Abstract

Aims/hypothesis Pancreatic islets have evolved remarkable, though poorly understood mechanisms to modify beta cell mass when nutrient intake fluctuates or cells are damaged. We hypothesised that appropriate and timely adjustments in cell number occur because beta cells release proliferative signals to surrounding cells when stimulated by nutrients and ‘bleed’ these growth factors upon injury.

Materials and methods In rat pancreatic islets, we measured DNA content, insulin content, insulin secretion after treatment, immunoblots of apoptotic proteins and the uptake of nucleoside analogues to assess the ability of γ -aminobutyric acid (GABA), which is highly concentrated in beta cells, to act as a growth and survival factor. This focus is supported by work from others demonstrating that

GABA increases cell proliferation in the developing nervous system, acts as a survival factor for differentiated neurons and, interestingly, protects plants under stress.

Results Our results show that DNA, insulin content and insulin secretion are higher in freshly isolated islets treated with GABA or GABA B receptor agonists. Exposure to GABA upregulated the anti-apoptotic protein B-cell chronic lymphocytic leukaemia XL and limited activation of caspase 3 in islets. The cellular proliferation rate in GABA-treated islets was twice that of untreated controls.

Conclusions/interpretation We conclude that GABA serves diverse purposes in the islet, meeting a number of functional criteria to act as an endogenous co-regulator of beta cell mass.

Keywords Apoptosis · Beta cells · GABA · GABA B receptor · Insulin secretion · Islet mass · Islet survival · Pancreatic islets · Proliferation

Abbreviations

BCL	B-cell chronic lymphocytic leukaemia
EC ₅₀	median effective concentration
GABA	γ -aminobutyric acid
GBR1	GABA B receptor subunit 1
GBR1-C	C-terminus of GABA B receptor subunit 1
GBR1-N	N-terminus of GABA B receptor subunit 1
GBR2	GABA B receptor subunit 2

Introduction

To maintain requisite hormonal stores, beta cells of the pancreatic islet are continuously remodelled through cell death and division. If healthy individuals increase nutrient

intake, for example, beta cell turnover is shifted toward expansion [1–3]. Significant increases in cell division are also observed when beta cells are injured [4, 5]. Present understanding of how injury or increased nutrients convert to signals enhancing cell mass is limited. The lineage studies by Dor et al. provided critical data suggesting that the mature beta cell, rather than an undifferentiated ‘progenitor,’ is central to this routine renewal process [6]. Nevertheless, much remains to be determined of how signals converge to initiate beta cell turnover under normal or adverse conditions.

Ideal regulators of islet cell renewal would be mediators of growth secreted by beta cells on nutrient stimulation and present at sufficiently high concentrations to act locally if leaked when beta cells are injured. Beta cells contain two candidates that meet these criteria, insulin and γ -aminobutyric acid (GABA). Much is known about the systemic role of insulin signalling in growth, and recent evidence also suggests that insulin mediates local beta cell growth responses [4, 7]. In addition, mounting evidence implicates GABA, predominantly viewed as a neurotransmitter, as an evolutionarily conserved regulator of survival and growth processes [8]. In plants, both GAD, as the enzyme of GABA synthesis, and GABA are upregulated with changes in pH or temperature [9] or with ripening [10], suggesting a role in plant protection. Additional evidence supports a role for GABA in plant development [11]. Similarly, GABA appears to be a conserved regulator of survival and growth in animals, having been shown to induce the maturation of red abalone from larvae to adults [12] and stimulate proliferation in regions of neurogenesis in the mammalian brain [13]. GABA also participates in neuronal migration [14], dendritic arborisation [15], the survival of striatal neurons [16] and proliferation of cerebellar neurons [17]. Accordingly, the presence of GAD and GABA signalling in both plants and animals suggests a signalling system conserved over billions of years [18].

In animals, GABA is synthesised and stored in peripheral organs as well as in the central nervous system. The highest concentration of GABA peripherally is found in beta cells of the pancreatic islet [19], at levels comparable with those observed in GABAergic brain nuclei [19, 20]. Work by others indicates GABA is released from beta cells in response to nutrients and depolarisation through a calcium-regulated secretion pathway [21–24]. Using electrophysiology, Wendt et al. estimated that concentrations of GABA within the islet reach levels sufficient for GABA to act as a paracrine signal [25]. Presently, however, information is limited concerning the functional consequence of GABA in pancreatic islets. GABA has been reported to act in part to inhibit islet alpha cell activity and glucagon secretion [21, 24, 25], but the available evidence is conflicting with regard to the role of GABA in regulating

insulin release from beta cells [26, 27]. Here we have examined the alternative possibility that GABA acts through receptor-mediated pathways to regulate growth and/or survival, as observed in other systems. This hypothesis is supported by the fact that the low concentrations necessary to modulate secretion locally are incongruent with the high concentrations of GABA present in beta cells.

The effects of GABA are mediated through three receptor types, ionotropic GABA A and GABA C receptors and metabotropic GABA B receptors. GABA B receptors contain two known subunits, GABA B receptor subunit 1 (GBR1; includes six splice variants) and GABA B receptor subunit 2 (GBR2), which heterodimerise to activate downstream effectors, in part via G protein-coupled signal transduction pathways. The GABA B receptor also contains a carboxy-terminal coiled-coiled domain shown to interact with transcription factors [28, 29] that provides a means to influence cellular responses independently of G proteins [30].

The present studies were undertaken to test whether physiological concentrations of exogenous GABA regulate cell replication or survival properties in freshly isolated rat pancreatic islets. The process of islet isolation, an important component of therapeutic strategies now under development for functional reconstitution of islets in diabetes, is known to increase cell death through apoptosis [31]. We found that GABA could prevent this cell loss and influence islet cell plasticity. We therefore used pharmacological agents and protein immunoblots to identify the receptor subtypes involved in this process and the downstream mediators of receptor signalling. Overall, the results support the hypothesis that GABA, released by islet cells during nutrient stimulation or due to cell injury, may act in an autocrine/paracrine manner to support or regenerate the number of islet cells necessary to maintain glucose homeostasis. This local, immediate signal would allow for rapid and efficient modification of islet cell number in response to increases in nutrient intake or acute cellular injury.

Materials and methods

Materials Fibrinogen, GABA and baclofen were from Sigma (St Louis, MO, USA), SCH50911 (a GABA B receptor antagonist) was from Tocris (Ellisville, MO, USA) and bromodeoxyuridine from Roche (Indianapolis, IN, USA). The CyQuant assay was from Molecular Probes (Eugene, OR, USA). Medium 199/Earle’s balanced salts was from Invitrogen (Carlsbad, CA, USA). Insulin radioimmunoassay reagents were from MP Biomedicals (ICN, Irvine, CA, USA). Immunoblot protein was measured using Micro BCA (bicinchoninic acid) reagents from Pierce (Rockford, IL, USA). C-terminus of GBR1 (GBR1-C) and GBR2 primary antisera were from Chemicon (Temecula,

CA, USA). Antiserum to N-terminus of GBR1 (GBR1-N) was raised in rabbit by Research Genetics (Carlsbad, CA, USA) using the 16 amino acid peptide corresponding to residues 201–216 of the GABA B receptor 1a subunit. Mouse anti-BrdU was from Becton Dickinson (San Jose, CA, USA). The secondary antisera rhodamine red-X anti-rabbit and Cy2 anti-guinea pig were from Jackson ImmunoResearch (West Grove, PA, USA). For immunoblotting, rabbit anti-B-cell chronic lymphocytic leukaemia (BCL)-XL was from Cell Signaling Technology (Beverly, MA, USA) and horseradish peroxidase-coupled anti-rabbit antiserum was from Bio-Rad (Hercules, CA, USA). The protease inhibitor was from Roche. Hepatocyte growth factor was from R & D Systems (Minneapolis, MN, USA).

Islet isolation and incubation Islets were isolated according to the method of Gotoh et al. [32] from pancreata of 150–200-g male Sprague-Dawley rats that were anaesthetised (pentobarbital 100 mg/kg i.p.) and subsequently killed. Islets were then size-selected to be <200 µm in diameter. Animals were maintained according to the rules and standards of the NIH and the Institutional Animal Care and Use Committee of Tufts University School of Medicine. To measure DNA content, islets were manually divided (while on ice) and placed in groups of ~80 islets per well in 96-well tissue culture plates. The islets were plated in contact with each other and in a small volume to allow adherence before the addition of medium to 200 µl. They were maintained at 37°C, in a CO₂ incubator, in M199 medium with Earle's balanced salts, 38 mmol/l NaHCO₃, 5.6 mmol/l HEPES, 10% normal calf serum and 10 mmol/l nicotinamide. For quantification of ³H-labelled thymidine incorporation, 35 hand-picked, freshly prepared islets were secured within a fibrin gel as described by Beattie et al. [33]. Islets were kept on ice during selection and plating. Once the fibrin gel was firm, M199 medium, modified as described above, was added to a final volume of 100 µl. To quantify BrdU labelling of islet cell nuclei, 40–50 freshly isolated islets were suspended in 10 µl of M199 medium with additives as listed above and allowed to attach to tissue culture treated 96-well plates, after which 200 µl of the modified M199 medium was added.

Measurement of DNA content Freshly isolated islets were incubated for 60 min with GABA (100 µmol/l), *S*-baclofen (100 µmol/l) or GABA plus the GABA B receptor antagonist SCH 50911 (100 µmol/l) or left untreated. These reagent concentrations are standard for all known GABA receptors, which are low-affinity and require micromolar amounts for saturation [34]. Unless otherwise stated, the glucose concentration in the suspending medium was 5.6 mmol/l. The islets were transferred to medium lacking test agents and incubated for an additional 3.5 h at

37°C. Incubation with 2× lysis buffer was at 37°C overnight, followed by freezing and thawing, and trituration through a 27-gauge needle. DNA content was quantified fluorometrically using the CyQuant assay according to the manufacturer's instructions.

Immunohistochemistry To reproduce conditions of islet isolation and enhance receptor expression, 6 ml of medium M199 were infused into the pancreatic duct of an anaesthetised rat. The pancreas was removed and incubated for 30 min in a 50-ml tube in a 37°C water-bath and agitated to simulate islet isolation, but in the absence of collagenase. The pancreas was fixed in neutral-buffered 2% paraformaldehyde for 30 min, then cryoprotected for quick freezing and sectioning at 8 µm. Sections were blocked for 1 h in PBS containing 3% normal goat serum and 0.2% triton, washed with PBS and incubated overnight at 4°C with primary antibodies diluted to the following concentrations: insulin (1:100), GBR1-C (1:2000) GBR1-N (1:2500) and GBR2 1:1,000. The sections were washed and incubated with secondary antibodies for 20 min at room temperature.

Measurement of insulin content Islet cell lysate (100 µl) was frozen for measurement of total cellular insulin. The lysate was diluted 1:7,500 in PBS and 100 µl of that dilution (or standards) were added to tubes lined with antibodies to insulin. Manufacturer-supplied buffer (Valeant Pharmaceuticals) containing ¹²⁵I-labelled insulin was added to each tube to bring the final volume to 1 ml. The tubes were incubated at room temperature overnight and washed, after which bound ¹²⁵I-labelled insulin was assayed on a gamma-counter.

Measurement of insulin secretion after treatment Freshly isolated small islets (20–30) were plated in clusters in 60–90 µl respectively of M199 medium in half-diameter 96-well plates. Islets were incubated for 60 min with test reagents, as above, or left untreated. After incubation, the medium was changed to KRB with 2.8 mmol/l glucose for washing and equilibration. The low-glucose medium was removed and fresh KRB with 11 mmol/l glucose was added for 60 min of islet incubation at 37°C in a 5% CO₂ incubator. The supernatant fraction was removed for measurement of insulin by RIA as described above.

Western blot For immunoblotting of BCL-XL, freshly isolated islets were incubated at the designated times, homogenised in radioimmuno-precipitation buffer (50 mmol/l Tris HCl, 150 mmol/l NaCl, 1% NP-40, 0.5% sodium deoxycholate, 0.1% SDS), subjected to SDS-polyacrylamide gel electrophoresis (75 µg/lane, 10% gels), transferred to nitrocellulose membranes and probed with

anti-BCL-XL antibody at 1:1,000 dilution. The same methods were used for the immunoblot of cleaved caspase 3, except that polyvinylidene difluoride membranes were used and probed with anti-caspase 3 antibody at 1:3500 dilution. Chemiluminescence was detected with reagents (SuperSignal West Femto; Pierce).

³H-labelled thymidine incorporation Freshly isolated islets in fibrin clots [33] were incubated for 1 h at 37°C in M199 medium containing varying concentrations of either baclofen or GABA along with 0.037 MBq/ml ³H-labelled thymidine. The medium was replaced with medium plus ³H-labelled thymidine but lacking GABA and baclofen and the islets incubated for an additional 3.5 h at 37°C. For time-dependent experiments, the duration of islet incubation with GABA in medium with 0.037 MBq/ml ³H-labelled thymidine varied between 0 and 90 min. The islets were then incubated without test reagents in medium M199 with 0.037 MBq/ml ³H-labelled thymidine for a total of 4.5 h. Islets were washed with PBS and 100 µl cold 5% trichloroacetic acid was added for 20 min to remove unincorporated label. The islets, in fibrin clots, were lysed by overnight incubation in 100 µl NaOH (1 mol/l). A shorter incubation time resulted in incomplete lysis. NaOH neutralisation was with 100 µl HCl (1 mol/l). Radioactivity was quantified using a liquid scintillation counter (Beckman, Fullerton, CA, USA).

Bromodeoxyuridine labelling Freshly isolated islets were incubated with 30 µmol/l BrdU in the presence or absence of GABA (100 µmol/l) or hepatocyte growth factor (20 ng/ml) for 1 h. The culture medium was replaced with fresh medium lacking both GABA and hepatocyte growth factor. After overnight culture, the islets were washed, immersed in optimal cutting temperature Tissue-Tek (Bayer, Pittsburgh, PA, USA) and quick-frozen in moulds. Sections (8 µm) were post-fixed for 10 min in acetone, followed by washing in PBS and denaturation by treating for 5 min with PBS containing 0.5% triton and subsequent exposure to 1.5 mmol/l HCl for 30 min. Sections were blocked, exposed to mouse anti-BrdU 1:50 for 1 h, washed and antibody labelling detected using Cy2 anti-mouse secondary antibodies (1:50 dilution). Nuclei were counterstained with propidium iodide (0.0001%).

Analysis of data The results reported in this manuscript reflect the findings of three or more experiments. The significance of changes was determined by one-way ANOVA followed by Tukey's multiple comparison test for significance or when sample size was less than ten (baclofen dose-response experiments) the Kruskal–Wallis test followed by Dunn's multiple comparison test. Chi-square analysis was used to determine the significant differences of treated and

untreated BrdU-labelled nuclei with significance defined as a change associated with a *p* value of less than 0.05.

Results

Islets treated with GABA and GABA B agonists maintain DNA content As shown in Fig. 1, incubation of freshly isolated islets in GABA-free medium for 4.5 h resulted in a 19.4±3.6% decrease in islet DNA, equivalent to the cell loss observed by others [31]. In contrast, islets incubated for the initial 60 min with GABA or the GABA B receptor agonist baclofen and then subsequently incubated in GABA-free medium retain the same DNA content as measured at time 0. This maintenance of islet DNA content was not observed when the GABA B receptor antagonist SCH 50911 was included with GABA in the incubation mixture (Fig. 1a). These experiments suggest that GABA, acting via GABA B receptors, activates cellular programmes capable of protecting the cells normally vulnerable to injury induced by islet isolation.

GABA and GABA B receptor agonists preserve islet insulin content To assess the sensitivity of the beta cell sub-population to GABA, we measured the effect of GABA treatment on maintaining islet insulin content (Fig. 1b). In these experiments we measured total insulin content of islet lysates at the end of the culture period and compared that to insulin content of islets frozen immediately after islet isolation (time 0). Islets left untreated had 14±6% more insulin after 4.5 h of culture than islets at time 0. Islets exposed to GABA during the first hour of the 4.5 h culture period contained 54±14% more insulin than control islets frozen at time 0 (Fig. 1b). Similarly, islets treated for 1 h with the GABA B agonist baclofen contained 45±9% more insulin than 0 time controls. These results suggest that GABA, acting via GABA B receptors, can regulate individual beta cell insulin content and/or beta cell mass.

Pretreatment of islets with GABA and GABA B receptor agonists enhances insulin secretion To further evaluate the effects of GABA specifically on beta cells, freshly isolated islets were cultured in the presence of GABA, the GABA B receptor agonist baclofen, GABA plus the receptor antagonist SCH 50911 or without treatment. After 1 h, islets were washed and equilibrated in KRB with 2.8 mmol/l glucose and then stimulated with KRB with 11 mmol/l glucose. After an additional 1 h of glucose stimulation, supernatant fractions were removed for RIA of secreted insulin. The islets were lysed for normalisation to DNA content. GABA-treated islets secreted 31.45±9% more insulin than controls (Fig. 1c). The increase was not

Fig. 1 GABA treatment protects islet DNA and insulin content and improves insulin secretion. Freshly prepared islets were cultured with or without GABA (100 $\mu\text{mol/l}$), *S*-baclofen (*S*-Bac) (100 $\mu\text{mol/l}$) or SCH50911 + GABA for 60 min and then placed in fresh medium lacking these agents for another 3.5 h. **a** DNA content was measured from islet lysates. Values are mean and SEM for five experiments and eight to 19 independent measurements. Insulin content (**b**) was also measured from islet lysates after no treatment, 1 h of GABA or *S*-baclofen treatment and 4.5 h total culture. Values are mean and SEM for three to five experiments and seven to 24 independent measurements. Statistical analysis was by one-way ANOVA. **c** Freshly prepared islets were cultured as above. Islets were washed and equilibrated in KRB with 2.8 mmol/l glucose. Low glucose KRB was removed and replaced with KRB with 11 mmol/l glucose for 60 min incubation at 37°. Supernatant fractions were removed for analysis of insulin secretion. Values are mean and SEM for three to five experiments and 11–25 independent measurements. * $p < 0.05$ and ** $p < 0.01$ compared with time 0 point control samples or control samples

statistically significant by one-way ANOVA, possibly due to the fact that insulin secretion was expressed as a ratio to DNA content, which the data suggested to have been maintained to a greater degree than controls. Islets treated with baclofen secreted $39 \pm 14\%$ more insulin than controls. Insulin secretion from untreated control islets was the same as that from islets treated with the antagonist to GABA B receptors + GABA.

GABA B receptors subunits are present on beta cells Our method of detecting GABA B receptors involved immunohistochemistry using antiserum that labels GBR1-C, our own anti-GBR1-N-terminal antiserum and antiserum to GBR2. The C-terminus antiserum, targeting full-length GBR-1, evenly labels all cells in moderate to small-sized islets, including cells that co-label for insulin (Fig. 2a–c). Cells that do not label for insulin also show receptor expression. Both GBR1 and GBR2 were immunohistochemically detected in rat islets. In some islets, as in the nervous system [34], labelling for both the GBR1 and GBR2 subunits appeared equal (Fig. 3a–c), while in others labelling for GBR2 appeared greater than for GBR1 (Fig. 3e–g).

GABA-treated islets upregulate the anti-apoptotic protein BCL-XL and reduce activation of pro-apoptotic caspase 3 The process of islet isolation is known to cause a percentage of cells to die by apoptosis [31]. Therefore, to investigate possible mechanisms for GABA-induced cell survival, we evaluated the ability of GABA to regulate the anti-apoptotic proteins BCL2 and BCL-XL. No GABA effects on BCL2 levels were observed in freshly isolated islets, but GABA influenced BCL-XL production in a time-dependent manner. BCL-XL levels were increased over controls after 60 min of GABA treatment (180 min after pancreatectomy) and remained at higher levels 1 h after GABA was removed (Fig. 4a,b). Although these changes appear to be quite rapid, the cascade signalling cell death or cell survival is likely to be activated when the pancreas is perfused and blood supply is terminated during the islet isolation process. The isolation and plating of islets provides an additional 2 h for protein synthesis. We also point out that the reagents used detect changes in protein levels in the femtogram ($\text{g} \times 10^{-15}$) range. To further examine the possibility that GABA might regulate islet cell apoptosis, the effect of GABA treatment on the activation of the pro-apoptotic protein caspase 3 was evaluated. Freshly isolated islets treated with GABA showed substantially less cleaved, activated caspase 3 than untreated controls (Fig. 4c,d). These results support the findings of increased cell survival in GABA-treated islets as measured by DNA content and suggest that one mechanism effecting this is regulation of pro- and anti-apoptotic proteins.

GABA stimulates pancreatic islet cell proliferation In addition to influencing cell survival, GABA also increases the incorporation of ^3H -labelled thymidine into islet cell DNA (Fig. 5), suggesting a role in cell replication. Half-maximal stimulation of ^3H -labelled thymidine incorporation into islet DNA was observed in the presence of approximately 1 $\mu\text{mol/l}$ GABA and a maximal response was observed in the presence of 10 $\mu\text{mol/l}$ GABA (Fig. 5a).

Fig. 2 Co-localisation of insulin and GABA B receptor subunits in pancreatic beta cells. Pancreas sections were examined by confocal microscopy using antibodies directed against (a) insulin and (b) GBR1-C. c Merged images from panels (a) and (b). Scale bar=10 μ m

These data correlate with the pharmacological concentrations necessary for neurotransmission [34]. Similar to its effect on islet DNA content (Fig. 1), 3 H-labelled thymidine incorporation into islet DNA was also increased when islets were incubated with the GABA B receptor agonist baclofen. The median effective concentration (EC_{50}) for this response to baclofen is approximately 600 nmol/l and a maximal response was noted when 1 μ mol/l baclofen is present (Fig. 5b). The stimulatory effect of GABA was first apparent after a lag period of approximately 60 min and increased with longer exposure to GABA (Fig. 5c). The uptake of 3 H-labelled thymidine over the few hours of these experiments probably reflects the short cell cycle of beta cells, namely 14.9 h [35]. GABA exposure has also been shown to reduce

the duration of each phase of the cell cycle in neural progenitors [13].

Finally, as shown in Fig. 6, GABA increased the rate of islet cell proliferation as measured by nuclear labelling with the nucleoside analogue BrdU. BrdU was included in the medium during and following 60 min exposure of islets to GABA. As noted by others [1, 33, 35], under resting conditions and without GABA, nuclear labelling with BrdU is infrequently observed (Fig. 6a). In contrast, nuclear labelling with BrdU was markedly increased in the presence of GABA (100 μ mol/l) (Fig. 6b). Insulin-containing beta cells in rats are primarily located in the core of the islet (Fig. 6c) where BrdU nuclear labelling is prominent (Fig. 6d). Using a double labelling technique, many cells

demonstrating GABA-stimulated nuclear BrdU labelling were found to contain insulin. The rate of BrdU nuclear labelling induced by GABA was approximately double that observed in the absence of GABA (Fig. 6e), a rate similar in magnitude to that elicited by a known islet cell mitogen, hepatocyte growth factor [36] (Fig. 6e). These findings of increased labelling of dividing cells, especially in the core of the islet, support the notion that GABA plays a role in beta cell replication.

Discussion

Taken together, our results indicate an important role for GABA in protecting and replenishing pancreatic islet cells. Our results also implicate beta cells as a principal target of the GABA-induced biological effects, since we demonstrated: (1) the production of GABA B receptors on beta cells (as have others [23, 37]); (2) the higher insulin content and secretion from islets exposed to GABA or baclofen; and (3) BrdU/insulin co-labelling in the core of treated islets.

This evidence, that GABA affects beta cells and activates compensatory mechanisms involved in their viability, suggests potential roles for GABA in the

Fig. 5 GABA stimulates ^3H -labelled thymidine incorporation into islet DNA. Freshly isolated islets were incubated with ^3H -labelled thymidine (0.037 MBq/ml) and varying concentrations of either GABA (**a**) or baclofen (**b**) for 1 h. They were then transferred to fresh medium without the test reagents and incubated for an additional 3.5 h. The mean cpm for the controls was $2,511 \pm 237$ and $2,543 \pm 202$. **c** Time-dependence of GABA-stimulated ^3H -labelled thymidine incorporation. treatment of diabetes. First, our finding that GABA treatment protected DNA and insulin content of isolated islets suggested to us that maintaining a critical concentration of GABA in the media during isolation and culture may provide a means to diminish the routinely observed cell loss occurring with these procedures prior to islet transplant. Second, these studies address issues of optimal islet transplant location and suggest that islets transplanted as a group under conditions of low flow would be more likely to sustain optimal levels of GABA. Islets that separate into individual cells or small cell clusters, or islets exposed to blood flow may not accumulate adequate GABA concentrations to activate survival programmes, accounting for some of the diminished function of transplanted islets observed over time [31]. Third, systemic restoration of GABA, particularly for patients with type 1 diabetes, may be a potentially important therapeutic strategy. Because beta cells are depleted in these patients by autoimmune attack, and in addition because GAD, the

Fig. 6 GABA stimulated BrdU incorporation into islet DNA. Freshly isolated islets were incubated with BrdU, with or without GABA (100 μmol/l) or hepatocyte growth factor (HGF) (20 ng/ml) for 1 h and then cultured without GABA or HGF. **a–d** Fluorescence microscopy of: untreated sample (**a**), a sample incubated with GABA (**b**), the sample from panel (**b**) stained for insulin (red) (**c**), and (**d**) an overlay of insulin staining and BrdU. principal GABA-synthesising enzyme, is an initial autoimmune target in this process, it is likely that GABA is severely reduced at an early stage of beta cell pathogenesis. Therefore, our in vitro findings that GABA exerts protective and proliferative effects raise the possibility that replenishing this amino acid in vivo may provide a means to maintain islet cell number and thereby maintain normal mechanisms of glucose control. This concept is supported by the in vivo findings of Beales et al., who administered the GABA B receptor agonist baclofen orally to non-obese diabetic mice, a model of type 1 diabetes, and found that the treatment significantly delayed the onset of diabetes

[38]. Moreover, Tian et al. found that sustained systemic GABA treatment suppressed diabetogenic T cells in the non-obese diabetic mouse, preventing diabetes onset [39] for up to a year in >80% of treated mice. The possibility that GABA acts systemically raises the additional question of which diabetes complications could be ameliorated by restoring GABA levels.

An argument against a therapeutic role for GABA or baclofen on islets could be made on the basis of findings by Kash et al., indicating GABA is not essential for islet development, as islet mass was found to be normal in neonatal mice lacking genes encoding the GABA synthetic enzymes GAD65 and GAD67 [40]. However, an alternative interpretation of those results is that islets develop normally because GABA is present in the maternal circulation at concentrations of 0.580 to 4 μmol/l [20, 41], near the EC_{50} value for GABA B receptor activation [34]. Therefore, maternally derived levels of GABA could suffice to activate fetal GABA receptors, preventing any deficiencies that might otherwise result. It is also likely that additional factors, such as lactogenic hormones [42], could support islet neogenesis during development, providing sufficient stimulus even in the absence of fetal-derived GABA.

To our knowledge, these studies are the first to demonstrate a GABA-induced effect on the apoptotic proteins BCL-XL and caspase 3, as well as on beta cell replication. This ability to suppress apoptosis and act as a mitogen indicates that GABA and its receptors may play a critical role in islet cell viability and function. Furthermore, given that physiologically relevant concentrations of GABA are present in the circulation, the question of systemic GABA actions arises, as well as the possibility that GABA, like insulin, activates trophic programmes in other organs. This premise is supported by findings that GABA is secreted from vesicles in a calcium-regulated manner [23, 43, 44], circulates in the blood stream at physiological concentrations [20, 41, 43] and activates effector systems through GABA receptors (both GABA A and GABA B) on many peripheral tissues [37, 39, 43, 45–50]. Avenues of GABA-related study appear to be plentiful and augur well for the possibility that additional comprehensive treatments for diseases like diabetes remain accessible.

Acknowledgements The authors thank Y. Chen for her technical assistance, J. Tatro and S. Roffler-Tarlov for critical comments on this manuscript and J. White for statistics expertise. This work was supported by Public Health Service grants K08-NS01923 and DK63344 (to B. Ligon), and by the Gastroenterology Research on Absorption and Secretion Program (DK34928 to B. Ligon) and the Surgery Department of Tufts-New England Medical Center.

Duality of interest None of the authors involved in this study had any duality of interest.
