Abstract We congratulate the authors for a stimulating and valuable manuscript, providing a careful review of the state-of-the-art in cross-sectional and time-series benchmarking procedures for small area estimation. They develop a novel two-stage benchmarking method for hierarchical time series models, where they evaluate their procedure by estimating monthly total unemployment using data from the US Census Bureau. We discuss three topics: linearity and model misspecification, computational complexity and model comparisons, and, some aspects on small area estimation in practice. More specifically, we pose the following questions to the authors, that they may wish to answer: How robust is their model to misspecification? Is it time to perhaps move away from linear models of the type considered by Fay and Herriot (J Am Stat Assoc 74:269–277, 1979), Battese et al. (J Am Stat Assoc 83:28–36, 1988)? What is the asymptotic computational complexity and what comparisons can be made to other models? Should the benchmarking constraints be inherently fixed or should they be random?.

1 Linearity and model misspecification

The authors review previous work in cross-sectional and time-series benchmarking thoroughly, and propose a new cross-sectional two-stage time series benchmarking method. This method is mathematically well-posed and carefully thought-through. It is applied to the estimation of unemployment totals at the state-level and census-divisions (aggregate state-level estimates). However, with respect to model validity, the analysis does not go beyond evaluating coefficients of variation with respect to the direct estimates. Furthermore, although the application here may satisfy the modeling assumptions, it is important that methods are built to be robust to general model misspecification. As one of the authors recently writes, checking model validity is very important in small area estimation (Pfeffermann 2013).

The method proposed here relies on a form of the celebrated Fay-Herriot model (Fay and Herriot 1979). That model, and that of Battese et al. (1988), were major achievements for small area estimation, but rest on simplifying assumptions, especially of linearity, which are not always valid. These modeling assumptions were not checked in Pfeffermann et al. (2014), and we are unable to check them ourselves since the covariates are not given.¹ To illustrate what would be involved in such a check, however, we look at cross-sectional data on child poverty from the the Small Area and Income Poverty Estimate (SAIPE) Program at the US Census Bureau.² The response variable is the rate of child poverty in each state (in 1998), and the covariates are an IRS income-tax-based pseudo-estimate of the child poverty rate, the IRS non-filer rate, the rate of food stamp usage, and the residual term from the regression of the 1990 Census estimated child poverty rate. We fit an additive model, which strictly nests the linear model implied by the Fay-Herriot assumptions. Figure 1 shows the estimated partial response functions, which are clearly nonlinear for three of the four covariates.

If, on examination, the data in Pfeffermann et al. (2014) are not linear, then the exact method they propose does not apply. However, semiparametric and non-linear models are also available in the small area literature. For example, models including penalized splines (P-splines) have been already used. In particular, Ugarte et al. (2009) use P-splines to model and forecast dwelling prices in the different neighbourhoods of a Spanish city and Militino et al. (2012) use P-splines to estimate the percentage of food expenditure for alternative household sizes at provincial level in Spain using the Spanish Household Budget Survey. Generalized linear mixed models are also common in disease mapping, an important application of small area estimation. For details, see Ugarte et al. (2014) and references therein. It seems important to determine how robust the Pfeffermann et al. (2014) method is to nonlinearity, and how it must be modified to handle highly nonlinear systems.

¹ It would be easier to perform such checks, and to make comparisons to our methods, if the code and data were made publicly available. This has been done for small area models by Molina and Marhuenda (2013), and advocated for statistical computation more generally by Stodden et al. (2013).

² This dataset was used before in Datta et al. (2011), with a Fay-Herriot model, and is publicly available at <http://www.census.gov/did/www/saipe/data/statecounty/data/1998.html>.

Fig. 1 Fitting of a generalized additive model to the 1998 SAIPE data. The *top left plot* is fairly linear, whereas the others deviate from linearity, suggesting the need for either a transformation or a nonparametric approach. In any case, this suggests that as in other disciplines non-linear models (e.g., generalized linear mixed models, kernel smoothers, splines) may be good directions to explore

2 Time complexity, model comparisons, and benchmarking

Benchmarking requires that estimates at a lower level of aggregation (perhaps counties) must match the estimates at a level of higher aggregation (the state total for example). [Pfeffermann \(2013\)](#) and [\(2014\)](#) discussed many advances in small area estimation and benchmarking, making the novel contributions very clear in terms of methodological advancements.

2.1 Time complexity and model comparisons

The procedure of [Pfeffermann et al. \(2014\)](#) is not the first attempt at two-stage benchmarking for time series. The key difference between their method, and the earlier one of [Ghosh and Steorts \(2013\)](#), is that the newer procedure cannot be calculated at once, but must be computed in two separate stages. It is not clear to us how one ought to choose between these methods in any particular application. A sensible reason to prefer one method would be that its underlying model fits better. This raises issues of model specification, as we mentioned above, as well as model comparison. The

latter is not discussed by [Pfeffermann et al. \(2014\)](#), but would seem to deserve serious attention.

Another, less statistical criterion for choosing between methods would computational complexity, however it is not clear which will always be the clear winner. The Bayesian approach of [Ghosh and Steorts \(2013\)](#) must wait for the Markov chain Monte Carlo to come close to convergence, but once it has a posterior sample, estimation is instantaneous, since most solutions are Bayes estimators in a reduced action space. For [Pfeffermann et al. \(2014\)](#), on the other hand, we ask what is the computational complexity of their method (and empirically how fast is it)? This requires further analysis.

2.2 Benchmarking with error

[Pfeffermann et al. \(2014\)](#) clearly explain the distinction between external and internal benchmarking. We focus here on external benchmarking, where there is an additional source of information that can be used for the purpose of the benchmarking procedures. Many papers have included external benchmarking in the last few years. For example, see [Datta et al. \(2011\)](#), [Ghosh and Steorts \(2013\)](#) and [Bell et al. \(2013\)](#) for details.

Production of small area estimation motivates “traditional” Bayesian benchmarking, wherein sub-domain estimates are optimized subject to the constraint that the weighted average equals some total for the domain (usually the direct estimate) ([Datta et al. 2011](#); [Ghosh and Steorts 2013](#); [Wang et al. 2008](#); [Pfeffermann et al. 2014](#)). This is effective when, for example, the goal is to match a direct domain estimate. However, it does not address situations where the direct estimate is imprecise, there is additional information at the domain level (e.g., an indirect estimate), or the domain is itself a sub-domain of a higher level. In such situations, it is more natural to treat the additional information as random rather than fixed. Thus, instead of making it a hard external constraint, it should be embedded into a probabilistic model, along with the sub-domain data. We bring this up because it is hard to believe that the direct domain estimates used in [Pfeffermann et al. \(2014\)](#) are fixed and without error. The uncertainty in these “external” quantities ought to be incorporated into the benchmarking, using the kind of probabilistic approach just mentioned. Preliminary investigations ([Steorts and Louis 2014](#)) suggest that under normality and linearity, such embeddings may produce almost the same results as the “traditional” approach. This equivalence breaks down as we move away from normality and linearity. Even if the specific application of [Pfeffermann et al. \(2014\)](#) does prove to be nearly-linear and nearly-Gaussian, non-linearity and non-normality are important in modern applications. We would very much like to see [Pfeffermann et al. \(2014\)](#) take up the challenge of probabilistic external benchmarking.

3 Small area in practice

Many users of small area estimation are more interested in practical considerations than in the underlying theory. Given the methods of [Pfeffermann et al. \(2014\)](#) for two-stage benchmarking and those of [Ghosh and Steorts \(2013\)](#), the advantages and

disadvantages of each approach are not clear except in the obvious case when the benchmarking needs to be separated into a two-step procedure due to a time-series as Pfeffermann et al. (2014) describes. It would perhaps be helpful if the authors could provide some practical guidance as to the benefits of their proposed methodology, as well as examples of settings in which they may outperform other approaches in the literature.

In the simulation study, the authors considered a reasonable number of small areas and time points. However, this might not be the case in many practical situations and typically out of sample areas could be present as the domains become increasing small. Examples include certain regions, provinces, and departments of Europe. In the United States, geographical regions include states, counties, regions, blocks, block-groups, etc. Can the same type of conclusions be made if the number areas and time points are both smaller (and in the presence of out of sample areas)? In addition, the authors give an application, dealing with states and census divisions, where the census divisions are aggregations of the states. How many of the states and census divisions are small areas after 2000 in terms of the coefficient of variation? Clarification here would be helpful towards practical applications to much smaller regions that are of interest. To summarize, do the methods always hold in practice and if not, when do they break down?

We again emphasize the contributions from the authors have made regarding both a review of benchmarking and a novel extension to benchmarking in time series. These have led us to ask important questions surrounding model misspecification, linearity, external benchmarking, and computational costs. Are we approaching benchmarking and small area methods in the most sound way, and if not, what should change?
