Imaging the mantle transition zone beneath eastern and central China with CEArray receiver functions*

Xinling Wang[†] and Fenglin Niu

Department of Earth Science, Rice University, Houston, TX 77005, USA

Abstract We analyzed a total of 37 427 receiver-function data recorded by national and regional broadband seismic networks of the China Earthquake Administration to study the mantle transition zone beneath eastern and central China. Significant topography on both the 410-km and 660-km discontinuities was clearly imaged in the 3D volume of CCP (common-conversion-point) stacked images that cover an area of 102.5°E–122.5°E and 22.0°N–42.0°N. 3D crustal and mantle velocity models were used in computing the Ps time moveouts to better image the absolute depths of the two discontinuities. We found that the 660-km discontinuity is depressed up to 25 km along the east coast of China, indicating the presence of the subducted Pacific slab in the region. More interestingly, a double 660-km was observed beneath the Huanghai Sea, which was not seen from the 410-km discontinuity. We found a strong and localized anomaly beneath the Quaternary Datong volcano located at the northeastern edge of the Ordos Plateau in North China. The 410-km is depressed by as much as 15 km beneath the volcano. If the amount of the depression is caused by unmodeled low velocity anomaly in the upper mantle, it requires either a strong (4%–8%) localized low velocity anomaly near the lithosphere–asthenosphere boundary or ~1.5% low velocity column across the entire upper mantle above the 410-km. The latter could suggest a deep origin of the Datong volcano, although it was usually attributed to edge-driven convection by most of the literatures.

1 Introduction

The present-day tectonic setting of China is featured by an Indian-Eurasian collision in the west and a Pacific subduction in the east. The interaction of the Eurasian, Indian, and Pacific Plates has resulted in a unique topographic contrast between eastern and western China. The two regions are bounded by a ~100 km wide, NNE trending lineament known as the North South Gravity Lineament (NSGL) (Figure 1a). The prolonged collisions in the west have shaped the region west of the NSGL into plateaus and highlands with elevations of ~500–6 000 m above the sea level. On the other hand, the rollback of the Pacific slab appeared to play a dominant role in shaping the area located at the east of the NSGL, which is comprised primarily of

extensional basins with an altitude <200 m. Besides the topographic contrast, the two regions also have very different seismicity, gravity anomaly, heat flow, crustal and lithosphere structure. Although the geological and structural contrast between eastern and western China can be roughly explained by the interaction between the Eurasian, Pacific, and Indian Plates, it is still unclear whether this contrast is caused dominantly by a crustal or a mantle process, or a combination of both. Based on a high-resolution image of the P-wave velocity structure beneath China, Huang and Zhao (2006) observed a good correlation between the locations of the NSGL and the western front of the subducted Pacific slab in the transition zone. They further suggested that the subhorizontally lying Pacific Plate at the base of the upper mantle forms a big mantle wedge that defines the extensional area at Earth's surface. This correlation, however, is not so clear in the tomographic images of Li and van der Hilst (2010).

While seismic tomography offers a direct way to map a descending slab with a high seismic velocity,

Figure 1 (a) Map showing the major tectonic setting of China and its surrounding areas. Arrows indicate the subduction of the Pacific and Philippine Sea Plates, and the collision of the Indian Plate on the east and southwest sides of China, respectively. The red rectangular region shows the location of the study area. Cyan lines indicate the descending Pacific, Philippine and Indian Plates. Gray dash lines represent the boundaries of the major tectonic blocks in the study region. (b) Map showing the broadband seismic stations (red triangles) of the CEArray. The thick grey line and the red star indicate the North South Gravity Lineament, and the Quaternary Datong volcano, respectively. The two white lines, AA' and BB', indicate the locations of the two profiles shown in Figure 3. Inset (c) shows the 124 teleseismic events (red circles <50 km, cyan circles >50 km) used in this study.

receiver function data provides an indirect approach to image a subducting slab when it enters the mantle transition zone (e.g., Niu et al., 2005; Huang et al., 2010). The 410-km and 660-km seismic discontinuities that bound the mantle transition zone are associated with the temperature-sensitive phase transitions from olivine to wadsleyite (Katsura and Ito, 1989) and from ringwoodite to perovskite plus magnesiowustite (Ito and Takahashi, 1989), respectively. The latter is also known as the post-spinel transformation. Because the two phase-transitions have positive and negative Clapeyron slopes, respectively, a decrease in temperature results in a decrease in the depth to the 410-km discontinuity and an increase in the depth to the 660-km discontinuity. Lateral variations in the transition-zone thickness, as well as variations in the depths of the two discontinuities thus can be used to indirectly map out a descending slab. Chen and Ai (2009) analyzed a large amount receiver function data recorded in North China and obtained detailed images of the 410-km and 660-km discontinuities beneath North China. They were able to identify the subducted Pacific Plate from their images and confirmed the same correlation between the NSGL and the front of the Pacific slab beneath North China.

The recent rapid growth of broadband seismic observation in China has opened a new era for imaging the crustal and mantle structure and dynamics beneath China. In this study, we took advantage of the recently opened dataset collected by the national and regional seismic networks operated by the China Earthquake Administration (CEA). We applied receiver function analysis techniques to the data to image the mantle transition-zone structure beneath the eastern and central China. Our primary goal is to seek better understanding of the long-standing question on the role that the Pacific subduction has been playing in determining the western front of the extension regime. The new dataset and seismic images, on the other hand, also offer insights to our general understanding of the nature of the two discontinuities as well as the thermal state at the base of the upper mantle.

2 Data and analysis

2.1 CEAArray

Completed in early 2007, the new CEA seismic network consists of a backbone national seismograph network, 31 provincial networks, and several small aperture arrays with more than 1000 stations including 850+ broadband stations (Zheng et al., 2009). The 1000+

stations formed a large 2D areal array with an aperture ~ 6700 km from east to west and ~ 3500 km from north to south. For the remainder of this paper, we will refer to these stations as the CEAArray. Station spacing varies drastically from location to location. We calculated the number of stations in a circular bin with a radius of 1° at a meshed grid of $1^\circ \times 1^\circ$ and found that the numbers vary from 0 to 53 (Figure 2). The eastern and central China (red box in Figure 2) is relatively well covered by stations, with an inter-station spacing of ~ 30 – 100 km, allowing the use of modern array techniques, such as common-conversion-point (CCP) gathering and pre-stack depth migration to image the upper mantle and transition zone structure beneath the array.

We visually examined all the earthquakes with magnitude greater than 5.0 and in the epicentral distance of 30° – 90° recorded between July of 2007 and early August of 2008. We chose 124 earthquakes with good signal-to-noise ratio (SNR). These earthquakes provide a reasonably good distance and azimuth coverage (Figure 1 inset), although a large portion of the events are clustered in the western Pacific and the Java trench with a back azimuth between 30° and 210° .

2.2 Receiver functions

We first rotated the two horizontal components of the seismograms to the radial and transverse components. Niu and Li (2011) found a significant portion of the CEAArray stations had problems in orientation. We used their estimates of component azimuth, which were determined from P-wave particle motions. We further projected the two components to the principal directions (longitudinal and in-plane transverse) computed from the covariance matrix. The receiver functions were then computed from the data projected into this coordinate system (hereafter referred as to P- and SV-component) (Vinnik, 1977; Niu and Kawakatsu, 1998; Niu et al., 2005).

We employed the “water-level” deconvolution technique (Clayton and Wiggins, 1976) to generate receiver functions:

$$E_{\text{RF}}(\omega) = \frac{V(\omega) \cdot P^*(\omega)}{\max\{|P(\omega)|^2, k \cdot |P_{\text{max}}(\omega)|^2\}} \cdot \exp\left[-\left(\frac{\omega}{2a}\right)^2\right]. \quad (1)$$

Here k and a are two constants that define “water level” and the corner frequency of the Gaussian low pass filter. We used $a=1.5$ in this study, equivalent to a corner frequency of 0.5 Hz. $P(\omega)$ and $V(\omega)$ are the spectra of the P and SV components. We used a 100 s time window

Figure 2 Map showing the density of seismic station across China. Station density is calculated from the number of stations located in a circular cap with a radius of 1 degree. A station density of 9 and 25 roughly corresponds to an inter-station spacing of 100 km and 50 km, respectively. Red box indicates the study area.

(5 s and 95 s before and after the P wave) to compute the source spectrum of each earthquake. We further screened receiver functions with various methods (Chen et al., 2010) to eliminate noisy data. The total number of receiver functions used in the CCP imaging is 37 427.

2.3 CCP gathering

We applied the CCP stacking technique to the receiver-function data to image the P to S conversion events and their lateral variations beneath the array (e.g., Dueker and Sheehan, 1997; Niu et al., 2005). For an assumed conversion depth, d , we first computed the relative arrival time of the converted phase Pds with respect to the direct arrival by ray tracing the two phases using the 1D IASP91 velocity model (Kennett and Engdahl, 1991). We also kept the geographic location of the conversion points and gathered the receiver functions that share the same conversion points. We divided the study area (22°N to 42°N, 102.5°E to 122.5°E) into meshed grids of 0.1° by 0.1°, and used a circular cap with a radius of 1 degree for gathering the receiver functions. The total number of the caps is 40 401 (201×201), and there are significant overlaps among the caps. This

serves to lowpass filter the topographic relief on the two discontinuities with a corner wavelength roughly equivalent to the size of the caps, approximately 200 km. We then summed all the receiver functions within a 0.1 s window centered on the arrival time of Pds using an N th-root stacking technique (Muirhead, 1968). For the i th cap, let $r_k(t)$ represents the k th receiver function gathered in the cap, and t_{dk} is the Pds arrival time for a discontinuity with a depth of d , an N th-root stack, $R(d)$, is given by

$$R_i(d) = y_i(d)|y_i(d)|^{N-1}, \quad (2)$$

where

$$y_i(d) = \frac{1}{K} \sum_{k=1}^n w_k \text{sign}[r_k(\tau_{dk})] |r_k(\tau_{dk})|^{1/N}. \quad (3)$$

Here K is the total number of receiver functions gathered at the i th cap. w_k is a Gaussian weight function

$$w_k = \frac{\exp\{-x_k^2/a^2\}}{\sum_{n=1}^K \exp\{-x_n^2/a^2\}}. \quad (4)$$

Here x_k is the distance between the cap center and the conversion point of the k th-event. The Gaussian width parameter, a , was set to be the same as the cap radius. We chose $N=4$ to reduce the uncorrelated noise relative to the usual linear stack ($N=1$), recognizing that this suppresses conversions with significant dip away from the horizontal. We varied d from 300 km to 800 km in increments of 1 km. The depth stacked receiver functions along latitude 35°N and longitude 120°E are shown in Figures 3a and 3c, respectively.

To better image the absolute depths of the two discontinuities, we further used a 3D crustal model derived from Pn travel times (Sun and Toksöz, 2006) to

correct anomalies on the relative Ps travel time. The crustal model has a four-layer crust (sedimentary, upper, middle and lower crust) with a horizontal resolution of $1^\circ \times 1^\circ$. We also used the whole mantle P (Fukao et al., 2001) and S-wave velocity models (Grand, 2002) to calculate travel-time anomalies resulting from heterogeneities in the mantle. It seems that both the crustal and mantle corrections are rather minor. The gathered receiver functions based on 3D time moveouts are shown in Figures 3b and 3d, respectively. Compared to Figures 3a and 3c, the depth of the two discontinuities changes by less than 5 km.

Figure 3 Depth sections of the CCP gathered receiver functions along latitude 35°N computed from a 1D (a) and 3D (b) reference velocity model. (c) and (d) are similar to (a) and (b) except for along longitude 120°E . The locations of two sections are shown in Figure 1. Note the clear P-to-S conversion from the 410-km and 660-km discontinuities. Ellipses indicate the regions with a double-branched 660-km discontinuity.

3 Results and discussion

As shown in Figure 3, both the 410-km and 660-km discontinuities can be identified easily from the two depth sections. We manually picked the two discontinuities from all the stacked receiver functions. The average depth of the 410-km and the 660-km is 418.2 km and 673.7 km, respectively. The 410-km is roughly similar to the global average (418 km) while the 660-km is about 14 km deeper than the global average (660 km) obtained from SS precursor studies (Flanagan and Shearer, 1998; Gu and Dziewonski, 2002). Consequently the transition zone thickness is 255.5 km, 13.5 km thicker than the global average. Gu and Dziewonski (2002) found that in general continents are underlain by a thicker transition zone than oceans, and the transition zone beneath the Eurasian Plate is ~ 9 km thicker than the global average. The observed thick transition zone here thus is consistent with theirs and may indicate that the average temperature within the transition zone is lower here due to a rather complicated subduction history including the subduction of the Pacific Plate since Jurassic.

The lateral variation of the 410-km relief is shown in Figure 4a with the counts of the Ps conversion points in each cap (Figure 4b). The discontinuity beneath the west side of the NSGL (413.9 km) appears to be significantly shallower than the east side (421.9 km). This difference is unlikely related to the presence of the subducted Pacific slab which penetrates the 410-km at a location further east to the study region (Fukao et al., 2001; Huang and Zhao, 2006; Li and van der Hilst, 2010). Rather it is likely that the east-west contrast observed here is caused by unmodeled velocity structure in the upper mantle. Li and van der Hilst (2010) found that the lithosphere beneath the Precambrian Ordos and Sichuan basins has substantially high seismic velocities and the high velocity regions extend to at least 250 km deep. The 410-km beneath the two basins are ~ 10 km shallower than the surrounding areas, suggesting the shoaling of the 410-km is rather an artifact of the reference model. We note that the uplift shown at the upper left corner of the map (labeled as UL in Figure 4a) is not robust since we have almost no data coverage in this region. The most prominent feature of the 410-km relief map shown in Figure 4 is a ~ 15 km depression beneath the Quaternary Datong volcano located at the northeastern edge of the Ordos Plateau in North China. Interpreting this depression will be combined with transition-zone thickness in the later part of the discussion.

As shown in Figure 3, the 660-km beneath the Huanghai Sea south of the Shandong peninsula appears to have two branches. We picked the depth of the two branches and the lateral variations based on these picks are shown in Figures 5a and 5b, respectively. Chen and Ai (2009) also found a double-branched 660-km roughly in the same areas. Beside the double 660-km, we also observed an east-west contrast in the depth of the discontinuity. The region located at the west side of the NSGL has a shallower 660-km (666.9 km) than the east side (680.2 km) does. As discussed in the last paragraph, part of this contrast is likely to result from unmodeled 3D velocity heterogeneities. The NSGL seems to well coincide with the western edge of the area with a significantly depressed 660-km. Huang and Zhao (2006) found that the western front of the subhorizontally lying Pacific Plate inside the transition zone is spatially consistent with the NSGL. They suggested that the subducting Pacific Plate might have significant influence on surface topography. Chen and Ai (2009) also found the same correlation from the transition-zone thickness map beneath North China.

The mantle transition-zone thickness computed from the depths of the two discontinuities is shown in Figure 6a. Here we removed the mean value to show lateral variations of the transition-zone thickness. We found a thickened transition zone around the western Huanghai Sea where a double-branched 660-km is observed. Li and van der Hilst (2010) found a NNE trending high velocity anomaly (TZ2 in their Figure 4) beneath the Bohai and Huanghai Seas between 30°N and 40°N . They interpreted it as the subducted Pacific Plate during late Cretaceous and Paleogene (Figure 6b). The anomalous region on our transition-zone thickness map is located between 30°N and 37°N . We have many data that sample the Bohai Sea region, so the northern edge of the anomaly should be well constrained. However, if the transition zone beneath the Bohai Sea has a low v_P/v_S ratio in addition to the high P-wave velocity, then the transition zone can be significantly (>5 km) underestimated.

The western front of the anomaly is located at $\sim 115^\circ\text{E}$, two to three hundreds kilometers east to the NSGL. The good correlation observed between the surface topography and the depth of the 660-km is absent here. Since estimates of transition zone thickness are less influenced by 3D velocity structure above the 410-km discontinuity, the transition zone thickness has been considered as a better thermometer of the transition zone compared to the absolute depth estimates of the

Figure 4 (a) Map showing the depth variations of the 410-km discontinuity. Note that the average depth was removed from the depth. The thick grey line indicates the North South Gravity Lineament. The thin grey lines show the boundaries of the major tectonic blocks in the study region. (b) Number of receiver functions gathered at each grid point for stacking. Note that due to the number of events recorded at each station varies significantly, so the conversion density map shown here is slightly different from the station distribution maps shown in Figures 1 and 2.

Figure 5 Map view of the depth variations of the 660-km discontinuity picked from the deep (a) and the shallow branch (b) of the 660-km discontinuity. Light shades indicate regions with only a few receiver functions (<30) that can be used for stacking. Consequently, the results shown in these regions may not be robust. The solid red line outlines the region with a two-branched 660-km discontinuity. The thin and thick grey lines represent tectonic block boundaries and the North South Gravity Lineament, respectively.

Figure 6 (a) Map showing the thickness variations of the transition zone (TZ). In the region where a double-branched 660-km is observed, depths of the deep branch of the 660-km discontinuity were used in computing transition zone thickness. (b) Map showing the subducting Pacific Plate along the east coast and southwest Japan at late Oligocene (Hall, 2002), currently being replaced by the subducting Philippine Plate due to the opening of the Philippine Sea. Black lines with solid triangles indicate the trench locations ~20 Ma ago. Cyan dash lines show the current plate boundaries, and solid gray lines illustrate active spreading centers.

two discontinuities. Thus we tend to argue that the correlation between surface topography and the transition zone structure proposed by previous studies is questionable and requires further quantitative investigation. It also seems that this correlation is not shown in the tomographic images of Li and van der Hilst (2010). As we discussed above, the transition thickness map shown here still suffers from unmodeled velocity heterogeneities in the transition zone, it is hard to make a definitive argument whether the surface topography is controlled by the subducted Pacific slab. Both the India-Asia collision and the eastward retreat of the Pacific subduction could play a role in determining the boundary between the compressional and extensional terranes.

Although the 410-km beneath the Datong volcano shows a prominent ~15 km depression, the transition zone thickness beneath the volcano appears to be rather normal (Figure 6). While a normal transition zone implies that the origin of the observed volcanism is likely within the upper mantle, the depth extent of the upwelling associated with the volcanism is not well constrained here. Based on the observed ~15 km depression on the 410-km, we estimated the amount of ve-

locity anomalies in the upper mantle. If the depression is caused by an unmodeled low velocity anomaly in the upper mantle, it requires either a strong (4%–8%) localized low velocity anomaly near the lithosphere-asthenosphere boundary or ~1.5% low velocity column across the entire upper mantle above the 410-km. The latter is more consistent with the results from recent tomographic study of Li and van der Hilst (2010), who found a prominent low-velocity anomaly extending to almost 400 km beneath the Datong volcano.

Xu et al. (2005) analyzed the geochemical and isotopic compositions of alkali and tholeiitic basalts collected from the Datong volcanic field. They found that the alkali basalts have relatively homogeneous geochemical and isotopic compositions similar to oceanic island basalts. Thus the alkali basalts are likely derived from asthenosphere. The tholeiitic basalts appear to be originated near the lithosphere-asthenosphere boundary, which is located ~50–70 km deep below surface. Based on the geographic distribution of the alkali and tholeiitic basalts, which were found progressively from northwest to southeast, they suggested the lithosphere beneath the volcanic field thins progressively from northwest to southeast before it deeps drastically beneath

the Taihangshan mountain range. The rapid change in the depth of the lithosphere-asthenosphere boundary induces a secondary convection, the so-called edge driven convection, and results in a small-scale upwelling responsible for the observed volcanism. The scenario thus suggests a shallow origin near the lithosphere-asthenosphere boundary for the volcanism occurred at Datong if the lateral scale of the convection is limited in local scale. Thus further seismic studies are needed to provide better images under the volcano.

Observation of multiple velocity jumps at depths between 650 km and 750 km have been reported by many studies. Niu and Kawakatsu (1996) found a complicated 660-km at the tip of the subducting Pacific Plate beneath northeastern China. They interpreted the observed triple velocity jumps to result from garnet transformations together with the post-spinel phase transition. Ai et al. (2003) confirmed the presence of this multiple-discontinuity structure in a broader area beneath northeastern China. They also found the regions with multiple seismic discontinuities are intermittently distributed, and are mixed with regions with a simple depressed 660-km discontinuity, which suggests that the phase diagrams of the non-olivine minerals are extremely sensitive to temperature, as shown in the calculation of Vacher et al. (1998). Simmons and Gurrola (2000) found multiple seismic discontinuities near the base of the transition zone beneath southern California, where there is no subducting slabs. Hirose et al. (1999) found that the post-garnet transformation starts at 26 GPa (equivalent to a depth of 720 km) and 2000 K and completes within a 1 GPa interval. Simmons and Gurrola (2000) employed this phase change to interpret their observation. A 2000 K at ~ 700 km depth implies a 1650 K adiabat, which is slightly higher than the regular mantle potential temperature of 1550 K proposed by McKenzie and Bickle (1988). A slightly elevated temperature agrees with the low seismic velocities observed beneath southern California.

The double-branched 660-km is not observed along the entire strike of the Cretaceous-Paleogene Pacific slab, rather it is found only in a narrow area with a NS extension of ~ 350 km (Figure 6). We noticed that this multiple-branch feature is not shown at the 410 km discontinuity (Figure 3). In addition, this feature is always shown in the CCP images regardless of whether a 1D or 3D reference model is used. Thus we believe it is a robust feature reflecting the nature of the 660-km in the area rather than a numerical artifact. The double-branched 660-km region observed here, on the

other hand, is much smaller than those observed by Gao et al. (2010) with the China National Digital Seismic Network (CNDSN). Single station stacking method was used in their study. In principle, as the conversion points at the 660-km spread in a quite large area (~ 2.5 degrees in radius), the single-station stacking method has the risk of mapping depth variations of a discontinuity into multiple ones. This could be one possible explanation of the observed discrepancy, although more careful comparison of the two methods with a similar dataset is needed in order to clear this issue.

Temperature plays a key role in determining the phase diagram of garnet. It has been shown that at very lower temperature condition (1000 K adiabat) garnet dissolves into ilmenite at around 620 km and stays stable down to 710 km depth when it starts to transform into perovskite (Vacher et al., 1998). These phase changes together with the post-spinel reaction of the olivine produce a multiple jumps in seismic velocity. As temperature increases, the stable depth range of ilmenite decreases drastically. At a regular mantle adiabat (~ 1550 K), the garnet dissolves into perovskite directly at roughly the same depth of the post-spinel phase transition, which leads to a single and enhanced velocity jump. At higher temperature, the post-garnet phase transition requires a higher pressure than the post-spinel reaction does. The post-garnet transformation completes in a 30–50 km depth range (Hirose et al., 1999; Akaogi et al., 2002; Vitos et al., 2006), implying a second velocity jump below the main 660-km caused by the post-spinel phase change.

The observed lateral distribution of the double-branched 660-km thus provides strong constraints on the lateral variation in temperature at the base of the transition zone. Based on the three scenarios discussed above, the double-branched 660-km region is likely to have a very low temperature, cold enough to allow ilmenite to be stable. The remaining slab, being continuously warmed for millions of years, is not cold enough to allow a stable ilmenite to exist. Instead, garnet transforms directly into perovskite, and this transformation occurs at roughly the same depths where ringwoodite dissolves into perovskite plus magnesiowüstite. The temperature of the remaining slab is, however, still significant low (~ 100 K) compared to its surrounding regions, resulting in a depressed 660-km. In general temperature at the base of the transition zone in our study area is not high enough to promote a prominent post-garnet phase transition at a great depth. Thus we do not see any multiple-branched 660-km, like those ob-

served in southern California (Simmons and Gurrola, 2000) outside the Cretaceous-Paleogene Pacific slab. The observed lateral variation in temperature within the subducted slab could also be related to the spatio-temporal evolution history of the subduction along the east coast of China (Figure 6b). Due to the northeastward retreat of the Izu-Bonin-Mariana trench, the subduction along the east coast of China was closed progressively from south to north, resulting in an increase in the volume of subducted slab toward the north. This may explain why the northern section of the slab is colder than its southern neighbor. This is another possible interpretation for the limited distribution of the double-branched 660-km observed here, which is related to the subduction geometry. It is conceivable that the post-garnet phase transition needs to occur in a broad area in order to be imaged by a relatively low-frequency dataset used in this study.

4 Conclusions

We investigated the mantle transition-zone structure beneath eastern and central China using a large amount of waveform data recorded at the national and regional seismic networks of the China Earthquake Administration. The CCP images from receiver function data showed the following features of the 410-km and 660-km discontinuity beneath the study region: (1) Although there is good correlation between the surface topography and the estimated depths of the two discontinuities, the western front of the subducting Pacific Plate does not seem to be obviously correlated with the topographic boundary between eastern and western China, suggesting that the Pacific subduction is not necessarily the sole process in controlling the western extent of the eastern terrane of China; (2) The Quaternary Datong volcano is underlain by a localized low velocity anomaly that may extend to ~400 km below the surface; (3) The presence of the Pacific Plate subducted during the late Cretaceous and Paleogene is manifested by a double-branched 660-km discontinuity located beneath the Huanghai Sea and surrounding regions with a moderately depressed 660-km.

Acknowledgements We would like to thank the Data Management Center of the China Earthquake Administration for providing the waveform data, and two anonymous reviewers for critical and constructive reviews. This work was supported by NSF under grant EAR-063566.
