (k4,min^{1}) is also present (4K model). In addition we added to both models a volume term (V,%). Parameters were estimated in each subject by weighted nonlinear least squares with optimal weights, i.e. equal to the inverse of measurement error variance (assumed proportional to counts, inversely to scanning time with a scale factor estimated a posteriori). RESULTS. The 3K model rate parameters were successfully identified: k1=0.031±0.006 (SE), mean precision 10%; k2=0.409±0.0129, 9%; k3=0.032±0.004, 6%. Also V was successfully estimated: 1.1±0.5(16%). The extraction coefficient (ml/min-gram muscle) was 0.23±0.02(3%). The 4K model rate parameters exhibited different values with expected deteriorated precision: k1=0.043±0.012(9%); k2=0.617±0.232(11%); k3=0.053±0.006(16%); k4=0.017±0.002(29%). V was reliably estimated only in 2 subjects. The extraction coefficient was 0.29±0.02(39%). The Akaike parsimony criterion was slightly in favour of 3K model. CONCLUSION. The 3K model with an additional volume term looks the most parsimonious one. The addition of the volume term and an accurate description of the measurement error are of utmost inportance for arriving at a reliable assessment of parameters and their precision. Additional work is required to i) evaluate other models in the basal state; ii) extend the models for studying elevated insulin states; iii) move from an FDG to a glucose picture by measuring the Lumped Constant under different experimental conditions.

986

EFFECTS OF ENDURANCE TRAINING ON MYOCARDIAL AND SKELETAL MUSCLE FATTY ACID BETA-OXIDATION.

T.O. Takala, P. Nuutila, M. Luotolahti, M. Haaparanta, J. Bergman, M. Mäki, J. Knuuti. Department of Medicine and PET Center, University of Turku, Finland.

We have previously shown, that endurance training reduces myocardial and increases skeletal muscle glucose uptake. To measure whether myocardial or skeletal muscle fatty acid oxidation is altered by training, we studied eight male endurance athletes (age 27±2.3 yrs, BMI 21.4±1.0 $kg/m^{2,}$ VO_2max 68±3.4ml/kg/min), and nine sedentary controls matched for characteristics other than VO_2max (49±8.0 ml/kg/min, p<0.001). Myocardial and femoral muscle fatty acid oxidation rates were measured during euglycemic hyperinsulinemia (serum insulin 60mU/L) with 14(R,S)-[^{18}F]fluoro-6-thia-heptadecanoicacid ([^{18}F]FTHA) and positron emission tomography (PET). During hyperinsulinemia whole body glucose uptake was 49 % higher in the athletes than in the controls (59±9.5 vs 40±9.4 µmol/kg/min, p<0.001). Myocardial fatty acid beta-oxidation indexes per kilogram of myocardium calculated by multiplying fractional [^{18}F]FTHA uptake and serum free fatty acid concentration were similar in the athletes and controls (10.1±5.1 vs 10.2±3.8 µmol/kg/min, ns). Skeletal muscle fatty acid beta-oxidation index in femoral region was 1.68±0.76 µmol/kg/min in the athletes and 1.15±0.41 µmol/kg/min in the controls (ns). Myocardial or skeletal fatty acid beta-oxidation rates were not correlated with VO_2max. In conclusion, myocardial and skeletal muscle fatty acid beta-oxidation rates per gram of tissue during euglycemic hyperinsulinemia are not altered in endurance athletes compared to sedentary controls.

987

EXTRACELLULAR AND INTRACELLULAR GLUCOSE UNDER BASAL CONDITIONS IN MAN

F. Shojaee-Moradie, °D.A. Cavan, H. De La Paz , *R. Hovorka, S. Imuere, N.C. Jackson, R.H. Jones and A.M. Umpleby, Dept of Medicine, UMDS, London, °Bournemouth Hospital, Bournemouth, *MIM Centre, City University, London, UK

The glucose analogue, 3-O-methyl glucose (3OMG), is transported by glucose transporters but is not metabolised by intracellular enzymes. It can therefore be used to estimate the rates of glucose transport across the plasma membrane, and in a two compartment model of glucose metabolism it provides a measure of the flux from the central to the remote compartment. Using 3OMG and U-13C-glucose (U13CG) we quantified whole-body glucose kinetics in two fasting normal male subjects each on two occasions using a two compartment model. After basal blood sampling a bolus of U13CG (5 mg/kg) and 3OMG (8 mg/kg) was administered intravenously without perturbing fasting insulin concentrations. Blood samples were taken every two minutes for 20 min, then every 5 min to 90 min. Plasma concentrations of the two tracers were measured by GC-MS analysis. The parameters of the proposed model of glucose kinetics with removal from both compartments were estimated with precision. The fractional rate constants for removal from the central and peripheral compartments were similar (k_{01}:0.93±0.11; k_{02}: 0.95±0.26 $x10^{-2}$ min^{-1}; mean±SD) and both central to peripheral and peripheral to central compartments were k_{21}: 3.38±1.26; k_{12}: 5.14±2.19 $x10^{-2}$ min^{-1}. The distribution volume of the central compartment (148±16 mL/kg) indicated that this compartment can be associated with the extracellular volume. The peripheral compartment was considered to represent the intracellular volume. The model indicated that 36% of the total glucose (1.22±0.23 mmol/kg) is distributed in the intracellular fluid resulting in an intracellular glucose concentration of 1.1 mmol/L (intracellular volume of 400 mL/kg assumed). Intracellular irreversible removal represented 36% of total glucose uptake. The kinetics of glucose transport into and out of the cells is rapid (26±11 and 22±10 µmol/kg/min) compared to hepatic glucose output (11±2 µmol/kg/min). The model suggested that under basal conditions in man intracellular glucose concentration is an important contribution to the total glucose pool.

988

AEROBIC CAPACITY AND INSULIN ACTION

Turpeinen J-P., Lappalainen J., Rantala A., Lilja M., Ikäheimo M., Ebeling T., Savolainen MJ. and Kesäniemi YA. Department of Internal Medicine and Biocenter Oulu , University of Oulu, Oulu, Finland

In this study we focused on the relationship between oxygen uptake in volitional maximal exercise treadmill test and insulin and glucose levels in oral glucose tolerance test (OGTT) in a population based sample of healthy, non-smoking, middle-aged (45 - 65 years) men (n=89). An inverse relationship was observed between $\dot{V}o_{2max}$ and 2-hour insulin level: the regression coefficient was -0.067 (SE 0.023, p=0.00). The relationship was -0.051 (SE 0.023, p=0.02) between anaerobic threshold oxygen uptake (AnT $\dot{V}o_2$) and 2-hour insulin level, -0.112 (SE 0.029, p=0.00) between aerobic threshold oxygen uptake (AerT $\dot{V}o_2$) and 2-hour insulin level. When adjusting $\dot{V}o_2$ and 2-hour insulin level to the body weight, age, exercise amount and intensity, left ventricule mass (LVM/BMI), stroke volume (SV/BMI), volitional effort (respiratory exchange ratio, RER and maximal heart rate, MHR) and smoking history no significant relationship (p=0.11-0.80) was observed between $\dot{V}o_2$ and 2-hour insulin level. When comparing $\dot{V}o_2$ and AUC for glucose we could find significant inverse relationship between $\dot{V}o_{2max}$ and AUC for glucose -0.151 (SE 0.074, p=0.04), between AnT $\dot{V}o_2$ and AUC for glucose -0.193 (SE 0.073, p= 0.01) and between AerT $\dot{V}o_2$ and AUC for glucose -0.397 (SE 0.091, p=0.00). When adjusting $\dot{V}o_2$ and AUC for glucose to the body weight, age, exercise amount and intensity, LVM/BMI, SV/BMI, volitional effort (RER and MHR) and smoking history AUC for glucose at the AerT contributed significantly to this relationship (p=0.00). Comparing the means of glucose and insulin values (oneway ANOVA) between different exercise amount and intensity groups no statistically significant relationship (p=0.14 - 0.92) in any exercise amount or intensity level was observed. In conclusion: 1. poor physical fitness described as AerT $\dot{V}o_2$ is inversely associated to AUC for glucose. 2. In these sedentary subjects no relationship between exercise amount, intensity and insulin or glucose levels was noted.

989

MATHEMATICAL DEMONSTRATION THAT INSULIN RESISTANCE IN OBESE SUBJECTS IS NOT DUE TO SLOW INSULIN TRANSFER ACROSS CAPILLARIES.

D. Araújo, D.A. García-Estévez and J. Cabezas-Cerrato. S. de Endocrinología. C.H U S. Santiago de Compostela University. Santiago de Compostela. Spain

As implemented in their program MINMOD, some of the parameters and variables of the equations representing Bergman's minimal model of glucose metabolism have no simple rational relationship with the kinetic constants and constants of proportionality of the minimal model as such. In this work we implemented the original version of the minimal model, which does not suffer from this problem, and used it to investigate the source of insulin resistance among obese but otherwise healthy subjects. A frequently sampled intravenous glucose tolerance [FSIGT] test was performed in 38 healthy subjects of varying degrees of obesity [standard FSIGT test in 21 and tolbutamide FSIGT test in 17 subjects] in order to compare MINMOD and "modified" equations [M1]. The implementation of the original Bergman's minimal model leads the follow equations: $dG/dt = -[p_1^{M1}+X^{M1}]\cdot G + p_4^{M1}$ and $dX^{M1}/dt = -p_2^{M1}\cdot X^{M1}+p_3^{M1}\cdot I$, being p_1^{M1}: glucose effectiveness at zero insulin; $X_{basal} = [p_3^{M1}/p_2^{M1}]\cdot I_{basal}$ and $p_4^{M1} = [p_1^{M1}+X^{M1}_{basal}]G_{basal}$. Since there was no significant difference between the lean and obese groups as regards p_2^{M1}, the lower insulin sensitivity of the obese subjects may be attributed entirely to the difference in p_3^{M1}, i.e. to differences in k_2 and/or $[k_4 + k_6]$. Assuming that interstitial insulin [I'] is higher in obese subjects than in lean subjetcs, we have mathematically demonstrated that the proportionality constants of the model [k_4 and k_6] were lower in obese subjects than in lean subjetcs, but not the rate constant for insulin transfer across capillaries, k_2. This conclusion follows from the ratio observed between the average p_3 values of lean and obese [ob] subjects, $p_3^{M1}{}_{lean}/p_3^{M1}{}_{ob} = 1.22$ [1]; the ratio observed in this work between $[X^{M1}{}_{lean}]^{AUC}$ and $[X^{M1}{}_{ob}]^{AUC}$, the area under the curve [AUC] of $X^{M1}(t)$ during the FSIGT test, of lean and obese subjects, $[X^{M1}{}_{lean}]^{AUC}/[X^{M1}{}_{ob}]^{AUC} = 1.39$ [2]. Writting explicitly equation 2 $[(k_4 + k_6)\, I'^{AUC}]_{lean} / [(k_4 + k_6)\, I'^{AUC}]_{ob} = 1.39$ [3]. Since $I'_{lean}{}^{AUC} / I'_{ob}{}^{AUC} < 1$ this implies that $[k_4 + k_6]_{lean} / [k_4 + k_6]_{ob} > 1$ and hence $[k_4 + k_6]_{lean} > [k_4 + k_6]_{ob}$. Moreover, since explicitly equation 1 is: $[k_2\,(k_4 + k_6)]_{lean} / [k_2\,(k_4 + k_6)]_{ob} = 1.22$ [4], replacing equation 4 in equation 3: $[k_{2\,ob} / k_{2\,lean}] / [I'_{lean}{}^{AUC} / I'_{ob}{}^{AUC}] = 1.14$. Since $I'_{lean}{}^{AUC} / I'_{ob}{}^{AUC} < 1$, we concluded that $k_{2\,ob} > k_{2\,lean}$. In conclusion, our results suggest that low insulin sensitivity in these subjects is due to receptor and/or post-receptor events rather than to slow transfer of insulin across capillary endothelium into the interstitial space.

990

AEROBIC CAPACITY, INSULIN ACTION AND MUSCLE MORPHOLOGY

Turpeinen J-P[1]., Rantala A[1]., Leppävuori J[2]., Kaila K[3]., Salo J[4]., Lilja M[1]., Savolainen MJ[1]. and Kesäniemi YA[1]. Department of Internal Medicine and Biocenter Oulu[1], Department of Sport Medicine, Deaconess Institute of Oulu[2], Department of Pathology[3], Department of Anatomy, University of Oulu[4], Oulu, Finland

The purpose of the study was to investigate the relationship between oxygen consumption in volitional maximal exercise treadmill test, insulin and glucose levels in oral glucose tolerance test (OGTT) and distribution of muscle fiber type (I and II) in m. vastus lateralis in a population based sample of healthy, non-smoking, middle-aged (45-65 years) men (n=54). Marginal relationship was observed between 1-hour insulin level and muscle fiber type I: the regression coefficient was -0.079 (SE 0.043, p=0.07). A significant relationship was observed between muscle fiber type I and capillary/muscle fiber ratio: 25.4 (SE 10.3, p=0.01). Capillary/muscle fiber ratio was related to $\dot{V}o_{2max}$ 0.837 (SE 0.251, p=0.00) and AnT $\dot{V}o_2$ (anaerobic threshold) 0.407 (SE 0.182, p=0.03). An inverse relationship was observed between muscle fiber type I and RER (respiratory exchange ratio) at AerT (aerobic threshold) -119.6 (SE 57.9, p=0.04). A significant relationship was observed between average muscle fiber type I surface area (μm^2) and body weight (kg) 0.005 (SE 20.6, p=0.01). Body weight was also related to capillary/muscle fiber ratio 0.005 (SE 0.02, p=0.03). In conclusion: 1. One hour insulin level in OGTT might be affected by the histologically determined proportion of muscle fiber type I and thus indirectly by the capillary/muscle fiber ratio. 2. Energy metabolism in maximal treadmill exercise test in sedentary subjects is affected by both muscle fiber type I and capillary/muscle fiber ratio. 3. Size of the muscle fiber type I and capillary/muscle fiber ratio is affected by the body weight.

DIFFERENCES IN KINETICS OF INTRACELLULAR pH AND 31P CELL METABOLITES IN SKELETAL MUSCLE OF NIDDM AND CONTROLS

S. Jacob[1,3], S. Widmaier[1,2], T. Hoess[1,2], E. J. Henriksen[5], M. Bunse[1,2], H. J. Tritschler[4], W.-I. Jung[1,2], O. Lutz[2], H.-J. Augustin[3], and G. J. Dietze[1], [1]Hypertension and Diabetes Research Unit, Max Grundig Clinic, Bühl, [2]Institute of Physics, University of Tübingen, [3]Dept. of Internal Medicine, Baden-Baden, [4]ASTA Medica, Frankfurt, Germany, [5]Dept. Physiology, University of Arizona, Tucson, USA

^{31}P NMR spectroscopy provides a noninvasive and very precise tool to monitor intracellular pH (pH_i) and cell metabolite concentrations such as PCr, Pi, and G6P.

The aim of the present study was to investigate these parameters under hyperglycemic - hyperinsulinemic clamp conditions (DeFronzo protocol with minor modifications) by ^{31}P NMR spectroscopy of the human calf muscle using a Siemens 1.5 T whole-body imager. The spectra of four patients with NIDDM (D) and three normal healthy subjects (N) were recorded at a time resolution of 3.2 min in order to get insight into the time-course of potential biochemical changes.

We found clear differences in the changes of pH_i (see Fig. 1) and PCr between N and D: both parameters were found to decrease markedly more in N as compared to D.

Only in the control group N the corresponding kinetics of G6P exhibits a marked elevation during the first 30 min and remains then almost constant. Pi increases by almost 20 % with minor differences between both groups.

Thus, this technique is capable of detecting incredibly small changes of the intracellular homeostasis of H^+, PCr, Pi, and G6P. Furthermore, the differences found provide additional insight into the impaired glucose metabolism in NIDDM patients.

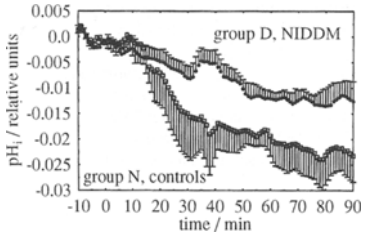

Fig. 1: Relative changes of pH_i in patients with NIDDM (means ± SEM, n=4) and controls (n=3). The time resolution of the original data was 3.2 min per spectrum. To match the clamps in each group, a linear interpolation was carried out leading to an appearantly higher time resolution of 1 min.

992

EFFECTS OF AEROBIC CAPACITY AND FAT MASS ON THE INSULIN RESPONSE AFTER AN ORAL GLUCOSE LOAD

Y.Higaki, N.Shono and M.Nishizumi Dept. of Community Health Science, Saga Medical School, Saga, Japan.

The effects of aerobic capacity and fat mass on the insulin response after an oral glucose load were investigated in 21 college students. The maximal oxygen uptake was measured on a cycle ergometer by the leveling off criterion. Fat mass was measured with an impedance technique. Body mass index (BMI) was calculated as weight divided by squared height. All subjects underwent an oral glucose tolerance test after the overnight fasting period of 12 h. Their subjects were divided into three groups based on their insulin response after an oral glucose load: the first group showed a hyper- and prolonged-insulin response; HI (n=6), the second group showed a lower-insulin response; LI (n=6), and the third group consisted of other subjects; MI (n=9). The maximal oxygen uptake in the HI group (29.6 ± 3.3 ml/kg/min) was significantly lower than that in the LI group (42.5 ± 3.1 ml/kg/min, $P<0.05$). Although no significant difference was observed in the body mass index between the HI (24.6 ± 1.9) and the LI groups (22.2 ± 0.4, $p>0.05$), the body fat and the waist hip ratio were significantly higher in the HI group (26.8 ± 3.5 %, 0.87 ± 0.03) than in the LI group (16.2 ± 1.1 %, 0.76 ± 0.01, $P<0.05$). All subjects in the LI group performed regular exercise, while none of the subjects in the HI group performed any regular exercise. These results may thus suggest that an inactive life style, a decreased aerobic capacity and an increased body fat accumulation all appear to result in an increased insulin response after a glucose load.

993

IN VIVO MICRODIALYSIS WITH 2-(^{18}F)FLUORO-2-DEOXY-D-GLUCOSE FOR STUDYING GLUCOSE METABOLISM: A NEW METHOD

R. Paul, M. Haaparanta, J, Bergman, E.-L. Kämäräinen and O. Solin. Oy Eli Lilly Finland Ab, Vantaa; Turku PET Center, University of Turku; Helsinki University Central Hospital; and Accelerator Laboratory, Åbo Akademi University, Turku, Finland

2-(^{18}F)Fluoro-2-deoxy-D-glucose (FDG) has been validated as a radioactive tracer for measuring glucose metabolism (intracellular uptake and phosphorylation) by positron emission tomography. Microdialysis, again, is a technique for measuring extracellular fluid (ECF) concentrations of substances in tissues in vivo. METHOD: We have combined microdialysis and FDG to follow changes in the extracellular FDG concentration in fasting (N=5) and nonfasting (N=5.) healthy adult Sprague-Dawley rats given a bolus injection of insulin. Anesthetized rats were inserted with microdialysis probes in the jugular vein, liver and femoral muscle. 5-min fractions of the dialysate were collected for 110 minutes; 2 IU of insulin were injected iv. 70 min after the injection of 2.0 - 3.0 mCi (specific activity 2 Ci/ng) of FDG. The proportion of FDG and FDG 6-PO_4 in tissue homogenates at the end of the experiments were determined by HPLC. RESULTS: The elimination $T_{1/2}$ in muscle of fasting rats was lower than fed rats (25±2 min vs. 34±9 min) indicating that glucose is mobilized more slowly from the ECF into the myocytes of fed than fasted rats. Insulin reduced the $T_{1/2}$ in all tissues by about 60 % implying that insulin mobilizes glucose from the plasma into the tissues and from the ECF of muscles into the myocytes. Insulin raised the proportion of FDG 6-PO_4 in all tissues - most markedly in the liver - which agrees with the concept that insulin promotes glycogen synthesis. COMMENT: These and other results obtained by our method (data not shown) agree what is known about the kinetics of glucose and the effects of insulin on glucose kinetics and metabolism. The microdialysis + FDG method is a new and valid method for studying the kinetics and metabolism of glucose in the ECF and agrees well with the results obtained with PET in humans. Pharmacological manipulations can be measured reliably with this method, as shown by the effects of insulin on FDG metabolism. Our method offers also a new approach for studying the effects of drugs on glucose metabolism.

994

THE EFFECT OF SINGLE BOUT OF ENDURANCE EXERCISE ON MUSCLE CARBOHYDRATE AND LIPID METABOLISM IN RAT MODEL OF NIDDM

M.Strączkowski, I.Kowalska, I.Kinalska, J.Górski* Department of Endocrinology, Department of Physiology*, Medical School, Białystok, Poland

A rat model of NIDDM can be produced by neonatal injection of a low dose of streptozotocin (STZ) combined with later introduction of a high fat-diet. The aim of the present study was to estimate whether the single bout of endurance exercise influence the glycogen, triacylglicerol (TG) and phospholipid concentrations in muscle and liver in rats with experimental NIDDM. To test this , the glycogen, TG and phospholipid concentration was estimated in the liver and red and white part of the gastrocnemius muscle in basal conditions and after endurance exercise on a treadmill. Experiments were carried out on male Wistar rats fed from 8 to 11 week of age with isocaloric standard or high - fat diet (59% calories as fat) with previous injection of low dose of STZ (45mg/kg) or vehicle at 2 days of age (I - control group: vehicle + standard diet, II - STZ + standard diet -STZ, III - vehicle + high- fat diet-HFD, IV-STZ + high-fat diet-STZ/HFD). In all groups plasma concentrations of fasting glucose, insulin, NEFA and TG were measured. Marked hyperglycemia was observed in STZ/HFD group ($p<0.05$). Exercise decreased significantly glucose level in all studied groups. Insulin levels decreased after exercise in all studied groups, but no statistical difference was observed. Basal liver glycogen was markedly lower in HFD ($p<0.05$) and STZ/HFD group($p<0.05$) than in the control. Glycogen concentration after exercise fell significantly in examined tissues in all groups in comparison to basal conditions, but did not differ markedly with control group. A significant TG accumulation in examined tissues was observed in all studied groups in comparison to control. Single bout of exercise decreased TG concentration in white and red part of gastrocnemius muscle in STZ/HFD group ($p<0.05$, $p<0.002$) but it remained still significantly higher in studied groups vs respective control values. Exercise did not change significantly plasma TG and NEFA concentrations.A significant decrease of phospholipids concentrations was observed after exercise in all examined tissues in STZ group vs basal conditions.We conclude that single bout of exercise has a beneficial effect on TG metabolism in rat model of NIDDM.

995

THE EFFECT OF BLOOD FLOW ON MUSCLE GLUCOSE UPTAKE DURING ACUTE INSULIN RESISTANCE IN RAT

M Niklasson, A Holmäng and P Lönnroth[1], The Wallenberg laboratory and [1]The Lundberg laboratory for Diabetes Research, Sahlgrenska Hospital, Gothenburg, Sweden

The influence of blood flow on muscle glucose uptake during acute epinephrine (E) induced insulin resistance and ß-adrenergic blockade with propranolol (P) was investigated during an euglycemic hyperinsulinemic clamp in female rats. To assess the interstitial glucose concentration and the local skeletal blood flow, microdialysis was performed in medial femoral muscle in both legs with perfusion by 1% albumin containing ^{14}C-ethanol. The blood flow was assessed indirectly by means of the ethanol outflow : inflow ratio (%). E caused a significant decrease in glucose infusion rate which was completely restored during P-infusion (12.9±1.6 vs. 4.5±0.7, and 13.4±1.7 mg/kg/min, $p < 0.0001$). Interstitial glucose concentrations were significantly higher during ß-adrenergic stimulation (4.7±0.2 vs. 5.5±0.2 mmol/l, $p < 0.05$) which decreased during infusion with P (4.6±0.3, $p < 0.05$). Ethanol outflow : inflow ratio remained unchanged during ß-adrenergic stimulation (8.3±0.7 vs. 9.0±0.8 %, n.s) but decreased significantly during infusion with P (11.1±0.77, $p < 0.05$).
Data show that the rapid reduction of muscle glucose uptake is accompanied by an increase in interstitial glucose concentration without any alterations of the local blood flow. The results indicate that the mechanisms behind acute insulin resistance resides in the muscle cells and that the microcirculation becomes less rate-limiting for the glucose disposal in this state.

996

EXERCISE INCREASES PANCREATIC ß-CELL MASS IN THE OLETF RAT, A MODEL OF NIDDM

K. Shima, I. Kuroda and M. Zhu
University of Tokushima, Tokushima, Japan

Both caloric restriction (D) and exercise training (Ex) ameliorate the diabetic state via similar mechanisms, one of which is an increase in insulin sensitivity. In order to determine if exercise training causes an increase in the ß-cell mass in OLETF rats that show decreases in the proliferative capacity of ß-cells and their mass (Diabetes 45:941, 1996) and whether these interventions act differently, ß-cell masses and insulin content in the pancreata of male OLETF rats were determined after a 9 week period of 70% caloric restriction or spontaneous exercise training using a training wheel. ß-cell mass was quantified by manual point counting of insulin immunostained sections.

Both interventions caused a similar increase in insulin sensitivity in the control OLETF rats [GIR $\mu mol \cdot kg^{-1} \cdot min^{-1}$: 53.9±5.7 (control) vs. 83.8±6.8 (D) and 98.8±10.7 (Ex)], which resulted in lower plasma IRI concentrations for the D group (229±33 pM) and for the Ex group (274±45 pM) as compared to the controls (371±48 pM). The ß-cell mass, adjusted for body weight, was significantly higher for the excercise trained group than for the other two groups [33.6±6.6 (Ex) vs. 24.9±4.9 (D) and 25.4±2.7 mg/kg BW (control)]. In terms of insulin content, a similar trend was found [50.1±8.9 (Ex) vs. 40.8±6.3 (D) and 27.8±8.7 µg/kg BW (control)].

These data suggest that exercise training has a positive effect in terms of ameliorating the diabetic state and that it results in an increase in both ß-cell mass and insulin sensitivity.

997

STEADY STATE INTERSTITIAL MUSCLE INSULIN CONCENTRATION IS LOWER THAN IN PLASMA.

M. Sjöstrand, A. Holmäng and P. Lönnroth. Lundberg Laboratory for Diabetes Research, Department of Internal Medicine, Gothenburg, Sweden

Measurements in lymph and adipose tissue have indicated that interstitial insulin concentration is ~ 40% lower than in plasma. Hitherto, measurements of insulin in muscle interstitial fluid have not been performed. We have developed a new calibrated microdialysis technique allowing correct assessments of interstitial peptide concentrations and this was employed to estimate the insulin concentration in medial femoris muscle in 10 individuals (age:37±3, BMI:25.1±4.3) during an euglycemic hyperinsulinemic clamp. At steady state, b-glucose was 5.7±0.2 $mmol \cdot l^{-1}$, p-insulin was 188±20 $mU \cdot l^{-1}$ and interstitial muscle insulin was 99±22 $mU \cdot l^{-1}$, ($p<0.01$). At a higher insulin infusion rate steady state p-insulin concentration was 444±52 $mU \cdot l^{-1}$, and interstitial insulin 330±33 $mU \cdot l^{-1}$ ($p<0.01$). The data show for the first time that high physiological and supraphysiological plasma insulin levels give 30-50% lower interstitial concentrations of insulin in the muscle and, further, suggest the importance of capillary delivery as a regulating step for the insulin effect.

998

COST BENEFIT ANALYSIS OF A PHYSICAL ACTIVITY PROGRAMME FOR PATIENTS WITH NIDDM

N. Latham, M. Dudfield andH.J.Bodansky.

Regular exercise is an accepted component of the management of NIDDM, but despite the benefits of exercise, few patients follow an exercise prescription. This study aimed to measure the cost and benefits of a holistic programme designed to encourage NIDDM patients to take regular exercise. Over 6 weeks, 234 consecutive outpatients previously diagnosed with NIDDM (107 female, 127 male; age 57 ± 10; age range 31-78,) were invited to attend a local leisure centre for exercise testing, lifestyle counselling and participation in a supervised physical activity programme. Only 27 (11%) attended testing and counselling with 14 (6%) participating in the physical activity programme for 3 months. Costs incurred were: leisure professionals time £187; exercise testing and screening £420; activity classes £272; administration £263; total cost £1142 (£81 per person). After 3 months participation, according to a questionnaire appraisal, 13 subjects benefited from enhanced physical, mental and social well being. In conclusion, the initial costs of this method were high for such a low participation rate, yet, it is clear, that individuals attending greatly valued the holistic benefits and their involvement. Alternative less expensive strategies are urgently required to encourage and motivate more NIDDM patients to exercise regularly.

999

SKELETAL MUSCLE, A SITE FOR THE ANTIDIABETIC EFFECT OF S15261. AN *IN SITU* MICRODIALYSIS STUDY.

O. Della-Zuana, E. Douillet and J. Duhault, Institut de Recherches Servier, Suresnes, France

In obese, insulin-resistant ageing rats and in a model of NIDDM (sand rat), chronic treatment with L-3 [2- [2- [4- [α - fluorenylacetylaminoethyl] benzoyloxy] ethylamino] 1-methoxyethyl]trifluoromethylbenzene (S15261) resulted in an increase of peripheral insulin sensitivity as revealed by the intravenous glucose tolerance test and by euglycaemic hyperinsulinaemic clamp. It could be considered that up to as much as 70 % of the glucose supplied i.v. is metabolized in the muscles. Since the clamp showed no effect of the drug on hepatic glucose production skeletal muscles are a putative target for S15261. **Aim of the study**: Microdialysis was used to gain insight into the substrate exchanges in the interstitial space of skeletal muscle of anesthetized (Forene®) male Sprague Dawley rats treated with vehicle or S15261 10mg/kg or 25mg/kg orally. **Methods**: The dialysis probes were inserted parallel to the muscle fibers between the soleus and the gastrocnemius and perfused with 5mM ethanol in Ringer buffer. The dialysis perfusion flow was 1µl/min. Following a stabilization period (40 min) the animals were treated with the vehicle or the drug and samples were collected every 20 min during the subsequent three hour-period. Ethanol, lactate and glucose in the dialysate were measured by enzymic methods. **Results**: The inverse ethanol outflow/inflow ratio (initial 5.06±0.4) remains constant throughout the study in any group, indicating the absence of variation in the local blood flow. Basal dialysate glucose concentration (mM) were 5.55±0.48, 4.77±0.38 and 4.78±0.19 in control, S15261 10mg/kg and S15261 25mg/kg treated rats respectively. Only in the latter two groups was a significant decrease in glucose concentration in the dialysate observed (-16% $p \leq 0.01$ and -31% $p \leq 0.001$ respectively). Similarly the lactate concentration (0.96±0.08 mM) in the dialysate was decreased only in the treated groups (a 38% decrease $p \leq 0.001$ and a 48% decrease $p \leq 0.001$ respectively) versus the initial values. **Conclusion**: The ethanol technique provides a valid measure of change in local tissue blood flow. No change was observed in control or treated groups. Both glucose and lactate concentration were decreased in S15261 treated rats only. The present results taken together with previous data favour a peripheral site of action for this drug, although the exact mechanism of action remains unknown.

1000

RESISTANCE TRAINING IMPROVES THE METABOLIC PROFILE IN INDIVIDUALS WITH NIDDM.

J.Eriksson, A.Honkola and T.Forsén. Soini Primary Health Care Center, Soini, Finland and National Public Health Institute, Helsinki, Finland.

Background and objectives: Aerobic endurance exercise has traditionally been advocated in the treatment of non-insulin-dependent diabetes mellitus (NIDDM) while the potential role of resistance training has often been overlooked. The aim of the present study was to determine the effect of circuit-type resistance training on blood pressure, lipids and long-term glycemic control (HbA1c) in NIDDM subjects.

Methods: Thirty eight NIDDM subjects were enrolled in the study; 18 NIDDM subjects participated in a 5 month individualized progressive resistance training program (moderate intensity, high-volume) twice a week, while 20 NIDDM subjects served as controls.

Results: The exercise group showed improvements in total cholesterol (6.0±.3 to 5.3±.3 mM; $p<0.01$), LDL-cholesterol (3.90±.22 to 3.35±.21 mM;$p<0.01$) and triglycerides (1.91±.25 to 1.53±.22 mM; $p<0.01$). Also the difference between the change in HbA1c (0.5%) between the groups reached statistical significance ($p<0.01$).

Conclusions: Circuit-type resistance training seems to be feasible in moderately obese, sedentary NIDDM subjects and the inclusion of circuit-type resistance training in exercise training programs for NIDDM subjects seems appropriate.

BLUNTED VASODILATORY EFFECT OF INSULIN IN HYPERTENSIVE OBESE SUBJECTS

K. Magnusson, H. Siebecke, T. Heise, C. Weyer, L. Heinemann and P.T. Sawicki; Dept. of Metabolic Diseases and Nutrition, Heinrich-Heine-University of Düsseldorf, Germany

We studied the vasodilatory effect of insulin in obese patients with insulin resistance and essential hypertension. The reproducibility of insulin induced changes in blood flow was measured in 8 obese hypertensive subjects (age 32±9 years; BMI 31.8±5.8 kg/m², systolic BP 149±16 mm Hg, diastolic BP 89±13 mm Hg (mean±SD)) and 10 healthy subjects (age 22±2 years (p=0.119); BMI 22.6±2.0 kg/m² (p=0.002); systolic blood pressure 125±11 mm Hg, diastolic 74±10 mm Hg (both p<0.01)) by means of venous occlusion plethysmography (Compactus 712, Gutmann, Eurasburg, Germany) on two different study days. Blood flow was measured in 10 min intervals during hyperinsulinaemic euglycaemic glucose clamps (target blood glucose 5.0 mmol/l, study duration 6 h) with three different insulin infusion steps (120 min each): 0.5, 2.5 and 5.0 mU/kg/min. Mean blood flow values of both legs were calculated. Insulin resistance of the obese hypertensive patients was indicated by a significantly lower insulin sensitivity index (1.6±0.4 ml/min/1.73 m² / µU/ml) in comparison to healthy volunteers (2.9±1.0 ml/min/1.73 m² / µU/ml; p=0.002). No significant differences were observed between both days within the groups (p=0.300 and 0.676). Infusion of insulin increased blood flow significantly (p<0.05) in healthy subjects from 3.2±0.6 ml/min/100 ml tissue during infusion step 1 (serum insulin 132±30 pmol/l) to 4.4±0.6 (802±125 pmol/l) in step 2 and 4.7±1.0 (1782±362 pmol/l) in step 3. In contrast, blood flow did not change in obese hypertensive subjects from 3.3±0.6 ml/min/100 ml tissue during infusion step 1 (serum insulin 275±167 pmol/l) to 3.7±0.5 (1267±157 pmol/l) in step 2 and 3.9±0.6 (3638±1568 pmol/l) in step 3, indicating lack of major dilatory effect of insulin on vasculature of obese hypertensive subjects. The blood flow values and their changes registered on day 2 were comparable to those registered on day 1. In conclusion, a consistant resistance to the vasodilatory effect of insulin was observed in obese hypertensive subjects. This may contribute to the development of essential hypertension in these patients.

1002

LOW HABITUAL TOTAL ENERGY EXPENDITURE IS ASSOCIATED WITH THE METABOLIC CARDIOVASCULAR SYNDROME N.J.Wareham[1], S.H.J.Hennings[1], C.D.Byrne[2], N.E.Day[1]. Departments of Community Medicine[1] and Clinical Biochemistry[2], University of Cambridge.

To investigate the role of habitual energy expenditure in the aetiology of the metabolic cardiovascular syndrome (MCS), 164 randomly selected volunteers aged 30-40 years were recruited from a population register and underwent a standard 75g oral glucose tolerance test. 4-day total energy expenditure were assessed using the heart rate monitoring method with individual calibration of the relationship between energy expenditure and heart rate. This method has previously been validated against doubly-labelled water and is an accurate, cheap, non-invasive and objective method for estimating energy expenditure. Energy expenditure was expressed as physical activity level (PAL), a weight independent measure where PAL = total energy expenditure (MJ/day) / basal metabolic rate (MJ/day). A sub-group of 22 subjects underwent 4 day heart rate monitoring on 3 further occasions at 4 monthly intervals. From these repeat tests the reliability coefficient for PAL was determined. This coefficient is required to adjust the odds ratio for measurement error in the exposure. The MCS was defined as the presence of one or more of 4 features of the syndrome (hypertriglyceridaemia, low HDL cholesterol, impaired glucose tolerance or diastolic hypertension). The odds ratio between increasing quartiles of PAL and the MCS was 0.68 (95% c.i. 0.47-0.99, p=0.043). Adjustment for measurement error corrected this odds ratio to 0.40. We conclude that low habitual energy expenditure is associated with this syndrome and that the strength of the association is heightened by adjusting for measurement error.

1003

MYOCARDIAL GLUCOSE UPTAKE IS ENHANCED IN ESSENTIAL HYPERTENSION INDUCED LEFT VENTRICULAR HYPERTROPHY.

H.Laine, P. Nuutila, M.Luotolahti, A. Jula, I. Kantola, H.Yki-Järvinen and J. Knuuti. Turku University Departments of Medicine and Turku PET-Center, Turku, Finland.

We have previously shown that insulin stimulated myocardial glucose uptake (GU) is increased in untreated patients with essential hypertension without left ventricular hypertrophy (LVH-). In the present study we determined whether hypertension, with or without LVH, alters insulin stimulated glucose uptake via alterations in heart oxygen consumption. For this purpose, heart GU, flow and oxygen consumption were measured in 7 nondiabetic hypertensive men with LVH (LVH+; age 42±2 yrs, LV mass 161±9 g/m²) treated with ACE-inhibitors or/and Ca-antagonists (BP 136± 15/81±5 mmHg), in 10 similarly treated hypertensive patients without LVH (LVH-,LV mass 109±14 g/m², BP 134±16/86±10 mmHg) and in 6 normotensive normal men (CONT, 129±10/79±6). Myocardial GU and oxygen comsumption were measured during euglycemic hyperinsulinemia (insulin ~70 mU/L) using PET. Myocardial GU (µmol·100g⁻¹·min⁻¹) was 38% higher in LVH+ (109±26) than in CONT (79±18, p<0.05) and averaged 96±8 µmol·100g⁻¹·min⁻¹ in LVH-. Myocardial blood flow was similar in all groups. Myocardial oxygen consumption (mL·100g⁻¹·min⁻¹) was positively correlated with myocardial glucose uptake (r=0.59, p<0.01). When glucose uptake was compared between groups using oxygen consumption as a covariate, glucose uptake rates did not anymore differ between the groups. These data demonstrate that the impact of hypertension on insulin stimulated heart glucose uptake can be attributed to differences in cardiac energy requirements as determined by direct measurement of heart oxygen consumption in vivo.

EXCESS PURINE DEGRADATION DURING SEMI-ISCHEMIC FOREARM TEST IN DIABETIC PATIENTS.

Y.Tanaka[1], I Hisatome[1], K Narasaki[1], S Teshima[1], H Ochi[1], T Ikeda[1], Shigemasa[1], and A Takeda[2] 1: Tottori University, Yonago, Japan. 2: Matsue Red Cross Hospital, Matsue, Japan.

The aim of this study was to investigate whether the microvascular abnormality exists in the skeletal muscle of diabetic patients. In eleven diabetic patients and six healthy controls, forearm exercise was performed by squeezing a hand dynamometer for 2 minutes at one second interval under semi-ischemia by pressing upper arm with mean arterial pressure. Venous blood samples were collected from the antecubital vein to measure blood lactate, plasma ammonia (NH_3) and hypoxanthine (HX) at 0, 2, 6, 12, and 60 minutes after exercise. We defined seven patients as the excess response group (E) in whom plasma HX increment exceeds the mean+2S.D. levels of the control group (C) and the other four patients as the normal response group (N). The maximum increments in plasma HX and NH_3 in E (16.8±3.2 µmol/l and 122±60 µmol/l) were significantly greater (p<0.05) than those in C (3.6±3.0 µmol/l and 32±34 µmol/l) and N (2.9±2.9 µmol/l and 27.4±12.7 µmol/l). There were no significant differences in plasma HX and NH_3 between N and C. The maximum increment in plasma lactate was observed at 2 minutes in all three groups. The maximum increments in plasma lactate both in E (5.4±1.5 mmol/l) and N (3.6±1.0 mmol/l) were significantly higher (p<0.05) than that of C (1.7±0.5 mmol/l). Plasma lactate level in N promptly decreased to the level of C at 4 minutes. In E, however, plasma lactate level was kept still higher than those in other groups even at 10 minutes. The prevalence of diabetic retinopathy was higher in E than in N (86% vs. 25%). These data indicate that microvascular abnormality was developed also in the skeletal muscle of diabetic patients.

1005

Insulin resistance and hypertension:role for microcirculation?

E.H. Serné, C.D.A. Stehouwer, J.C. Ter Maaten, P.M. ter Wee, J.A. Rauwerda, A.J.M. Donker and R.O.B. Gans. Department of Internal Medicine AZVU, ICaR, Vrije Universiteit, Amsterdam, The Netherlands.

The association between hypertension and insulin resistance is well established but presently unexplained. Among several possible explanations, a connection between the two abnormalities can be envisioned at the level of the microvasculature in skeletal muscle (Figure). To test this hypothesis skin microcirculatory function was assessed in a group of 14 healthy, normotensive, glucose tolerant and non-smoking subjects, age 33±14.5 yrs (mean±SD), BMI 24.3±3.1 kg/m^2 showing a wide range in insulin sensitivity. Insulin sensitivity was assessed with the hyperinsulinaemic euglycaemic clamp technique and expressed as M/Ix100 in mg/kg/min per pmol/l. Videomicroscopy was used to measure skin capillary density and capillary recruitment after occlusion. Skin blood flow responses to acetylcholine (Ach, which acts via the endothelium) and sodium nitroprusside (SNP, a smooth muscle relaxant) were evaluated by iontophoresis in combination with laser Doppler fluxmetry. 24-h ambulatory blood pressure monitoring was used to measure blood pressure. Insulin sensitivity showed a large variation (0.87-4.41) and correlated with mean arterial blood pressure (MAP) during daytime (r=-0.50, p=0.05). Percentage capillary recruitment correlated with 24-h MAP (r=-0.58, p<0.05) and insulin sensitivity (r=+0.82, p<0.01). Furthermore, Ach-mediated vasodilation correlated with insulin sensitivity (r= +0.84, p<0.01) and percentage capillary recruitment (r= +0.69, p<0.01) but not with MAP. SNP-mediated vasodilation did not show a correlation to MAP or insulin sensitivity. In conclusion, microcirculatory function may link insulin resistance to elevated blood pressure.

SUPPRESSION OF INSULIN-INDUCED VASODILATION IN INSULIN RESISTENT NIDDM PATIENTS.

J. KINOSHITA, Y. TANAKA, T. TOJIMA, T. ONUMA and R. KAWAMORI. Dept. of Medicine, Juntendo University, Tokyo, Japan.

Aim and Methods. To evaluate the vasoactive effect of insulin on insulin resistance, blood pressure, cardiac output and total vascular resistance of 16 NIDDM patients without macroangiopathy were investigated by non-invasive pressure wave analysis in forearm during hyperinsulinemic euglycemic clamp study. ***Results.*** During the clamp study, mean blood pressure (MBP) remained unchanged. Cardiac index (CI; cardiac output/body surface area) significantly increased by 31% (P<0.01) at 2 hour after initiating insulin infusion. In contrast, total peripheral resistance (TPR) decreased by 23% (P<0.01) at that time. Although no significant correlation between glucose infusion rate (GIR) as a marker for the muscular insulin sensitivity and the increasing rate of CI during clamp study was observed, the decreasing rate of TPR showed positive correlation with GIR (r=0.59 at 1 hour and r=0.65 at 2 hour; both P<0.05. ***Conclusion.*** These results suggest that an impairment of insulin-induced vasodilation may associate with muscular insulin resistance. Thus, increment of cardiac output and suppression of insulin-induced vasodilation may contribute to pathogenesis of hypertension in insulin resistent NIDDM patients with hyperinsulinemia.

DIVING ON INSULIN

U. Thurm, C. Lutrop, M. Lerch and R. Landgraf, University Clinic, Munich, Germany

Until now insulin - dependent diabetics are banned from every scuba - diving activity by the majority of the scuba diving associations and the majority of physicians. No study has been performed, to investigate, if diabetics can dive safely under controlled conditions. Based on some basic research a special open water scuba diving course for IDDM has been organized. The training included detailed metabolic control (i. e. blood glucose, hematocrite, blood pressure, fluid intake, pulse rate and lactate testing prior and after each dive, detection of exertion level and mean air consumption) in seven diabetic divers and age, sex and diving experience matched seven non - diabetic control persons. The participants for the course came from Australia, Europe and the United States. They had been selected carefully, considering their general physical and medical fitness and the quality of diabetes control and care and knowledge and management of their disease. It was found diabetic divers had to drink additional amounts of fluid (up to twice the amount required for non - diabetic divers) to effectively avoid dehydration. All diabetic divers had to reduce their short - acting insulin between 30% to 70 % before each dive and their long - acting insulin up to 50% to avoid hypoglycaemia. The reduction had to be increased according to the numbers of dives per day and the amount of diving days. Additionally they had to increase their daily carbohydrate intake up to 200 %. All adaptations had to be done with each diver on an individual basis, according to his/ her blood glucose levels measured 60, 30 minutes and directly before and after every dive - the blood glucose levels prior to the dive were aimed to be in a range between 180 - 240 mg/ dl, afterwards around 100 - 140 mg/ dl. By these limits any episode of hypoglycaemia under water was avoided and ketones were not present at any time. This research project showed that careful selection of the participants in combination with a structured training programme including special under water carbohydrate intake (glucose gel) can enable insulin - dependent diabetics to dive safely.

1009

INCREASED NORADRENERGIC PRESSOR RESPONSE, BUT NORMAL PERIPHERAL VASCULAR NORADRENERGIC RESPONSE IN NIDDM .

FC Huvers, CHA de Haan, AJHM Houben, PW de Leeuw, BHR Wolffenbuttel, NC Schaper; Dept. of Int. Medicine, university hospital Maastricht, The Netherlands.

Introduction: An increased pressor response to an i.v. infusion of noradrenaline (NA) has been reported in NIDDM, compatible with an increased vascular smooth muscle cell (VSMC) responsiveness to NA. Since systemic (i.v.) infusions are difficult to interpret as no distinction can be made between central and peripheral effects, we performed both systemic (i.v.) and local NA infusions in normotensive, non-obese, NIDDM patients to determine blood pressure, forearm arteriolar and peripheral venous NA responsiveness. **Patients and Methods:** 16 NIDDM patients, median age 61(57-63) yrs. (interquartile ranges), BMI 25.2 (24.3-26.1) kg/m^2, mean arterial pressure (MAP) 93 (89-98) mmHg, and 17 healthy volunteers (HV), 58 (53-63) yrs., BMI 24.9 (23.0-25.7) kg/m^2, MAP 93 (85-100) mmHg were studied. In *study I* (n=9 and 10, resp.) the response of forearm blood flow (FBF) to 3 doses of ***i.a.*** NA (0.025, 0.1, 0.4 μg/min) was measured by strain gauge plethysmography. Subsequently, the systemic ***i.v.*** NA dose which elevated MAP by 20 mmHg was determined (NA20). In *study II* (n=14 and 14, resp.) the venous constrictor response to a cumulative local infusion of NA was measured in a dorsal handvein.The maximal venous constrictive response (Emax) and the drug dose generating half maximal response (EC50) were calculated. **Results:** In *study I* no differences were observed in FBF responsiveness to ***i.a.*** NA. The NA20 dose was lower in the NIDDM patients relative to HV: 5.3 (4.1-7.6) vs 8.0 (6.1-10.0) μg/kg/min, $p<0.04$. In *study II* no differences were observed in EC50 and Emax between the NIDDM subjects and the HV: 1.09 (0.82-1.35) vs 0.81 (0.60-1.02) log ng/min and 94 (82-107) vs 87 (79-94)%, respectively. **Conclusions:** Non-obese normotensive NIDDM patients have an increased pressor response to NA. This increased response is not related to a defect in skeletal muscle resistance arterioles or peripheral veins. Probably a defect is present in the baroreceptor system and/or other vascular beds in NIDDM.

1010

INCREASE IN ENDOGENOUS LACTATE IN RESPONSE TO EXERCISE DOES NOT PROTECT THE BRAIN DURING HYPOGLYCAEMIA IN HUMANS.

P.Bottini, C.Lalli, A.Baccarelli S.Pampanelli, M.Ciofetta, P.Del Sindaco, M.Lepore, P.Brunetti and G.B.Bolli. University of Perugia, Perugia, Italy.

Experimental infusion of *exogenous* lactate (LACT) protects brain metabolism and function during insulin hypoglycaemia (hypo). To test the hypothesis that also spontaneous increase in *endogenous* LACT, such as that occurring during exercise, exerts similar effects, plasma counterregulatory hormones (adrenaline and noradrenaline, A and NA; glucagon, IRG; growth hormone, GH; cortisol, CORT) and autonomic and neuroglycopenic symptoms score (AS, NS) were measured in 7 normal volunteers during hypo+exercise (Study 1, S1), or hypo without exercise (Study 2, S2) or exercise without hypo (Study 3, S3) (random order). Steady-state exercise (cycloergometer, 80 min at 110 watts) was performed in S1 and S3, whereas in S2 subjects remained seated. Insulin (1 mU/kg/min) + variable glucose were infused iv from 20 to 80 min to induce hypo in S1 and S2 (plasma glucose 2.8 mmol/l) or maintain euglycaemia in S3. Results.

	Hypo+ Ex+ (S1)		**Hypo+ Ex-** (S2)		Hypo- **Ex+** (S3)	
(min)	0	80	0	80	0	80
LACT(mmol/l)	1.1±0.1	3.2±0.4	1.2±0.1	1.8±0.1	1.3±0.1	2.8±0.3
A(nmol/l)	0.3±0.1	8.1±1.1	0.2±0.04	3.7±0.8	0.3±0.1	0.6±0 2
NA(nmol/l)	2.3±0.2	7.7±0.9	1.7±0.2	2.4±0.3	1.74±0.2	6±0.9
IRG (pg/ml)	242±23	407±44	212±24	302±43	252±21	251±26
GH (μg/l)	2.7 ±1.2	80±10	1.4±0.6	37±10	1.4±0.2	31±10
CORT (nmol/l)	386±93	552±83	386±83	469±83	386±138	303±140
AS (score)	1.5±0.4	9±1.1	1±0.3	6.9±1.6	1.6±0.8	5.3±1.1
NS (score)	0.6±0.2	8±1.3	0.4±0.2	6.6±0.3	0.2±0.1	3±0.8

Conclusions. In the only physiological condition in which *endogenous* LACT increases, i.e. exercise, counterregulatory hormone and symptom responses to hypo are not blunted. The fact that the brain responds to decrease in plasma glucose, not to increase in LACT, indicates that the former, not the latter is critical for brain metabolism and function.

1011

EVIDENCE OF BLUNTED INSULIN KINETICS IN NIDDM PATIENTS - A MICRODIALYSIS STUDY

P.-A. Jansson, P. Sandfloo and P. Lönnroth, Lundberg Laboratory for Diabetes Research, University of Göteborg, Göteborg, Sweden.

Previous studies have shown that capillary delivery might be ratelimiting for the effect of insulin in both animals and man. These findings suggest that the capillary endothelium could be a regulating step of importance for mechanisms behind insulin resistance. In the present study we employed abdominal subcutaneous microdialysis (BAS ultrafiltrating membrane, cut off 30kD, 1 μl/min) during a two-step euglycemic insulin clamp. Ten male non-insulin dependent diabetic (**NIDD**) and 10 male non-diabetic control subjects (**C**) were studied after fasting overnight (Age: 57±2 (Mean±SE) vs 57±2 yrs, BMI: 29.3±0.90 vs 30.4±1.6 kg/m^2, P-Insulin: 12±2 vs 10±2 mU/l and B-HbA1c: 7.1±0.4 vs 4.7±0.2 % ($p<0.001$), respectively). During a low insulin infusion rate (**L**) (120-mU/m^2/min) mean peripheral steady state insulin concentrations during the last hour were 217±40 vs 207±15 mU/l (n.s.) and after a rapid switch to a high insulin infusion rate (**H**) (240-mU/m^2/min) mean peripheral insulin levels were 452±96 vs 543±49 (n.s.), respectively. There was a significant delay in T_{max} for interstitial insulin in **NIDD** (129±9) as compared to **C** (73±10 min) ($p<0.01$) but no significant differences between the groups in the subcutaneous insulin levels at each step were seen. Furthermore, glucose infusion rate (GIR) during the insulin clamp was lower in **NIDD** than in **C** at both **L** (7.16±0.78 vs 9.27±0.78 mg/kg/min, $p<0.05$) and **H** (8.60±0.85 vs 10.59±0.63, $p<0.05$). In conclusion, the data indicate similar abdominal subcutaneous insulin levels but a slower increase in interstitial subcutaneous insulin in NIDDM compared to non-diabetic subjects during an insulin clamp. Capillary delivery of insulin seems, thus, to be delayed in NIDDM.

1012

SCIATIC NERVE SEVERANCE PRODUCES HAEMODYNAMIC CHANGE AND INSULIN RESISTANCE IN MUSCLE

J.M. Youd, S. Rattigan, M.A. Vincent and M.G. Clark. University of Tasmania, Hobart, Australia

Severance of the sciatic nerve *in vivo* leads to insulin resistance in previously innervated lower leg muscles. In the present study a modified constant-flow perfused rat hindlimb technique (femoral veins cannulated) was used to assess intrinsic vascular resistance, oxygen uptake, and insulin sensitivity of the 24 h-denervated lower leg (DL) compared to the sham-operated contralateral lower leg (CL) and sham-operated (both leg) control hindlimbs (S2L). Insulin (2 mU.ml^{-1})-mediated 2-deoxyglucose uptake was impaired in tibialis anterior, extensor digitorum longus, gastrocnemius white, plantaris and soleus of DL when compared to CL. There was evidence for changes in vascular resistance: perfusate flow from DL (1.87±0.2) was lower than that from CL (3.04±0.20; $P<0.05$, n=5) which was higher than that of either leg of S2L (2.2±0.1 ml.min^{-1}.leg^{-1} ;$P<0.05$, n=5). Perfusate aorta-femoral vein oxygen differences were unchanged [585±24 (DL), 610±15 (S2L) and 513±12μM (CL)], and thus the oxygen uptake ($\dot{V}O_2$) was less for DL (66.0±8.2) than CL (93.3±6.0 μmol.h^{-1}.leg^{-1};$P<0.05$, n=5). It is concluded that sciatic nerve severance in one leg leads to a loss of insulin sensitivity when compared to the contralateral leg. Perfused hindlimb studies reveal a haemodynamic change with decreased flow in the denervated lower leg, compensated by an increased flow in the contralateral lower leg. Decreased $\dot{V}O_2$ by the denervated lower leg is consistent with a decrease in muscle nutritive flow, which may account for the apparent insulin resistance.

1013

RESTING ENERGY EXPENDITURE IN SOUTH ASIANS AND WHITES WITH TYPE 2 DIABETES MELLITUS.

P. Pacy, V. Bhardwaj and Robinson A.C.J.[1] Edward V11 Hospital, Windsor, UK and [1] St Mary's Hospital, London, UK.

Insulin resistance syndrome is more common in South Asians than whites. This study was designed to examine whether this reflects differences in energy expenditure. Resting energy expenditure (REE) was measured between 5-45 minutes by indirect calorimetry (Deltatrac) after a 10h overnight fast. There were no differences in clinical characteristics (mean ± SD) between South Asians (19M, 10F; age 54 ± 10 years; weight 78 ± 20 kg; body mass index 29 ± 7 kg/m^2; diabetes 6 ± 5 years; fat 29 ± 13%; HbA1c 8 ± 2%) and Whites (19M, 10F; age 57 ± 8 years; weight 79 ± 12 kg; body mass index 29 ± 5 kg/m^2; diabetes 5 ± 5 years; fat 29 ± 10%; HbA1c 8 ± 2%). In comparison to whites, South Asians had lower measured REE (1547 ± 258 versus 1684 ± 203 kcal/d, unpaired t-test p< 0.05) with Department of Health predicted values of 1631 ± 245 and 1641 ± 197 kcal/d respectively. In contrast REE/fat free mass was similar (30 ± 7 versus 31 ± 5 kcal/kg). We suggest that the lower REE in South Asians not only predisposes them to positive energy balance and hence weight gain and ultimately insulin resistance but will reduces the therapeutic impact of calorie restriction.

1014

INSULIN ACTION IN ADIPOCYTES FROM BLACK AND WHITE WOMEN: RELATIONSHIP TO VISCERAL FAT AND INSULIN SENSITIVITY INDEX, Si.

J Albu, JA Johnson, SK Fried, and FX Pi-Sunyer, Columbia University, New York, NY and Rutgers University, New Brunswick New Jersey, USA.

We assessed adipocyte insulin resistance in 23 black (B) and 23 white (W) obese (BMI 35±1 vs. 36±1, mean±SEM), age-matched, premenopausal, non-diabetic women when body fat distribution was characterized by magnetic resonance imaging of visceral (VAT) and subcutaneous abdominal (SCAT) adipose tissue. B and W groups were not different with regard to VAT area (119±11 vs. 142±13 cm^2, range 33-239 in B and 25-258 in W) or VAT/SCAT area ratio (0.29±0.03 B, 0.30±0.03 W). *In vivo* insulin sensitivity of glucose metabolism was also measured as sensitivity index (Si) by the minimal model (2.3±0.5 B and 2.5±0.5 W, p=NS). *In vitro*, insulin's effects on glucose metabolism and on lipolysis were measured in collagenase-isolated abdominal subcutaneous adipocytes. Insulin sensitivity (as ED50) and responsiveness (as the difference between response at baseline and the maximal insulin concentration) were measured against lipolysis stimulated by either adenosine deaminase (ADA) or 8-bromo cyclic AMP (8brcAMP), and for glucose transport (GT) using trace amounts of ^{14}C-glucose. Insulin ED50 for ADA-stimulated lipolysis was related to VAT/SCAT ratio ($p<0.05$), similarly in B and W women. Insulin ED50 for either ADA- or 8brcAMP-stimulated lipolysis was also related to Si ($p<0.05$) similarly in B and W women. In contrast, VAT/SCAT and Si did not correlate with ED50 of insulin to stimulate GT, but it did relate to the responsiveness of GT to insulin (GTR) in W ($p<0.05$) but not in B women. In W women, both Si and GTR decreased with a high VAT/SCAT, while B women maintained a uniformly lower responsiveness of GT to insulin in adipose tissue. We conclude that a) abdominal subcutaneous adipocytes from B and W women with comparable levels of visceral adiposity are equally sensitive to the antilipolytic effect of insulin; and b) there is a dissociation between the effect of insulin on lipolysis and on GT in adipose tissue of B women. This may relate to the higher propensity to obesity and diabetes for B as compared to W women, independent of adipose tissue distribution.

1015

RESTING ENERGY EXPENDITURE IN NON INSULIN DEPENDENT (NIDDM) DIABETIC MEN

P. Pacy, A.C.J. Robinson[1], V. Bhardwaj, R.Gray[1] and R Scott. Edward V11 Hospital, Windsor, UK, [1]St Mary's Hospital, London, UK.

Dietary manipulation remains the cornerstone of management in NIDDM. Daily calorie intake is calculated from resting energy expenditure (REE) and physical activity levels. The limited ability to measure REE results in this variable being derived by predictive equations. This study was designed to examine the validity of this approach. The clinical details (mean ± SD) of the NIDDM men were: n = 69; age 57 ± 10 years; weight 85 ± 18 kg; body mass index 28 ± 5 kg/m^2; HbA1c 8 ± 2%; duration of diabetes 5 ± 5 years). REE was measured (MREE) after 10h overnight fast by indirect calorimetry (Deltatrac) between 5-45 minutes and compared with that derived from Schofield (S), Harris-Benedict (HB), Owen (O), Department of Health (DH) and Mifflin (M). Overall no significant differences (paired t-test) were noted between MREE (kcal/d), 1752 ± 289 and 1736 ± 278 (S), 1722 ± 306 (HB), 1746 ± 188 (O) or 1789 ± 243 (DH) although that of 1656 ± 243 (M) was lower (p< 0.0001). The limit of agreement between measured and derived values (bias ± 95% CI) was very wide highlighting the problems in using predictive REE to calculate energy requirements in individuals although they appear satisfactory in NIDDM as a group. This finding is similar to non diabetics.

1016

IN VIVO LIPOLYSIS IN OBESE, NONDIABETIC, BLACK AND WHITE WOMEN: RELATIONSHIP TO VISCERAL FAT DISTRIBUTION

J Albu, DE Matthews, and FX Pi-Sunyer. Columbia University, New York, NY and University of Vermont, Burlington, VT, USA.

We examined the relative contribution of visceral vs subcutaneous abdominal adipose tissue (VAT and SCAT areas, by magnetic resonance imaging) to the systemic lipolytic rates (LIPO), measured *in vivo* with deuterated glycerol and ^{13}C-palmitate infusions (as turnover rates, RaGlyc, RaPalm). LIPO was measured in the basal state in 21 black (B) and 18 white (W), obese (BMI, mean±SEM, 35±1and 34±1; % fat by DEXA, 45±1 and 46±1), premenopausal (36±1and 34±1 yrs), nondiabetic women and, in a subset of subjects (10B and 10W), during a pancreatic euglycemic clamp, at lower (42±18 pM) and then higher (114±30 pM) insulin (I) levels. B and W women were matched by VAT(116+10 and 125±13; range 33-239 and 25-258 cm^2) and VAT/SCAT. Basal RaPalm was same(139±10 vs 135±8 umole/L, p=ns) while basal RaGlyc was slightly lower in B women (244±14 vs 285±15, umole/L, $p<0.06$). The degree of suppression of LIPO by I during the clamp (%S) varied widely (56-72% and 14-69% for RaGlyc, and, 28-55% and 19-64% for RaPalm, for B and W groups, respectively). The slopes of the relationship between basal RaGlyc, basal RaPalm, %S of palmitate or glycerol and regional fat were not different between groups, even after adjusting for age, total fat mass (FM) and fat free mass (FFM), therefore results of multiple regression are for the groups combined. Basal RaPalm related significantly to WHR ($r=0.32$, $p<0.05$) and SCAT ($r=0.43$, $p<0.01$) but not to VAT($r=0.1$, p=ns), while basal RaGlyc related significantly to VAT($r=0.4$, $p<0.05$) and not to SCAT ($r=0.22$, p=ns). After adjusting for age, FM and FFM, none of the body fat distribution variables significantly predicted RaPalm or RaGlyc. %S did not relate to SCAT; only VAT was a predictor of %S after adjusting for age, FM and FFM, partial $r= -0.76$, $p<0.001$ for RaGlyc and partial $r=-0.62$, $p<0.05$ for RaPalm). In obese, nondiabetic women, the absolute amount of VAT accumulation does not appear to significantly contribute to the basal FFA turnover rates, although VAT is the best predictor of the ability of insulin to suppress lipolysis systemically.

1017

RELATIONSHIP BETWEEN HUMAN LEPTIN AND SUBCUTANEOUS FAT BUT NOT VISCERAL FAT

S. King, J. Bryson, C. Burns, R. Donnelly and I. Caterson. Dept of Endocrinology, Royal Prince Alfred Hospital, Camperdown, NSW, Australia.

Leptin, the protein product of the obese *(ob)* gene produced by adipocytes has been shown to be elevated in obesity and related to body mass index (BMI) and % body fat. Central visceral obesity is associated with many metabolic defects, including insulin resistance. The aim of this study was to investigate the relationship between circulating leptin levels, the type of body fat and insulin resistance in nondiabetic obese subjects before and after 12 weeks on a dietary regime. 22 subjects were included in the study (10M, 12F; BMI: 38.3 ± 0.95 ; Age 20 - 52 years). Insulin sensitivity was measured by hyperinsulinaemic euglycaemic clamp (40mU/m^2/min). Subcutaneous and visceral adipose tissue areas were determined by a single scan computerised tomography at L4. Fasting serum leptin was measured using a human leptin RIA kit (Linco). Before intervention, fasting serum leptin levels ranged from 8.13 - 81.33 ng/ml, with females having significantly higher levels than males (F: 49.0 ± 5.6; M: 17.2 ± 1.3, $p < 0.0001$). Leptin was associated with BMI ($r = 0.519$, $p = 0.0134$) and WHR ($r = -0.564$, $p = 0.0063$) but not fasting insulin ($r = 0.274$, $p = 0.2166$) or insulin sensitivity ($r = 0.198$, $p = 0.3762$). Leptin was highly correlated with subcutaneous fat ($r = 0.612$, $p = 0.0065$) but not visceral fat ($r = 0.010$, $p = 0.9643$). Insulin sensitivity was negatively correlated with visceral fat area ($r = -0.508$, $p = 0.0158$). Weight loss was accompanied by reduced subcutaneous and visceral fat areas and improved insulin sensitivity. Serum leptin levels fell significantly in the males but not in the females. The same relationships seen pretreatment between leptin levels, fat distribution and insulin sensitivity were maintained after intervention. These studies confirm the relationship between insulin resistance and visceral abdominal adiposity and suggest that circulating leptin is not related to the degree of insulin sensitivity or visceral obesity but is related to the amount of subcutaneous fat.

1018

DO GENES OR ENVIRONMENT EXPLAIN THE RELATIONSHIPS BETWEEN CENTRAL FAT, INSULIN AND GLUCOSE?.

K Samaras[1], TV Nguyen[1], AB Jenkins[2], PJ Kelly[3] and LV Campbell[1]. 1 Garvan Institute of Medical Research, 2 University of Wollongong, NSW, Australia; Twin Research Unit, St Thomas' Hospital, London UK.

Central adiposity, a pivotal component of Syndrome X, is under strong genetic influence and closely relates to fasting insulin and glucose. Whether these inter-relationships are due to shared genetic or environmental influences is not known.

To address this, we studied a group of 220 healthy female twins (59 MZ pairs, 51 DZ pairs, mean age (±SD) 52±14 years, BMI 25.4±4.2kg/m^2). Fasting glucose was measured by the glucose oxidase method, insulin by radioimmunoassay and central fat by dual energy X-ray dispersive absorptiometry.

Central fat was positively related to log insulin ($r=0.59$, $p=0.0001$) and glucose ($r=0.49$, $p<0.001$). Log insulin related to glucose ($r=0.25$, $p=0.0002$). Univariate model-fitting indicated the heritability (proportion of phenotypic variance attributed to genetic factors) for central fat, insulin and glucose was 57%, 44% and 77% respectively. Multivariate modelling (Cholesky decomposition analysis) indicated 27% (of the 57%) of the genetic variance of central fat is due to genes shared with insulin, while no genetic influence is shared with glucose. On the other hand, the majority of heritability of glucose (73%) is due to specific genes that regulate glucose and only 4% is shared with genes that affect insulin. Shared environmental influences explained 46% of the covariance observed between insulin and central fat and 57% of the covariance between glucose and insulin. The reciprocal model of glucose influencing fasting insulin levels fit the observed data best, rather than the converse model where insulin regulates glucose.

These data suggest the relationship between insulin and central fat is not solely genetic but that substantial common environmental influences exist. These results reinforce the need for ongoing work to modify environmental influences whilst the respective genes are being identified.

RELATIONSHIP BETWEEN PLASMA LEPTIN LEVEL AND FAT DISTRIBUTION IN JAPANESE NIDDM PATIENTS

H. Maruyama, H. Hirose, K. Nakamura, and T. Saruta.
Keio University School of Medicine, Tokyo, Japan

Leptin, recently discovered peptide secreted exclusively from adipocytes, regulates appetite and energy expenditure. In this study, we investigated the relationship between plasma leptin level and blood pressure (SBP and DBP), plasma glucose and lipid profiles (TC, TG, HDL-C and FFA) and fat distribution (V-fat and S-fat) in mildly- to moderately-obese Japanese NIDDM patients (aged 57±13, BMI 26.7±3.4, HbA1c 7.3±1.5% (SD)). Plasma leptin and insulin were measured with RIA (Linco and Eiken Co., respectively). In men, plasma leptin (5.0±2.6 ng/ml, n=73) was correlated with BMI (r=0.64), DBP (r=0.34), IRI (r=0.43), FFA (r=0.31), S-fat (r=0.77) and V-fat area (r=0.67); and in women (6.2±1.0 ng/ml, n=38) with BMI (r=0.63), IRI, (r=0.70) and S-fat area (r=0.67) ($p<0.05$ for all). There was no correlation between leptin and FPG or HbA1c. These data suggest that plasma leptin is associated with insulin, DBP, FFA and fat distribution in Japanese NIDDM patients.
