ABSTRACT

Eukaryotic DNA is hierarchically packaged into chromatin to fit inside the nucleus. Dynamics of the chromatin structure plays a critical role in transcriptional regulation and other biological processes that involve DNA, such as DNA replication and DNA repair. Many factors, including histone variants, histone modification, DNA methylation and the binding of non-histone architectural proteins regulate the structure of chromatin. Although the structure of nucleosomes, the fundamental repeating unit of chromatin, is clear, there is still much discussion on the higher-order levels of chromatin structure. Identifying the structural details and dynamics of higher-order chromatin fibers is therefore very important for understanding the organization and regulation of gene activities. Here, we review studies on the dynamics of chromatin higher-order structure and its relationship with gene transcription.

KEYWORDS chromatin, higher-order structure, dynamics, transcriptional regulation

The accessibility of eukaryotic DNA is dependent on the packing density of chromatin fibers in the nucleus. It has been clear that the dynamics of higher-order chromatin compaction is one of the key regulators of gene transcription. Crystal X-ray studies have defined the structure of nucleosomes, the basic units of chromatin, at high resolution; they consist of 147 bp of DNA wrapping around an octamer of histones (two copies each of H2A, H2B, H3 and H4) approximately 1.7 times (Luger et al., 1997). The primary structure of chromatin, a “beads-on-a-string” nucleosomal fiber with nucleosomes connected by linker DNA, is highly compacted into a condensed 30 nm chromatin fiber which is typically regarded

as the secondary structure (Robinson and Rhodes, 2006). Further compaction of chromatin fibers may form other higher-level chromatin structures, but so far details of these structural levels remain obscure. Although it is clear that the hierarchical formation of chromatin higher-order structure includes intra-nucleosome interactions, nucleosome-nucleosome interactions, intra/inter-chromatin fiber interactions and interactions between chromatin and chromatin architectural proteins, the interplay between these interactions and the detailed arrangement of nucleosomes within chromatin higher-order structures, including 30 nm fibers, still remains largely uncharacterized. In this review, we focus on recent progresses in elucidating the detailed structure of higher-order chromatin and their structural dynamics in eukaryotic gene regulation.

STRUCTURE OF THE 30 nm CHROMATIN FIBERS: SOLENOID VS ZIG-ZAG MODEL

Early examinations of chromatin higher-order structure in nuclei and chromosomes *in situ* have yielded disappointingly little information. It is very difficult to adequately resolve nucleosomes and linker DNA in compact chromatin under conditions in the nucleus, and to trace the paths of chains of nucleosomes. Many investigators have focused on native chromatin isolated from nuclei. Based on electron microscopy (EM) studies of native chromatin fibers, two models have been proposed for 30 nm fibers; the one-start solenoid model and the two-start Zig-Zag model (Fig. 1). The solenoid model suggests that the nucleosome array folds into a one-start helix with adjacent nucleosomes connected by bent linker DNA (Widom and Klug, 1985). In the second model, nucleosomes are arranged in a Zig-Zag mode to form two stacks of nucleosomes connected by straight linker DNA which criss-crosses between each stack (Woodcock et al., 1984; Williams et al., 1986). Although the chromatin isolated

Figure 1. Solenoid (A) VS Zig-zag (B) model for 30 nm chromatin fibers. The positions of the first, second, third, and seventh nucleosomes (N1, N2, N3, and N7) in the linear DNA sequence are marked in the insets to clarify the arrangement of nucleosomes in the chromatin fiber in both models. from nuclei is mostly native, it is very heterogeneous with different DNA sequences/linker lengths and different histone compositions/modifications. The irregular spacing between nucleosomes in native chromatin makes it difficult to define the detailed structure of chromatin.

To distinguish between these two models, an *in vitro* system using strong “nucleosome positioning” sequences (Dorigo et al., 2004) has recently been developed to generate well-defined and regular spacing nucleosomal arrays. Using this system, Richmond and colleagues have successfully reconstituted tetranucleosomal arrays on a “widom 601 nucleosome positioning” sequence, and propose a two-start crossed-linker model based on crystal X-ray diffraction (Schalch et al., 2005). The two-row Zig-Zag ribbon conformation was also observed on much longer reconstituted arrays by EM studies and cross-linking assays (Dorigo et al., 2004). However, the crystal structure was determined for a tetranucleosomal array, which is too short to form a solenoid structure. A very short nucleosome repeat length (NRL, 167 bp), which is uncommon in nature, was used. Furthermore, the data were obtained at a very high concentration of Mg^{2+} (120 mM) in the absence of linker histone. Rhodes and colleagues have proposed an alternative one-start interdigitated solenoid structure based on EM/cryo-EM studies (Robinson et al., 2006). They analyzed chromatin fibers reconstituted under more native conditions in the presence of linker histone with a wide range of NRLs (177–237 bp) and in low divalent salt concentrations (1.6 mM Mg^{2+}). It has been reported that Mg^{2+} plays an important role in chromatin condensation *in vivo*, with the average concentration in nuclei changing from 3 mM at interphase to 17 mM at metaphase (Strick et al., 2001). Although some studies have proposed

that the linker histone is dispensable for the compaction of reconstituted nucleosomal arrays under high concentrations of Mg^{2+} (Schalch et al., 2005; Shogren-Knaak et al., 2006), Rhodes and colleagues have found that both the linker histone and NRL play a critical role in the formation of chromatin higher-order structures (Routh et al., 2008). The linker histone has also been considered to be essential for 30 nm chromatin fiber formation based on early EM studies on native chromatin (Thoma et al., 1979). The precise structural role of linker histone in the 30 nm chromatin fiber still remains to be determined. It is also worth noting the physiologic relevance of the 30 nm chromatin fiber. Although there is a lack of *in vivo* evidence for the existence of 30 nm fibers, fibers assembled under physiologic conditions *in vitro* can be used to define the mechanism of chromatin dynamics. Elucidating the structure of unmodified 30 nm fibers is essential for understanding the structural principles of chromatin dynamics and their relationship with gene regulation.

CHROMATIN DYNAMICS AND GENE REGULATION

During DNA replication and gene transcription, the accessibility of DNA is believed to be highly regulated by the dynamic nature of chromatin higher-order structures. DNA methylation, histone modifications, histone variants and the binding of non-histone architectural proteins have been shown to be crucial in regulating the dynamics of chromatin structures. Acetylation of core histones prevents chromatin from folding into 30 nm fibers and reduces the ability of chromatin to self-assemble into higher-order structures. Peterson and colleagues have reported that acetylation of histone H4 on lysine 16

(H4K16), a mark of transcription activation, can inhibit higher-order chromatin folding induced by Mg^{2+} (Shogren-Knaak et al., 2006). The acetylation of H3K56 results in increased breathing of DNA ends (Neumann et al., 2009; Watanabe et al., 2010). The H3K56Q mutation (to mimic acetylation) affects the oligomerization of subsaturated nucleosomal arrays, but not of saturated arrays, suggesting that H3K56 acetylation plays an important role in keeping nucleosome-free regions accessible to DNA binding proteins (Watanabe et al., 2010). The histone variant H2A.Z has been shown to increase the size of acidic patches on the surface of nucleosomes and facilitate chromatin folding into higher-order structures (Fan et al., 2004). H2A.Bbd, which is largely excluded from the female inactive X chromosome in mammals, plays an important role in destabilizing nucleosomes and unfolds the chromatin fiber locally. The incorporation of H2A.Bbd into chromatin also leads to greater efficiency in the acetylation of histone tails by p300 and results in an increase in transcriptional activation (Angelov et al., 2004).

Chromatin binding proteins, including linker histones and non-histone architectural proteins, play a critical role in assembling and maintaining unique chromatin higher-order structures. Linker histones have long been proposed to be involved in the formation of higher-order chromatin structure and in gene regulation (Zlatanova et al., 2000; Catez et al., 2006). Interaction of chromatin with linker histone H1 limits the mobility of nucleosomes and the accessibility of chromosomal DNA. The *in vitro* chromatin study has demonstrated that the formation of highly compacted 30 nm chromatin fibers requires the incorporation of histone H1 and the deacetylation of core histones (Li et al., 2010). The dynamics of H1 binding to chromatin is regulated by its subtypes and post-translational modifications. Phosphorylation of histone H1 has been found to weaken the binding of H1 to nucleosomes, and provides a signal for the disassembly of chromatin higher-order structures during interphase (Hendzel et al., 2004). It is still not well known whether the different subtypes have distinct roles or if they regulate specific promoters. We have recently shown that the malignant brain tumor (MBT) protein L3MBTL1 can compact nucleosomal arrays dependent on mono- and di-methylation of H4K20 and H1bK26, and negatively regulate the expression of a subset of genes (Trojer et al., 2007). In addition to the modification activity on core histone tails, in which polycomb repressive complex 1 (PRC1) can ubiquitylate H2AK119 and PRC2 methylates H3K27, respectively, the Polycomb group (PcG) proteins can also directly compact reconstituted nucleosomal arrays *in vitro* to repress gene transcription (Francis et al., 2004). Heterochromatin protein 1 (HP1) has been demonstrated to bind to methylated H3 tails via their N-terminal chromodomain and chromatin fiber-containing histone variant H2A.Z, and to compact or bridge chromatin fibers into higher-order heterochromatin structures by forming dimers via its chromoshadow domain (Bannister et al., 2001; Fan et al., 2004).

The study of structural dynamics for higher-order chromatin is critical for understanding the molecular mechanisms of epigenetic effects on gene transcription. It is very important to correlate the dynamics of chromatin structures with their gene functions. However, most recent studies on higher-order chromatin structures are based on nucleosomal arrays reconstituted *in vitro* on recombinant strong "nucleosome positioning" DNA sequences. It is difficult to integrate information on chromatin structure and biologic function using this system. We have successfully developed a new *in vitro* system using native DNA sequences and RSF/NAP-1 for reconstituting more natural chromatin fibers which can be used directly for both structural and functional analyses (Li et al., 2010). Based on this system, we have demonstrated that transcription factors RAR/RXR can bind to the PEPCK promoter embedded in highly compacted chromatin *in vitro*. Following the binding of RAR/RXR, recruitment of histone-modifying enzyme p300 and ATP-dependent chromatin remodeler SWI/SNF disassemble the highly compacted chromatin fiber which then undergoes nucleosomal rearrangement to allow the activation of the PEPCK gene (Li et al., 2010).

PERSPECTIVES AND CONCLUSIONS

In spite of the large volume of information now available on the dynamics of chromatin structure, much more detailed structural information on higher-order chromatin, especially on the 30 nm chromatin fiber and its relationship with gene regulation, still needs to be further clarified. As mentioned above, more native experimental systems need to be developed to integrate the structure and dynamics of higher-order chromatin and gene function. In addition, improved techniques may be needed to help clarify and perhaps redefine chromosomal structures. Cryo-EM, which enables direct high-resolution observation of cell structures in a close-to-native state, can be used to analyze the detailed arrangement of nucleosomes in higher-order chromatin. Dubochet and colleagues have used cryo-EM and image processing to analyze the structure of chromatin fibers in human mitotic chromosomes and have proposed the melt model of mitotic chromosome structure (Eltssov et al., 2008). Flexible nucleosomal arrays may fold into 30 nm chromatin fibers in interphase through intra-array nucleosomal interactions under dilute conditions, and may compact into more condensed structures under high chromatin concentrations in mitosis through inter-array nucleosomal associations. It is not yet clear whether higher-order chromatin structures are formed directly between 30 nm fibers or via some other intermediate states. More careful experiments are needed to analyze the detailed structure of chromatin fibers under different conditions. Super-resolution optical imaging techniques could potentially also be used to analyze higher-order chromatin structures and their detailed dynamic changes

during transcription activation and repression *in vivo/vitro*. Fluorescence resonance energy transfer (FRET) analysis, a powerful tool for determining intramolecular distances from 2 nm to 10 nm in biomolecules has been used to directly investigate the conformational dynamics of oligonucleosomes. The effect of the linker histone H1, histone acetylation and salt conditions on the structure and dynamics of trinucleosomes has been studied via bulk solution FRET (Bussiek et al., 2006; Poirier et al., 2009). Lamond and colleagues have adapted multiphoton fluorescence lifetime imaging microscopy (FLIM) with FRET to quantitatively analyze chromatin fiber compaction in living cells (Llères et al., 2009). Furthermore, when extended to the single-molecule level, FRET can potentially give detailed information on structural distribution, allowing heterogeneous populations and structural substrates to be characterized (Koopmans et al., 2007; Gansen et al., 2009). Although H3K56 acetylation does not affect the compaction of chromatin fibers, quantitative single-molecule via bulk solution FRET analysis on mononucleosomes has revealed its subtle effects by increasing DNA breathing 7-fold at the entry-exit point (Neumann et al., 2009). By selectively labeling donor and acceptor fluorophores on DNA and/or histone proteins, the detailed arrangement of nucleosomes in higher-order chromatin and the dynamics of nucleosomes and chromatins can be explored. We expect that these new techniques will enable us to further understand the structure and dynamics of higher-order chromatin and the underlying mechanisms of gene transcription.
