Abstract Iron particles were immobilized onto non-woven carbon fiber via electroplating for use in a microbial fuel cell (MFC). Electroplating was performed under an applied voltage at a current of 0.2 A for 5, 10, and 15 min. The scanning electron microscope (SEM) observations show that 5 min was not adequate for the particles to be immobilized, whereas 10 and 15 min of electroplating resulted in an adequate number of particles on the surface. To evaluate the strength of the binding of iron via electroplating on the surface of the fiber, the samples were washed with pure water and observed using an SEM. The 10 min electroplated sample has a larger surface area, which is suitable for the MFC anode, than the 15 min electroplated sample. According to X-ray photoelectron spectroscopy and X-ray diffraction analysis, the peaks corresponded to those of Fe₂O₃, and the sample dipped into tannic acid shows the peaks of Fe₃O₄. The amount of biofilm of *Shewanella oneidensis* MR-1 was evaluated using crystal violet staining, and living bacteria were counted as colony forming units. Electroplated Fe₂O₃ and Fe₃O₄ were found to be effective for producing biofilm and immobilizing *S. oneidensis* MR-1.

Keywords Microbial fuel cell · Non-woven carbon fiber · Iron oxide · *Shewanella oneidensis* MR-1 · Electroplating

Introduction

Respiration is one of the main energy acquisition processes of living microorganisms, and many living microorganisms depend on this efficient energy conversion mechanism. Electron donors and acceptors are required for respiration and heterotrophic microorganisms deliver the electrons, acting as a relatively strong reducing substance to O₂, such as glucose. Glucose is oxidized to CO₂, and O₂ is reduced to H₂O. An inorganic compound including nitrogen or sulfur is used as an electron acceptor in the microorganism, and a metal-ion represented by iron or manganese is sometimes used. ATP is used to accumulate energy in living cells through this process. Alternatively, a microbial fuel cell (MFC) is used to convert the Gibbs free energy of redox reactions into electrical energy via movement of electrons and ions separately.

Shewanella oneidensis MR-1 is often used in an MFC. The processes of *S. oneidensis* MR-1 to transfer electrons to the electrode can roughly be classified into three categories. One process is called indirect electron transport, which concerns the mediator. The mediator having oxidation–reduction activity receives an electron from the cells and shuttles the electron between the electron acceptor and the electrode. In the case of *S. oneidensis* MR-1 secreting a derivative of quinone and flavin to the outside of the cells, it is possible to use these excretions as mediators [1–4]. Another process is called direct electron transport. *S. oneidensis* MR-1 is a metal-reducing and facultative anaerobic bacterium. This microorganism produces the outer membrane cytochromes called OmcA and MtrC at high density onto the cell surface via anaerobic cultivation. Unlike indirect electron transport involving mediator dispersion, an electron that is generated in the cell directly moves to the solid surface of the electrode through the

outer membrane cytochromes [5–14]. *S. oneidensis* MR-1 produces electrically conductive pilus-like appendages [8] called bacterial nanowires [15] in direct response to the electron-acceptor limitation.

In addition, *S. oneidensis* MR-1 forms a biofilm of extracellular polysaccharide. The biofilms formed on the anode surface used for an MFC plays an important role in extracellular electron transfer. The relation between the cell density and the power generation output using the *S. loihica* PV-4 strain was previously studied [16]. The study found that the current density was hardly changed with increasing microbial density in microbial suspension. This result shows that the biofilm formed on the electrode surface contributes to current generation and becomes the main current generation source. By comparing the power generation output between the PV-4 strain formed biofilm and the *S. oneidensis* MR-1 added mediator, the current density and the coulomb efficiency of strain PV-4 were found to be higher than those of *S. oneidensis* MR-1 [5]. This result shows the electron transfer to the electrode via the mediator is limited by the diffusion of the mediator [17]. A biofilm can facilitate the bacterial electron transfer efficiency in an MFC primarily due to the much higher biomass densities and higher bacterial viability caused by anode respiration [8, 18–20]. From these results, in an MFC, the advantage of the formation of a biofilm on the electrode is understood to be the large specific surface area for the electrogenic microorganism. Although the electron is generated from the cell but the biofilm, these reports do not show the number of living cells for the given amount of the biofilm.

Metal-reducing bacteria such as *S. oneidensis* MR-1 have been studied to understand their ability to recognize the surface of iron oxide and to initiate extracellular electron transfer to an attached iron oxide as a terminal process in its metabolism [21, 22]. Moreover, iron oxide may promote the biofilm formation of *S. oneidensis* MR-1 onto an electrode [23].

Non-woven carbon fibers (NWCFs) are suitable for use as electrodes of MFCs because they have good conductivity, a large surface area, and relatively low cost. NWCFs have been used in many studies. For example, an ITO glass slide coated with carbon graphite fiber used as the anode showed much higher current density than the non-coated slide when *S. loihica* PV-4 was used in an MFC [24]. In another report, an NWCF electrode for MFCs interposed between iron nets showed 1.5 times higher power density compared with that for MFCs without the iron nets [25]. In another report, NWCFs were used in a type of MFCs called a Slalom-flow cassette-electrode microbial fuel cell [26]. As mentioned above, the development of an NWCF coated with ferric oxide is important to improve the current density. However, there are few reports regarding the coating technique, except for a chemical vapor deposition technique [27]. However, the chemical vapor deposition

technique requires a large-scale apparatus and is an expensive method. As a result, another method to immobilize iron oxide onto NWCFs is necessary.

Therefore, in this study, iron oxide immobilized NWCFs were developed using an electroplating technique. The redox state and crystal structure of iron oxide particles immobilized onto NWCFs using this electroplating technique were determined using X-ray analysis. Moreover, the amounts of biofilm and the number of living cells of *S. oneidensis* MR-1 on this electrode were quantified.

Experimental

Materials and chemicals

Non-woven carbon fiber (NWCF) firming polyacrylonitrile was specially made by Japan Vilene Co., (Tokyo, Japan). The lengths of fibers are about 50 mm and the diameter is about 7 μm , and the mass per unit area of NWCF is 100 g/m². Iron (II) sulfate heptahydrate ($\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$) as electrolyte solution and crystal violet were purchased from Nacalai Tesque, Inc (Kyoto, Japan). Saponin (Practical grade, MP Biomedicals LLC, France) and tannic acid were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). *S. oneidensis* MR-1 (ATCC 700550) was obtained from the American Type Culture Collection.

Iron plating on NWCF

A 1 g of $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ was dissolved in 100 mL of distilled water and used as electrolyte of electroplating method. NWCF is cut into 3×5 cm, then immersed in the beaker and connected to negative and positive side of power supply (SN-5B, Kenis Ltd., Osaka, Japan). The NWCFs were adjusted the distance at 6 cm and depth at 3.5 cm. Electroplates were carried out under current at 0.2 A (22 V) for 5, 10 and 15 min. After electroplating, the samples were washing with pure water (using about 50 mL) till the pH became neutral promptly, because in the process of electroplating, the H_2SO_4 is produced in the solution and soaked in the NWCF. This causes pH decrease which inhibits the growth of microorganism for MFC. The samples were cut in half (1.5×5 cm) and one piece was dried at room temperature. To evaluate how strong the iron was plated on the surface of the fiber, another piece was put in 150 mL of pure water and stirred with magnetic stirrer at 250 rpm for 24 h, then dried at room temperature.

Tannic acid treatment

The 1.7 g of tannic acid is dissolved in 50 mL of distilled water and poured to petri dish. The iron plated for 10 min

on NWCF (1.5×5 cm) was cut in half and dipped in petri dish containing tannic acid solution for 24 h. Then the sample was washed with 50 mL of pure water and dried at room temperature.

Biofilm growth on non-woven carbon fiber

Shewanella oneidensis MR-1 was first grown aerobically in Luria–Bertani (LB) medium at 30 °C for 18 h preparing pre-culture. The pre-culture was inoculated in 5 mL of flesh LB medium in testing tube to $OD_{600} = 0.1$ and incubated with shaking at 120 rpm at 30 °C for 24 h. The iron plated NWCF of the dimensions of 1×1 cm were soaked into the culture then incubated with shaking at 120 rpm at 30 °C for 24 h. After incubation, samples were washed in 0.85 wt% of NaCl solution. As a control, non-inoculated LB medium and non-iron plated NWCF were used.

Analytical methods

Observations of the phase of iron plated NWCF were carried out by scanning electron microscope (SEM) (JSM-6510A, JEOL Ltd., Tokyo, Japan) operated at 15 kV. Surface elemental analysis of iron plated NWCF was performed using X-ray photoelectron spectroscopy (XPS) (JPS-90MX, JEOL Ltd.). An Mg $K\alpha$ radiation with voltage of 8 kV and current of 5 mA were applied. The phase structures of iron plated NWCF were measured by X-ray diffraction analysis (XRD) (RINT 2500 V, Rigaku Co., Tokyo, Japan) and were scanned from 10° to 100° in 2 theta using Cu $K\alpha$ radiation.

For SEM analysis, the samples incubated with *S. oneidensis* MR-1 were fixed with 1 v/v% glutaraldehyde in 0.1 M phosphate buffer (pH 7.2) for 30 min at 4 °C. Subsequently, they were dehydrated in graded ethanol series (50, 60, 70, 80, 90, 95 and 100 v/v%). After dehydration, the samples were put in *n*-butanol followed by frozen at −8 °C and dried under vacuum. The dried samples coated with platinum were examined using SEM.

To evaluate the biofilm formation, the samples incubated with *S. oneidensis* MR-1 were fixed with 2.5 mL of methanol for 20 min and then were stained with 2.5 mL of 0.75 w/v% crystal violet [28, 29]. To eliminate residual crystal violet, the stained samples were washing under running tap water. After the stained samples were air-dried, crystal violet absorbed on samples was dissolved in 2.5 mL of 33 v/v% acetic acid. The absorbance of crystal violet eluted was measured at 600 nm [28, 29].

To evaluate the viable bacteria count, the samples were washing with 0.1 M PBS buffer (pH 7.2) and then vortexed in 1 mL of 0.5 w/v% saponin solution for 2 min. Serial tenfold dilutions of the suspension obtained were prepared

and then 100 μ l of dilutants were plated onto LB agar plates. After incubation for 48 h at 30 °C, the number of colonies on the agar plates was measured and then colony forming unit (CFU) was calculated [30, 31].

Results and discussion

Photographs of an iron plated NWCF produced after electroplating for 10 min for the subsequent processing stages are shown in Fig. 1a–c. After washing with pure water, the surface of the NWCF exhibits a black color (Fig. 1a); then, after 24 h of air drying, the surface of the NWCF turns from black to brown (Fig. 1b). Finally, the change of the surface following the tannic acid treatment presented in Fig. 1c shows that the color of the particles deposited on the NWCF changed from brown to black. This color change indicates that plated iron changed to γ -

Fig. 1 Photograph of iron plated NWCF for 10 min. **a** Washing with pure water, no-drying, **b** after 24 h, drying and **c** tannic acid treatment, after drying

FeOOH, α -Fe, and γ -Fe₂O₃, characterized brown color and called lepidocrocite or iron oxide hydroxide, iron, and maghemite, or iron (III) oxide, respectively, during the drying process. In addition, the γ -FeOOH, α -Fe, and γ -Fe₂O₃ were reduced to Fe₃O₄, characterized by the black color and called magnetite or iron (II, III) oxide, due to the tannic acid treatment. Furthermore, this is confirmed by XRD analysis. To our knowledge, studies of the effect of iron on biofilm formation of *S. oneidensis* involve only pure iron [32]; we were unable to find a study that compared several iron compounds for biofilm formation. Hence, the results of this study are interesting.

Morphology of iron plated NWCF

SEM analysis showed that the surface of the NWCF appears smooth (Fig. 2a). In contrast, the results of electroplating at different times (5, 10, and 15 min) are shown in Fig. 2b–d. The electroplating for 5 min was not sufficient to coat iron onto the NWCF (Fig. 2b). In contrast, the electroplating for 15 min resulted in abundant deposition of iron (Fig. 2d). As shown in Fig. 2c and d, the particles of iron were closely packed on the surface of the NWCF, resulting in a large surface area. Such a large surface area is advantageous to electron transport from the cell to the anode.

The results of the stability test of plated iron on the NWCF are shown in Fig. 3. As shown in Fig. 3a, particle aggregates were distributed throughout the NWCF, and each NWCF was enclosed with particle sheets (Fig. 3b). The characteristics of the particles following electroplating for 10 min were better than those following electroplating for 15 min because of the large surface area suitable for application to an MFC. Thus, we choose the case of performing iron electroplating at 0.2 A for 10 min.

Surface elemental analysis of an iron plated NWCF

To examine the composition of iron on the NWCF at different plating times, XPS spectra of Fe_{3/2}, O1s, and C1s are shown in Fig. 4. The sample electroplated for 5 min shows peaks of 718, 538, and 290.8 eV for Fe_{3/2} (Fig. 4a), O1s (Fig. 4b), and C1s (Fig. 4c), respectively, while the corresponding peaks appeared at 715, 533–534, and 289 eV, respectively, for the samples electroplated for 10 and 15 min. This observation suggests that the initial layer of iron electroplated onto the NCWF has a different structure from the iron of the upper layer.

The phase structure of iron plated NWCF

The XRD profiles for the iron coated NWCF for 5 and 10 min of electroplating are shown in Fig. 5a and b, respectively. The diffraction peak appearing at the 2θ value of 25.54° is the characteristic reflection of carbon graphite crystals in the composite. The characteristic peaks of an α -Fe crystal were observed for the sample electroplated for 5 min; the assignment was determined on the basis of the Crystallography Open Database (9013415). Additional peaks of γ -FeOOH and γ -Fe₂O₃ were presented for the sample electroplated for 10 min, as determined on the basis of the Crystallography Open Database (9009154) and (9006317), respectively. These peaks may be caused by the electroplating process of iron on the NWCF: first, the

Fig. 4 XPS in the **a** Fe_{2p_{3/2}}, **b** O1s and **c** C1s regions for NWCF, and iron plated NWCF of different times (5, 10 and 15 min)

Fig. 5 X-ray diffraction patterns of iron plated NWCF for **a** 5 min, **b** 10 min and **c** after tannic acid treatment for 24 h. The symbols; α-Fe (circle), γ-FeOOH (triangle), γ-Fe₂O₃ (square), Fe₃O₄ (diamond)

NWCF was covered with α-Fe, and then the layers of γ-FeOOH and γ-Fe₂O₃ were deposited.

Clearly, the diffraction peaks of γ-FeOOH and γ-Fe₂O₃ appeared for the sample electroplated for 10 min (Fig. 5b), which is because of the increase of the amount of immobilized iron with the electroplating time. Furthermore, Fig. 5c shows the XRD pattern of the iron plated NWCF after treatment with tannic acid for 24 h. The figure shows that all the diffraction peaks can be assigned to γ-FeOOH, α-Fe, and Fe₃O₄ (COD 9005840). In other words, γ-Fe₂O₃ transformed to Fe₃O₄ due to the tannic acid treatment.

Effect of iron oxide on the biofilm formation by *S. oneidensis* MR-1

Using the NWCF and the iron plated NWCF, the biofilm formation by *S. oneidensis* MR-1 was demonstrated over 24 h with shaking. Expectedly, the biofilm formation by *S. oneidensis* MR-1 was observed on iron plated NWCF after 24 h of incubation. However, no biofilm formation was observed on the NWCF (Fig. 6). It has been reported that *S. oneidensis* MR-1 exhibits an affinity to iron oxide [22, 23]. These results suggest that the iron oxide on the NWCF promoted biofilm formation by *S. oneidensis* MR-1.

To quantitatively evaluate the biofilm formation, the NWCF and the iron plated NWCF after 24 h of incubation with *S. oneidensis* MR-1 were assayed using crystal violet staining. The respective absorbance values observed via the assay with the NWCF after 24 h of incubation ($A_{600} = 0.655$) were compared with those for the iron (Fe₂O₃ and Fe₃O₄) plated NWCF after 24 h of incubation ($A_{600} = 1.309$ and 1.205 , respectively) (Fig. 7). This result indicated that biofilm formation by *S. oneidensis* MR-1 on the NWCF grown enough after 24 h of incubation. The iron plated NWCF showed a higher amount of biofilm than NWCF after 24 h of incubation. This result is in good agreement with the result of the SEM analysis. Compared with the case of NWCF, the amount of biofilm on the iron plated NWCF was approximately twofold higher after 24 h of incubation. This result may be due to the higher surface area of the iron plated NWCF compared with the bare NWCF, thereby enabling more *S. oneidensis* MR-1 to attach. In fact, iron oxide has a hollow structure and provides a high surface area. This finding suggests that iron oxide provides not only affinity with *S. oneidensis* MR-1 but also a high surface area with the NWCF.

To understand the cell viability on the NWCF, the CFU was measured. The respective CFU increased when assayed with the iron (Fe₂O₃ and Fe₃O₄) plated NWCF ($2.77 \times 10^6/\text{mL}$ and $2.675 \times 10^6/\text{mL}$, respectively) compared with that with the bare NWCF ($2 \times 10^6/\text{mL}$) (Fig. 8). In addition, the amount of biofilm formed was

Fig. 6 SEM images of the attachment of *S. oneidensis* MR-1 on **a** the NWCF, **b** the Fe_2O_3 plated NWCF and **c** the Fe_3O_4 plated NWCF

Fig. 7 Quantification of biofilm formation on NWCF, Fe_2O_3 and Fe_3O_4 plated NWCF after 24 h incubations. The amount of biofilm was evaluated using crystal violet staining. The absorbance of crystal violet eluted was measured at 600 nm after washing with saline solution for 15 min. This assay was performed in duplicate, and the mean value is presented with *error bars* representing standard deviations from the mean. *White bars*, without *S. oneidensis* MR-1 (control); *gray bars*, with *S. oneidensis* MR-1

Fig. 8 CFU of *S. oneidensis* MR-1 on NWCF, Fe_2O_3 and Fe_3O_4 plated NWCF after 24 h incubations. This assay was performed in duplicate and the mean value is presented with *error bars* representing standard deviations from the mean

approximately 1.385 times that on the bare NWCF. This result is in good agreement with the results of SEM analysis and crystal violet staining.

Taken together, it was concluded that almost all the biofilm was formed after 24 h of incubation and that iron oxide promotes biofilm formation by *S. oneidensis* MR-1 and results in a high surface area. Electroplated iron oxide was immobilized onto the NWCF with sufficient strength, thereby enabling the use of the coated NWCF as an electrode. The results presented herein provide a pathway to a novel immobilization technique for depositing iron particles onto NWCFs for use in MFCs.
