

Mitigating Dictionary Attacks on Password-Protected Local Storage

Ran Canetti, Shai Halevi, and Michael Steiner

IBM T.J. Watson Research Center, Hawthorne, NY, USA

Abstract. We address the issue of encrypting data in local storage using a key that is derived from the user's password. The typical solution in use today is to derive the key from the password using a cryptographic hash function. This solution provides relatively weak protection, since an attacker that gets hold of the encrypted data can mount an off-line dictionary attack on the user's password, thereby recovering the key and decrypting the stored data.

We propose an approach for limiting off-line dictionary attacks in this setting *without relying on secret storage or secure hardware*. In our proposal, the process of deriving a key from the password requires the user to solve a puzzle that is presumed to be solvable only by humans (e.g, a CAPTCHA). We describe a simple protocol using this approach: many different puzzles are stored on the disk, the user's password is used to specify which of them need to be solved, and the encryption key is derived from the password *and the solutions of the specified puzzles*. Completely specifying and analyzing this simple protocol, however, raises a host of modeling and technical issues, such as new properties of human-solvable puzzles and some seemingly hard combinatorial problems. Here we analyze this protocol in some interesting special cases.

1 Introduction

The motivation for this work is the common situation where we need to protect local storage that is physically readable by anyone, and moreover the only source of secret key material are the human users of the system. For example, think of a multi-user system where each user has an account, and where a browser lets users store personal information and site-specific passwords on the shared disk under the protection of a password. Another example is a laptop whose disk is searchable when captured and access to data is protected by a password. The common solution for this case is to derive a cryptographic key from the user-supplied password (possibly together with a public, locally stored salt), and use that key to encrypt the information (see e.g. [Kal00]).

This practice is quite problematic, however, since an attacker can perform dictionary searches for the correct password. In contrast to the case of password-based key exchange where off-line dictionary attacks can be effectively mitigated using cryptographic tools, here the lack of any secret storage seems to make such attacks inevitable. Thus, typical applications use a key-derivation-function such

as SHA1 repeated a few thousand times to derive the key from the password, in the hope of slowing down off-line dictionary attacks. Although helpful, this approach is limited, as it entails an eternal cat-and-mouse chase where the number of iterations of SHA1 continuously increases to match the increasing computing powers of potential attackers. (This approach can be thought of as a naive instantiation of the “pricing via processing” paradigm of [DN92].)

This work aims to improve the security of local storage by relying on the human user for more than just supplying the initial password. Namely, we envision an interactive key-generation process involving a human user and the automated program, at the end of which a key is generated. Specifically, we propose to make use of puzzles that are easily solvable by humans but are hard to solve for computers, as in [Naor96, vAB⁺03]. That is, the user would supply a password, then it would be asked to solve some puzzles, and the key would be derived from both the password and the solutions of these puzzles.

One approach for combining puzzles and passwords was proposed by Pinkas and Sandler [PS02] in the context of a client-server interaction. In their solution the server asks the client to solve some puzzles, and if the client solves these puzzles correctly then the password is used in the usual way. This approach cannot be used in our setting, however, since it requires the server to keep the correct answers in storage for the purpose of comparing them with the solutions provided by the user. In our setting there is no server that can check the user’s answers, and no secret storage to keep the solutions to the challenge puzzles.

Another potential solution, proposed by Stubblefield and Simon [SS04], is to use puzzles (called *Inkblots*) to which each individual has its own personal and repeatable answers that are unpredictable even by other humans. Then, a (hopefully) high entropy key can be derived from the user’s solutions. In essence, this method uses the answers to the puzzles as a high-entropy password. If feasible, such an enhanced password generation mechanism is indeed very attractive, but the strong unpredictability requirements severely limit the class of potentially appropriate puzzles.

We combine the traditional password mechanism with human-solvable puzzles in a different way: At system setup, a large number of puzzles are generated and stored, *without their solutions*. The user-supplied password is then used to choose a small number of puzzles out of the stored ones. The user is asked to solve these puzzles, and the key is derived from the password *and the solutions to the puzzles*. The point here is to force the adversary to solve a considerable number of puzzles per each password guess, thus limiting its power to exhaustively search for the password.

The class of puzzles that are useful for our scheme is rather broad. We only need to be able to automatically generate puzzles, have individual human users answer these puzzles in a consistent way across time, and have the answer be unpredictable to a computer. In particular, there is no need to generate puzzles together with their answers, as required in the case of CAPTCHAs [vAB⁺03]. In fact, there need not even exist a single “correct” answer; each individual might have its own answer, as long as it is repeatable. On the other hand, there is no

need that answers by one human are unpredictable by other humans, as required for Inkblots. We call this class of puzzles by the generic term **human-only solvable puzzles** (HOSPs). The Appendix suggests ideas for HOSPs that are neither good CAPTCHAs nor good Inkblots but might be suitable for our scheme.

As simple as this scheme sounds, analyzing it (or even completely specifying it) takes some work. For starters, one needs to determine how many puzzles to store on the disk and how many of these should the legitimate user solve in order to get access to the encrypted data. Also, one needs to specify the function that maps user passwords to sets of puzzles and the function that maps puzzle-solutions to cryptographic keys. (We call the first function **Expand** and the second function **Extract**. These suggestive names are motivated later.) Still more difficult questions are what hardness properties we need of the puzzles in use for this scheme to be secure, or even what attack model should be considered here. We elaborate on these issues below.

1.1 Formalizing the Attack Model

The overall goal of the scheme is to generate a pseudorandom key, meaning that feasible attackers should only have small advantage in distinguishing the key from random. The term “feasible” is typically defined as probabilistic polynomial time (PPT), so it is tempting to define security in the standard way:

Security, first attempt: A scheme is secure if given everything that is stored on the disk and a candidate key, no PPT algorithm can distinguish between the case where the key is generated by the scheme and the case where the key is chosen at random (except perhaps with small advantage).

However, this definition ignores the fact that the attacker may have access to humans that can solve puzzles for it. Indeed, a known attack against systems that deploy CAPTCHAs is for the attackers to ship the same CAPTCHAs to their own web sites, asking their visitors to solve them. We thus need to extend the model, allowing the attacker to recruit some humans for help.

Devising a rigorous model that captures attackers with human help raises various issues, both technical and philosophical. Indeed, we do not even have good models for describing *honest* human participants in our protocols, let alone potentially malicious human attackers. For instance, should human help be restricted to solving puzzles? If so, how to model the quality of the answers? Are they always “correct”, in the sense that one human can predict the answers of another human? Does it make sense to restrict the attacker to ask for solutions of puzzles that are actually used in the scheme, or can it query for solutions to other puzzles as well? Is it legitimate to use a human in order to determine which puzzles to ask solutions for? The problem becomes even more intricate when one wishes to somehow *quantify* the amount of human help involved.

This work takes a rather simplistic approach, assuming that humans are only accessed as puzzle-solving oracles. This assumption can be justified to some extent if we view the attacker’s human helpers not as malicious but rather as basically honest users that were tricked into helping the attack. Still, one should

keep in mind that this model is not completely realistic. We further simplify the model by assuming that the oracle always returns the “correct” answer provided by the legitimate user. Furthermore, we only count the overall number of puzzles that the attacker asks to solve, not differentiating between “hard” and “easy” ones. That is, our notion of security has the following flavor:

Security, better attempt: *A scheme is secure if given everything that is stored on the disk and a candidate key, and given limited access to puzzle-solving humans, no PPT algorithm can distinguish between the case where the key is generated by the scheme and the case where the key is chosen at random (except perhaps with small advantage).*

An additional simplifying assumption we make is that the adversary only queries its oracle on puzzles that are explicitly used in the scheme (i.e., puzzles that are written on the disk). That is, we do not consider the possibility that an adversary may be able to modify a puzzle z to obtain a puzzle z' , so that the solution of the original puzzle may be easier to find given the solution for z' . (Indeed, with existing CAPTCHAs one may slightly change the puzzle without changing the solution at all.) Following [DDN00], we refer to this concern as malleability of puzzles. Intuitively, a useful puzzle systems should be “non-malleable”, in the sense that any query to the human oracle can help in solving at most a single puzzle out of the puzzles used in the system.

This seems to be the first time that such malleability issues are raised in the context of human-solvable puzzles (in fact, in the context of any non-interactive puzzle system), and that formalizing reasonable non-malleability properties for puzzles is an interesting challenge. This is a topic for future research.

Computational Hardness of Puzzles. The assumption that we make on the hardness of puzzles is that given a random puzzle z (And without any help from humans), it is hard to distinguish the real solution of z from a “random solution” taken from some distribution. (Clearly, this is stronger than just assuming that computing solutions is hard.)

In a little more details, a puzzle is essentially a samplable distribution of problems with the additional property that humans can associate a solution with each problem in a repeatable way across time. This last property is captured in the model by having a puzzle-solving oracle H (for Human), which is an arbitrary deterministic function. The solution to a puzzle z is then defined as $H(z)$. The hardness assumption is formulated roughly by saying that given a random puzzle z , no PPT algorithm (that has no oracle access) can distinguish the “right solution” $H(z)$ from a “random solution” that is drawn from some distribution. The amount of hardness is measured in terms of the min-entropy of this distribution, denoted μ . See more discussion in Section 2.1.

A Generic Attack. We illustrate the capabilities of the attacker in our model by describing a generic attack against our scheme. Assume that there is an algorithm that given a puzzle generates a set of M “plausible solutions” that is guaranteed to include the right solution. (Hence this attack treats the puzzle

system as if it has $\mu = \log M$ bits of pseudo-entropy.) Also, assume that the attacker has a dictionary D that is guaranteed to include the user's password.

The attacker gets an alleged key k^* and some n puzzles z_1, \dots, z_n , and it needs to decide if the key is “real” or “random”. It goes over the entire dictionary, expanding each password into the corresponding set of puzzles. Then it goes over all plausible solutions to each puzzle, extracts the corresponding key from each vector of plausible solutions, and keeps a list of all the solution-vectors that yield the input key k^* . These are the “consistent solutions”.

The attacker then uses its human oracle in order to narrow down this list of consistent solutions. It adaptively queries the human oracle for solutions to puzzles, purging from the list all the vectors that contain a wrong solution to any puzzle. (The puzzles to be queried are chosen so as to maximize the information obtained by each query, e.g. by querying puzzle that appears in the most consistent solution vectors.) Finally, the attacker checks how many remaining consistent solutions are left for each password, and applies the maximum-likelihood decision rule to determine whether these numbers are more likely to be generated for a random key or for the “real key”. The statistical advantage of this attack stems from the fact that for a “real” key k^* we expect to have one more consistent solution than for a “random” key (i.e., the actual solution).

It can be seen that to have significant advantage, the attacker must query its oracle on all but at most $m/\log M$ puzzles indexed by the actual password. Our analysis indicates that this is not just a property of this particular attack; we get essentially the same bound on the advantage of *any* attack.

1.2 Towards a Fully Specified Scheme

Below we elaborate on how to determine the functions `Expand` (mapping passwords to puzzles) and `Extract` (mapping solutions and passwords to keys). This involves fixing a number of parameters, namely the number n of puzzles stored on the disk, the number ℓ of puzzles that a user is required to solve to obtain access to the data, and the length m of the generated key.

The Expand Function. The resilience of the scheme against exhaustive password search comes from the need of the adversary to solve many puzzles (using its human oracle) in order to check each password guess. To this end, `Expand` must ensure that no large set of passwords are mapped a small set of puzzles.

Let q be a bound on the number of puzzle queries that the attacker can make, and let μ be the assumed hardness of the puzzle system. It is clear that to have many “missed puzzles”, the attacker must only be able to query its oracle on a small fraction of the stored puzzles, so we must store on the disk $n \gg q$ puzzles. Let $I = \{i_1, i_2, \dots, i_q\}$ be the indexes of puzzles that the attacker queries to its puzzles solver. We say that I “fully covers” a specific password `pw` if all the indexes in `Expand(pw)` are in the set I , and we say that I “almost covers” `pw` if at least $\ell - (m/\mu)$ of the indexes in `Expand(pw)` are in I . Our goal is to design the function `Expand` so that the attacker cannot have a small set of indexes that “almost covers” too many passwords.

This property is related to the quality of `Expand` as an expander graph: Consider a bipartite graph with passwords on the right and (indexes of) puzzles on the left, and where a password `pw` is connected to all the indexes in `Expand(pw)`. Then a good expansion from right to left means that there is no large set of passwords that are fully covered by a small set of indexes (i.e., all their neighbors are included in a small set of indexes). The property that we need is stronger, namely that there is no large set of passwords that are even “almost covered” by a small set of indexes. In terms of expansion, we need that any subgraph of `Expand` (with the same set of nodes) in which the degree of nodes on the right is $\ell - \lceil m/\mu \rceil$ also has good expansion from right to left.

In Section 3.2 we analyze the cover properties of a truly random `Expand` function (which essentially tells us what is the best that we can expect from any function) and also briefly discuss plausible explicit constructions for `Expand`.

The Extract Function. Intuitively, the main property needed from function `Extract` is good randomness extraction, namely to compute a pseudorandom key from a set of solutions that is somewhat unpredictable to the attacker. When using the above modeling of hardness of puzzles, namely that the “right solutions” to the puzzles are indistinguishable from “random solutions” that are drawn from a distribution with sufficient min-entropy, this intuition can be formalized in a straightforward way: namely as long as the input to `Extract` has sufficient min-entropy, the output should be random. Thus, it is sufficient if the function `Extract` is a (strong) randomness extractor [NZ96].

1.3 Security Analysis

We provide two different analyses for the security of our construction. In each of these analyses we bound the advantage of an attacker as a function of the number of queries that it makes to its puzzle-solving oracle. (This is somewhat similar to the case of interactive password-based protocols where the advantage of an attacker is bounded as a function of the amount of interaction between the attacker and the honest participants.) In both analyses we reduce the security of the scheme to the assumption that an attacker cannot distinguish the “right solution” to random puzzles from “random solutions”.

The first analysis (Section 4) uses a notion of security that follows the game-based approach for defining security of keys [BR93, BPR00]. The second analysis (Section 5) is done in the UC security model [Can01]. The “ideal functionality” that we present in this analysis follows the approach of [CHK⁺05], in that it lets ideal-world adversary make only a limited amount of password queries. This analysis requires some additional properties from the puzzles and an additional “invertibility” property from `Extract`; see details within.

Organization. Section 2 defines key-generation and recovery schemes (KGR) and human-only solvable puzzles. Section 3 presents the scheme and provides some combinatorial analysis of the properties of `Expand`. Sections 4 and 5 contain the two analyses of the scheme as described above, Section 6 has a concrete instantiation of the scheme, and Section 7 lists some open research problems.

Appendix A suggests some potential implementations of human-solvable puzzles. Throughout, proofs are omitted for lack of space.

2 Password-Based Key Generation and Recovery Using Puzzles

Our goal is to generate a random encryption key that is recoverable by the legitimate user but still looks random to an attacker. Namely, we have two procedures: *key-generation* and *key recovery*, where the former can potentially store on the disk some information that the latter can use for recovery. In our setting, both of these procedures take as input the user’s password (which should be thought of as a “weak secret”). Also, we allow them to interact with the legitimate user, modeled as a puzzle-solving oracle. The formal definition of the needed functionality proceeds as follows:

Definition 1 (Key Generation and Recovery). *A key generation and recovery scheme consists of two PPT algorithms with oracle access, $(\text{kGen}, \text{kRec})$:*

$(\text{key}, S) \leftarrow \text{kGen}^H(1^m, \text{pw}, \text{aux})$. *The randomized procedure kGen takes as input the security parameter and a password (and potentially also some other auxiliary input). It is given access to a human puzzle-solver and it outputs a key and (typically) some additional storage S .*

$\text{key} \leftarrow \text{kRec}^H(1^m, \text{pw}, S)$. *The procedure kRec takes as input the security parameter, a password, and the additional storage S . It is given access to the oracle H and it returns the key.*

The pair $(\text{kGen}, \text{kRec})$ is correct with respect to a specific oracle H if for every $k \in \mathbb{N}$, $\text{pw} \in \{0, 1\}^$ and every (key, S) in the support of $\text{kGen}^H(1^m, \text{pw})$ it holds that $\text{kRec}^H(1^m, \text{pw}, S) = \text{key}$. In this case we sometime call the triple $(\text{kGen}, \text{kRec}, H)$ a Key-Generation-and-Recovery system (KGR for short).*

The key generation stage can be partitioned to a system set-up stage, which would include the generation of puzzles and is common to all users, and an actual generation stage where the key is generated from the password provided by the user. We do not formally enforce this partitioning to allow for potential optimizations that involve the user in the generation of the puzzles. We also note that the auxiliary input to the key-generation procedure is meant to allow the user to provide some personal input that might help generate (or “personalize”) the puzzles; see discussion in the Appendix.

2.1 Human-Only Solvable Puzzles

For our purposes, a puzzle is a randomized puzzle-generation algorithm G with the additional property that random puzzles are solvable in a mostly consistent way by most humans. That is, the same person gives the same answer to a given puzzle at different times (although this consistent answer may vary from person to person). To enable asymptotic analysis, we let the puzzle generation algorithm G take as input the security parameter and also quantify the hardness of the resulting puzzles as a function of the security parameter.

Definition 2 (Puzzles). A puzzle-system is a pair (G, H) , where G is a randomized puzzle generator that takes as input 1^m (with m the security parameter) and outputs a puzzle, $z \leftarrow G(1^m)$, and H is a solution function. That is, the value $a = H(z)$ is the solution of the puzzle z .

In order to be useful for our application, we need the puzzle system to be consistently-solvable by humans but not easily solvable by computers. The specific hardness assumption that we make is that efficient algorithms cannot distinguish the right solution $H(z)$ from “random”. We call this hardness assumption the *solution indistinguishability* of the puzzle system, and quantify it by the amount of randomness in the “random” solution.

Definition 3 (Solution indistinguishability). Let $\mu = \mu(m)$ be a function of the security parameter. A puzzle system (G, H) has μ bits of pseudo-entropy if for every puzzle z in the support of the output of $G(1^m)$ there is a distribution $R(z)$ with min-entropy at least $\mu(m)$ such that the correct solution is indistinguishable from a solution taken randomly from $R(z)$, even when given both correct and random solution to polynomially many other puzzles. That is, for every polynomial $n = n(m)$ the following two ensembles are computationally indistinguishable:

$$\left\{ (z_1, a_1, (z_2, a_2, a'_2), \dots, (z_n, a_n, a'_n)) : \begin{array}{l} z_1, \dots, z_n \xleftarrow{\$} G(1^m), a_1 \leftarrow H(z), \\ a_i \leftarrow H(z_i), a'_i \xleftarrow{\$} R(z_i) \ (i = 2 \dots n) \end{array} \right\}_m$$

and

$$\left\{ (z_1, a'_1, (z_2, a_2, a'_2), \dots, (z_n, a_n, a'_n)) : \begin{array}{l} z_1, \dots, z_n \xleftarrow{\$} G(1^m), a'_1 \xleftarrow{\$} R(z), \\ a_i \leftarrow H(z_i), a'_i \xleftarrow{\$} R(z_i) \ (i = 2 \dots n) \end{array} \right\}_m$$

We note that if the puzzle system is a CAPTCHA where the puzzles can be generated together with their solution, and if the distributions $R(z)$ are efficiently samplable given z , then there is no need for the tuples (z_i, a_i, a'_i) . Also, a simple hybrid argument shows that t -fold repetition of (G, H) multiplies the pseudo-entropy by t :

Observation 1. Let μ, t be functions of the security parameter where t is polynomially bounded. Let (G, H) be a puzzles system, and let (G^t, H^t) be the t -fold repetition of it, where t puzzles are generated and solved independently. If (G, H) has μ bits of pseudo-entropy then (G^t, H^t) has $t\mu$ bits of pseudo-entropy. \square

Finally, we reiterate that the security models that are described in subsequent sections give the adversary access to the same oracle H that is used by the scheme. This represents the fact that, for analyzing security, we make the worst-case assumption that all humans provide the same answer to the same question, thus the adversary can employ other humans to reproduce the answers provided by the legitimate user. One can possibly model the case where people predict the answers of each other only in a “partial”, or “noisy” way. Still, it is stressed that for the correctness of the scheme we only need that the same user answers consistently with itself.

3 The Scheme

The scheme uses a puzzle system (G, H) as above, where G is used directly by the key-generation procedure and H is assumed to be available as an oracle at both key-generation and key-recovery time. The scheme depends on two internal parameters: the number of puzzles that are stored on the disk (denoted n) and the number of puzzles that the user needs to solve (denoted ℓ). We think of ℓ as a constant or a slowly increasing function, and $n = \text{poly}(k)$. In addition, we have a universe W of passwords (e.g., $W = \{0, 1\}^{160}$ if using SHA1 to hash the real password before using it.) W should not be confused with the potential dictionary $D \subset W$ from which passwords are actually chosen, which is not known when the scheme is designed. The scheme uses two randomized functions, $\text{Expand}_{r_1} : W \rightarrow [n]^\ell$ and $\text{Extract}_{r_2} : \{0, 1\}^* \rightarrow \{0, 1\}^m$, that are discussed later in this section. Given all these components, denote $n = n(m)$ and $\ell = \ell(m)$, and the scheme works as follows:

$\text{kGen}^H(1^m, \text{pw})$. Generate n puzzles, $z_i \leftarrow G(1^m)$, $i = 1, 2, \dots, n$, and choose the keys r_1, r_2 for Expand and Extract at random. (This can perhaps be carried out off-line at system setup.) Then set $\langle i_1, \dots, i_\ell \rangle \leftarrow \text{Expand}_{r_1}(\text{pw})$ and query the oracle H for the solutions, setting $a_{i_j} \leftarrow H(z_{i_j})$ for $j = 1, \dots, \ell$. Finally, compute $\text{key} \leftarrow \text{Extract}_{r_2}(a_{i_1}, \dots, a_{i_\ell}, \text{pw})$ and then all the solutions are discarded. The “additional storage” that is saved to the disk consists of the puzzles $\langle z_1, z_2, \dots, z_n \rangle$ and the keys r_1, r_2 .

$\text{kRec}(1^m, \text{pw}, \langle z_1, \dots, z_n \rangle, r_1, r_2)$. Compute the indexes $\langle i_1, \dots, i_\ell \rangle \leftarrow \text{Expand}_{r_1}(\text{pw})$, query the oracle H for the solutions $a_{i_j} \leftarrow H(z_{i_j})$ for $j = 1, \dots, \ell$, and recover the key as $\text{key} \leftarrow \text{Extract}_{r_2}(a_{i_1}, \dots, a_{i_\ell}, \text{pw})$.

We remark that if the puzzle system in use is in fact a CAPTCHA system (where puzzles are generated together with their solution) then the key-generation procedure need not query the oracle H . Also, if the puzzle system is such that puzzles remain hard to solve even when the randomness of G is known (and Expand is a random oracle) then the puzzles need not be stored at all. Instead, the value $\text{Expand}(\text{pw})$ can be used as the randomness to G , thus generating the puzzles “on the fly”.

3.1 The Function Extract

The role of Extract is to extract an m -bit pseudorandom key from the pseudo-entropy in the human solutions to the puzzles. Given our solution indistinguishability assumption (cf. Definition 3), this can be achieved by using a strong randomness extractor [NZ96] for the function Extract , as long as we are willing to live with some loss of pseudo-entropy (since to get a close-to-random m -bits output from an extractor you need $m' > m$ bits of min entropy in the input). Below and throughout the analyses, we therefore assume that Extract is a strong extractor (e.g., a pairwise-independent hash function) and denote by m' the amount of min-entropy that is needed in the input to Extract in order for the output to be close to a uniform m -bit string.

3.2 The Function Expand

The role of the function `Expand` is to map passwords to indexes of puzzles in such a way that the attacker would have to solve many puzzles (i.e., invoke the puzzle-solving oracle H many times) to check each new password guess. Specifically, our goal is to make sure that as long as the attacker does not make too many queries to its puzzle-solving oracle, most passwords would have enough unsolved puzzles to get $m' > m$ bits of pseudo-entropy. (Recall that m' is the amount of min-entropy that is needed in the input to `Extract` in order for the output to be close to a uniform m -bit string.)

To make this more precise, fix the randomness r_1 and think of the function $E = \text{Expand}_{r_1}$ as a bipartite graph with the password universe W on the right and the indexes $\{1, \dots, n\}$ on the left, and where each $\text{pw} \in W$ is connected to all the indexes in $E(\text{pw})$. If the puzzle system has μ bits of pseudo-entropy then we denote by $\ell^* \stackrel{\text{def}}{=} \lceil m'/\mu \rceil$ the number of puzzles that the attacker should miss in order for the key to be pseudo-random.

We say that a set I of indexes on the left almost covers a password $\text{pw} \in W$ on the right if pw has no more than ℓ^* neighbors that are not in I . (I.e., pw has at least $\ell - \ell^*$ neighbors in I .) The *almost-cover* of a set I relative to mapping E , dictionary D and parameter ℓ^* is:

$$\text{acvrSet}_{\ell^*}(I, E, D) \stackrel{\text{def}}{=} \{\text{pw} \in D : |E(\text{pw}) \setminus I| \leq \ell^*\}.$$

What we want is that for any set of $q \ll n$ puzzles z_{i_1}, \dots, z_{i_q} that the attacker has solutions for, and any (large enough) potential dictionary $D \subset W$, the set $I = \{i_1, \dots, i_q\}$ only covers a small fraction of the passwords in D . We denote by $\text{acvr}_{\ell^*}(q, E, D)$ the cover number of E , namely the fraction of passwords in D that can be almost-covered by q puzzles:

$$\text{acvr}_{\ell^*}(q, E, D) \stackrel{\text{def}}{=} \frac{\max_{|I|=q} |\text{acvrSet}_{\ell^*}(I, E, D)|}{|D|}$$

We would like the expected cover-number of Expand_{r_1} (over the choice of r_1) to be sufficiently small. The property of having a small cover number is related to the expansion of the graph E (from right to left): We want any large enough subset of the nodes on the right to have more than q neighbors on the left, even when removing ℓ^* edges from every node. In other words, every subgraph of E where the degree of nodes on the right is $\ell - \ell^*$ should be a good expander.

To get a sense of the obtainable parameters, we first provide an analysis in the random-oracle model (i.e., assuming that `Expand` is a random function). Later we discuss solutions based on limited independence and speculate about other plausible constructions.

The Cover Number of a Random Function. The following technical lemma bounds the probability of having a very large cover number in terms of various parameters of the system. This lemma depends on many parameters so

as to make it applicable in many different settings. We later give an example of some specific setting.

Lemma 2. Fix $\ell, \ell^*, n, q \in \mathbf{N}$ such that $q < n$ and $\ell^* = (1 - \alpha)\ell$ for some $\alpha > 0$, and also fix some finite set $D \subset W$. Denote $\epsilon \stackrel{\text{def}}{=} 2^{H_2(\alpha)}(q/n)^\alpha$ where H_2 is the binary entropy function. If ϵ^ℓ is small enough so that there exists $\rho > 0$ for which

$$e \cdot (\epsilon^\ell)^{\rho/(1+\rho)} < \frac{(1 + \rho)H_2(q/n)}{\log(1/\epsilon^\ell) |D|/n}$$

then for any $\delta > 0$ we have

$$\Pr_E \left[\text{acvr}_{\ell^*}(q, E, D) > (1 + \delta) \frac{(1 + \rho)H_2(q/n)}{\log(1/\epsilon^\ell) |D|/n} \right] < 2^{-n\delta H_2(q/n)}$$

where the probability is taken over choosing a random function $E : D \rightarrow [n]^\ell$. □

An Example. Assume that we have $q/n = 0.01$, $|D| = n$, $\ell = 8$ and $\ell^* = 4$. In this case we have $\alpha = (\ell - \ell^*)/\ell = 1/2$ and therefore $\epsilon = 2^{H_2(\alpha)}(q/n)^\alpha = 2\sqrt{q/n} = 0.2$, and $H_2(q/n) \approx 0.0808$. One can verify that in this case $e \log(1/\epsilon^\ell)/H_2(q/n) \approx 625 = 1/\epsilon^{\ell/2}$ which means that the requirement in the assertion of Lemma 2 is satisfied for $\rho = 1$. Plugging these values for ρ, ϵ, ℓ and $H_2(q/n)$ in the expression from Lemma 2 we get for any $\delta > 0$

$$\Pr_E [\text{acvr}_{\ell^*}(q, E, D) > (1 + \delta) \cdot 0.0087] < 2^{-n\delta/12.38}$$

It follows that the expected value of acvr over the random choice of E is at most $(1 + \delta) \cdot 0.087 + 2^{-n\delta/12.38}$. Assuming large enough value for n (e.g., $n > 4000$) and plugging a small enough value for δ , this expected value is no more than 0.9%.

Note that the trivial way of “almost covering” passwords in this case will be for the attacker to make four queries for each password, and since we assume that there are n passwords and we have $q/n = 0.01$ then the fraction of passwords that will be almost covered this way will be $0.01/4=0.25\%$. Hence, in this case the upper bound tells us that the attacker cannot do better than four times the obvious attack.

Limited Independence. Storing a completely random function from the password universe W to the set of puzzle indexes $[n]$ is not realistic in most cases. A first attempt at obtaining a concrete construction is to replace a completely random mapping with an X -wise independent mapping for some X . (In terms of storage on the disk, it is acceptable to store a description of an $O(n)$ -wise independent function, since we anyway need $O(n)$ storage to store the n puzzles.)

When Expand is ℓt -wise independent then one can use the t -moment inequality instead of Chernoff bound. The bound that we get for any $\delta > 0$ is

$$\Pr_E [\text{acvr}_{\ell^*}(q, E, D) > \tau + \delta] < \binom{n}{q} \cdot \frac{\tau}{\delta^t |D|^{t/2}},$$

where again we have $\epsilon \stackrel{\text{def}}{=} 2^{H_2(\alpha)}(q/n)^\alpha$. Using an ℓn -wise independent mapping (so $t = n$) and setting $\delta = 2/\sqrt{|D|}$ we get

$$\Pr_E \left[\text{acvr}_{\ell^*}(q, E, D) > \tau + \frac{2}{\sqrt{|D|}} \right] < \binom{n}{q} \cdot \frac{\tau}{2^n} < 2^{q \log n - n}$$

We thus get:

Lemma 3. Fix $\ell, \ell^*, n, q \in \mathbb{N}$ such that $\ell^* = (1 - \alpha)\ell$ for some $\alpha > 0$ and $q < n/(4 \log n)$, and fix a finite set D such that $|D| > n$.

The expected value of $\text{acvr}_{\ell^*}(q, E, D)$ over the choice of E as an ℓn -wise independent mapping from W to $[n]$ is at most $\epsilon^\ell + 2/\sqrt{|D|} + 2^{q \log n - n}$ where $\epsilon \stackrel{\text{def}}{=} 2^{H_2(\alpha)}(q/n)^\alpha$. \square

More Efficient Constructions. Although feasible, the solution of using ℓn -wise independent mapping is far from being satisfactory, as it entails very large storage and computational cost. Providing more efficient constructions that are provably good is an open problem.

One possible direction here is to extend for our purposes the result of Alon et al. [ADM⁺99]. In that work they considered a mapping from n balls to n buckets, and analyzed the size of the largest bucket. They proved that although “generic pairwise independent function” cannot ensure anything smaller than $n^{1/2}$, using a random linear mapping (over the binary field) has expected largest bucket of only $\tilde{O}(\log n)$. This can be thought of as a very special case of our application with $\ell = q = 1$, $\ell^* = 0$ and $|D| = n$. We thus speculate that perhaps using ℓ independent linear maps could give us a reasonable bound also for our application.

4 Game-Based Security Analysis

In this section we analyze the security of our scheme with respect to a “game-based” notion of security (as in [BR93]). In the formulation below the key generation scheme is run on a password pw that was randomly chosen from a dictionary. The adversary is then given the generated storage, plus a value that is either the real generated key or a random value of the same length. In addition, the adversary is given oracle access to H . The adversary’s advantage in distinguishing between the two cases is measured as a function of the number of H -queries (q), and the size of the dictionary from which the passwords are chosen (d):

Definition 4 (Game-based security definition). Let $\alpha : \mathbb{N} \times \mathbb{N} \rightarrow [0, 1]$ be a function, let $(\text{kGen}, \text{kRec}, H)$ be a key-generation and recovery system, and let \mathcal{C} be a class of attackers with oracle access.

We say that $(\text{kGen}, \text{kRec}, H)$ is secure up to α with respect to \mathcal{C} if for any attacker $A \in \mathcal{C}$, any polynomially related $d, m, q \in \mathbb{N}$ and any $D \subset W, |D| = d$, the following two probabilities differ by at most $\alpha(d, q) + \text{negl}(m)$, where negl is a negligible function:

$$\begin{aligned}
p_{\text{real}}(A) &\stackrel{\text{def}}{=} \Pr[\text{pw} \in_R D, (\text{key}, S) \leftarrow \text{kGen}^H(1^m, \text{pw}) : A^{H_q}(\text{key}, S) = 1] \\
p_{\text{rand}}(A) &\stackrel{\text{def}}{=} \Pr[\text{pw} \in_R D, (\text{key}, S) \leftarrow \text{kGen}^H(1^m, \text{pw}), \\
&\quad \text{key}' \in_R \{0, 1\}^{|\text{key}|} : A^{H_q}(\text{key}', S) = 1]
\end{aligned}$$

where H_q answers the first q queries as H does, and answers later queries by \perp .

Conservative Adversaries. For our analysis to go through, we need to restrict the attacker to only query its puzzle-solving oracle H on puzzles that explicitly appear in the storage S of the scheme. This is done to prohibit “puzzle mauling attacks” as discussed in Section 2.1. Essentially, this restriction reflects the assumption that each H -query helps in answering only a single puzzle, and that getting an H -answer to a puzzle does not help solving another puzzle.

Definition 5 (Conservative adversaries). *An adversary against our KGR scheme is called conservative if it only queries its oracle on puzzles that are explicitly included in the “additional storage” output of the key-generation routine.*

Security Statement. We are now ready to state our main result concerning the security of our scheme. Let m be the security parameter and let $\delta, \mu, d, \ell, m', n, q$ be other parameters (that may be functions of the security parameter), and denote $\ell^* \stackrel{\text{def}}{=} \lceil m'/\mu \rceil$. Below we assume that that $\binom{\ell}{\ell^*}$ is polynomial in m . (Recall that ℓ is the number of puzzles that the honest user needs to solve, so we typically think of it as a constant or $\log m$, hence assuming that $\binom{\ell}{\ell^*}$ is polynomial in m is reasonable.)

Let Expand_{r_1} be a randomized mapping of passwords to indexes and let Extract_{r_2} be a strong randomness extractor [NZ96], extracting m bits that are δ away from uniform given any distribution with m' bits of min-entropy. Lemma 4 below essentially asserts that as long as there are at least m' bits of pseudo-entropy in the puzzles that are mapped to the right password but are not queried by the attacker, the attacker cannot have any significant advantage in distinguishing real from random. Specifically, we show that the advantage of the attacker is essentially the fraction of passwords in the dictionary that are almost covered by its queries to the puzzle-solving oracle.

Lemma 4. *Under the conditions from above, the scheme from Section 3 using Expand and Extract is secure up to α with respect to the class of conservative adversaries, where α is defined as*

$$\alpha(d, q) \stackrel{\text{def}}{=} \delta + \max_{|D|=d} E_{r_1} [\text{acvr}_{\ell^*}(q, \text{Expand}_{r_1}, D)].$$

Comment. We note that the solution indistinguishability assumption and the use of strong extractor can be replaced with the more specific assumption that the output of Extract is pseudorandom. Namely, we can assume directly that given ℓ^* puzzles without their solution and $\ell - \ell^*$ puzzles with solution and given r_2 and key , an attacker cannot tell if the key was computed as $\text{Extract}_{r_2}(a_1, a_2, \dots)$ or was chosen at random. The proof under this (weaker) assumption is very similar to the proof of Lemma 4.

5 UC Security Analysis

In our second security analysis we use the UC security framework [Can01], and the presentation here assumes familiarity with this framework. We incorporate the human oracle H in the model by providing the adversary and the parties running the protocol with access to H . The environment is not given direct access to H ; rather, it has access to H only via the adversary. This restriction represents the assumption that the puzzles used in an instance of the protocol are “local” to that instance, in the sense that they are generated within that instance, and furthermore the corresponding solutions are not affected by external events.

In addition, as in Section 4 we focus on conservative adversaries that ask H only on puzzles that were directly provided by the protocol. This technical restriction represents the “meta-assumption” that the puzzles are such that obtaining a solution for one puzzle does not help in solving a different puzzle. (Admittedly, this assumption may not always hold, and somewhat restricts the pool of potential implementations.)

The Ideal Password-Based Key Generation and Recovery Functionality. We define the ideal functionality representing the security specification that we wish to obtain. The functionality, $\mathcal{F}_{\text{PKGR}}$, is presented in Figure 1. $\mathcal{F}_{\text{PKGR}}$ is parameterized by a dictionary D of possible passwords, the maximum number p of allowable password queries by the adversary, and the length m of the generated key. At the first activation $\mathcal{F}_{\text{PKGR}}$ expects the user to provide a password pw , along with a session identifier sid . (Formally, the sid may specify the identities of the user and the computer.) $\mathcal{F}_{\text{PKGR}}$ then generates a random m -bit key key and outputs it to the computer. Finally, it notifies the adversary that a key was generated. If pw is not in the dictionary then it also gives it to the adversary in full. (Formally this means that no security is guaranteed for passwords not in the dictionary. But note that the scheme itself does not depend on the actual dictionary, so we can always let the parameter D be the set of passwords that are “actually used by users”.)

Next, whenever $\mathcal{F}_{\text{PKGR}}$ receives a password pw' together with a request to recover the key, it outputs the key to the computer only if pw' is the same as the stored password. This request may come from anyone, not only the legitimate user. Finally, $\mathcal{F}_{\text{PKGR}}$ answers up to p password guesses made by the adversary.

The main security guarantee of $\mathcal{F}_{\text{PKGR}}$ is that the adversary can make only p password guesses. If none of these guesses succeeds, then the key is indistinguishable from a truly random m -bit key. For reasonable values of m , this provides strong cryptographic security. Also, $\mathcal{F}_{\text{PKGR}}$ makes no mention of puzzles. Indeed, puzzles are treated as part of the implementation, geared toward limiting the number of password guesses.

Note that $\mathcal{F}_{\text{PKGR}}$ obtains the password directly from the environment. This formulation (which follows the formulation in [CHK⁺05]) provides some strong guarantees. First, there is no a-priori assumption on the distribution from which the password is taken, as long as it is taken from D . In fact, this distribution may not even be efficiently generatable, since it may depend on the initial input

of the environment. Second, we are guaranteed that in any scheme that realizes $\mathcal{F}_{\text{PKGR}}$ the local storage of the computer cannot be correlated in any way with the password *and the key*.

The fact that $\mathcal{F}_{\text{PKGR}}$ is parameterized by D , and furthermore provides no security for passwords not in D , is a limitation that comes from our simulation procedure. Ideally, we would like to guarantee that $\mathcal{F}_{\text{PKGR}}$ does not depend on D at all and provides security for any password string. Realizing such a functionality is an interesting future challenge.

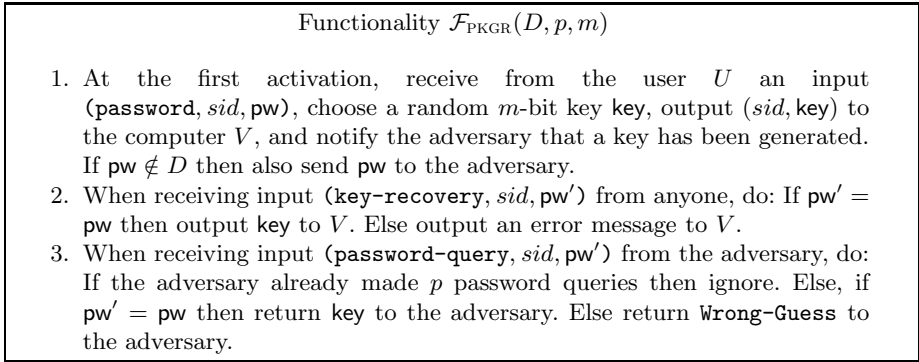

Fig. 1. The ideal functionality $\mathcal{F}_{\text{PKGR}}$, parameterized by a dictionary D , the maximum number p of password queries, and the length m of the generated key

Invertibility of Extract. In order to show that the scheme realizes $\mathcal{F}_{\text{PKGR}}$ we need to make an additional “invertibility” assumption on function **Extract** with respect to solutions of puzzles: What we need is that given an m -bit key key and given $\ell - \ell^*$ solution to ℓ puzzles, one can efficiently compute ℓ^* plausible solutions to the remaining puzzles that would map the entire solution vector to the given key, $\text{Extract}(\dots) = key$.

Below let (G, H) be a puzzle system with μ bits of pseudo-entropy, where the right solution for each puzzle z is indistinguishable from a solution drawn from $R(z)$, let f_r be a randomized function, and let $\ell \geq \ell^*$ be integers.

Definition 6. We say that f is strongly invertible w.r.t. the puzzle system (G, H) and the parameters ℓ, ℓ^* if there exists an efficient inversion algorithm I that given randomness r , key key , any string pw , ℓ puzzles z_1, \dots, z_ℓ generated via G , and a set of $\ell - \ell^*$ solutions $a_{\ell^*+1}, \dots, a_\ell$ such that $a_i \in R(z_i)$, outputs values a_1, \dots, a_{ℓ^*} such that $a_i \in R(z_i)$ and $f_r(a_1, \dots, a_\ell, pw,) = key$.

Furthermore, for randomness r , key , z_1, \dots, z_ℓ and any pw and $a_{\ell^*+1}, \dots, a_\ell$, the output of I is indistinguishable from sampling at random $a_i \in R(z_i)$ for $i = 1, \dots, \ell^*$ subject to the constraint $f_r(a_1, \dots, a_\ell, pw,) = key$.

If the distributions $R(z)$ are efficiently samplable given z and m is small enough (so that 2^m is polynomial in the relevant efficiency parameters) then I can simply

sample the solutions a_1, \dots, a_{ℓ^*} from the appropriate distributions until it find a solution vector that match the given key. Alternatively, if we have a puzzle-system for which $R(z) = \{0, 1\}^k$ for some k and Extract is a linear function (e.g., a linear universal hash function) then inversion is possible even for large m via linearity.

UC-Security of Our Scheme. Consider the scheme from Section 3 with parameters n , ℓ , and m , and let D be the dictionary used by the user. Assume that (G, H) be a puzzle system with μ bits of pseudo-entropy, assume that Extract extracts m bits that are negligibly close to uniform from any distribution with $m' > m$ bits of min-entropy, and let $\ell^* = \lceil m'/\mu \rceil$. Finally assume that Extract is strongly invertible w.r.t. (G, H) with parameters ℓ , ℓ^* . Then we have

Lemma 5. *Under the conditions above, the scheme from Section 3 UC-realizes $\mathcal{F}_{\text{PKGR}}(D, p, m)$ relative to conservative adversaries that makes at most q queries to H , where $p = \text{Cover}(\text{Expand}, D, q)$.*

6 A Concrete Example

We describe a concrete instantiation of our scheme for a “medium security” application. The example builds on the numeric example in Section 3.2. Consider trying to get an 64-bit key using our scheme, while relying on a CAPTCHA system whose assumed hardness is (say) 16 bits of pseudo-entropy per instance. In terms of our analysis, we therefore have the parameters $m = 64$ and $\mu = 16$ (so $\ell^* = 64/16 = 4$). Assuming that each puzzle takes about 4KB to encode (which is the case for common CAPTCHAs) and restricting ourselves to number of puzzles that fit on a single 4.7GB DVD-R, we would like to store about $n = 10^6$ puzzles.

We assume that the odds of the attacker guessing a weak password are one in a million (per guess) so we assume the dictionary size is $|D| = 10^6$. Also, we would like the legitimate user to solve no more than $\ell = 8$ puzzles to access the encrypted data, and we assume that the attacker cannot get a human to solve for it more than $q = 10^4$ puzzles. (This seems like a safe assumption in most settings, but maybe not all of them.) In Section 3.2 it is shown that with this setting of the parameters, and when modeling Expand as a random function, we should expect the cover-number to be no more than 0.9%. Namely, an attacker that makes up to 10,000 puzzle-solving queries has at most 0.9% chance of “almost covering” the actual password. (Note that the obvious way of “almost covering” passwords yields success probability of 0.25%.)

A simple heuristic instantiation of the scheme for this setting of the parameters would be to use a cryptographic hash function to implement both the Expand and Extract functions. More specifically, to generate the key, choose (say) two 128-bit salt values r_1 and r_2 , get the user’s password pw and compute $h \leftarrow \text{HMAC-SHA1}_{r_1}(\text{pw})$. Parse the 160 bits of h as eight 20-bit indexes $i_1, \dots, i_8 \in [2^{20}]$. Generate 2^{20} CAPTCHAs and store then together with r_1, r_2 on the disk (or on a DVD-R). Then obtain the solutions to the eight relevant puzzles $a_{i_j} =$

$H(z_{i_j})$, $j = 1 \dots 8$, compute $h' \leftarrow \text{HMAC-SHA1}_{r_2}(a_{i_1} | \dots | a_{i_8} | \text{pw})$, and take as many bits of h' as needed for the key. To make use of the common practice for slowing down brute-force attacks, replace SHA1 with the iterated function SHA1^k for some reasonable k , say $k = 65536$.

Although this scheme allows the key to be longer than 64 bits, the above analysis only shows that with probability more than 99.1% we get “64-bit strength”. (One can similarly calculate the probability of getting “80-bit strength” which happens when the attacker misses five of the eight puzzles that are mapped to the user’s password, or the probability of getting “128-bit strength” when the attacker misses all the puzzles, etc.)

7 Future Work

This work investigates a new approach for deriving cryptographic keys from human passwords, improving the resistance against off-line dictionary attacks by having the user solve some puzzles and using the solutions in the key-generation process. Still, the analysis is quite preliminary and many questions remain unanswered, regarding constructions, modeling, and analysis. Below we list a few of these questions.

Building Puzzles. Perhaps a first challenge is to actually construct puzzle systems that are useful for schemes such as the one described in this paper. Of particular interest for our scheme would be puzzles that remain hard even when the attacker knows the randomness that was used to generate them. (As mentioned above, using such puzzle-systems we can forgo storing any puzzles on the disk, instead using the value $\text{Expand}(\text{pw})$ as randomness for the puzzle generation system.)

As discussed in the introduction, another important property of puzzles is “non-malleability”, namely preventing the adversary from using the solution to one puzzle to solve other puzzles. This question is interesting both on the level of designing puzzles that will make it hard for the adversary to “maul” them while maintaining solvability, and on the level of mathematical formalization. On the design level, a potentially interesting approach might be to use watermarking techniques to embed in the puzzle a message to the human reader that urges to not solve the puzzle outside a certain context.

Improving the Scheme. One obvious challenge is to find different constructions that will improve various characteristics of the current scheme (e.g., use less storage, improve security, etc.) An immediate question is to have an efficient explicit construction for Expand that provably has a small expected cover number (maybe by extending the work of Alon et al. [ADM⁺99]). Another direction is to split the key-generation process to two parts, where the first part generates a large amount of storage which is the same for all users and the second adds a small amount of user-specific storage that may depend on the password or on other information provided by the user. Another direction is to have a more interactive key recovery process, where the user’s answer to the current question effects the questions that it is asked next.

Improving the Analysis. The analysis can be improved in a number of ways. First, the hardness assumption on puzzles may be reduced to allow for non-negligible distinguishing probability between the real solution and a random one. Furthermore, one might want to assume only that *computing* the correct answer is hard.

Another immediate set of goals is to improve the current analysis (especially the one in the UC framework), and to find ways to relate the game-based security and the UC security notions.

Also, it would be nice to be able to formally model and argue about non-conservative adversaries, namely adversaries that query the human oracle on puzzles different than the ones used in the scheme. What security properties can be guaranteed against such adversaries?

Another plausible extension of our security model is to consider an attacker that can modify the storage on the disk and then watch the output of the key-recovery procedure with this modified storage. (This seems related to the issue of puzzle malleability that we mentioned above.)

Also, it may be useful to have an algorithm to compute (or bound) the cover number of a given Expand function with respect to a given dictionary. This seems harder than computing/bounding the expansion of a graph, since here we need to compute/bound the expansion of any subgraph of a given degree.

A more speculative research direction is to try and obtain reasonable general models for human users (or even human attackers) in systems such as the ones described in this work.

A Possible Implementations of Puzzles

The notion of puzzles used in our scheme is rather relaxed, and consequently has a large number of potential implementations. One set of implementations are the existing and potential implementations of CAPTCHAs, e.g. the ones described in [Naor96, vAB⁺03]. These implementations, however, require that the solutions to puzzles are uniquely defined and generatable together with the puzzles. This seems like a strong limitation on implementations. Another set of implementations are the potential implementations of Inkblots, described in [SS04]. These implementations, however, are required to be “private”, in the sense that the solution given by one human is unpredictable (and, in fact, pseudorandom) even to other humans. Again, this seems to be a strong limitation on implementations.

Below we list some potential approaches for implementation that are not included in any of these classes. That is, the answers to these puzzles are somewhat subjective and not necessarily unique. Still, answers of different individuals may be similar. As pointed out in [NP97] in a different context, validity of these proposals should be evaluated by testing on human individuals.

Personal ranking: Puzzles may include pictures of different persons, to be ranked by coolness, or age, or taste in clothing. Alternatively, puzzles may include different pictures or descriptions of food, to be ranked by tastiness, spiciness, etc.. Alternatively, a puzzle may depict several randomly generated drawings to be ranked by personal liking, an audio puzzle may sound several short melodies to be ranked by liking, etc.

Face recognition: Puzzles may include pictures of several faces, and the question is which if these faces most resemble people known to the user (e.g., parents or other family members). Furthermore, puzzles can be “personalized” by asking the user to provide, at system set-up, pictures of close family

members. These pictures might then be mixed with random pictures to generate puzzles. (This proposal takes advantage of the fact that recognizing faces is one of the most highly specialized visual capabilities of humans.)

Personal clustering: Puzzles may include a bunch of various unrelated objects, and the question is which three objects “go together” the best, or are the most “closely related” or “look alike”. The objects can be people, household items, cartoons, or a mix of all categories. (This implementation approach was proposed by Ronitt Rubinfeld.)

Imaginative inferring: Puzzles may portray a scene and ask questions about what happened a minute ago, or what will happen in a minute. Alternatively, questions can be asked regarding what happens outside the borders of the picture.

Personal association: Puzzles may depict an object (e.g., a person) and ask which familiar objects (persons) does the object in the picture remind.

Finally, we note that to prevent “mauling attacks,” the puzzle generator must make sure that randomly generated puzzles are “different enough” from each other so that a solution to one randomly generated puzzle will not help in solving another randomly generated puzzle.
