Abstract Gas refineries are among the most water-intensive industries in the world. The Fajr Jam gas refinery is one such example, located in the southern Iran. The indiscriminate use of aquifer resources for this highly profitable industry creates tragedy of the commons effects, causing significant environmental controversy and threatening the long-term water security of the region. It behooves decision makers, therefore, to examine a broad range of adaptive water management strategies for this industry. The implementation of such strategies requires understanding the preferences and potential conflicts that may emerge among competing stakeholder interests. This quantitative social scientific study examines stakeholder preferences among water management options through the lens of social capital. Elite stakeholder representatives (including agricultural organizations, governmental organizations, the Water, and Power Authority, Department of Health, Bureau of Water and Wastewater) were canvassed through a survey instrument using paired comparisons. Data were analyzed using Expert Choice software and an analytic hierarchy process technique. The results show that accountability is the

main criterion for selecting the best water sources and ranked first with the Eigenvector 0.62. Also, the results show that the least important criterion was social cohesion with the Eigenvalue 0.033. The criteria of partnership and trust ranked as two and three with Eigenvalues 0.215 and 0.133, respectively. The results indicate that the construction of salt water transmission from the sea ($A = 0.240$) is the preferred option among other alternatives, and this is confirmed by sensitivity analysis.

Keywords Water resource preference · Jam gas refinery · Iran · Petrochemicals industry · Multi-stakeholder environmental management · Social capital

Introduction

Iran holds the third largest known oil reserves and the second largest natural gas reserves globally [1]. It also harbors a petrochemical industry that produces 42.5 million tons of basic chemicals, fertilizers, polymers, feedstock, and fuels annually [2]. Water is a critical component of petrochemical industry operations, with large water volumes used in fuel production primarily for processing and cooling. Based upon global averages, crude oil refineries require an average 50–60 gal of water per barrel of crude during production. Refinery water consumption is, however, differentiated by the manufacturing process, alongside the level and types of technology used. Refineries use water for making petroleum products by vapor, for transfer of temperature, transfer of raw materials or waste products, and for mechanical activities. In oil exploration and production, water consumption depends on the source and location of the fossil fuel resource, the recovery technology, and the amount of produced water re-injected for oil recovery [3].

With a recent downturn in global oil and gas prices, downstream producers (specifically refineries) are increasingly looking to reduce their operating costs. Water efficiency is a key component of this cost saving. However, in many refineries, water use efficiency is poor, due primarily to technological limitations and outdated water management practices. Moreover, underground water from aquifers and groundwater sources are commonly used for domestic, industrial, and irrigation purposes in Asian countries. However, over-exploitation of these sources severely jeopardizes water supply and water quality [4]. This threatens regional water security and increasing energy requirements for pumping technologies. The depletion of aquifers and other ground water sources can have secondary environmental effects such as land subsidence. Therefore, there are both operational and environmental benefits to the identification of alternative water sources in such cases [5]. In our Iranian case study, the Tehran Oil Refining Company began in 2014 an annual transfer of 20 million cubic meters of water from treated wastewater and sewage treatment plant water to restore about 60% of drinking water to the supply system. The Jam gas refinery is one of the largest gas refineries in Iran, located in Jam City, Bushehr Province. In total, the value of water used in oil refining is 4–20 times more profitable than comparative use in the agricultural sector. However, the refinery has used underground water of the Plain of Jam Township within its production system, severely depleting the resource. This requires an immediate remediation action to prevent total underground water depletion to the affected area. Thus, policy-makers are confronted with the problem of balancing economic gains from fossil fuel products against water stress-related socio-economic and environmental impacts.

In the academic and policy literatures on assessing water resource options, by far the most commonly used tool is that of multiple criteria analysis (MCA)—a body of assessment techniques which rank or score the performance of alternative decision options against multiple criteria (typically measured in different units). This technique is common to water management practice because of the competing objectives commonly identified. Yet the criteria used for assessment must be evaluated against performance measures, and so commonly used criteria of assessment tend to be aspects such as computational efficiency, explicitness of trade-offs, and the quantity of useful information supplied [6]. Yet there is a growing recognition of the need to move beyond these explicitly quantitative performance measures to assess and integrate so called *soft* social factors, preferences, and values into water resource management practice, and to understand different values and preferences from the “bottom up,” i.e., through empirical research into stakeholder preferences [7].

As is common in contested environmental resource management processes, a socially and environmentally acceptable solution requires the negotiation of multiple stakeholder

interests among dependent businesses, regional and national governments, citizen-stakeholder representatives, third sector organizations, and environmental protection groups. In this study, we define stakeholders under a commonly held definition as those individuals or groups with a specific interest in the outcome of decisions, or those that will be directly or indirectly affected by the achievement of petrochemical industry organization objectives [8]. We assume that under conditions of resource management decision-making, there will be conflicts of interest among competing worldviews. Overcoming conflict and reaching (some degree) of consensus among competing water management outcomes are a key criterion of the Jam gas refinery’s continued economic success, environmental responsibility, and its social license to operate within the region [9]. This is true, not only for the Jam gas refinery, but for the oil and gas sector world-wide, and so our proposed methodology has applications beyond our case study. The role of stakeholder perspectives has been recognized as an influential factor in both the social acceptance of new technologies and of broader policy success [10, 11]. This is specifically true for adaptive water resource management solutions [12–15]. As Sharp [16] asserts, there is a growing move away from unseen technical fixes to water management problems, towards more participatory and stakeholder engagement-led approaches. Developing tools to assess stakeholder preference is, therefore, an important research priority. It is necessary to provide tools for effective stakeholder engagement in order to ensure equitable and socially acceptable water resource management outcomes.

Successful adaptive water management from an engagement-led perspective must approximate the diversity of positions and interests and thus increase the practical likelihood of acceptability, implementation, and effectiveness of proposals [17]. Multi-stakeholder appraisal approaches to environmental management and sustainability problems have grown exponentially since the early 1990s [8]. Managing effective stakeholder appraisal of technological options requires both a representative (or at least diverse) and selection of actors that support competing interests [18]. With stakeholder diversity, however, come issues of mutual trust, competition, and conflict resolution. Where consensus (or at least a lack of protracted disagreement) is required in water resource management, representative interests must build trust, social learning, and cohesion towards shared goals, and have buy-in to the process (i.e., participate with one other and have accountability in reaching collective decisions). To this end, we examine the issue of water source choice as a matter of collective action between competing stakeholder interests. We specifically employ the concept of *social capital* as a key factor in the success of water management outcomes. We presuppose that social relations of trust, shared and collective norms, and networks of association represent the means through which a common and agreed strategy can be upheld among competing stakeholder interests [19–21].

To summarize: our principal research objective is to select among water resource management options for the Jam gas refinery case by examining multiple stakeholder perspectives through a social capital theory framework.

Theoretical Framework

In this study, our underlying assumption is that socio-cultural factors shape the way individuals perceive alternative water resource strategies. The basis for this assertion lies in Bisung and Elliott's (2014) work, exploring a framework linking social capital with community management of water resources. They argue that social capital influences water management practice by shaping collective action, knowledge, attitudes, and behaviors [22]. At its heart, social capital offers a route to sustainable management and governance of common pool resources [23]. Stemming from Hardin's (1968) Tragedy of the Commons (ToC) model, we presuppose that water management is a common pool resource depletion and degradation issue. This is because water resources are shared collectively under conditions where the benefits of water extraction are reaped by an individual (or single group within the collective), leading individuals (or in this case profit-making organizations) to take actions that degrade the resource over the longer term [24]. Though Hardin argued that resolution of ToC problems involves mutual coercion, mutually agreed upon, in order for collective action to preserve resource quality (and in this case, water quantity), Ostrom critiques that governing the commons is dependent less upon coercion, and more upon agreement. Whereas Hardin argued for state control or privatization of the resource as the primary means to protect against common pool resource degradation, Ostrom advocates an alternative approach: critiquing Hardin's assumption that the users of the resource will not communicate the problem to one another and try to reach an agreement about how to manage the resource in such a way as to avoid common pool resource degradation. Ostrom advocated a system of resource management involving self-organized governance systems (including collaborative, multi-stakeholder environmental management) dependent upon effective communication, trust and reciprocity—which this study, through its measurement of social capital within stakeholder networks attempts to assess in order to improve water management practices [25]. It is necessary, therefore in our research, for group boundaries to be defined: rules that govern water use must meet local needs and conditions, rules about resource use are mutually agreed upon and participatory, and dispute resolution and sanctions can be put in place [25]. In order for this to happen effectively, social rules, norms, and behaviors within common pool resource management need to be understood, and social capital provides a framework or 'lens' through which these issues can be explored.

Social capital is a broad concept, one that has proven both difficult to define and difficult to measure [26]. Though traced to Hanifan's work [27] in the early twentieth Century, the modern sociological concept of *social capital* can be traced to Jacobs's (1961) description of relational resources within a community and family, and its later popularization following Putnam's *Bowling Alone* analogy [19]. Using the economic analogy of capital, social capital is conceptualized as a resource that can be accumulated or drawn upon in times of need. Unlike traditional tangible resources (e.g., financial or human capital), social capital is distinctive in that it exists in the structure of relationships between actors, and is, therefore, jointly owned [28]. Social capital, unlike other capital resources, is not physically tradable, but is an emergent phenomenon from the interaction of social practices and shared norms and values. Though intangible and difficult to quantify, harnessing social capital has the potential to offset other capital costs, such as those associated with organizational governance and operational overheads. Alternatively, it has been described as the factors that "glue" society together [29] and defined as "the social connectedness of a community that enables people, organizations, and communities to work together collaboratively for mutual benefit" [30]. Moreover, because individuals can draw from social capital in their communities, it can operate at both an individual and community level [31].

Despite a lack of conceptual consensus, three key types of social capital are commonly cited [32]. Firstly, *bonding* social capital represents close personal ties within groups, such as families and friends. Second, *bridging* social capital represents loose ties between people who may or may not share similar characteristics or networks (such as workmates and acquaintances). Third, *linking* social capital reflects relationships that reach across explicit, formal, or institutionalized power gradients in society. Collectively, these forms of social capital are productive, self-reinforcing and cumulative, and if harnessed effectively can ultimately improve economic performance. Social capital enables participants to act effectively and to pursue shared objectives (and thus is not always socially "positive"—oppressive or criminal networks can harness social capital as well). From an organizational perspective, harnessing these collective social capital resources is a key factor in effective collaborative governance, in stakeholder engagement and in maintaining a social license to operate—essentially a trust relationship with the community in which it operates [33]. Gaining social capital can potentially decrease the financial cost of operation of an action [34], and this is particularly true in cases where operations invoke controversy—such as the case in contested environmental management disputes [35–37].

Effective stakeholder involvement can build social capital within and among an organization's stakeholder networks. Building social capital ensures that stakeholders buy into

shared objectives, management plans and organizational strategies. Building a stock of social capital will likely increase their willingness to contribute to the achievement of such objectives [38]. Though widely recognized as important to stakeholder management, definitions of social capital are fluid and contested. There are, however, a number of recurrent themes that we identify: namely *trust*, *social cohesion*, *accountability* and *participation* [39–42]. The aim of this research is to define which among these social capital factors have the most impact upon water source preference. Also, we aim to evaluate this in relation to indices for the aforementioned four concepts.

Trust, in this context is the confidence held within a stakeholder network that others will act on commitments reliably and with reciprocity. It is a core mechanism through which social capital is mobilized for collective action towards a common goal [43]. Trust is dependent upon characteristics of individuals and their setting, including institutions, the nature and extent of social networks, and individual characteristics. Trust may also be related to an individual's tolerance for risk, since trusting another individual may, in many cases, carry risks [44].

Social cohesion, stemming from the work of the sociologist Durkheim, relates to loyalty and solidarity as necessary components for any society [45]. Durkheim (1893) argued that there is no clear definition of the concept of social cohesion and it cannot be measured directly. In his view, “joint loyalty and solidarity” are key factors in social cohesion. According to Durkheim, there are two types of solidarity: mechanical solidarity and organic solidarity. Mechanical solidarity refers to the traditional uniformity of collective values and beliefs and organic solidarity refers to the modern relationships between people that are able to work together [46]. Therefore, social cohesion is taken into account as a precondition towards the use of social capital and development. The feeling of “being together” with other people, feeling safe [47], and having a sense of belonging, inclusiveness and legitimacy is also included in this concept [48]. In practice, development organizations such as the World Bank consider social cohesion as important for economic prosperity and sustainable development within communities [49].

Our third component of social capital theory is *accountability*. Humans are fundamentally social animals; interaction with others and a sense of shared responsibility within social groups is deeply important. Accountability is the means by which humans accept responsibility (or are held responsible) for their moral actions towards others within and between social groups. This leads to our fourth concept of *participation*—a concept that is widely theorized and applied in stakeholder management processes. It is, broadly speaking, the point at which civil society and citizen-stakeholder interests are brought into decision-making process within environmental management. It is, in essence, a form of social interaction within civil society [50]. This includes the involvement of organizations, associations or other volunteer

groups, and those activities which through them, citizen stakeholders become involved in community affairs and are directly or indirectly involved in shaping social life [51]. Participation can be offered at two levels. The first is mental participation, which tend to be the result of social participation and other factors underlying people's sense of trust. The second is at a more objective level. Participation is also the social practices of engagement with fellow members of social networks, either through formal “invited” engagement processes instigated by authorities seeking input from stakeholder on proposed policies and plans, or else uninvited “bottom up” participation of stakeholders seeking to influence the outcomes of such policies and plans from the outside [52]. It is this collective action of invited and uninvited social participation that is an important component of social capital [53].

As mentioned, social capital generally refers to the collectively owned asset which resides in and is derived from durable relationships between actors and/or social units [54]. It is reported to be a productive resource that boosts organizational growth and innovation performance [55], potentially leading to mutually beneficial outcomes including better group communication and knowledge sharing and enhanced use of intellectual capital [56]. Social capital mobilization can also

Table 1 The criteria and indicators

Criteria	Code name	Indicator
Social participation	M1	Local managers engage in the process of water resources management
	M2	The use of local engineers and experts in the selection and management of water resources
	M3	Stakeholder partnership in the operation and maintenance
	M4	Official working of various agencies working in water resource management
Trust	A1	Trust between government agencies and organizations to each other
	A2	Trust between stakeholders
	A3	Local self-government bodies of the people
Social cohesion	AN1	Coordination between government agencies and stakeholders
	AN2	Coordination among government agencies
Accountability	MS1	Disregard for executives and high-ranking officials in matters related to water resources
	MS2	Responsibility governmental organizations on the protection of water resources
	MS3	The development of the water distribution network in the future
	MS4	Risk or risks associated with the destruction of personal intentions
	MS5	Environmental degradation caused by water resources

Fig. 1 Model of AHP to select the most suitable water source based on social capital

potentially alleviate a broader scarcity of resource and other capital constraints in peripheral communities [57]. In fact, the interplay of economic and social capital is a core aspect of social life. Its value for this research is that a social capital lens can be used to define the most appropriate option to facilitate the extraction of water with the least amount of stakeholder conflict, based upon the assertion that where more social capital exists among a range of stakeholders around a preferred water management option, that this will be the one which stimulates the least conflict, thus having the greatest opportunity for project success.

Methods

In defining stakeholder preference for water resource management options, we adopt a quantitative social scientific approach based upon a case study of the Jam City gas refinery—the largest in Iran. The study population was identified

through purposive sampling. It consisted of ten “elite” participants in governmental agencies. These include the Power and Water Authority, Department of Health, Agricultural organizations, the Water and Sewage Department, and the Department of the Environment in Bushehr Province. Collectively, these are the decision-makers for water allocation and are the ones that perform the paired comparisons. The study had two separate phases. In the first phase, we surveyed the literature on social capital and water management respectively, to define the appropriate criteria and indicators. The criteria and indicators are shown in Table 1.

In the second phase, we consulted four technical experts from the engineering company of Sazab Pardazan, to identify the range of technical options available for the Jam gas refinery. The selected water sources are as follows which used for paired comparisons to select among options:

- A: A sea water transmission line from the Persian Gulf to Jam City and establishing desalination technology
- B: Exploration for underground water sources, including groundwater/wells
- C: Artificial feeding and restoration of existing wells
- D: Supplying water from the river dam of Gavbandi
- E: Purification of urban sewage
- F: Calculate the water requirement of residential towns’ refinery and recycling water used.

Based on the criteria and indicators, the analytic hierarchy process (AHP) model provided and the pairwise comparison matrix was established (Fig. 1). Then weights related to the

Table 2 The pairwise comparison scale [62]

Intensity of importance	Definition
1	Equal importance both element
3	Weak importance one element over another
5	Essential or strong importance one element over another
7	Demonstrated importance one element over another
9	Absolute importance one element over another
2, 4, 6, 8	Intermediate values between two adjacent judgments

Fig. 2 Factors for prioritizing water source preference

options and criteria were determined by an expert review [58]. In this step, the authors used a linear model based on the criteria in line with those employed in other environmental/resource management case studies [59–61]. The elements of a particular level are compared pairwise with respect to a specific element in the immediate upper level. A judgment matrix was formed and used for computing the priorities of the corresponding elements. First, each criterion was compared pairwise with respect to the goal. The judgment matrix, denoted as A , was formed using the comparison. Therefore, let $A_1, A_2, \dots, A_n$, be the set of stimuli. The quantified judgments on pairs of stimuli, A_i, A_j , are represented by:

$$A = [a_{ij}] \quad i, j = 1, 2, \dots, n \quad (1)$$

The comparison of any two criteria C_i and C_j with respect to the goal is made using the questions of the type: of the two criteria C_i and C_j , which is more important and by how much? Saaty (1980) suggests the use of a 9-point scale to transform the verbal judgments into numerical quantities representing the values of a_{ij} . Table 2 lists the definition of the 9-point scale. A larger number assigned to the pairwise comparisons means larger differences between criteria levels. The entries a_{ij} are governed by the following rules:

$$a_{ij} > 0, \quad a_{ij} = \frac{1}{a_{ji}}, \quad a_{ii} = 1 \quad \text{for all } i \quad (2)$$

This scale can be applied with ease to criteria that can be defined both numerically and non-numerically. The relative importance scale is presented. The participants were instructed to specify their judgments of the relative importance of each criterion towards achieving the overall goal, and so a questionnaire was devised to assess stakeholder preferences among water resource management options using pairwise comparison. Based upon the weighted value that the

stakeholders finally assigned, the geometric mean value was used to compute decision-making community scores from all experts in order to formulate the weighted values selected for choosing the best water sources for the Jam gas refinery.

Having recorded the numerical judgments a_{ij} in the matrix A , the problem is then to recover the numerical weights ($W_1, W_2, \dots, W_n$) of the alternatives from this matrix. In order to do so, we use the following equation:

$$\begin{bmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & \ddots & \vdots \\ a_{n1} & \cdots & a_{nn} \end{bmatrix} \cong \begin{bmatrix} w_1/w_1 & \cdots & w_1/w_n \\ \vdots & \ddots & \vdots \\ w_n/w_1 & \cdots & w_n/w_n \end{bmatrix} \quad (3)$$

We multiply both matrices in Eq. (3) on the right with the weights vector $W = (W_1, W_2, \dots, W_n)$, where W is a column vector. The result of the multiplication of the matrix of pairwise ratios with W is nW , hence it follows:

$$Aw = nW \quad (4)$$

This is a system of homogenous linear equations. It has a non-trivial solution if and only if the determinant of $A - nI$ vanishes; that is, n is an eigenvalue of A . I is an $n \times n$ identity matrix. Saaty's method (Saaty, 1980) computes W as the principal right eigenvector of the matrix A ; that is,

$$Aw = \lambda_{\max} W \quad (5)$$

where $\lambda_{\max}$ is the principal eigenvalue of the matrix A . If matrix A is a positive reciprocal one, then $\lambda_{\max} \geq n$ (Saaty, 1990). If A is a consistency matrix, eigenvector X can be calculated by:

$$(A - \lambda_{\max} I)X = 0 \quad (6)$$

Here, using the comparison matrix, the eigenvectors were calculated by Eqs. (5) and (6). Then the consistency test is performed. The eigenvector method is the most popular method to estimate a priority vector [63]. Therefore, this reflects the

Fig. 3 Key indicators of the participation factor

Fig. 4 Key indicators of the *trust* factor

Inconsistency=0.0

importance of this criterion across all stakeholder participant perspectives.

Expert Choice Software (ECS) was used to achieve the goal of the present study, i.e., the preferred water resource management strategy for the Jam gas refinery.

Results

The results of paired comparison between the criteria of social capital are presented in Fig. 2. This shows that *accountability* is the main criterion for selecting the best water source and it is ranked first with the eigenvector 0.62. The least important criterion was *social cohesion* with the eigenvalue 0.033. The criteria of *partnership* and *trust* ranked as two and three with the eigenvalues 0.215 and 0.133, respectively.

The following sections examine the indices of different social capital dimensions with respect to water source preference:

Partnership

Figure 3 shows the result of paired comparisons of indicators for the *partnership* factor. Figure 3 shows that partnership is the most preferred indicator by local administrators in the process of water resources management (M1) (0.562). This suggests that local administrators' collaboration is the most important criterion in selecting water sources among other partnership criteria. Also, the indicator of "The use of local engineers and experts in the selection and management of water resources" is the least important in water source selection within the partnership factor (M2) (0.091).

Trust

The results of paired comparisons between *trust's* indicators are presented in Fig. 4. As shown in Fig. 4, the indicator of "trust between organizations and government agencies" is the

most important to select a water source strategy (A1 = 0.541). This reflects the importance of this indicator across the viewpoints of all stakeholders sampled. According to the results, the least important indicator was "local government" with the eigenvalue 0.174.

Social Cohesion

Results of paired comparisons between social cohesion's indicators are presented in Fig. 5. As shown in Fig. 5, the indicator of "coordination between government agencies and stakeholders" is the most important to select a water source strategy (AN1 = 0.544). This reflects the importance of this indicator across all stakeholder perspectives.

Accountability

Results of paired comparisons between accountability's indicators are presented in Fig. 6. As shown in Fig. 6, the indicator of "disregard for executives and high-ranking officials in matters related to water resources" is the most important to select water source (MS1 = 0.453). This reflects the importance of this indicator in the viewpoint of all stakeholders. According to the results, the least important indicator was "environmental degradation caused by water resources" with the eigenvalue (MS5 = 0.048).

Social Capital and Water Source Preference

The final scores for each water source alternative based on the relative weight of criteria and indicators were calculated. Then based on the final score, the most preferred water source was selected. Figure 7 shows the final results of water source preference.

We find that "the construction of salt water transmission from the sea" (A = 0.240) is the most preferred option among other alternatives, followed by alternatives "water use

Fig. 5 Key indicators of the *social cohesion* factor

Inconsistency=0.0

Fig. 6 Key indicators of the accountability factor

management” (F) and “purification of urban sewage” (E) in second and third place.

One of the most important indicators of judgment in relation to the accuracy of model results is the use of sensitivity analysis. The results of sensitivity analysis show how the options are ranked in comparison to their alternatives. In model building using the analytical hierarchy process, sensitivity analysis is a crucial step in determining if the solution is implementable and robust [64]. Sensitivity analysis is performed to test the stability of the priority ranking. Therefore, this work illustrates how the AHP model would be implemented to help engineers determine the manufacturing process yield quickly and effectively [65]. The expert choice software has some modes of sensitivity analysis, including performance, dynamics, gradient, and head-to-head sensitivity analysis. The results of the sensitivity analysis model to choose the best alternative shown in Figs. 8, 9 and 10.

Dynamic Sensitivity Analysis

This sensitivity analysis is used for the dynamic changing of the importance of factors, i.e., it is used to determine how these changes will affect the selection of alternatives. Therefore as per Fig. 8, under normal weighting, the factors of participation, trust, social cohesion, and accountability are equal to 0.215, 0.133, 0.033, and 0.620, respectively. According to these weights, option A is selected.

Performance Sensitivity Analysis

The sensitivity analysis shows how the alternatives ranked compare to the other alternatives. As can be seen in Fig. 9, option A started from 0.75 in the *participation* factor and increased to 0.95 in the *social cohesion* factor. The weight of this option was reduced from *social cohesion* to

accountability. The weight of this option then decreased to about 0.80 in *accountability*. The right column of the chart shows the total weight of the options. According to the results, option A is ranked first by all factors.

Gradient Sensitivity Analysis

The gradient sensitivity analysis of the options is shown in Fig. 10. The head-to-head points in the participation factor in option A and F is 0.47. In the *trust* factor, the head-to-head point of A and F is 0.09. Head-to-head points for the *social cohesion* factors A and F is 0.04. In the *accountability* factor, two alternatives of A and F overlapped completely.

Discussion

In order to achieve sustainable development, it is necessary to align economic growth with environmental protection and social cohesion simultaneously. The management of water resources in petrochemical refineries is one of the key areas of unsustainable practice within the manufacturing sector—an issue pertinent (but not exclusive to) Iranian society. In Iran, industrial water usage has increased greatly in the last century, principally due to the profitability of this industry when compared to other competing high water use sectors (specifically agriculture and domestic water consumption). The Jam gas refinery is one of the largest gas refineries in Iran, located in Jam City, Bushehr Province. Its impact upon local water stress is significant for the region. Allocation of water to the refinery must be economically efficient, technically practicable, and socially equitable. Therefore, there is a need for a suitable water allocation system in which water is considered as social and economic commodity [66]; and so determining a *socially* acceptable water management strategy is a key priority. We assert that water resource management success must inevitably involve the input of multiple stakeholder perspectives and

Fig. 7 Selecting the preferred water source

Fig. 8 Dynamic sensitivity analysis charts

preferences. To understand such preferences we use *social capital* theory because this facilitates an understanding of the most socially acceptable option for water extraction with the least degree of conflict—a factor crucial to project success under conditions where decisions are made in the context of collaborative, multi-stakeholder resource management. Social capital is one component of broader capital resources, which along with human, resource, and financial capital have an overall impact upon economic growth.

At first glance, social capital is commonly overlooked in understanding economic growth, in part because it is difficult to define and measure [26]. However, it plays an effective role in the structure and relationships between individuals, groups, and organizations. Involving stakeholders in water management practices is a key aspect of ensuring project success, with social capital indicators providing a useful tool for differentiating between the social acceptability of different technical options. The purpose of this study was to select the preferred water source based upon a quantitative evaluation from the perspectives of different elite stakeholder participants using

social capital criteria to differentiate between options and to demonstrate the effectiveness of such a method to other resource management options assessment processes. Despite there being no single definition of social capital to adhere to, we have derived core components of *participation*, *trust*, *social coherence*, and *accountability* as measurable indicators from our assessment of the sociological literature. The results of paired comparisons showed that among these four factors of social capital it is *accountability* that is deemed the most important factor.

In terms of preferred options, transmission of seawater from the Persian Gulf to the Jam Township has been identified by experts as the first priority among the competing options. We then assessed this using sensitivity analysis because this is a reliable indicator of judgment in relation to the accuracy of model results. According to all sensitivity analysis models, this alternative was considered as the first priority. This alternative is likely to generate the least conflict of interest between competing stakeholders; however, this option has high financial capital intensity and supporting infrastructure

Fig. 9 Sensitivity analysis performance

Fig. 10 Gradient sensitivity analysis

requirements. Based on the research and expert input in the first phase of the study, we establish that seawater transmission requires the construction of a 40-km pipe and three desalination stations with the capacity of 17,000 m³ water. Also, it should be noted that this option can have negative consequences on the regional ecosystems due to the accumulation of salt from seawater. Seawater transmission also has high capital cost (specifically of desalination plant technology), but also suffer high maintenance costs over the lifecycle of their operation. A sea water desalination option would, therefore, require comprehensive research into the regional ecosystem services, capital costs and socio-economic impacts. The second alternative of improved water efficiency would provide water for Jam gas refinery through calculating the water requirements of nearby residential towns and increasing water recycling domestically, thus easing localized water stress and increasing resource availability for the refinery. Our results show that this option also generates low conflict of interest among the stakeholder participants. More than 2000 m³ water is wasted daily in the region: encouraging greater water use efficiency has a high degree of social acceptance among stakeholder interests. Behavioral management of consumer water consumption practices through economic incentivization is thus advised.

Finally, it should be considered that this study presents a stakeholder preference analysis tool for use in other environmental resource management contexts. In the process of planning major infrastructure projects, achieving options that are both low financial cost and generate low stakeholder conflicts is a high priority. By using this tool (potentially as part of a multi-criteria assessment, or alongside it) it is possible to map social capital indicators across technology options. This has the potential to reduce environmental management conflicts among competing perspectives—improving both the environmental and social performance of plans and projects by revealing options that are likely to generate low social conflict and thus greater levels of public acceptance. Such a method is both easy to administer, using small *n* respondent sample survey techniques, and yet sufficiently robust to choose among competing options based upon relevant social criteria.
