Abstract To generate information essential for the implementation of breeding schemes suitable for village poultry producers in Ethiopia, a survey was conducted aimed at defining the socioeconomic characteristics of the production environments in different geographic regions, understanding the important functions of chickens, identifying farmers' choice of chicken breeds and the underlying factors that determine the choice of genetic stock used. The survey included both questionnaire survey and a participatory group discussion. A total of 225 households (45 households from each of five *Woredas*) were interviewed. The questionnaire was designed to collect data covering general information on village poultry production such as socio-management characteristics, production objectives, population structure, breed choice and trait preferences, market preferences of specific traits, and farmers' selection practices. The participatory farmers' discussions were designed to involve stakeholders in defining the breeding objective "traits" and deriving their

relative importance in the production environment based on the different functions of chickens and "traits" identified in the interviews. The results showed that production of eggs for consumption is the principal function of chickens in most regions followed by the use as source of income and meat for home consumption. The production system in all geographic regions studied revealed similar features generally characterized by extensive scavenging management, absence of immunization programs, increased risk of exposure of birds to disease and predators, and reproduction entirely based on uncontrolled natural mating and hatching of eggs using broody hens. Farmers' ratings of indigenous chickens with respect to modern breeds showed the highest significance of the adaptive traits in general, and the superior merits of indigenous chickens to high yielding exotic breeds in particular. Adaptation to the production environment was the most important attribute of chickens in all the study areas. The high significance attributed to reproduction traits indicates the need for maintaining broody behavior and high level of hatchability while breeding for improved productivity of indigenous chickens for village conditions. The market price of chickens is primarily dictated by weight, but farmers rated growth (males) and number of eggs followed by growth (females) as the production traits they would like the most to be improved. Therefore, the ultimate breeding goal should be to develop a dual-purpose breed based on indigenous chicken genetic resources with any of the comb types other than single for all the regions studied having the most preferred white body plumage for farmers in the Amhara region and red body plumage for those in Oromia, Benshangul-Gumuz, and Southern regions.

Introduction

Increased productivity of the poultry subsector by using exotic breeds in Ethiopia failed to become a sustainable option mainly because this strategy recurrently faced the problem of birds not being adopted widely by the rural farmers due to several socioeconomic and environmental challenges (Teklewold et al. 2006). The management conditions under which the animals are produced vary along the existing production systems which were broadly classified into the village, small-scale commercial, and large-scale commercial systems based on flock size, production objectives, and level of specialization and/or technology use (FAO 2008). A review by Gueye (1998) indicated that nearly 80% of the estimated 1.3 billion chickens in Africa comprise indigenous breeds raised by village farmers under extensive systems. In Ethiopia, the village system contributes to more than 90% of the national chicken meat and egg output. This system is generally characterized by small size of unimproved indigenous flock per household, birds maintained under scavenging regimens in the backyards with little or no supplemental feeding, no separate shelters except for night enclosures in the family house, and lack of health care.

Despite their importance indigenous breeds are under threat due to various factors such as changing production systems and indiscriminate crossbreeding (Besbes 2009). There are very few examples of breeding programs for indigenous breeds in Africa and around the world. Recently a genetic improvement program has been initiated for increasing productivity of indigenous chickens of Ethiopia through selective breeding, as a means both to improve the livelihood of poor people as well as conserve the existing genetic diversity through utilization. Developing appropriate animal breeding programs for village conditions requires defining the production environments and identifying the breeding practices, production objectives, and trait choices of rural farmers (Solkner et al. 1998).

The traits traditionally considered as criteria for selecting breeding stock are important in describing the adaptive attributes and genetic merits of the indigenous chickens and in identifying farmers' choice of chicken breeds and the underlying factors that determine the choice of genetic stock used. The market preferences for specific traits identified in the current study could be used to compliment or stimulate further work on economic valuation of the traits (Scarpa 1999). However, even in the absence of economic values, the results could be used to simulate alternative breeding schemes by using appropriate genetic parameters and deriving relative weights for the breeding objective traits using the desired-gain selection-index method as suggested by Solkner et al. (2008). Solomon (2008) found that farmers' ratings of trait categories they

preferred to be improved in sheep in traditional systems were based on economic grounds and could be translated into economic weights that are comparable to economic values derived from profit equations. A similar approach could be adapted for developing breeding systems for indigenous poultry.

The objectives of this study were (1) to identify the socioeconomic characteristics of the production environments in different geographic regions, (2) to gain understanding of the traditional selection practices, and (3) to identify and prioritize the breeding objectives and trait preferences of village producers through a participatory approach.

Material and methods

In each of the study regions two types of data collection were applied. Firstly, individual farmers were interviewed and a list of detailed information was obtained. Secondly, and based on the results of the individual interviews, farmers were asked to discuss in groups on what they considered as most important regarding selection decisions and market value.

Description of study sites

The survey sites were selected considering agro-ecology, socioeconomic significance of chicken production, and population of indigenous chickens based on the atlas published jointly by IFPRI and CSA (2006). Five *Woredas* (district) were covered in the study: Farta, Mandura, Horro, Konso, and Sheka. The ecological and demographic features of the study areas were described in Tables 1 and 2.

Data collection and analysis

The interview was designed to collect two sets of data. The first set covered general information on household characteristics and poultry holdings. The second set included data on more specific aspects of village poultry production such as socio-management characteristics, production objectives, population structure, breed choice and trait preferences, market preferences of specific traits, and farmers' selection practices. A total of 225 households (45 households from each *Woreda*) were interviewed. The interview data were analyzed using descriptive statistics, and the percentage of respondents was reported for each parameter.

The subsequent participatory farmers' discussions were designed to involve stakeholders in identifying the breeding objective "traits" and deriving their relative importance in the different production environments. In total seven independent groups of farmers were formed in each region, where each group comprised of five to seven members. The

^b *Woreda* is an administrative domain at the third level down a “Region” and immediately below a “Zone”

groups consisted of neighboring farmers following a transect walk in the villages. In order to address the variations in the opinions of farmers in different agro-ecological regions, the production system was classified into two “sub-systems”: low altitude and high altitude systems. Three regions were selected to represent the two “sub-systems” (Mandura for the low altitude and, Farta and Horro for the high altitude production “sub-system”).

As point of departure for the discussions, the results of the individual interviews were summarized according to (1) identified overall objectives of keeping chickens (egg or meat production, income generation, cultural/religious roles), (2) “traits” affecting consumer preferences in purchasing and/or selling chickens (live weight, plumage color, comb type), (3) “traits” farmers desired to be considered in improving village chickens (adaptation, growth, egg production, plumage color, “qumena,” comb type, reproduction). The “traits” were defined in composite terms such as “adaptation” (comprising disease and stress tolerance, flightiness/

ability to escape predators, scavenging vigor), “live weight/growth” (weight gain, live weight at market age/adulthood), “egg production” (annual egg number, persistency of egg laying), “reproduction” (broodiness, hatchability of eggs), and “qumena” (conformation/erectness, visual attraction/color, size). Farmers who had adopted exotic chickens (i.e., modern, genetically improved chickens, mainly Rhode Island Red) were asked to rate their opinions on the comparative production, reproduction, and behavioral performance of indigenous chickens with respect to modern ones.

The discussions were aimed at coming to consensus regarding the ranking of the traits in the three categories, and in some cases, on the preference for indigenous or exotic chickens. Per category, a list of the different functions of chickens and “traits” identified in the interviews was prepared into separate flip charts and presented to each group for rating them according to their order of importance. The ratings were carried out by assigning different weights, ranging from 1 to 4 for the different functions of

Table 2 Demographic characteristics of sample households (% of respondents)

	Farta	Mandura	Horro	Konso	Sheka	Total

Major ethnic community	Amhara (100)	Amhara (44) Gumuz (28) Agew (19) Oromo (7)	Oromo (100)	Konso (96)	Shaka (84) Kaffa (7) Menja (5)	

chickens and “traits” affecting market preferences and, weights 1–5 and 1–7, respectively, to rate the relative importance of the “traits” farmers desired to be improved in males and females (the highest weight=most important, the lowest weight=least important). Each group discussed thoroughly and assigned relative weights, on consensus or majority vote otherwise, with the aid of a facilitator. Averages of the relative weights assigned by the groups in each region were finally ranked and compared using Wilcoxon signed ranks test.

To get an impression on the viability of the populations, the effective population size was determined (Falconer and MacKay 1996):

$$N_e = (4 \times N_m \times N_f) / (N_m + N_f)$$

and the increase in inbreeding per generation as

$$\Delta F = 1 / (2N_e)$$

where N_e is the effective population size, N_m the number of breeding males, N_f the number of breeding females, and ΔF the inbreeding coefficient.

Results

Family and farm characteristics

The majority of the respondents were Christian males with at least elementary level of education (Table 1). Eight ethnic communities were comprised in the five survey sites. Except in Mandura, where the community was found to be a mixture of three communities other than the local Gumuz community (27.9%), all the other geographic regions were populated almost entirely by specific communities native to that area (Table 2).

Functions of chickens

Except in Mandura and Horro, where chickens are raised importantly as source of income, egg production (for home

consumption) is the most important reason for keeping chickens in all regions studied. Meat production (for home consumption) is second in importance in Oromia (Horro) and Southern regions. The function of chickens as source of cash income was rated to be as important as (Horro) or more important than egg and meat production (Mandura). It is second in importance to egg production in Farta. In Konso, the principal purpose of raising chickens is for home consumption and their value as income source is third in importance. Only about 5% of the respondents in Farta and Konso included the cultural–religious role of chickens rating it fourth in importance whereas all the others did not state the significance of this function (Table 3).

Socio-management factors

The major management factors describing chicken production in the different regions studied are presented in Tables 4 and 5. All of the households surveyed kept indigenous chickens managed extensively under traditional management regimens. Sixty-two percent of the households in Konso and more than 75% of the households in Farta, Horro, and Mandura practice supplementary feeding of scavenging chickens whereas confined management of chickens with commercial feeding is not known at all in any of the regions studied. Most of the farmers in the Amhara (Farta, 73%) and Oromia (Horro, 69%) regions sheltered chickens in the family house whereas almost equal proportion of those in Mandura and Sheka provided both separate shelter and sheltered in the family house. This is in contrast to Konso, where 80% of the farmers had separate shelters to house chickens.

Immunization services (Table 5) are almost nonexistent (95%) for village chickens in all regions surveyed. However, unlike most of the farmers in the Amhara Region (Farta, 79%) where treatment of sick birds is not common, most households in Oromia region (Horro, 70%), and about 50% of the households in the Southern and Benshangul-Gumuz regions had awareness of and access to curative medication.

There is no systematic mating in any of the regions studied. Thus, breeding of village chickens is completely uncontrolled and replacement stock is produced through natural incubation using broody hens. Whereas only 24% of the total number of respondents left broody hens to stop this behavior naturally, the remaining majority practiced different methods to modify the broody behavior, in times when incubation was not desired and the hens were required to resume laying faster. Some of the most popular methods reported were: hanging the hen upside-down (59% in Horro and 46% in Konso), moving the hen to neighbor houses (69% in Farta and 41% in Mandura). Together, these two are the most important methods commonly practiced by most of the farmers in the surveyed regions. Changing the location of brooding nest is very popular in Konso (42%), little is known in all other regions (3–9%).

Traits of adaptive and economic importance

In the discussion among farmers who had adopted modern chickens, the Rhode Island Red (RIR), the most popular and widely adopted chicken in the regions studied, was used as the reference breed. Only data from Farta, Horro, and Sheka were considered because there a relatively larger number of farmers adopted (16% in Farta, 33% in Horro, and 25% in Sheka). In terms of adaptive traits and consumption the indigenous chickens were considered favorable. Most of the respondents claimed that the modern breed is poor in disease and stress tolerance (86%) and in the ability to escape predators prevalent in their village conditions (96%). The modern breed generally required higher level of management (83%) often hard to afford and are poor scavengers (86%) compared to indigenous chick-

	Equal	0	0	0	0
	Inferior to MB	17	7	0	8

^a Rhode Island Red was the reference modern breed (MB)

ens. In addition, 77% of the farmers in Horro and 90% in Sheka claimed that hatchability of eggs obtained from the modern breed is inferior to eggs from indigenous chickens. Likewise, most of the respondents have the opinion that the eggs (90%) and meat (92%) obtained from modern breeds have poorer taste (Table 6). This was also confirmed by the lower market preference for eggs from exotic chickens. In the opinion of 98%, 74%, and 93% of the total respondents pooled over all regions RIR chickens were rated superior in egg production, meat yield, and egg size, respectively, to the indigenous chickens (data not shown).

Plumage color, live weight, and comb type were important traits affecting market price of chickens (Table 7). Live weight is the most important attribute in all geographic markets followed by plumage color except in the Southern

region where comb type affects market price more than plumage color. The type of chicken breed does not have much influence on market preference. The market for eggs is not sensitive to the egg characteristics (egg size and shell color) except that it attached higher preference for eggs of indigenous chickens to those from exotic breeds in all geographic regions (data not shown).

Farmers' selection practices

All farmers interviewed in the different regions practiced selection on breeding and replacement males and females based on four trait categories: plumage color, live weight, comb type, and "qumena" (Table 8). Similar trait categories are used to select both males and females in all regions. Farmers in the Amhara (Farta) and Oromia (Horro) regions

Table 7 Farmers' rating^a of trait categories/factors most influencing price of live chickens marketed in different regions of Ethiopia

“Qumena”	2	30	22	13	3	14

^a Percentages do not add up to 100% since respondents selected based on more than one trait category

give the highest emphasis for plumage color while in the Southern region (Konso and Sheka) live weight is used as the most important selection criteria. The emphasis given to each trait category is largely similar across the sexes except that, unlike for males, live weight is most important in Mandura (64%) and almost equally important to comb type in Farta for selecting breeding females.

Although each of these trait categories consisted of different component traits farmers described the specific trait components for only two of the four trait categories used as selection criteria, plumage color, and comb type (Table 9). White and red plumage colors were identified as the two important component traits used for selecting on the basis of body plumage. Red is the most favored plumage in the Benshangul-Gumuz (Mandura), Oromia (Horro), and Southern Regions (Konso and Sheka), whereas white is the body plumage color more favored by the Amhara community (Farta) irrespective of the sex of the birds. Farmers in the South, however, displayed a much stronger distaste for chickens having white plumage color compared to the others. Similarly, farmers in all regions recognized only two types of combs for the trait category, comb type: “Netela” meaning Single and, “Dirib” that actually comprised all comb types other than “Single” (i.e., rose, pea, walnut, and duplex combs). “Dirib” is a favored comb type both for females (68%) and males (90%) suggesting that most of the

farmers placed equally higher preference for any comb type other than single. No specific trait components were identified for the other trait categories, weight, and “qumena,” except that all farmers stated that they selected birds that are “heavier,” in respect of their age mates, and those having attractive “qumena” judging subjectively by hand “weighing” and visual appraisal.

Effective population size and inbreeding in village chickens

A considerable proportion, ranging from 31% to 55.6%, of the farmers interviewed in the different regions did not own breeding males. Most of them shared breeding males with neighbors. To get some impression on the effective population size and increase in inbreeding over generations, effective population size were calculated based on the flocks of farmers who possessed their own breeding males. The largest effective population size was recorded in Konso with the subsequent lowest inbreeding coefficient (Table 10).

Rating trait categories for genetic improvement

Farmers’ participatory rating of the importance of different trait categories is presented in Table 11. Adaptive traits (specifically disease and stress tolerance, flightiness, and

scavenging vigor) in both males and females, growth in males and number of eggs in females, ranked first and equal in importance in low altitudes. In the highlands adaptation is second in importance to growth (males) and egg production (females). Plumage color of birds (low altitude) and comb type (high altitude) were identified as the traits farmers would like the least to be improved in both classes of sex. Farmers in both altitude regimens attributed a comparable and high emphasis to traits related to reproduction in females, even more important than growth. “Qumena” of birds is relatively more important to the farmers in low altitudes than those in the highlands.

Discussion

Functions of chickens

Like in any other village poultry systems in developing countries, there is no specialized egg or meat chicken production in Ethiopia. Egg production is the principal function of chickens followed by the use as source of cash income and meat. Village chicken in other parts of Africa also played similar roles. In Zimbabwe chickens served as an investment and source of security for households in addition to their use as sources of meat and eggs for consumptions and of income (Muchadeyi et al. 2007). Although previous studies in some parts of Africa (Gondwe 2005; Muchadeyi et al. 2007) indicated that the cultural/religious role of indigenous chicken types is important, the results of the present study did not support the significance of this function.

Socio-management characteristics and important attributes of indigenous chickens

The village poultry production environment in all geographic regions studied is generally characterized by extensive scavenging management, no immunization pro-

grams, increased risk of exposure of birds to disease and predators, and reproduction entirely based on uncontrolled natural mating and hatching of eggs using broody hens. Most of these features were also shared by many other African countries (Aboe et al. 2006; Gondwe and Wollny 2007; Harrison and Alders 2010) although some countries such as Mozambique have started successful vaccination programs against one of the major killer diseases, Newcastle disease (Harrison and Alders 2010). On average, 83% of the farmers in this study provided supplementary feeding. Recent studies in Ghana and Mozambique also showed that from 90% to 100% of farmers offered supplementary feeds to their chickens (Aboe et al. 2006; Harrison and Alders 2010). However, unlike farmers of Mozambique who mostly provided separate shelters and

Table 11 Farmers’ participatory rating of trait categories they would like the most to be improved for chickens in low (Mandura) and high (Farta and Horro) altitudes

Trait category for males	Low altitude	High altitude
Adaptation	4.14 (1)	3.93 (2)
Growth/weight	4.14 (1)	4.21 (1)
Plumage color	1.14 (4)	3.07 (3)
Comb type	2.14 (3)	1.86 (5)
“Qumena”	3.43 (2)	1.93 (4)
Trait category for females		
Adaptation	5.14 (1)	5.36 (2)
Number of eggs	5.14 (1)	6.00 (1)
Growth/weight	3.86 (4)	3.86 (4)
Plumage color	1.29 (6)	3.57 (5)
Comb type	2.71 (5)	1.64 (7)
Reproduction (broodiness, hatchability of eggs)	5.00 (2)	5.07 (3)
“Qumena”	4.86 (3)	2.50 (6)

Numbers in parenthesis indicate ranks based on Wilcoxon signed ranks test. Ranks of trait categories within a column bearing different numbers are significantly different from each other ($P < 0.05$)

rarely housed their chickens in their homes (Harrison and Alders 2010) more than 50% of the farmers in this study housed chickens in the family dwellings at night.

Farmers' ratings of indigenous chickens for various traits/trait categories compared to a reference exotic breed revealed the important adaptive attributes of indigenous chickens. Adaptability of an animal is generally described in terms of traits enabling them to survive, reproduce, and be productive in the limits of their production condition (Parayaga and Henshal 2005). Indigenous chickens were rated to have superior merits with regard to traits such as disease tolerance, tolerance to cold and heat, ability to escape from predators, scavenging, and broody behaviors and hatchability of eggs which are important in adaptation to the village environment; and those traits, such as taste of egg and meat, affecting consumption preference and consequently market value. A review by Islam and Nishibori (2009) indicated that in Bangladesh and many other developing countries, the meat and eggs of indigenous chickens is highly preferred for its taste and suitability for special dishes resulting in even higher market prices for these chickens than their exotic counterpart. Earlier studies on adoption of poultry breeds in Ethiopia (Teklewold et al. 2006) indicated that these trait categories were among the principal factors determining farmers' adoption of improved chicken breeds.

Morphologic traits such as plumage color and comb type were also found to have significant economic values beside other quantitative traits related to growth and egg production. Like in other parts of the world (Jiang 1999), there were specific choices for plumage colors affecting market preferences in the different geographic regions surveyed. The current result indicated that plumage color followed by comb type is only second in importance to live weight in affecting market preference of chickens. In Northern Ethiopia both producer–sellers and intermediary traders attached the highest preference for plumage color. For producer–sellers feather distribution, having either feathered or naked neck is equally important as plumage color followed by breed and comb type whereas for intermediaries comb type is second in importance (Aklilu 2007). The market preferences in this study were based on the opinions of producer–sellers and it was found that very little or no special preference was attributed to the type of breed marketed.

Farmers' selection practices

Farmers involved in virtually all forms of agricultural production practiced selection of varying scale and intensity for the traits they considered important under their production environment. Village farmers in this study traditionally attached greater selection emphasis to mono-

genic qualitative traits, plumage color (white in the Amhara region and red in all the rest) and comb type, next to the only quantitative trait (growth). “Qumena” as a composite trait category mainly deriving from general qualitative characteristics such as conformation is also given an important emphasis. This trait category was described similarly and attributed comparable level of importance in other species of livestock produced by village farmers (Solomon 2008). Similarly, Muchadeyi et al. (2009) reported that poultry farmers in Zimbabwe traditionally selected compact and mature birds rather than angular and tallish ones as breeding stocks though they attached no emphasis to plumage color.

There were almost no differences in the selection of male and female chickens in terms of both the selection criteria employed and emphasis given to the selection traits under the traditional selection practices. The selection practices were limited to trait categories which either influenced market price differentials immediately and directly or observed and/or measured on the selection candidate itself. For instance, although egg production is the most important function of chickens in all households it was not considered as a selection criterion.

However, considering that the trait categories selected in both sexes were consistent to those preferred by the local chicken market, it seems that market of chickens is the principal factor dictating farmers' selection practices in Ethiopia. Lack of information on egg production of the selection candidate was a less likely reason for farmers' not including this trait in their selection criteria because even in the absence of recording, it could have been possible to select the best female and male offspring for egg production at least by recalling the laying performance of their parents which should be simple due to the very small flock size owned per family.

Effective population size and inbreeding in village chickens

The effective population size ranged from 3.19 (Sheka) to 5.22 (Konso) and the number of breeding individuals is very small. The effective population size found in this study was too low compared, for instance, with the average size (15.4) reported for village chickens of Jordan (Abdelqader et al. 2007). Subsequently the rate of inbreeding is quite high in all regions studied here particularly due to the small flock size characterizing this production system, an overall average of 3.4 chickens per household, which is extremely small compared to the average size of 42 reported for Jordan village chickens (Abdelqader et al. 2007) and other African countries such as Ghana, Malawi, Zimbabwe, and Mozambique where it ranged from 13 to 29 (Aboe et al. 2006; Gondwe and Wollny 2007; Muchadeyi et al. 2007; Harrison and Alders 2010). The extremely small flock size

in this study confirms the drastic drop in the total population of chickens in Ethiopia since the past decade (Dana et al. 2010). On the other hand, though the number of breeding individuals per household is low, the fact that market is also an important source of breeding males might contribute towards reducing further inbreeding. In any case, it should be noted that the estimates on the effective population size as well as rate of inbreeding in the village flocks are not very accurate due to the existing breeding system, which are entirely based on uncontrolled natural mating, and absence of breeding males in many households keeping chickens (see Table 8).

Selection traits and breeding objectives

Farmers' participatory definition and ratings of the trait categories they liked to be improved were different from those employed traditionally as selection criteria. They included additional economically important traits related to adaptation, egg production, and reproduction. For instance, farmers both in the low altitude (Mandura) and high altitude regions (Farta and Horro) traditionally exerted the highest emphasis on body plumage color next to body weight for selecting males and females. However, following the participatory rating of trait categories, it was one of the traits farmers would like the least to be considered in improving both classes of sex. Adaptation to the production environment was the most important attribute of chickens both in the lowland and highlands in males as well as females (except in the highlands where it is considered second in importance following egg number). Almost similar order of ranking was reported by Muchadeyi et al. (2009) for village chickens in Zimbabwe where farmers across all ecological regions attributed the highest importance to reproductive performance, growth, and survival in the production environment rating plumage color as the least important. In Jordan, village farmers considered egg production as the most important criterion, followed by mothering ability and body weight, for selecting their breeding stock (Abdelqader et al. 2007). Thus, it is advisable to incorporate these traits in the selection schemes while setting up breeding programs targeting village poultry producers in different regions of Ethiopia.

Conclusion

There is a clear need to base genetic improvement programs for village poultry producers on indigenous chicken genetic resources. This is emphasized by the fact that the adaptive traits in general, and the superior merits of indigenous chickens to high yielding exotic breeds in particular, were rated of the highest significance by the local farmers. Egg

production is the principal function of chickens followed in respective order by their use as source of cash income and meat. The market price of chickens is primarily dictated by weight, but farmers rated growth (males) and number of eggs followed by growth (females) as the traits they would like the most to be improved. Therefore, the ultimate breeding goal should be to develop a productive dual-purpose breed that can survive and reproduce under the production environment of village farmers.
