Abstract A peeling linear inversion method is presented to study the upper mantle (from Moho to 800 km depth) velocity structures with receiver functions. The influences of the crustal and upper mantle velocity ratio error on the inversion results are analyzed, and three valid measures are taken for its reduction. This method is tested with the IASP91 and the PREM models, and the upper mantle structures beneath the stations GTA, LZH, and AXX in northwestern China are then inverted. The results indicate that this inversion method is feasible to quantify upper mantle discontinuities, besides the discontinuities between $3h_M$ (h_M denotes the depth of Moho) and $5h_M$ due to the interference of multiples from Moho. Smoothing is used to overcome possible false discontinuities from the multiples and ensure the stability of the inversion results, but the detailed information on the depth range between $3h_M$ and $5h_M$ is sacrificed.

Key words: upper mantle; receiver function; peeling; linear inversion

1 Introduction

Inversion of the upper mantle velocity structure using observed receiver function (ORF) $r^o(t)$ is not easy because the amplitude of the first-transmission seismic phases and the crustal multiples are much larger than those of P_{410S} and P_{660S} , and conception about the upper mantle in $r^o(t)$ is not clear. Therefore, the inversion depth of many previous results only reached the Moho and the uppermost mantle. Some studies, however, attempted to extract more information from the deeper upper mantle. Liu et al. (1997) used a complex spectrum ratio of the receiver functions to invert the crust and uppermost mantle structures below 10 China Digital Seismograph Network stations down to a depth of 100 km. Vinnik et al. (2004) inverted the velocity structure down to 150 km depth beneath central Tianshan using P and S receiver functions. Julià et al.

(2005) combined the receiver functions with surface wave to invert the crustal and upper mantle velocity structure of eastern Africa down to the depth of 300 km. Zhou and Yang (2003) proposed a peeling genetic algorithm of $r^o(t)$ and extended the inversion depth to 700 km. This method divides the crust and upper mantle into several parts and inverts their velocities step by step from the crust to the depth of 700 km, which presents a new way to study the deep discontinuities in the upper mantle. But the efficiency of this method is not satisfactory due to the excessive parameters used in the inversion. In addition, the results of deeper structures are distorted for the cases with incorrect or unstable shallow structures. Although the genetic algorithm method is very good for searching for the global optimal solution, it inevitably falls into the local optimal solution.

Here, the peeling linear inversion method of $r^o(t)$ tries to investigate the upper mantle velocity structure by fixing the crustal structure from previous results. The velocity between the Moho and 800 km depth is inverted by peeling part of $r^o(t)$ corresponding to the crust. A simple initial model is used in the inversion.

Based on numerical tests, the influence of the error of the crustal and upper mantle velocity ratio is analyzed, and it is then reduced by smoothing some special depth ranges.

The method is tested with two global Earth models. The ORFs in the stations GTA, LZH, and AXX in northwestern China are used to invert the upper mantle structure beneath the stations.

2 Method

2.1 Concept of peeling

The time windows of $r^o(t)$ should be set from initial P arrival to 80 s to study the crustal and upper mantle velocity structure. The phase amplitude of $r^o(t)$ in the upper mantle discontinuities is small even if the P_{660} s amplitude, the strongest phase of the upper mantle discontinuities, is only one-third of that of the P_{MS} . Information on the upper mantle discontinuities in ORFs is very minimal due to the existence of noise, thus, identifying this weak signal is oftentimes difficult. The fitting window will concentrate in the 0–20 s range during inversion when the crustal and the upper mantle structures are completely inverted. This time window just contains the information about the crust and uppermost mantle, so the upper mantle structure cannot be inverted effectively. The peeling method is a possible solution for this problem. Based on previous crustal structure results, the upper mantle structure is inverted using linear inversion. The steps are as follows:

1) The crustal structure obtained from the receiver functions and surface wave dispersion curves in many regions can be used to construct initial model of the crust. During the inversion, the crustal structure is fixed by adjusting the parameters.

2) The upper mantle structure is generally identical for different regions compared with crustal structure, so a common and simple initial model of the upper mantle is used. $r_{\text{crust}}(t)$, the part of $r^o(t)$ corresponding to the crust, is nearly invariable because of fixed crust model, so the upper mantle structure is adjusted to fit $r_{\text{mantle}}(t) = r^o(t) - r_{\text{crust}}(t)$, the residual part of $r^o(t)$.

2.2 Linear inversion of the upper mantle velocity structure

2.2.1 Program and parameters

The program package PROGRAMS.330 (Hermann and Ammon, 2002) is adopted to invert the upper mantle structures with $r^o(t)$. The thickness or the velocity of each layer m_i in the inversion can be changed, and the parameters are adjusted so as to control the

variation of the unknown thickness or velocity at a certain depth. The detailed information about the parameters is presented as following.

The relationship among the vectors of the velocity model $\mathbf{M}(m_1, m_2, \dots, m_i)$, initial model $\mathbf{M}_0$, and residual S between $r^o(t)$ and the synthetic receiver function predicted from the theoretical model can be expressed as

$$\begin{pmatrix} D \\ \sigma \Delta \end{pmatrix} \mathbf{M} = \begin{pmatrix} S \\ 0 \end{pmatrix} + \begin{pmatrix} D\mathbf{M}_0 \\ 0 \end{pmatrix}, \quad (1)$$

where D is a matrix containing the partial derivatives of the waveform with respect to changes in the layer velocities for model $\mathbf{M}_0$, Δ is the roughness matrix of the model, and σ is a balancing factor between the variance of the model and fitness of the observed data. $\Delta = \mathbf{W}_1 \mathbf{W}_2$, where $\mathbf{W}_1$ is a general smoothing matrix, which minimizes the difference between adjacent values of the change in m_i from the initial model, and is expressed as

$$\mathbf{W}_1 = \begin{pmatrix} 1 & -1 & 0 & \cdots & 0 \\ 0 & 1 & -1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & -1 \\ 0 & 0 & 0 & \cdots & 1 \end{pmatrix}. \quad (2)$$

In this form, $\mathbf{W}_1$ can force a degree of smoothness on the changes in m_i . If $\mathbf{W}_1 = \mathbf{I}$, there is no smoothness constraint in the inversion. $\mathbf{W}_2 = \text{diag}\{\chi_1^{-1}, \chi_2^{-1}, \chi_3^{-1}, \dots, \chi_n^{-1}\}$ is constructed by weighted factor χ_i for each layer, and used to provide a relative weight to the constraints. For example, to force a sharp discontinuity at a given boundary when smoothing constraint is employed, χ_i^{-1} is made small. To select appropriate values of $\mathbf{W}_1$ and $\mathbf{W}_2$, the value of m_i can be changed sharply at some depths where discontinuity might exist. The model can also be smoothed at some depths where no discontinuity might be presented.

2.2.2 Initial model of the upper mantle

The linear inversion method result depends greatly on the initial model, so constructing an initial model is very critical. Two initial models are constructed for the inversion in our study.

1) The first initial model (Figure 1a). Many studies have shown that “410” and “660” are global discontinuities, and other discontinuities in the upper mantle have been detected (Anderson and Bass, 1986; Shearer, 1990; Shearer and Flanagan, 1996) although they are

not global. The initial model (from Moho to 800 km) is obtained from IASP91 model (Kennett and Engdahl, 1991) without first-order discontinuity. The velocity values around the depths of 410 and 660 km are permitted to change sharply in order to search for the discontinuities. Details on the initial steps are as follows: firstly, the entire upper mantle is divided into many thin layers from Moho to 800 km depth. The thickness of each layer h_i is determined according to the resolution of $r^o(t)$ using Gauss filter factor $\alpha=1.5$, which increases from

Figure 1 (a) Numerical test of the linear inversion method for the IASP91 model. Thin line stands for IASP91 model, dotted line for initial model, and solid thick line for inversion model. (b) Receiver functions of the inversion and IASP91 models.

and 620–700 km, v_s can be changed sharply by introducing a large χ_i . If the stacking result of the ORFs shows other discontinuities at some depths, the velocities can be permitted to change largely around these depths by controlling the χ_i value. The model is flattened to calculate the synthetic receiver function in the inversion because the IASP91 model is spherical. The final inversion result is still a spherical model.

2) As shown in Figure 2a, the second initial model is also a one without a first-order discontinuity, but the previous result from the upper mantle in the study area. In the present paper, the model between Moho and 350 km depth is used to as the initial model based on the inversion results of the wave dispersion curve combined with the local structure.

Figure 2 (a) Numerical test of the linear inversion method for the PREM. Gray line stands for PREM, dashed line for initial model, and black line for inversion model. (b) Receiver functions of the inversion and PREM models.

2.2.3 Detailed steps

The linear inversion is carried out according the following two steps. Firstly, the approximate depth range in the upper mantle is estimated in reference to the stacking results of $r^o(t)$ after the moveout correction (Yuan et al., 1997). χ_i is set to 5.0 in this depth range, and is fixed to 1.0 in the other depth ranges in the upper mantle, whereas χ_i is taken as 0 in the crust, which ensures that the velocity values are not changed during the inversion process. A total of 40 iterations are made for the initial model in linear inversion. Then, the crustal velocity is also iterated in the last 10 times with $\chi_i=0.2$ in the crust, and $\chi_i=1$ in the upper mantle. These values can reduce the effect of deviation from the crustal structure. Secondly the “410” or “660” discontinuity in the above inversion result is often a gradient layer instead of a first-order discontinuity. The mean value of the depths of the gradient layer is considered as the depth of the discontinuity. Subsequently, the depths of the discontinuities are input into initial models to construct a new initial model. The upper mantle velocity is inverted based on this initial model. In the former 40 iterations, v_{S_i} and h_i are changed, χ_i is fixed to 5, and smoothing is not applied. In the 41st to 50th iterations, only the v_{S_i} values in the crust and upper mantle are considered. The final inversion results are the crustal and upper mantle velocity model.

2.3 Error analysis

2.3.1 Error in upper mantle velocity

The covariance matrix of the inversion parameters in equation (1) can be described as follows (Ammon et al., 1990):

$$[\text{cov}M] = (\Delta^{-1}V(\Lambda^2 + \sigma^2I)^{-1}\Lambda U^T)\delta d\delta d^T. \\ [\Delta^{-1}V(\Lambda^2 + \sigma^2I)^{-1}\Lambda U^T]^T, \quad (3)$$

where δd is the error of d , U and V are orthogonographical matrix arising from singular value decomposition of $D\Delta^{-1}$. $D\Delta^{-1}=U\Lambda V^T$. Λ is a diagonal matrix composed of the positive eigenvalue of matrix $(D\Delta^{-1})(D\Delta^{-1})^T$.

Assuming that the observed data are independent of each other but with the same variance E^2 , $\delta d\delta d^T=E^2I$ yields

$$[\text{cov}M] = E^2\Delta^{-1}V(\Lambda^2 + \sigma^2I)^{-1}. \\ \Lambda^2(\Lambda^2 + \sigma^2I)^{-1}V^T(\Delta^{-1})^T. \quad (4)$$

The velocity covariance matrix can be calculated using equation (4) if E^2 is known in advance. E^2 can be estimated according to the signal-to-noise ratio (SNR) of

the observed waveforms. The waveforms of the R and Z components can be expressed as

$$\begin{cases} R(t) = R_S(t) + R_N(t) \\ Z(t) = Z_S(t) + Z_N(t) \end{cases} \quad (5)$$

The subscripts ‘N’ and ‘S’ represent the noise and signal, respectively. Then, we have

$$r^o(t) = r_S^o(t) + r_N^o(t). \quad (6)$$

According to the theory of receiver function $R(t) = Z(t) \otimes r^o(t)$, we can get

$$R_S(t) + R_N(t) = [Z_S(t) + Z_N(t)] \otimes [r_S^o(t) + r_N^o(t)]. \quad (7)$$

For the high-SNR records, $Z_S(t) \gg Z_N(t)$ or $Z(t) \approx Z_S(t)$, thus

$$R_S(t) + R_N(t) \approx Z_S(t) \otimes r_S^o(t) + Z_S(t) \otimes r_N^o(t) \approx Z_S(t) \otimes r_N^o(t). \quad (8)$$

And for the non-noise ORFs, $R_S(t) = Z_S(t) \otimes r_S^o(t)$, then

$$R_N(t) = Z(t) \otimes r_N^o(t). \quad (9)$$

In this paper we cut the waveforms prior 20 s to the direct P as $R_N(t)$, so $r_N^o(t)$ can be obtained by cutting the waveforms on $R_N(t)$ in the time window. The square of the maximum value of $r_N^o(t)$ is considered as the value of E^2 . Then, the velocity error can be calculated by equation (4).

2.3.2 Error of the depth of discontinuity

The Gauss filter factor α is equal to 1.5 during the time deconvolution. The resolution of the layer thickness of $r^o(t)$ with different α values has been discussed by Cassidy (1992), in which the thickness resolution for “410” and “660” were approximately 4.0 and 4.5 km, respectively, for $\alpha=1.5$. These two values are considered as the errors of h_{410} and h_{660} in this study.

3 Numerical tests of the peeling linear inversion method

The synthetic receiver functions of the IASP91 model are used to test the method. The steps and parameters are the same as those mentioned in section 2.2. As shown in Figure 1, the depths of h_{410} and h_{660} in the inversion model are 410 and 657 km, respectively, and the mean error of v_S is only 0.052 km/s, therefore all of the parameters are very close to those of the IASP91 model.

The synthetic receiver function of the preliminary

reference Earth model (PREM) (Dziewonski and Anderson, 1981) is also used to do the same numerical test as the IASP91. A strong positive signal is present around 24 s, which could be the P-to-S phase for one discontinuity. Thus, $\chi_i=5$ is set in the 200–240 km-depth range to determine the discontinuity in the depth range. Figure 2 shows the result of the numerical test. Three discontinuities are found at the depths of 222, 401, and 671 km, respectively, which are close to those of the PREM (220, 400, and 670 km). The velocity is also consistent with that of the PREM. The mean error of v_S is 0.079 km/s.

The results of the above numerical tests indicate that the peeling linear inversion is feasible, and the initial model is general. For example, the inversion result with the initial model based on the IASP91 model is also viable for the synthetic receiver function of PREM.

Similarly, the inversion results of v_S and the depth of the first-order discontinuity are satisfactory in the numerical tests. However, no information is available in the receiver functions for some second-order discontinuities (~ 200 km depth in IASP91 and ~ 600 km depth in PREM). Therefore, the method is invalid for second-order discontinuity due to a large error appearing near

the depth in the second-order discontinuity.

4 Application to the stations GTA, LZH, and AXX

The linear inversion method mentioned above is applied in three stations, namely, GTA, AXX, and LZH, in northwestern China. We select the teleseismic waveforms of the events with $M_S \geq 5.5$ and epicentral distance 30° – 90° from November 2000 to October 2005. The corresponding $r^o(t)$ is then constructed by deconvolving the vertical component from the radial component using an iterative approach (Ligorria and Ammon, 1999). A distance moveout correction for the P-to-S converted phases is adopted (Yuan et al., 1997) to give prominence to P_{dS} (P-to-S phase from the discontinuity to the depth d) phases for all ORFs. Based on the IASP91 model, all the P_{dS} phases are shifted according to the epicentral distance of 65° with a 20 km-depth source, then the travel times of P_{dS} phases of different epicentral distance are aligned. Figure 3 shows the stacking results after the moveout correction for the three stations. We can see the clear phases, P_{410S} and P_{660S} , from the upper mantle discontinuities in Figure 3.

Figure 3 Stacking of the receiver functions after moveout correction of the station GTA with 156 events (a), for the station AXX with 140 events (b), and for the station LZH with 118 events (c).

The GTA station is chosen as an example to describe the data processing and inversion step. The inversion result beneath the station GTA is shown in Figure 4. The initial model is constructed based on the crustal (Ma and Zhou, 2007) and upper mantle models from the surface wave (Huang et al., 2003). Three ORFs with high SNR are selected to invert the crustal and upper mantle structures with the same step described

in section 2.2. Phases P_{MS} , P_{410S} , and P_{660S} are very clear, thus the smoothness around 51, 410, and 660 km is very small, whereas the smoothness is large in the other depth ranges. The depths of h_{410} and h_{660} are 398 and 655 km, respectively. The v_S error is 0.023 km/s estimated by the method in section 2.3.2.

The same method is used to invert the crustal and upper mantle structures beneath the stations LZH

(Figure 5) and AXX (Figure 6). Table 1 lists the h_{410} , h_{660} , v_S error, and number of $r^o(t)$ for each station. The possible error from the crust structure will be discussed in the next section (as shown in Figure 7).

The disturbances with 4% and 2% noise are added to the IASP91 and PREM models, respectively. Thick lines denote the true model, and thin lines denote inverted results for different errors.

5 Discussion and conclusions

Some deviations certainly exist between the real crustal structures and the reference model. Such deviation may result from the velocity value, Moho depth, velocity ratio, or all of them. The inversion results are affected by these deviations. The influences from these possible deviations are discussed as follows.

1) Influence from the crustal velocity error. Crustal models with respective errors of $\pm 4\%$ and $\pm 2\%$, based on the IASP91 model and PREM, are used to construct the initial model according to the steps outlined in section 2.2.2. The peeling linear method is used to invert the upper mantle structure (Figure 7a and c). The results indicate that the depth range with the largest error in the inverted results is in the range of 120–190 km for the IASP91 model and 80–150 km for the PREM. Some false discontinuities exist in this depth range.

2) Influence from the Moho depth error. The error of the Moho depth h_M is approximately 1–2 km from the receiver function and the surface wave. Based on the above information, the h_M error model is constructed. h_M changes by values of ± 2 and ± 1 km based on the IASP91 model and PREM, respectively. The peeling linear method is used to invert the upper mantle structure (Figure 8a and c). The depth ranges with the largest error in the inverted results are still 120–190 km for the IASP91 model and 80–150 km for the PREM, respectively.

The depth ranges with the largest error are the same for the above two types of error models because the arrival of the multiples in the $r^o(t)$ from the Moho for the error models deviates from the IASP91 and PREM models. The multiples can be explained by the direct conversion phases from deeper discontinuities; thus, false discontinuities exist in the inverted results

Figure 8 Numerical tests for the error of the Moho depth without (a, c) or with (b, d) smoothing between $3h_M$ and $5h_M$. Disturbances with 2 and 1 km are added to the Moho depth for the IASP91 and PREM models, respectively. Thick lines denote the true model, and thin lines denote inverted results for different errors.

in the depth range of 120–190 km for the IASP91 model and 80–150 km for the PREM.

3) Countermeasures to decrease the influences from the crust error. The errors of the crustal model have influence on the inversion results in some depth ranges based on the above numerical tests. The depth range with the largest error is $3h_M$ – $5h_M$ in the inversion model. To ensure stability and reliability at this depth range, the previous results are used to construct the initial model. Another valid method is the velocity smoothness ($\chi_i=0.25$) in the depth range of $3h_M$ – $5h_M$. Figures 7b, d and 8b, d show the inversion results with smoothness for the numerical tests mentioned above. The velocity errors become smaller with smoothness. The false discontinuities in the $3h_M$ – $5h_M$ depth range also disappear. The detailed velocity structures in this depth range are also smoothed, and the real discontinuities in this depth range cannot be inverted.

4) Influence from the error of v_P/v_S ratio in the upper mantle. The v_P/v_S ratio was fixed in the above method in reference to the IASP91 model. Anyway, the velocity ratio is generally different for IASP91 and the real-Earth models. Zhu and Kanamori (2000) indicated that the estimation of the Moho depth is affected by v_P/v_S ratio. The depths of the upper mantle discontinuities are also influenced by the value of v_P/v_S ratio. Figure 9 shows the ratio in the upper mantle beneath the three stations (GTA, AXX, and LZH) from the v_P and v_S tomography (Qu et al., 2007). The v_P/v_S ratio from the tomography is close to the IASP91 model with a mean error about -0.01 . Therefore, v_P/v_S ratio of the IASP91 model can be used to invert the upper mantle structures for the three stations.

To sum up, in the present paper, the upper mantle structures beneath the three stations (GTA, AXX, and LZH) in northwestern China were inverted using the peeling linear inversion method, which was tested by using the IASP91 and PREM models. Based on the crustal model and prior information from ORFs, the weighted factor χ_i and smoothness matrix Δ were combined to peel the shallow structure from the Earth model, and the discontinuities were highlighted by suppressing the possible false discontinuities in some depth ranges.

However, the details of the velocity structure in the depth range between $3h_M$ and $5h_M$ were lost in the inverted results because of the smoothness. The velocity value was not fixed but varied in a narrow range for $\chi_i=0.25$. The initial model refers to the surface tomography in this region, thus the inverted model is reasonable.

Figure 9 v_P/v_S ratio from the tomography with P and S phases beneath the three stations. The value of IASP91 is also plotted.

In addition, the inverted result is sensitive to the v_P/v_S ratio. The tomography from the P and S phases shows that the difference between the IASP91 and the Earth models beneath the three stations in the present study is very small. The average difference is just -0.0128 . Such difference induces a small error in the result, implying the local model should be used to construct the initial model to reduce the error of the inversion result.
