The determination of cell fate is one of the key questions of developmental biology. Recent experiments showed that feedforward regulation is a novel feature of regulatory networks that controls reversible cellular transitions. However, the underlying mechanism of feedforward regulation-mediated cell fate decision is still unclear. Therefore, using experimental data, we develop a full mathematical model of the molecular network responsible for cell fate selection in budding yeast. To validate our theoretical model, we first investigate the dynamical behaviors of key proteins at the Start transition point and the G1/S transition point; a crucial three-node motif consisting of cyclin (Cln1/2), Substrate/Subunit Inhibitor of cyclin-dependent protein kinase (Sic1) and cyclin B (Clb5/6) is considered at these points. The rapid switches of these important components between high and low levels at two transition check points are demonstrated reasonably by our model. Many experimental observations about cell fate decision and cell size control are also theoretically reproduced. Interestingly, the feedforward regulation provides a reliable separation between different cell fates. Next, our model reveals that the threshold for the amount of WHIskey (Whi5) removed from the nucleus is higher at the Reentry point in pheromone-arrested cells compared with that at the Start point in cycling cells. Furthermore, we analyze the hysteresis in the cell cycle kinetics in response to changes in pheromone concentration, showing that Cln3 is the primary driver of reentry and Cln1/2 is the secondary driver of reentry. In particular, we demonstrate that the inhibition of Cln1/2 due to the accumulation of Factor ARrest (Far1) directly reinforces arrest. Finally, theoretical work verifies that the three-node coherent feedforward motif created by cell FUSion (Fus3), Far1 and STerile (Ste12) ensures the rapid arrest and reversibility of a cellular state. The combination of our theoretical model and the previous experimental data contributes to the understanding of the molecular mechanisms of the cell fate decision at the G1 phase in budding yeast and will stimulate further biological experiments in future.

Keywords: cell fate decision; feedforward mechanism; mathematical modeling; hysteresis; reversibility

INTRODUCTION

Cells from across biological kingdoms are continuously engaged in the process of decision making. Through decision making, unicellular and multicellular organisms take information from their surroundings (including neighboring cells) and process these data through complex signal transduction and genetic circuits to further

modulate cellular phenotypes. Therefore, the selection of cell fate in response to both internal and external stimuli is essential in a cell's life [1]. Much progress in understanding the circuitry underlying decision making, as well as the advantages of the underlying strategic logic implemented therein, has come from budding yeast, the simplest eukaryote [2].

Mathematical modelling is an important method in

computational and systems biology because it provides the ability to analyze and visualize the complex connections of components in cellular systems. In recent years, the mitogen-activated protein kinase (MAPK) signaling pathway and gene regulatory networks in yeast have been studied extensively and in depth through mathematical modelling and quantitative analysis [3–5].

A previous model of the pheromone pathways [6] proposed an explanation of the graded response of the MATa mating type after stimulation with the pheromone α -factor. Due to the lack of G1 cyclins, check point analysis in cell cycle is unable to be developed in this model. In [7], G1 cyclins are taken into account, and a new model for analyzing the cell fate decision mechanism at the Start transition point is constructed. This model explains how the crosstalk between cyclins and signal pathways determines the cell fate decision. Specifically, the function of mutual inhibition between Cln1/2 and Far1 is demonstrated [8,9]. Unfortunately, without S cyclin proteins, the G1/S transition cannot be analyzed using the model proposed in [7]. A recent research work is focused solely on studying the function of the mutual inhibition between Clb5/6 and Sic1 at the G1/S transition point [10]. The studies in both [7] and [10] are based on positive feedback regulation. Furthermore, a recent experiment about cellular transitions has shown that the stability of the pheromone-arrested state results from the coherent feedforward regulation of the cell cycle inhibitor Far1 [11,12].

Due to complexity in highly interconnected biochemical networks, many related questions need to be further explored. For example, whether S cycling proteins at G1/S transition may interfere with the molecular regulation that allows a single cell to choose between two different fates is still unknown. The exact roles of feedforward regulation in the cell fate decision process are not well established. Moreover, the potential mechanism for rapid arrest and reversibility of cell fate in pheromone-arrested cells is not clear. The feedback-driven hysteresis also remains to be addressed. Thus, it is crucial to thoroughly characterize the features of the cell fate decision network in budding yeast when both motifs associated with the G1/S transition and feedforward regulation are considered.

In this study, we extend these previous models above to present an integrated model that is composed of two subsystems: a G1 phase cell cycle network and a pheromone-induced MAPK pathway. In particular, several important components and regulations, including the transcription regulation of Far1 by Ste12 and the mutual inhibition between Clb5/6 and Substrate/Subunit Inhibitor of cyclin-dependent protein kinase (Sic1), are considered. The cell fate decision occurring at the Start point and the cell size control closely associated with the

G1/S point are both described quantitatively. The underlying mechanism for the different reentry behaviors between pheromone-arrested cells and cycling cells are presented. Finally, the coherent feedforward regulation-mediated rapid response and effective separation of cell fate are illustrated. Our work can enrich our understanding of the dynamics and functions of the interaction network that is responsible for selecting between cell cycle commitment and mating arrest.

RESULTS

Mathematical model

The aim of our work is to clarify the mechanism underlying the feedforward regulation-mediated cell fate decision when two crucial three-node motifs (i.e., the Cln1/2-Sic1-Clb5/6 motif and the Fus3-Far1-Ste12 motif) are involved. Motivated by some previous works [5–7,10], a full mathematical model is built by combining the schematic diagrams in Figure 1A and Figure 1B. Several assumptions, which are listed below, simplify the model.

- The reactions related to the promotion and inhibition of state transitions, as well as the reactions related to transcriptional regulation, are written using Michaelis-Menten kinetics. Meanwhile, phosphorylation reactions are described in terms of mass action laws.

- The stimulus is stable and sufficient when a pheromone signal is required, and the concentrations of $G_{\alpha\beta\gamma}$, Ste11 and STerile (Ste7) are assumed to be constant.

- For the transcriptional factors SCB binding factor (SBF) and MCB-binding factor (MBF), both of initial concentrations are equal to 100 nM, but SBF has a stronger effect than MBF on the promotion of Cln1/2 and Clb5/6. Additional details are presented using the parameters in Table S1 in the Supplementary Materials.

In addition, the detailed network descriptions (Figure S1), which include a subsystem of the cell cycle, a subsystem of the pheromone-induced MAPK pathway and the interactions between the two subsystems, are listed in the Supplementary Materials. The model dynamics are characterized by ordinary differential equations (ODEs), which are presented in the Appendix. The related parameter values and initial concentrations are listed in Table S1 and Table S2 of the Supplementary Materials, respectively, which are mostly acquired from the available literature [6,7,10].

Determination of the Start point in cycling cells

In yeast, the G1 checkpoint is vital because it determines whether a cell enters the mitotic cycle or engages in a mating program. Only one fate can be selected from the

possible two cell fates at the G1 checkpoint. From a system dynamics point of view, the G1 checkpoint is a bistable switch [13–16]. If a cell is not given with any treatment during the next cell cycle at its birth, this type of

cell is termed a cycling cell. Moreover, if no special circumstances are noted, the cycling cell is termed a cycling wild-type (WT) cell. The G1 checkpoint of a cycling cell is termed the Start point [17,18].

Previous studies have identified the fractions of Whi5 protein that are removed from the nucleus as the main indicator for the status of the G1 checkpoint trigger [13]. In the recent work of our group, the Start point is quantified mathematically by the largest derivative in the dose-response curve, which can be obtained from the relationship between the activation of Whi5 (i.e., the proportion of Whi5 that has been exported from the nucleus at 30 min) and the pheromone application time [7]. The pheromone application time at the Start point is considered the critical addition time, and the fraction of Whi5 at the Start point is termed the Whi5-threshold.

The critical fractions of Whi5 for cycling cells obtained from the statistical analysis of biological data and the mathematical definition are both approximately equal to 0.5 [7,13]. Therefore, in this study, we still use our original definition [7] to characterize Start point.

Determination of the Reentry point in pheromone-arrested cells

However, if a cell is pre-exposed to pheromone during the next cell cycle or at birth, it will take longer time to reenter the cell cycle [12]. That is to say, the G1 checkpoint is delayed. In this case, the G1 checkpoint is named a Reentry point [12]. In particular, a cell pre-exposed to 240 nM pheromone for 30 min is called a pheromone-arrested cell. As before, if no special circumstances are noted, a pheromone-arrested cell is termed a pheromone-arrested WT cell. The Whi5-threshold is approximately 0.6 for pheromone-arrested cells [12].

To characterize the Reentry point, our original definition is modified by adding pheromone to pheromone-arrested cells at 0–40 min and measuring the fraction of

Whi5 removed from the nucleus at 50 min (the pre-exposed duration is not included). The details are presented below.

Determination of the G1/S transition point

If a cell passes through the Start point (Reentry point) and enters the cell cycle, the next decision must be made about what time is suitable for entering S phase and starting DNA replication. The check point between the G1 and S phases is defined as the G1/S transition point. If a cell enters S phase earlier, it will become out of order because the DNA replication-related proteins will be inadequately prepared. However, if a cell enters S phase later, it will waste resources. Therefore, the decision about the G1/S transition point is critical.

Experimental studies have demonstrated that the G1/S transition point is connected to the cell volume [19–21]. A recent study demonstrated that the switch-like G1/S transition is driven by the degradation of Sic1 and that the timing of Sic1 destruction is set by Cln1/2-Cdc28 [10]. Due to the mutual inhibition between Sic1 and Clb5/6, the level of Sic1 decreases steeply while the level of Clb5/6 increases sharply at the G1/S transition point [10]. It is reasonable to suppose that the crossing point of the two levels is the G1/S transition point in our study (Figure 2A). Moreover, the relationship between the G1/S transition point and the corresponding volume will be analyzed.

Start point and cell fate decision in cycling cells

Here, the initial states of all cells are assumed to be at the beginning of the G1 phase, and the cells have already

Figure 2. Numerical experiments for cell size control in budding yeast. (A) The definition of the Start point and the G1/S transition point. The Start point occurs when 50% of Whi5 is removed from the nucleus, and the crossing point of the Clb5/6_{free} time course and the Sic1 time course is considered the G1/S transition point. (B) The relationship between the duration of cell cycle and the birth size.

finished at least one cell cycle. Meanwhile, Cln1/2, SBF and Whi5 are chosen to be the biomarker-like components of cell cycle commitment, and Ste5_{mem} and Fus3PP are chosen to be the biomarker-like components of mating arrest [22–24].

The addition of 240 nM pheromone to WT cells at various times results in different cell fates, as shown in Figure S2. Apparently, during the competition between the two groups of proteins, once one cell fate dominates, the proteins representing the other cell fate are suppressed completely. These results agree well with experimental data [13].

We further investigate the relationship between the time of pheromone addition and Whi5P activation, as shown in Figure S3. Our calculation for the curve of cell fate decision indicates that there is a sharp transition point at 3 min (i.e., the critical addition time is 3 min.), and the Whi5-threshold is 0.48. This result is consistent with the experimental observation that the Start point occurs when approximately half of Whi5-GFP (52±3%) has been exported [12,13]. Through a comparison with our previous model [7], here we find that once the fraction of Whi5 removed from the nuclear is beyond the Whi5-threshold, nearly all of Whi5 will be exported into the cytoplasm due to a slight increase of the addition time. A potential reason is that our model becomes more exquisite by adding transcription factor MBF and protein Clb5/6 so that the positive feedback mediated-transport of Whi5 is enhanced largely. Therefore, the Start point is more easily identified in this extended model.

Size control at Start point and G1/S point in cycling cells

Recent studies have shown that smaller cells have delayed Start transitions, which could imply that a critical size is required to initiate the cell cycle. Namely, if the beginning cell size after the previous division is smaller than a critical size, the cell need to grow to this critical size before entering Start point [17,19,25,26]. This feature is called cell size control or a Sizer. However, the period of time from the Start point to the G1/S point is almost fixed and is regarded as a Timer. Cell size control is important and has long been considered to be a main regulator of the length of the G1 phase of the cell cycle, resulting in small difference at cell size after several cycles [20,26]. So, it makes sense to clarify this mechanism.

Because asymmetric cell division is a universal mechanism for generating differentiated cells, in budding yeast, asymmetric cell division yields a larger ‘mother’ cell and a smaller ‘daughter’ cell. The regulation of gene expression is also asymmetric [25]. Therefore, before we explore the size control of the G1 phase using our model, the mother cell and daughter cell in the beginning of a cell

cycle should be defined theoretically. Based on the physiological conditions, for daughter cells, the initial size range varies from 10 fl to 28 fl, and the initial Cln3 concentration is 0 nM. Similarly, for mother cells, the initial size range varies from 30 fl to 70 fl, and the initial Cln3 concentration is 100 nM [20].

The cell volume is assumed to grow exponentially. Thus, the size at birth (V_0) can be related to the size (V) at an arbitrarily specified time by

$$\alpha T = \ln(V) - \ln(V_0), \quad (1)$$

where α is the growth rate of the cell, and T is the growth duration of the cell from birth to the specified time.

Suppose that T_1 and T_{G1} are the durations from birth to the Start point and to the G1/S point, respectively. Meanwhile, T_1 is considered as the arrest duration (the time from when the pre-exposed pheromone is removed to the Reentry point is also regarded as the arrest duration, namely, T_1). Moreover, V_1 and V_{G1} are the cell sizes at the Start point and the G1/S point, respectively. For consistency with the bio-experiment, T_1 and V_1 are determined by detecting the time point when 50% of Whi5 removed from the nucleus. T_{G1} and V_{G1} are derived by recording the crossing points of the Sic1 level and the Clb5/6_{free} level, respectively. More details are shown in Figure 2A. We can obtain the following equation:

$$\alpha T_1 = \ln(V_1) - \ln(V_0). \quad (2)$$

We can see from equation (2) that if the Start point is controlled by Sizer, i.e., the cell size V_1 is a constant, the slope of αT_1 versus $\ln(V_0)$ will be -1 . By contrast, if the Start point is controlled by Timer, for which T_1 is fixed, the slope will be 0 [19,20].

We investigate the relationship between V_0 and αT_1 through the growth process of daughter cells and mother cells with different sizes. For the convenience of analysis, we normalize the volume by the mean of the minimum and maximum volumes, that is:

$$\alpha T_1 = \ln(V_1/V_{\text{mean}}) - \ln(V_0/V_{\text{mean}}). \quad (3)$$

To facilitate observations, we also perform a linear fit to the lifetimes of the mother cells and daughter cells. Lastly, we still use the former symbols to express the normalized values (for example, V_0 denotes V_0/V_{mean}). Similarly, we explore the relationship between V_0 and αT_{G1} in the same manner. All results are presented in Figure 2B. The slope of the daughter cells in T_1 (filled circles) is steeper than the slope of the mother cells in T_1 (open circles), indicating that mother cells have weaker size control than daughter cells in T_1 . In contrast, we can see that the slope of daughter cells in T_1 (filled circles) and the slope of daughter cells in T_{G1} (filled squares) are almost equal. Similarly, the slope of mother cells in T_1 (open circles) and the slope of mother cells in T_{G1} (open squares) are

almost equal as well. Therefore, regardless of whether cells are daughter cells or mother cells, the value of α ($T_{G1} - T_1$) roughly is a constant, namely, the duration from the Start point to the G1/S point is almost fixed, so this period is a Timer. These results from our theoretical model agree well with experimental observations [19–21]. Moreover, in this simulation, the initial concentration of Cln3 is set 0 nM and 100 nM in daughter cells and mother cells respectively. And the initial volume which has an impact on the rate of Cln3 is perturbed. Therefore, a fact that G1 cyclin Cln3 had a dominant role in delaying daughters in G1 has been proven with our deterministic method, which had been validated by using statistical methods [20].

Reentry point and cell fate decision in pheromone-arrested cells

From the recent experiment [12], it has been shown that the Whi5-threshold for pheromone-arrested cells is obviously higher (approximately 0.64 ± 0.04). However, the biological mechanism is still unclear.

First, the time courses of key proteins under different conditions are plotted (Figures S4 and S5). For pheromone-exposed cells in 0 nM final α -factor, our simulation shows that these cells reach the G1/S point in approximately 50 min (Figure S4A). It is reasonable to check the cellular state at 50 min for cells whose pre-exposed duration is less than or equal to 30 min. Therefore, to calculate the Reentry point, we should measure the fraction of Whi5 removed from the nucleus at 50 min. From the time courses of pheromone-exposed cells (Figure S5), we find that if the addition time of pheromone is larger than 21 min, the fate of pheromone-exposed cells is changed from mating arrest into cell cycle.

We also study the relationship between the time of pheromone addition and Whi5P activation (Figure 3). The result indicates that the critical addition time is about 21 min. Compared with that of cycling cells in Figure S3, the critical addition time of pheromone-arrested cells is greatly delayed. Moreover, the Whi5-threshold is almost 0.58, so our theoretical model can predict the experimental value about the Reentry point successfully [12]. This finding suggests that the Whi5-threshold for pheromone-arrested cells is higher than that of cycling cells. Therefore, it is more difficult for pheromone-arrested cells to reenter the cell cycle than for cycling cells [12].

Cell hysteresis in a reinforced-arrest model

The higher Whi5-threshold for pheromone-arrested cells that is noted above suggests that pheromone arrest is

Figure 3. Relationship between the time of pheromone addition and Whi5P activation for pheromone-arrested cells. At the Reentry point, the maximum slope is achieved in this curve of cell fate decision. In pheromone-arrested cells, the Reentry point is defined by the export of approximately 58% of the nuclear Whi5.

reinforced. The reinforcement implies that pheromone-arrested cells should exhibit hysteresis kinetics in response to the pheromone concentration compared with cycling cells [12]. To elucidate the relationship between arrest duration and the history of exposure to pheromone, we calculate the arrest duration in the reinforced-arrest model.

We assume that the volumes of cycling cells at 0 min are set to be the same as the volumes of pheromone-arrested cells at 0 min, which have already grown for 30 min in the growth mode. In addition, to detect the Start point (and Reentry point) and determinate the arrest duration, the Whi5-thresholds of cycling cells and pheromone-arrested cells are set to 0.5 (Figure 2A) and 0.6 (Figure S4), respectively.

The numerical results of the hysteresis experiment are presented in Figure 4A. The arrest durations of these two types of cells in different pheromone concentrations are shown in Figure 4B. The pheromone-arrested cells take much longer to reenter the cell cycle than cycling cells, which are not previously exposed to the high-concentration pulse. This finding shows the hysteresis behavior in pheromone-arrested cells as observed in the experiment [12].

Cycling protein is the main driver of reentry

We further simulate *cln1Δcln2Δ* cells by reducing the generation rate of the Cln1/2 protein to 0.1 times the original rate. The hysteresis experiment is conducted once again for *cln1Δcln2Δ* cells. The results are shown in

Figure 4C. The hysteresis phenomenon disappears, suggesting that Cln1 and Cln2 are completely inhibited in pheromone-arrested cells [12].

The hysteresis experiment is also simulated for cells lacking the gene *cln3*. In *cln3Δ* cells, the generation rate of the Cln3 protein is reduced to 0.25 times the original rate, and the Whi5-threshold is not changed. Figure 4D shows that the arrest duration of *cln1Δcln2Δ* cells tends to be longer than that of WT cells, whereas the arrest duration of *cln3Δ* cells tends to be longer than that of *cln1Δcln2Δ* cells. The *cln3Δ* cells reenter the cell cycle much slowly than do the WT cells and *cln1Δcln2Δ* cells while still showing hysteresis. These results suggest that Cln3 is the primary driver of reentry and that Cln1/2 is the secondary driver of reentry.

Pheromone exposure leads to Far1 accumulation

Reentry into the cell cycle is more difficult for pheromone-arrested cells, and these cells exhibit hysteresis. Moreover, Figure 4C shows that the hysteresis phenomenon in pheromone-arrested model originates

from the inhibition of Cln1/2. As we know, Far1 is the inhibitor of Cln1/2. Thus, it is interesting to investigate whether the accumulation of Far1 is a potential mechanism for arrest reinforcement.

Far1PP (the concentration of phosphorylated Far1) and Far1T (the total concentration of Far1 and Far1PP, which is controlled by the transcription factor Ste12) are measured in cells exposed in 240 nM pheromone. Figure 5A shows the time evolutions of the concentrations of Far1PP and Far1T. Our theoretical result clearly demonstrates that Far1T is synthesized slowly, while Far1PP is produced rapidly. Thus, Far1T always accumulates with time when cells are exposed to pheromone. We can predict that pheromone-arrested cells produce more Far1T than that in cycling cells. Therefore, when they are stimulated again, the accumulated Far1T in pheromone-arrested cells will be phosphorylated rapidly into Far1PP, which has higher levels than that in cycling cells. The reentry of pheromone-arrested cells also becomes more difficult compared with that of cycling cells.

To verify our prediction for this feedforward motif of

Figure 4. Hysteresis in the cell cycle kinetics in response to changes in pheromone concentration. (A) Schematic of the hysteresis experiment. Experimental group cells are exposed to 240 nM α -factor for 30 min (pheromone-arrested cells), and control group cells are not treated with anything (cycling cells). Then, the two groups of cells are exposed to different α -factor concentrations (different conditions). (B) Duration of arrest in pheromone-arrested cells and cycling cells in different conditions. (C) Hysteresis experiment for cells lacking the gene *cln1/2*. (D) Arrest duration of pheromone-arrested cells lacking the gene *cln1/2*, pheromone-arrested cells lacking the gene *cln3* and pheromone-arrested WT cells in different conditions.

Figure 5. Dynamical analysis for the feedforward motif with slow transcription and fast phosphorylation. (A) Time courses of Fus3PP, synthesized Far1 (i.e., Far1T) and phosphorylated Far1 (i.e., Far1PP) in WT cells pre-exposed to 240 nM pheromone. (B) Phase diagram of the arrest duration and the Far1T abundance at the Reentry point for WT cells, *cln1/2Δ* cells, and *cln3Δ* cells for changes in the final pheromone concentration in the hysteresis experiment.

Fus3-Far1-Ste12, different types of pheromone-arrested cells (including pheromone-arrested WT cells, pheromone-arrested *cln1/2Δ* cells, and pheromone-arrested *cln3Δ* cells) are exposed to different final concentrations of pheromone from 0 nM to 240 nM. Then, we analyzed the relationships between the concentration of Far1T and the arrest duration for those cells at Reentry point. As shown in Figure 5B, our result implies that Far1 accumulation and the arrest duration at the Reentry point are almost positively correlated. Therefore, the arrest reinforcement potentially results from the accumulation of Far1.

Accumulated CDK inhibitor increases Whi5-threshold

In the experiment, the final concentration in the pheromone pulse is adjustable, whereas the duration of pre-exposure is fixed (30 min). Therefore, we further explore theoretically the effects of different pre-exposed durations on the Reentry point. By varying the pre-exposed duration (240 nM) from 0 min to 30 min and setting the final pheromone concentration to 0 nM, we record the Whi5-threshold using the method of threshold determination for pheromone-arrested cells presented above.

In Figure 6A, the variations in the Whi5-threshold for different pre-exposed durations are derived. As shown in insets of Figure 6A, the Whi5-thresholds are taken from the critical points in the curves of cell fate decision. The Whi5-threshold appears to increase. This finding is obvious and expected because pheromone-activated Fus3 inhibits the cycling protein via Far1, and it will become very difficult for Cln-CDK to occupy the dominant position when the amount of the inhibitor

Far1 increases. Therefore, the cell transition from arrest to the cell cycle requires a higher threshold.

The arrest duration and critical addition time in different conditions are given in Figure 6B. Both the arrest duration and the critical addition time increase first and then reach the saturation values when the duration of the pheromone pulse is longer than approximately 4.5 min. By comparing the two lines, we discover that they almost coincide. This overlap is inevitable because the transition of Whi5 at the critical addition time of pheromone (i.e., Whi5-threshold) is very sharp. Thus, the cell states are divided into two different fates by this critical addition time point (Figure S5C), and this time point is almost the same as the Reentry point (Figure S4A). Therefore, this result confirms that this time is really Reentry point.

Furthermore, we find that longer pheromone exposure makes cells more reluctantly commit to cell cycle reentry (i.e., longer arrest duration). This feature may be a robust design in biology because the larger threshold and longer arrest duration enhance the chance of mating with other partners.

Alternative Far1 regulatory mechanisms are deficient

Why has the fate decision system in budding yeast evolved into a coherent feedforward regulatory mechanism? To reveal the advantage of the Fus3-Far1-Ste12 feedforward motif, several alternative Far1 regulatory mechanisms are selected for slight adjustments. We compare three types of regulatory structures with the feedforward motif, including a positive feedback motif (PF motif), a transcription only motif (TO motif), a phosphorylation only motif (PO motif). Each motif is

Figure 6. Whi5-threshold and arrest duration are enhanced by increases in the pre-exposed duration. (A) The relationship between the pre-exposed duration and Whi5-threshold. (B) The relationship of the arrest duration and the critical addition time with pre-exposed duration.

embedded in the original networks. Then, the related equations are changed.

For the PF motif, equations B1 and B2 are changed into the following two equations:

$$\begin{aligned} \frac{d}{dt}[Ste2] = & -\kappa_1[Ste2] \left(\left(0.1 + \frac{kk_1[Fus3PP]^n}{kk_2 + [Fus3PP]^n} \right) \right. \\ & + \left(0.1 + \frac{kk_3[Ste12PP]^n}{kk_4 + [Ste12PP]^n} \right) \alpha(t) \\ & \left. + \kappa_2[Ste2_{active}] - \delta_1[Ste2_{active}] \right), \end{aligned} \quad (B1')$$

$$\begin{aligned} \frac{d}{dt}[Ste2_{active}] = & \kappa_1[Ste2] \left(\left(0.1 + \frac{kk_1[Fus3PP]^n}{kk_2 + [Fus3PP]^n} \right) \right. \\ & + \left(0.1 + \frac{kk_3[Ste12PP]^n}{kk_4 + [Ste12PP]^n} \right) \alpha(t) \\ & \left. - \kappa_2[Ste2_{active}] - \delta_2[Ste2_{active}] \right). \end{aligned} \quad (B2')$$

For the TO motif, we assume that all Far1 produced is active and that all regulation is governed by production, degradation and dilution. Equation A30 is removed, and equations A3 and A29 are modified into the following two equations:

$$\begin{aligned} \frac{d}{dt}[Cln1/2] = & k_2 + \frac{k_3[SBFA] + k_4[MBFP]}{1 + K_3[SBFA] + K_4[MBFP]} \\ & - d_2[Far1][Cln1/2] - d_3[Cln1/2], \end{aligned} \quad (A3')$$

$$\begin{aligned} \frac{d}{dt}[Far1] = & k_{24} + k_{25}[Ste12PP] - d_5[Cln1/2][Far1] \\ & - d_9[Far1]. \end{aligned} \quad (A29')$$

For the PO motif, we suppose that the total dosage of Far1 is equal to 200 nM. Equation A29 is changed as below:

$$\frac{d}{dt}[Far1] = 0. \quad (A29'')$$

All reaction motifs and their kinetic properties are organized in Figure 7A. In Figure 7B, the time courses of Cln3 and Far1_{act} are exhibited for the addition of α-factor at 2 min and the removal after 4 min. For the TO motif (Figure 7B3), a relatively slow increase in Far1_{act} is observed when α-factor is added, and the level of Far1_{act} is also decreased slowly when α-factor is removed. This result suggests that the TO structure cannot trigger rapid arrest and rapid reversibility. However, other motifs perform this function normally.

Moreover, the dependence of MAPK activity (which is measured via the concentration of Fus3PP) on α-factor for different conditions is also investigated by bifurcation analysis. The results are presented in Figure 7C. Comparisons reveal that the degree of MAPK activity cannot be derived when the concentration of α-factor ranges from 25 nM to 30 nM for the PF motif (Figure 7C2). The positive feedback creates a bi-stable response for this range of α-factor, leading to the loss of information. However, the MAPK pathway activity is linear over a broad range of extracellular pheromone concentrations, similar to its behavior for other motifs [24,27–29]. Hence, our result indicates that reversible positive feedback cannot monotonously encode extracellular information.

Next, we study the cell fate decision of pheromone-arrested cells with Reentry point. The results are shown in

Figure 7. Comparison between the feedforward motif and other structures. (A) Here, we consider four categories of networks that control the level of active Far1. (B) A general response for the networks to a square pulse of the mating pheromone. (C) The steady state relationship between MAPK activity and the mating pheromone. (D) Relationship between the time of pheromone addition and Whi5P activation. (E) Hysteresis experiment for different Far1 regulatory mechanisms. Only the feedforward regulation fulfills all requirements (rapid activation and reentry, ability to continually sense extracellular information, reliable separation of cell fates, and hysteresis effect).

Figure 7D. From these curves of fate decision, we find that there is not a Whi5-threshold for the TO motif (Figure 7D3). Further, we suppose there is a longer time for the G1 check point and the G1/S point for the TO motif, which thus extends the range of addition time. However, the Whi5-threshold is still undetected. This finding implies that the TO motif does not have a reentry threshold. In detail, the cell state would always be in mating arrest regardless of when α -factor is added due to the loss of fate decision ability. This is a fatal design

because it will lead to confusion in the biological regulation. However, other motifs have clear Reentry points.

Finally, the hysteresis experiment is conducted theoretically. The results for each of the different motifs are indicated in Figure 7E. The hysteresis effect of the PO motif is not evident (Figure 7E4), which means that for the PO motif, the memory of its history is not very strong. Moreover, this result proves that hysteresis behavior is resulted exactly from the accumulation of Far1. Further-

more, for the TO motif, there is no hysteresis curve due to the lack of a Reentry point (Figure 7E3).

By comparing the properties of all motifs, we easily find that the feedforward motif is the best design because it excels in the functions we have listed, whereas the other motifs do not. For example, the PF motif cannot encode external information monotonously, the TO motif lacks the functions of rapid arrest and rapid reversibility, and the PO motif cannot produce the hysteresis.

DISCUSSION AND CONCLUSION

The decision of the budding yeast between cell cycle commitment and mating arrest involves a complex process, including translocation of Whi5 between the cytoplasm and the nucleus, recruitment of the scaffold protein Ste5, multisite phosphorylation of Ste5 by Cln1/2, mutual inhibition between Cln1/2 and Far1, a series of transitions between the active and inactive states of kinase proteins, and so forth.

However, two important regulatory motifs were neglected in the previous models of cell fate decision. The first motif is the Cln1/2-Sic1- Clb5/6 motif, which is tightly associated with the G1/S transition in cell cycle subsystem. The potential roles of a double negative feedback loop between Clb5/6 and Sic1 and the inhibition of Cln1/2 by Sic1 in the maintenance and selection of different cell fates are still poorly understood. The second motif is the coherent feedforward loop created by Fus3-Far1-Ste12 in the MAPK pathway subsystem. Although the key functions of the feedforward loop in the cellular transition of pheromone-arrested cells have been investigated experimentally, the relationship between the structure of these motifs and dynamical features of the cell fate decision remains unresolved.

To identify the mechanisms underlying the cell fate decisions for cycling cells and pheromone-arrested cells, in this study, we construct a full mathematical model of the regulatory network for cell fate decision in the G1 phase of budding yeast. Specially, the Cln1/2-Sic1-Clb5/6 motif and the Fus3-Far1-Ste12 motif are taken into account. We find that the involvement of these two motifs in the cell fate decision network ensures the effective separation and flexible transition between different cell fates.

First, the Start point and the G1/S point in cycling cells are quantitatively reproduced. It is obvious that the Start point can be identified more easily in the present model than in our original model [7]. The alternating switching of key proteins between high and low levels are observed. Some reasonable observations for cell size control also emerge from our numerical experiments. Because the Cln1/2-Sic1-Clb5/6 motif can only be activated after the Start point in the simulation, we believe the Fus3-Far1-

Ste12 motif provides the improvement in our model's performance. This finding implies that feedforward regulation ensures the reliable separation of different cell fates.

Second, the Reentry point in pheromone-arrested cells is studied. The threshold for reentry in pheromone-arrested cells is exactly higher than the corresponding threshold for cycling cells. Moreover, the hysteresis behavior in cell cycle kinetics in response to changes in pheromone concentration is reproduced theoretically using our model [12]. We deduce that Cln3 is the primary driver of reentry and that the accumulation of Far1 directly reinforces arrest.

Finally, we confirm that Far1 accumulates slowly to ensure stability against size-dependent increases in Cln3 activity [21], because the small fluctuation of Cln3 level can be filtered due to the increase of CDK-threshold. Whereas fast phosphorylation cycles of Far1 allow rapid responses including rapid activation and reentry. Our results have shed light on the physiological functions of feedforward regulation and promoted our understanding of the molecular mechanisms of feedforward regulation-mediated cell fate decision in budding yeast.

Due to the complexity of the cell fate selection network, further work to refine our mathematical model is required. For example, the slope of the size control curves shown in Figure 2B is far from -1 . Compared with the real situation, the negative correlation between the duration of the Start phase and the birth size of daughter or mother cells is too weak. Moreover, as observed in Figure 5B, the phase diagrams for *cln3* and WT cells show a hook-like tail, which is the relationship between the concentration of Far1T at the Reentry point and the arrest duration when the final concentration of pheromone is less than 15 nM. As shown in Figure 6A, when the duration of pre-exposure to pheromone is shorter than 15 min, the Whi5-threshold is volatile. These local non-monotonic kinetics in cell fate decision are worthy of further consideration. In addition, to verify the stability of the cellular transition, a stochastic model [19,30–32] is expected in our next research. Sensitivity analysis is also required because only one set of parameters is used in our model [33,34].
