Another tool towards invasion? Polyp “bail-out” in *Tubastraea coccinea*

Known as a highly competitive invasive species that is spreading fast throughout the Atlantic Ocean, *Tubastraea coccinea* was first reported in Brazilian waters in the 1980s (Castro and Pires 2001). Since then, its occurrence has been reported across 3,000 km of the Brazilian coast, posing a major threat, particularly to sessile invertebrates. Among other characteristics, fast growth rate, early reproductive age, and year-round release of long-lived larvae are regarded as the main reasons for its success in colonizing new habitats (Glynn et al. 2008). After being collected at the São Sebastião channel (23°48'55"S, 45°24'01"W), Brazil, several colonies of *T. coccinea* were kept in an open-water system aquarium and plankton-fed every other day. Approximately 30 d after collection, one single polyp around 20 mm in length (when fully extended) was found separated from the “mother” colony (Fig. 1a–d). To check whether this phenomenon was related to polyp “bail-out” (i.e., detachment of a single, non-skeletonized adult polyp from the colony; Goreau and Goreau 1959) the single polyp was radiographed using conventional X-ray film, which confirmed the absence of a calcareous structure. After 7 months, the polyp was still alive, having secreted a new skeleton and attached to the substrate (Fig. 1e, f). Another five polyp bail-outs occurred from a stressed colony. In this case, it was possible to observe the tissue receding from the coenosteum before the detachment of polyps (Fig. 1g). Two of those polyps died in 1 week; however, the other three remained alive after 9 d. This observation demonstrates that under stressful conditions the polyps of *T. coccinea* are able to bail-out. In addition to its efficient reproductive strategies, polyp detachment may act as another propagation mechanism over long distances and, consequently, increases concerns about its invasive potential.
