Preface

Home to over 80% of all life on Earth, the ocean is the world's largest carbon sink and a key source of food and economic security for billions of people. The relevance of the ocean for humanity's future is undisputed—though not usually fully appreciated. The ocean has much greater potential to drive economic growth and equitable job creation, sustain healthy ecosystems, and mitigate climate change than is realised today. Lack of awareness of the potential as well as management and governance challenges pose impediments. Until these impediments are removed, ocean ecosystems will continue to be degraded and opportunities for people lost. A transition and a clear path to a thriving and vibrant relationship between humans and the ocean are urgently needed.

This collection identifies a path that is inspired by science, energised by engaged people, and emboldened by visionary leaders. The papers and reports in this compendium are assessments of knowledge commissioned by a unique collaboration among global leaders who asked the question, 'How might we use the ocean wisely without using it up?' These leaders established the High Level Panel for a Sustainable Ocean Economy (Ocean Panel) in September 2018 as a unique initiative led by heads of state and government from around the world who are committed to building a sustainable ocean economy in which effective protection, sustainable production and equitable prosperity go hand in hand. Collectively, these 17 nations represent nearly 46% of the world's coastlines and at least 44% of the world's exclusive economic zones. The Ocean Panel's shared vision is to sustainably manage 100% of ocean areas under their national jurisdiction, guided by Sustainable Ocean Plans. In the *Transformations*[1] document, which was developed in a process informed by the knowledge in this collection, the Ocean Panel also set out a new ocean action agenda for the decade. This far-reaching political document is the result of broad and diverse engagement, collaboration and consultation, and an unprecedented scientific knowledge base coming together to result in actions that move 'from the purpose to the impact'. It identifies 15 outcomes and 74 bold yet pragmatic actions to be taken across five critical areas—ocean health, ocean wealth, ocean equity, ocean knowledge and ocean finance—to transform humanity's relationship with and impacts upon the ocean, and to ensure that the myriad benefits and opportunities that the ocean provides can be sustainably enjoyed by all.

Early on in their deliberations, and before considering action, the Ocean Panel intentionally set out to 'Start with science, with knowledge'. They identified a series of topics for which they would commission syntheses of knowledge that would inform their policy and action agenda. To ensure the high quality and intellectual integrity of the Ocean Panel's commissioned research, they established an Expert Group consisting of a global group of over 70 experts renowned for their exemplary contributions to the full range of ocean-related disciplines considered in the Ocean Panel's work. Together, more than 250 experts and authors, with 44% being women, representing 48 countries have contributed to Ocean Panel-commissioned research to date. The Secretariat of the Ocean Panel provided additional substantial contribu-

tions and coordination. The resulting series of 16 Blue Papers and 4 Special Reports responded to the request from the Ocean Panel and provided timely analyses of pressing challenges at the nexus of the ocean and the economy.

The Blue Papers and Special Reports, included in this Blue Compendium, showcase the latest leading-edge science, knowledge and state-of-the-art thinking. They offer innovative ocean solutions in technology, policy, governance and finance realms that could help accelerate a transition to a more sustainable and prosperous relationship with the ocean. The comprehensive assessments have already informed policy making at the highest levels of government and motivated an impressive array of responsive and ambitious action across a growing network of leaders in business, finance and civil society.

The 16 Blue Papers ranged from food, energy and mineral production, genetic resources and conservation, to climate change, plastic pollution, technology, equity, illegal fishing, organised crime in fisheries and ocean accounting. **'The Future of Food from the Sea'** considers the status and future trends of food production through fisheries and aquaculture at regional and global scales, identifies opportunities of ocean-based food in achieving SDG 2: Zero Hunger, and provides recommendations for how current barriers might be overcome to transition to more sustainable and abundant food production from the ocean. '**The Expected Impacts of Climate Change on the Ocean Economy**' addresses how the compounding hazards of climate change will impact the ocean economy, specifically marine fisheries, aquaculture and tourism; highlights opportunities for effective institutions and markets to reduce these impacts; and provides recommendations for how countries can achieve blue economic growth by implementing policies and infrastructure that reduce risks and build resilience to climate change. **'What Role for Ocean-Based Renewable Energy and Deep-Seabed Minerals in a Sustainable Future?'** examines how and to what degree energy from the ocean, current developments in green technology and the potential for deep-seabed minerals can help meet rising technological demand and contribute to the climate agenda and achievement of SDG 7: Affordable and Clean Energy. It identifies solutions and future policy options and their potential impact, as well as addressing related safety and environmental concerns. **'The Ocean Genome: Conservation and the Fair, Equitable and Sustainable Use of Marine Genetic Resources'** considers the existing and potential benefits associated with the ocean genome and the threats it is facing, and explores how efforts to promote inclusive innovation and governance can contribute to more equitable sharing of benefits derived from the use of marine genetic resources. **'Leveraging Multi-Target Strategies to Address Plastic Pollution in the Context of an Already Stressed Ocean'** examines the leakage of plastics and other pollutants into the ocean and the resulting impacts on marine ecosystems, human health and the economy. The paper explores the kind of regenerative global industry that needs to be built, as well as integrated solutions to reduce all pollutants of the ocean, and highlights the role of science-based targets in measuring progress on ocean pollution. **'Technology, Data and New Models for Sustainably Managing Ocean Resources'** explores existing and breakthrough technologies, such as drones, artificial intelligence and blockchains, and the associated challenges and possibilities they pose for ocean management and improving understanding of ecosystems and human interactions with the ocean. **'Coastal Development: Resilience, Restoration and Infrastructure Requirements'** examines trends in coastal behaviour, explores trade-offs between restoration and infrastructure development and makes an economic and security case for resilient coastlines providing much-needed recommendations for new models for shipping and tourism. **'National Accounting for the Ocean and Ocean Economy'** highlights the critical role of national accounting as a tool in achieving a sustainable ocean economy, identifies major gaps in how the ocean, ocean services and ocean assets are currently treated in national accounts, and offers the methods and a roadmap for measuring and valuing ocean assets. **'Ocean Finance: Financing the Transition to a Sustainable Ocean Economy'** explores the next generation of financing mechanisms and the role insurance can play in supporting the ocean transition in an inclusive manner and recommends approaches to be phased out, as well as new solutions that incentivise sustainable management. **'Critical Habitats and Biodiversity: Inventory, Thresholds and Governance'** provides an inventory of the distribution of species and critical marine habitats exploring trends in drivers, pressures, impacts and responses; establishes thresholds for protecting biodiversity hotspots, as well as indicators to monitor change; and assesses the current legal framework, the gaps in ocean governance and management and the implications for achieving a sustainable ocean economy. '**The Human Relationship with our Ocean Planet**' illustrates the differing economic, legal, institutional, social and cultural relationships that people of varying cultures have with the ocean, through a historical lens, and charts a path towards inclusive ocean governance. '**The Ocean Transition: What to Learn from System Transitions'** examines past successes and failures and current dynamics of transitions, and explores alternative future transition pathways and policy responses that can drive to a more sustainable ocean. **'Towards Ocean Equity'** explores the distribution of the goods and services provided by the ocean; existing inequities and the resulting impacts spanning environmental, social and economic dimensions; and provides recommendations for addressing some of the underlying and systemic features of ocean inequities, as well as opportunities for policy to support a sustainable and just ocean economy. '**Integrated Ocean Management**' makes the case for integrated ecosystem-based management, one that combines value creation and the safeguarding of ecosystem health, identifying existing impediments in policy and practice and outlining steps and principles towards a successful integrated ocean management. **'Illegal, Unreported and Unregulated Fishing and Associated Drivers'** explores the drivers and consequences of illegal, unreported and unregulated (IUU) fishing, and provides a range of solutions to prevent and combat IUU fishing, from implementing international agreements to promoting new technologies and strengthening regional and international partnerships. '**Organised Crime in the Fisheries Sector'** presents the current state of knowledge on organised crime in fisheries and provides recommendations and best practices that promote an intelligence-led, skills-based cooperative law enforcement at a global level, facilitated by enabling legislative frameworks and increased transparency.

The four Special Reports illustrate how a sustainable ocean economy can create a healthy ocean, and vice versa, that provides solutions to global challenges. Collectively, they set out a new evidence-based narrative, in which the ocean is critical to achieving global targets to limit climate change and its detrimental effects to everyone's present and future, offers solutions for a sustainable and equitable recovery to current and future crises, and provides unparalleled opportunities to build a fair and just sustainable ocean economy. **'The Ocean as a Solution to Climate Change: Five Opportunities for Action'** evaluates the mitigation potential of a suite of ocean-based actions—renewable energy, transport, food production, ecosystems and carbon storage in the seabed—in 2030 and 2050 relative to a 1.5 °C and 2 °C pathway, explores their wider benefits to societies and economies, and highlights the enabling policy measures and research required for success. Building on this Special Report, **'A Sustainable Ocean Economy for 2050: Approximating Its Benefits and Costs'** examines the global net benefit and the benefit-cost ratio of implementing those sustainable ocean-based interventions, including conserving and restoring mangrove habitats, scaling up offshore wind production, decarbonising the international shipping sector and increasing the production of sustainably sourced ocean-based proteins, over a 30-year time horizon up to 2050. **'A Sustainable and Equitable Blue Recovery to the COVID-19 Crisis'** examines the impacts of the COVID-19 pandemic on the ocean economy and the role of ocean-based solutions in supporting sustainable and equitable recovery and enhancing resilience to future crises. Drawing on the latest scientific research and insights from the Blue Papers and the other Special Reports, **'Ocean Solutions That Benefit People, Nature and the Economy'** details a framework and a feasible action plan and practical solutions that when implemented could help achieve a sustainable ocean economy where people have more opportunities and better health, nature thrives and resources are distributed more equitably.

The impact of this collection of assessments of knowledge can be clearly seen in the *Transformations* announced by the Ocean Panel in December 2020. Many political leaders give lip service to grounding policy and action in science, evidence and knowledge. In this case, the connections are clear. Moreover, the benefit of basing commitments on expert knowledge continues in the Ocean Panel, as additional special reports are developed to inform subsequent action.

No transformative change could be possibly realised by just one actor, entity or sector. The governments of the Ocean Panel are leading by example on this transformative agenda, but are also working collaboratively with the public, private, financial, research and civil society sectors, to raise the profile of the ocean in international arenas, to develop a sustainable ocean economy and to successfully implement sustainable and equitable ocean management. The work of the Ocean Panel has triggered the formation of several coalitions and partnerships intended to promote and facilitate the Ocean Panel's ocean action agenda. Currently, there are ten multi-stakeholder initiatives, also called 'Action Groups', that collaborate to implement one or more of the priority actions in the *Transformations*, and whose strategies to tackle ocean issues have been informed by many of the Blue Papers and Special Reports.

Together, the 17 countries of the Ocean Panel recognise and promote the ocean as a smart investment with tremendous social, economic and environmental benefits. The ocean provides many of the urgent solutions humanity and the planet need, and it thus must be considered as our critical ally for global economic growth, climate resilience, social equity and future security and prosperity.

This Blue Compendium—representing one of the most comprehensive assessments in the ocean realm and already influencing policy and action—is the product of devoted efforts by numerous people. We are deeply grateful to the over 250 authors and reviewers who led, contributed to, and improved these knowledge assets. We also offer deep gratitude to the Secretariat of the Ocean Panel and colleagues at the World Resources Institute for their skilled guidance, editorial support, graphics, messaging and outreach. And we thank the active engagement of and trust placed in us by the Ocean Panel Leaders, their Sherpas, and teams. The partnerships, respect and new awareness that have emerged from the development of the Blue Compendium and Ocean Panel work are valued and they set an example for how governmental leaders and knowledge experts can engage productively to the benefit of society.

We close with the belief that the ocean is central to our collective future, that knowledge should inform action, and that partnerships will enable us to chart a course to use the ocean wisely without using it up.

About the Editors

Jane Lubchenco University Distinguished Professor at Oregon State University, is a marine ecologist with expertise in the ocean, climate change and interactions between the environment and human well-being, received a B.A. in biology from Colorado College, a M.S. in zoology from the University of Washington and a Ph.D. in ecology from Harvard University.

Her academic career as a professor began at Harvard University (1975–1977) and continued at Oregon State University (1977–2009) until her appointment as NOAA Administrator (2009–2013). Thereafter, she was the 2013 Haas Distinguished Visitor in Public Service at Stanford University, then Oregon State University's University Distinguished Professor.

In recognition of her scientific contributions, Jane Lubchenco is an elected member of the National Academy of Sciences and many other distinguished academies. She has received numerous awards including 24 honorary doctorates, most recently from the University of Oxford.

She co-founded three organisations that train scientists to be better communicators and engage more effectively with the public, policy makers, media and industry. She also co-founded PISCO (an integrated research/monitoring/outreach programme), the National Ocean Protection Coalition and the MPA Project that seeks to advance smart use of effective Marine Protected Areas.

She has also served in multiple governmental capacities. She was the U.S. Under Secretary of Commerce for Oceans and Atmosphere and Administrator of the National Oceanic and Atmospheric Administration (NOAA) and an inaugural member of President Barack Obama's Science Team from 2009 to 2013. From 2014 to 2016, she was the first U.S. State Department Science Envoy for the Ocean, serving as a science diplomat to China, Indonesia, South Africa, Mauritius and the Seychelles. And beginning in 2021, she leads the Climate and Environment team at the White House Office of Science and Technology Policy. Dr. Lubchenco's contribution to this work was completed solely in her capacity as a Professor at Oregon State University. The views expressed are those of the authors, and do not necessarily represent the views of the U.S. Government.

She has served as the President of numerous professional scientific societies including the Ecological Society of America, the American Association for the Advancement of Science (AAAS) and the International Council for Science (ICSU). She has served on multiple national commissions including the Pew Oceans Commission, the Joint Ocean Commission Initiative and the Aspen Institute Arctic Commission. She has led or contributed to multiple regional, national and international scientific assessments on climate change, biodiversity, Marine Protected Areas, the ocean, and the intersection of science and society. Most recently, she co-chaired the Expert Group for the High Level Panel for a Sustainable Ocean Economy, a pioneering partnership across over a dozen serving heads of state or government to harness science and action to protect the ocean effectively, produce from it sustainably, and prosper equitably.

Peter M. Haugan is Policy Director at Institute of Marine Research, Norway, and professor of oceanography at the Geophysical Institute, University of Bergen. He started his career as a Research Engineer in the oil and gas industry in 1982 doing reservoir model development with a degree in applied mathematics. He turned to oceanography and climate research in 1987 joining the Nansen Environmental and Remote Sensing Center where he became its Deputy Director in 1994. He joined the Geophysical Institute in 1996 but also spent 2 years at the University Centre in Svalbard and was Deputy Director of the Bjerknes Centre for Climate Research from its establishment in 2000. From 2003 to 2011 he was Director of the Geophysical Institute widening its scope to lead university-wide efforts in renewable energy, notably offshore wind. From 2019, he has led international work on global development at the Institute of Marine Research (IMR). During 2021-2022 he was part time on loan from IMR to the Norwegian Ministry of Foreign Affairs before taking up his present position at IMR.

The Future of Food from the Sea

1

Christopher Costello, Ling Cao, Stefan Gelcich, Miguel Angel Cisneros, Christopher M. Free, Halley E. Froehlich, Christopher D. Golden, Gakushi Ishimura, Jason Maier, Ilan Macadam-Somer, Tracey Mangin, Michael C. Melnychuk, Masanori Miyahara, Carryn L. de Moor, Rosamond Naylor, Linda Nøstbakken, Elena Ojea, Erin O'Reilly, Ana M. Parma, Andrew J. Plantinga, Shakuntala H. Thilsted, and Jane Lubchenco

Global food demand is rising, and serious questions remain about whether supply can increase sustainably (FAO 2018). Land-based expansion is possible but may exacerbate climate change and biodiversity loss, and compromise the delivery of other ecosystem services (Olsen 2011; Foley et al. 2005, 2011; Mbow et al. 2019; Amundson et al. 2015). As food from the sea represents only 17% of the current production of edible meat, we ask how much food we can expect the ocean to sustainably produce by 2050. Here we examine the main food-producing sectors in the ocean—wild fisheries, finfish mariculture and bivalve mariculture—to estimate 'sustainable supply curves' that account for ecological, economic, regulatory and technological constraints. We overlay these supply curves with demand scenarios to estimate future seafood production. We find that under our estimated demand shifts and supply scenarios (which account for policy reform and technology improvements), edible food from the sea could increase by 21–44 million tonnes by 2050, a 36–74% increase compared to current yields. This represents 12–25% of the estimated increase in all meat needed to feed 9.8 billion people by 2050. Increases in all three sectors are likely, but are most pronounced for mariculture. Whether these production potentials are realized sustainably will depend on factors such as policy reforms, technological innovation and the extent of future shifts in demand.

These authors jointly supervised this work: Christopher Costello, Ling Cao, Stefan Gelcich

Human population growth, rising incomes and preference shifts will considerably increase global demand for nutritious food in the coming decades. Malnutrition and hunger still plague many countries (FAO 2018; UNDP 2020), and projections of population and income by 2050 suggest a future need for more than 500 megatonnes (Mt) of meat per year for human consumption (Supplementary Information section 1.1.6). Scaling up the production of land-derived food crops is challenging, because of declining yield rates and competition for scarce land and water resources (Olsen 2011). Land-derived seafood (freshwater aquaculture and inland capture fisheries; we use seafood to denote any aquatic food resource, and food from the sea for marine resources specifically) has an important role in food security and global supply, but its expansion is also constrained. Similar to other land-based production, the expansion of land-based aquaculture has resulted in substantial environmental externalities that affect water, soil, biodiversity and climate, and which compromise the ability of the environment to produce food (Foley et al. 2005, 2011; Mbow et al. 2019; Amundson et al. 2015). Despite the importance of terrestrial aquaculture in seafood production (Supplementary Fig. 3), many countries—notably China, the largest inland-aquaculture producer—have restricted the use of land and public waters for this purpose, which constrains expansion (De Silva and Davy 2010). Although inland capture fisheries are important for food security, their contribution to total global seafood production is limited (Supplementary Table 1) and expansion is hampered by ecosystem constraints. Thus, to meet future needs (and recognizing that land-based sources of fish and other foods are also part of the solution), we ask whether the sustainable production of food from the sea has an important role in future supply.

J. Lubchenco, P. M. Haugan (eds.), *The Blue Compendium*, https://doi.org/10.1007/978-3-031-16277-0_1

Food from the sea is produced from wild fisheries and species farmed in the ocean (mariculture), and currently accounts for 17% of the global production of edible meat (FAO Fisheries and Aquaculture Department 2019; Edwards et al. 2019; FAO 2020; Nijdam et al. 2012) (Supplementary Information section 1.1, Supplementary Tables 1–3). In addition to protein, food from the sea contains bioavailable micronutrients and essential fatty acids that are not easily found in land-based foods, and is thus uniquely poised to contribute to global food and nutrition security (Kawarazuka and Béné 2010; Allison 2011; Golden et al. 2016; Hicks et al. 2019).

Widely publicized reports about climate change, overfishing, pollution and unsustainable mariculture give the impression that sustainably increasing the supply of food from the sea is impossible. On the other hand, unsustainable practices, regulatory barriers, perverse incentives and other constraints may be limiting seafood production, and shifts in policies and practices could support both food provisioning and conservation goals (Costello et al. 2016; Ye and Gutierrez 2017). In this study, we investigate the potential of expanding the economically and environmentally sustainable production of food from the sea for meeting global food demand in 2050. We do so by estimating the extent to which food from the sea could plausibly increase under a range of scenarios, including demand scenarios under which land-based fish act as market substitutes.

The future contribution of food from the sea to global food supply will depend on a range of ecological, economic, policy and technological factors. Estimates based solely on ecological capacity are useful, but do not capture the responses of producers to incentives and do not account for changes in demand, input costs or technology (Gentry et al. 2017; Troell et al. 2017). To account for these realities, we construct global supply curves of food from the sea that explicitly account for economic feasibility and feed constraints. We first derive the conceptual pathways through which food could be increased in wild fisheries and in mariculture sectors. We then empirically derive the magnitudes of these pathways to estimate the sustainable supply of food from each seafood sector at any given price (Costello et al. 2019). Finally, we match these supply curves with future demand scenarios to estimate the likely future production of sustainable seafood at the global level.

1 Sustainably Increasing Food from the Sea

We describe four main pathways by which food supply from the ocean could increase: (1) improving the management of wild fisheries; (2) implementing policy reforms of mariculture; (3) advancing feed technologies for fed mariculture; and (4) shifting demand, which affects the quantity supplied from all three production sectors.

Although mariculture production has grown steadily over the past 60 years (Fig. 1.1) and provides an important contribution to food security (Belton et al. 2018), the vast majority (over 80%) of edible meat from the sea comes from wild fisheries (FAO Fisheries and Aquaculture Department 2019) (Fig. 1.1b). Over the past 30 years, supply from this wild food source has stabilized globally despite growing demand worldwide, which has raised concerns about our ability to sustainably increase production. Of nearly 400 fish stocks around the world that have been monitored since the 1970s by the UN Food and Agriculture Organization (FAO), approximately one third are currently not fished within sustainable limits (FAO 2018). Indeed, overfishing occurs often in poorly managed ('open access') fisheries. This is disproportionately true in regions with food and nutrition security concerns (FAO 2018). In open-access fisheries, fishing pressure increases as the price rises: this can result in a 'backward-

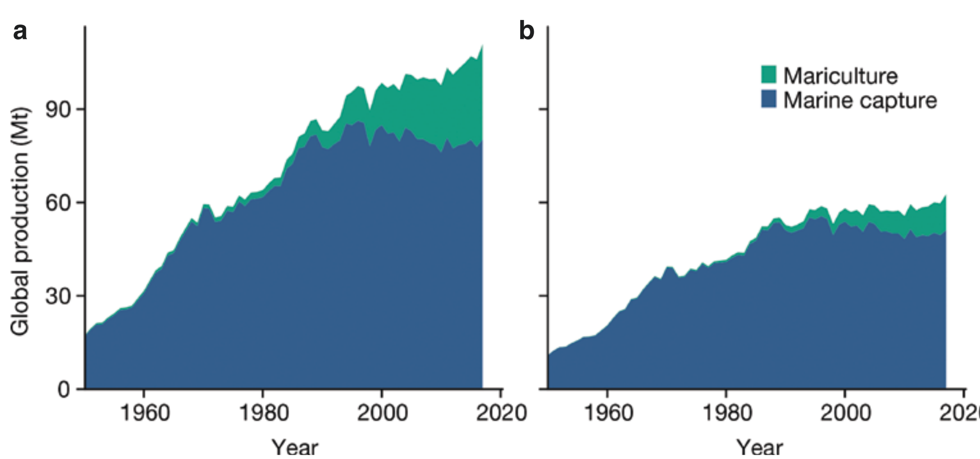

Fig. 1.1 Marine harvest and food from the sea over time (excluding aquatic plants). Data are from FAO Fisheries and Aquaculture Department (2019). (**a**, **b**) Harvests (live-weight production) (**a**) are converted to food equivalents (edible production) (Edwards et al. 2019) (**b**). In (**b**), there is also an assumption that 18% of the annual landings of marine wild fisheries are directed towards non-food purposes (Cashion et al. 2017)

bending' supply curve (Copes 1970; Nielsen 2006) (the OA curve in Fig. 1.2a), in which higher prices result in the depletion of fish stocks and reduced productivity—and thus reduced equilibrium food provision.

Fishery management allows overexploited stocks to rebuild, which can increase long-term food production from wild fisheries (Hilborn and Costello 2018; Hilborn et al. 2020). We present two hypothetical pathways by which wild fisheries could adopt improved management (Fig. 1.2a). First, independent of economic conditions, governments can impose reforms in fishery management. The resulting production in 2050 from this pathway—assuming that fisheries are managed for maximum sustainable yield (MSY)—is represented by the MSY curve in Fig. 1.2a, and is independent of price. The second pathway explicitly recognizes that wild fisheries are expensive to monitor (for example, via stock assessments) and manage (for example, via quotas)—management reforms are adopted only by fisheries for which future profits outweigh the associated costs of improved management. When management entities respond to economic incentives, the number of fisheries for which the benefits of improved management outweigh the costs increases as demand (and thus price) increases. This economically rational management endogenously determines which fisheries are well-managed, and thus how much food production they deliver, resulting in supply curve designated R in Fig. 1.2a.

Although the production of wild fisheries is approaching its ecological limits, current mariculture production is far below its ecological limits and could be increased through policy reforms, technological advancements and increased demand (Gentry et al. 2017; Joffre et al. 2017). We present explanations for why food production from mariculture is currently limited, and describe how the relaxation of these constraints gives rise to distinct pathways for expansion (Fig. 1.2b). The first pathway recognizes that ineffective policies have limited the supply (Abate et al. 2016; Gentry et al. 2019). Lax regulations in some regions have resulted in poor environmental stewardship, disease and even collapse, which have compromised the viability of food production in the long run (curve M1 in Fig. 1.2b). In other regions, regulations are overly restrictive, convoluted and poorly defined (The Sea Grant Law Center 2019; Davies et al. 2019), and thus limit production (curve M2 in Fig. 1.2b). In both cases, improved policies and implementation can increase food production by preventing and ending environmentally damaging mariculture practices (the shift from M1 to M3 in Fig. 1.2b) and allowing for environmentally sustainable expansion (the shift from M2 to M3 in Fig. 1.2b).

The second pathway to sustainably increase mariculture production is through further technological advances in finfish feeds. Currently, most mariculture production (75%) requires some feed input (such as fishmeal and fish oil) that is largely derived from wild forage fisheries (FAO 2018).

If fed mariculture continues using fishmeal and fish oil at the current rate, its growth will be constrained by the ecological limits of these wild fisheries (Froehlich et al. 2018a). Alternative feed ingredients—including terrestrial plant- or animal-based proteins, seafood processing waste, microbial ingredients, insects, algae and genetically modified plants—are rapidly being developed and are increasingly used in mariculture feeds (Klinger and Naylor 2012; Cao et al. 2015; Little et al. 2016; Shah et al. 2018). These innovations could decouple fed mariculture from wild fisheries (but may refocus pressure on terrestrial ecosystems) and could catalyse considerable expansion in some regions (Troell et al. 2014; Froehlich et al.

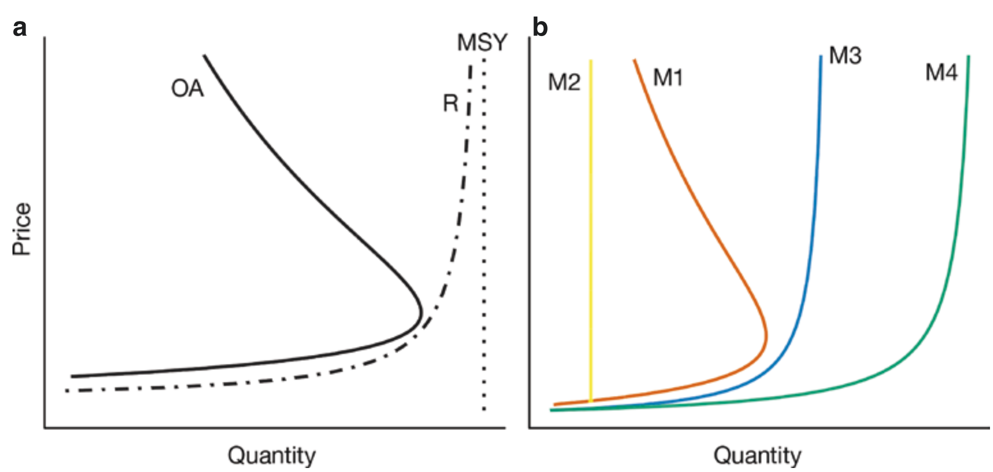

Fig. 1.2 Hypothetical supply curves for wild fisheries and mariculture, showing the influence of price on production quantity. (**a**) Wild fisheries. Curves represent poorly managed (open access) fisheries (OA); management reform for all fisheries (MSY); and economically rational management reform (R). (**b**) Mariculture. Curves represent weak regulations that allow for ecologically unsustainable production (M1); overly restrictive policies (M2); policies that allow for sustainable expansion (M3); and a reduced dependence on limited feed ingredients for fed-mariculture production (M4)

2018b). This has already begun for many fed species, such as Atlantic salmon—for which fish-based ingredient use has been reduced from 90% in the 1990s to just 25% at present (Aas et al. 2019). A reduced reliance on fishmeal and fish oil is expected to shift the supply curve of fed mariculture to the right (curve M4 in Fig. 1.2b). The final pathway is a shift in demand (aggregated across all global fish consumers), which affects all three production sectors. When the sustainable supply curve is upward-sloping, an increase in demand (rightward shift; for example, from rising population, income or preferences) increases food production.

2 Estimated Sustainable Supply Curves

We estimate supply curves of food from the sea in 2050 for the three largest food sectors in the ocean: wild fisheries, finfish mariculture and bivalve mariculture. We construct global supply curves for marine wild fisheries using projected future production for 4702 fisheries under alternative management scenarios (Fig. 1.3a). We model future production with a bioeconomic model based on Costello et al. (2016), which tracks annual biomass, harvest and profit, and accounts for costs associated with extraction and management (see Methods and Supplementary Information for details). Managing all fisheries to maximize food production (MSY) would result in 57.4 Mt of food in 2050 (derived from 89.3 Mt of total harvest, hereafter noted as live-weight equivalent), representing a 16% increase compared to the current food production (Fig. 1.3a). Under a scenario of economically rational reform (in which the management approach and exploitation rate of fisheries depend on profitability), the price influences production (Fig. 1.3a). At current mean global prices, this scenario would result in 51.3 Mt of food (77.4 Mt live-weight equivalent)—a 4% increase compared to current food production. These management-induced

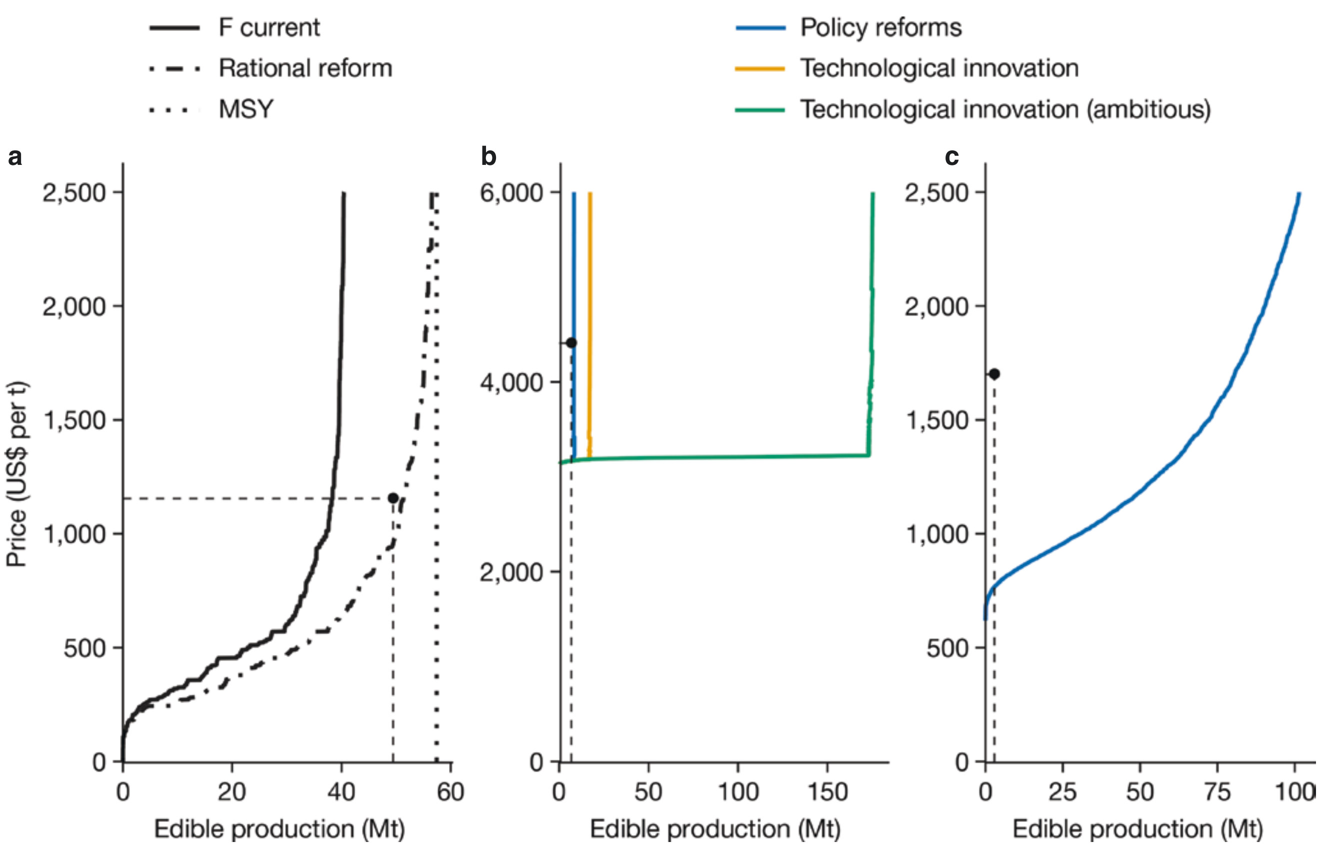

Fig. 1.3 Estimated sustainable supply curves for wild fisheries, finfish mariculture and bivalve mariculture. (**a**–**c**) Points represent current production and average price in each sector: marine wild fisheries (**a**), finfish mariculture (**b**) and bivalve mariculture (**c**). In (**a**), supply curves for annual steady-state edible production from wild fisheries are shown under three different management scenarios: production in 2050 under current fishing effort assuming that fishing only occurs in fisheries that are profitable (*F* current); the economically rational supply curve aimed at maximizing profitability (rational reform); and a reform policy aimed at maximizing food production, regardless of the economic considerations (MSY). In (**b**), supply curves for finfish (fed) mariculture show: future steady-state production under current feed assumptions and policy reform (policy reform); sustainable production assuming policy reform and a 50% reduction in fishmeal and fish oil feed requirements (technological innovation); and sustainable production assuming policy reform and a 95% reduction in fishmeal and fish oil feed requirements (technological innovation (ambitious)). In all cases, feed ingredients are from the economically rational reform of wild fisheries

shifts in supply are ultimately limited by the carrying capacity of the ecosystem. If current fishing pressure is maintained for each fish stock when profitable (*F* current, referring to the current fishing mortality rate), food production from wild fisheries is lower for most prices than under the two reform scenarios (owing to fishing too intensively on some stocks, and too conservatively on others) (Hilborn and Costello 2018): this supply curve is not backward-bending, as it reflects constant fishing pressures.

We estimate the production potential of mariculture at a resolution of 0.217° around the world for finfish and bivalves. Ecological conditions—sea surface temperature, dissolved oxygen and primary productivity—determine the suitability of each pixel for mariculture production. We build on previous models (Gentry et al. 2017) by including economic considerations (including the capital costs of vessels and equipment, and the operating costs of wages, fuel, feed, insurance and maintenance; Supplementary Tables 5–7) to determine whether farming an ecologically suitable area is economically profitable at any given price. Summing economically viable production for each sector at the global level for different prices produces two mariculture supply curves. This approach assumes that the most profitable sites will be developed first, but does not explicitly include challenges such as the cost of public regulation and the delineation of property rights. Farm design is based on best practice for sustainable production, and we therefore interpret the results as an environmentally sustainable supply. We examine a range of assumptions regarding production costs, and explore different technological assumptions with respect to the species type farmed for finfish mariculture (Methods, Supplementary Information section 1.3, Supplementary Table 9). The supply curve for finfish mariculture differs substantially among future feed-technology scenarios, although all of these scenarios foretell a substantial increase in annual food supply in the future compared to the current production of the sector (6.8 Mt of food) (Fig. 1.3b). However, the policy reform scenario—which assumes mariculture policies are neither too restrictive nor lax (curve M3 in Fig. 1.2b), but that fishmeal and fish oil requirements match present-day conditions—produces a modest additional 1.4 Mt of food at current prices. In this scenario, marine-based feed inputs limit mariculture expansion even as the price increases considerably.

Two feed-innovation scenarios—representing policy reform plus a 50% or 95% reduction in fishmeal and fish oil requirements, which we refer to as 'technological innovation' and 'technological innovation (ambitious)', respectively—can substantially shift the supply curve.

At current prices, future supply under these scenarios is predicted to increase substantially to 17.2 Mt and 174.5 Mt of food for technological innovation and technological innovation (ambitious) scenarios, respectively (Fig. 1.3b). Bivalve mariculture is constrained by current policy but not by feed limitations, and is poised to expand substantially under policy reform scenarios. At current prices, economically rational production could lead to an increase from 2.9 Mt to 80.5 Mt of food (Fig. 1.3c). Even if our model underestimates costs by 50%, policy reforms would increase the production potential of both fed and unfed mariculture at current prices. For fed mariculture, this remains true even when evaluating mariculture species with different feed demands (Atlantic salmon, milkfish and barramundi).

3 Estimates of Future Food from the Sea

Our supply curves suggest that all three sectors of ocean food production are capable of sustainably producing much more food than they do at present. The quantity of seafood demanded will also respond to price. We present three demand-curve estimates, shown in Fig. 1.4 (Methods, Supplementary Information). The intersections of future demand and sustainable supply curves provide an estimate of future food production from the sea. Because it is a substantial contributor to fish supply and—in some instances—acts as a market substitute for seafood, we also account for land-based aquatic food production (from freshwater aquaculture and inland capture fisheries; Supplementary Information section 1.4, Supplementary Tables 10–12). Estimates of future production from this fourth sector ('inland fisheries') are shown side-by-side in Supplementary Fig. 3 and Supplementary Tables 13, 14 (for quantities of food) and in Supplementary Tables 15, 16 (for live-weight equivalents), and are discussed with the results on food from the sea.

Even under current demand curves (green curves in Fig. 1.4), the economically rational reform of marine wild fisheries and sustainable mariculture policies (stocking densities consistent with European organic standards (European Union 2008)) under the technological innovation (ambitious) scenario could result in a combined total of 62 Mt of food from the sea per year, 5% more than the current levels (59 Mt). But we know that demand will increase as incomes rise and populations expand. Under the 'future demand' scenario (purple curves in Fig. 1.4), total food from the sea is projected to increase to 80 Mt. If demand shifts even more (as represented by our 'extreme demand' scenario; red curves in Fig. 1.4), the intersection of supply and demand is expected to increase to 103 Mt of food. Using the approach used by the FAO to estimate future needs, the world will require an additional 177 Mt of meat by 2050 (Supplementary Information section 1.1.6)—our results suggest that additional food from the sea alone could plausibly contribute 12–25% of this need. Another possibility we consider is that future consumers will not distinguish between fish-producing sectors, such that all sources of fish (including land-based) would be substitutes for each other. Adopting that assumption alters the supply-and-demand equilibrium, and implies

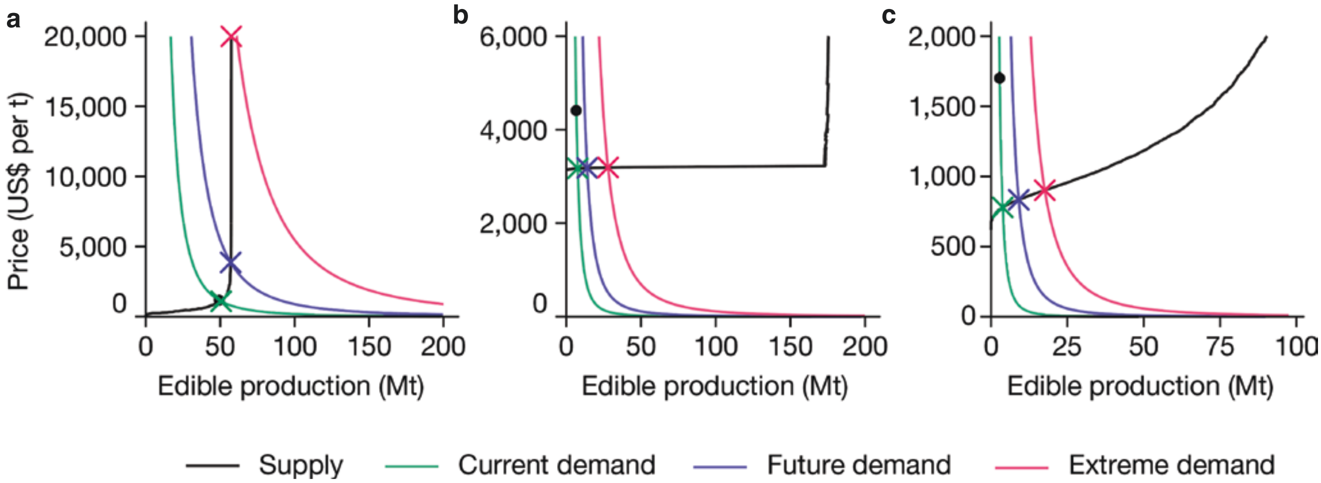

Fig. 1.4 Supply and demand curves of food from the sea for the three sectors. (**a–c**) Supply and demand curves for marine wild fisheries (**a**), finfish mariculture (**b**) and bivalve mariculture (**c**). In each panel, the solid black line is the supply curve from Fig. 1.3: for wild fisheries, the rational reform scenario is shown, and for finfish mariculture the technological innovation (ambitious) scenario is shown. Future demand refers to estimated demand in 2050; extreme demand represents a doubling of the estimated demand in 2050. The intersections of demand and sustainable supply curve (indicated with crosses) provide an estimate of the future food from the sea. Points represent current production and average price in each sector

that the increase among all sources of fish (sea and land) relative to the present could be between 90–212 Mt of food; under this scenario, expansion of aquatic foods alone could possibly exceed the 177-Mt benchmark.

Our results also suggest that the future composition of food from the sea will differ substantially from the present (Fig. 1.5). Although wild fisheries dominate edible marine production at present, we project that by 2050 up to 44% of edible marine production could come from mariculture (rising to 76% when all fish are substitutes and land-based fish are included under extreme demand scenarios (Supplementary Fig. 3, Supplementary Table 14)), although all sectors could increase production. Although even more substantial increases are technically possible (for example, fed mariculture alone is capable of generating at least the benchmark 177 Mt of additional meat), actually realizing these gains would require enormous shifts in demand.

Our models rely on a number of assumptions and parameters that are uncertain, and which may interact in nonlinear ways. To test the robustness of our main conclusions, we examine a range of scenarios and run an extensive sensitivity analysis (Supplementary Information). Across a wide range of cost, technology and demand scenarios, we find that sustainably harvested food from the sea: (1) has the potential to increase considerably in the coming decades; (2) will change in composition, with a greater future share coming from mariculture; and (3), in aggregate, could have an outsized role in meeting future meat demands around the world (Supplementary Figs. 1–4, Supplementary Tables 13–17).

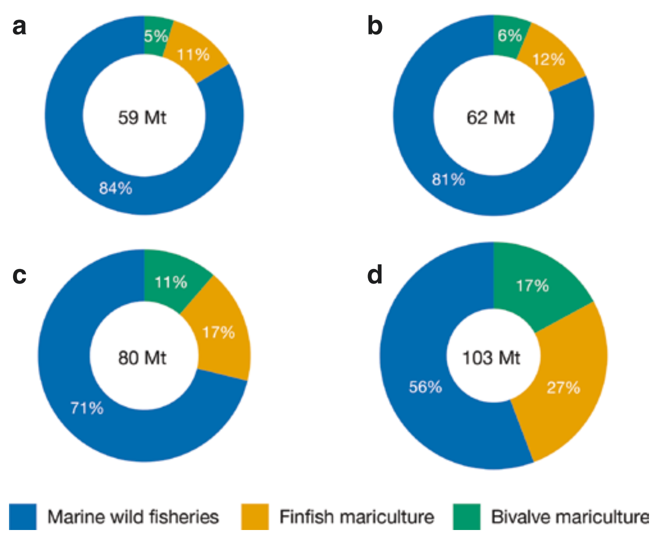

Fig. 1.5 Composition of current and future food from the sea under three alternative demand scenarios. (**a**) Composition of current (initial production) food from the sea. (**b–d**), Composition of future (2050) food from the sea under scenarios of current (**b**), future (**c**) and extreme (**d**) demand. The sustainable supply curves assumed for these predictions are: rational reform for wild fisheries; technological innovation (ambitious) for finfish mariculture; and policy reform for bivalve mariculture, as shown in Fig. 1.3. The total production of food from the sea per year is shown in the centre in each panel

4 Conclusions

Global food demand is rising, and expanding land-based production is fraught with environmental and health concerns. Because seafood is nutritionally diverse and avoids or lessens many of the environmental burdens of terrestrial food production, it is uniquely positioned to contribute to both food provision and future global food and nutrition security. Our estimated sustainable supply curves of food from the sea suggest substantial possibilities for future expansion in both wild fisheries and mariculture. The potential for increased global production from wild fisheries hinges on maintaining fish populations near their most-productive levels. For underutilized stocks, this will require expanding existing markets. For overfished stocks, this will require adopting or improving management practices that prevent overfishing and allow depleted stocks to rebuild. Effective management practices commonly involve setting and enforcing science-based limits on catch or fishing effort, but appropriate interventions will depend on the biological, socioeconomic, cultural and governance contexts of individual fisheries. Effective management will be further challenged by climate change, species composition changes in marine ecosystems and illegal fishing. Directing resources away from subsidies that enhance fishing capacity towards building institutional and technical capacity for fisheries research, management and enforcement will help to meet these challenges. Increased mariculture production will require management practices and policies that allow for environmentally sustainable expansion, while balancing the associated trade-offs to the greatest extent possible; this principle underpins the entire analysis. We find that substantial expansion is realistic, given the costs of production and the likely future increase in demand.

We have identified a variety of ways that sustainable supply curves can shift outward. These shifts interact with future demand to determine the plausible future equilibrium quantity of food produced from the sea. We find that although supply could increase to more than six times the current level (primarily via expanded mariculture), the demand shift required to engage this level of supply is unlikely. Under more realistic demand scenarios and appropriate reforms of the supply, we find that food from the sea could increase in all three sectors (wild fisheries, finfish mariculture and bivalve mariculture) to a total of 80–103 Mt of food in 2050 versus 59 Mt at present (in live-weight equivalents, 159–227 Mt compared to 102 Mt at present). When combined with projected inland production, this represents an 18–44% per decade increase in live-weight production, which is somewhat higher than the 14% increase that the Organisation for Economic Co-operation and Development (OECD) and the FAO project for total fish production during the next decade (OECD and Food and Agriculture Organization of the United Nations 2019). Under some scenarios, future production could represent a disproportionate fraction of the estimated total increase in global food production that will be required to feed 9.8 billion people by 2050. Substantial growth in mariculture will rely partly on public perceptions. Although there is some evidence of a negative public perception of aquaculture, it is highly variable by region and by context (Froehlich et al. 2017; Bacher 2015), and certifications and the provision of other information can help to alleviate concerns and expand demand (Bronnmann and Asche 2017).

These global projections will not have uniform implications around the world. For example, improved policies that shift the supply curve outward will decrease prices, but income-induced demand shifts will increase prices. Both effects increase production, but have vastly different consequences for low-income consumers. Bivalves may contribute substantially to food security by providing relatively low-cost and thus accessible food, because they have a high production potential at low costs compared to finfish production (Fig. 1.3). If all seafood is perfectly substitutable, bivalves could contribute 43% and 34% of future aquatic food under future and extreme demand scenarios, respectively (Supplementary Fig. 3)—which suggests potential large increases in production, provided demand is high enough. Trade also has an important role in distributing seafood from high-production to low-production regions, and in overcoming regional mismatches in price. The rate of international trade of seafood products has increased over past decades, and 27% of seafood products were traded in 2016 (FAO 2018), although major economic disruptions—such as the COVID-19 pandemic—can jointly reduce both supply and demand of traded seafood. On the other hand, trade may become increasingly relied upon as climate change alters regional productivity.

Substantially expanding the production of food from the sea will bring co-benefits and trade-offs, and will require national and inter-regional governance, as well as local capacity to ensure equity and sustainability. The improved management of wild fisheries can not only increase fish biomass, but also brings the co-benefit of improved livelihoods of fishers. However, there will be some short-term costs as overfished stocks rebuild to levels that support greater food provision. As mariculture expands, interactions with wild fisheries and other ecosystem services (via spatial overlaps, pollution and so on) must be constantly addressed. Ambitious technical innovation (that is, the substitution of marine ingredients with terrestrial-sourced proteins) can help to decouple fed mariculture from wild fisheries, but will probably refocus some pressure on terrestrial ecosystems. Climate change will further challenge food security. Estimates suggest that active adaptation to climate-induced changes will be crucial in both wild fisheries (Gaines et al. 2018) and mariculture (Froehlich et al. 2018c). Climate-adaptive management of wild fisheries and decisions regarding mariculture production (for example, the type of feed used, species produced and farm siting) could improve food provision from the sea under conditions of climate change.

We have shown that the sea can be a much larger contributor to sustainable food production than is currently the case, and that this comes about by implementing a range of plausible and actionable mechanisms. The price mechanism—when it motivates improved fishery management and the sustainable expansion of mariculture into new areas—arises from change in demand, and acts on its own without any explicit intervention. The feed technology mechanism is driven by incentives to innovate, and thus acquire intellectual property rights to new technologies. When intellectual property is not ensured, or to achieve other social goals, there may be a role for public subsidies or other investments in these technologies. The policy mechanism pervades all three production sectors, and could make—or break—the ability of food from the sea to sustainably, equitably and efficiently expand in the future.

5 Methods

Sample size was a census of all available fisheries data. No experiments were conducted.

Here we describe our methods in brief: detailed methods, sensitivity analyses and robustness checks are provided in the Supplementary Information.

5.1 Sustainable Supply Curves

The supply of food from marine wild fisheries is jointly determined by ecosystem constraints, fishery policy and prevailing economic conditions. Estimated supply curves show the projected 2050 production quantity at a given price, incorporating harvesting costs, management costs and fishery-specific engagement decisions for individual fisheries. Current management of the 4702 marine fisheries included in our study range from open access to strong target-based management (Costello et al. 2016). Using data from the RAM Legacy Stock Assessment Database (Ricard et al. 2012), the FAO (FAO Fisheries and Aquaculture Department 2019; Costello et al. 2016; Melnychuk et al. 2017; Mangin et al. 2018), we calculate three supply curves that represent summed global production from established wild fisheries for a range of prices (Fig. 1.3). The first (*F* current) assumes that all fisheries in the world maintain their current fishing mortality rate if profitable (that is, fisheries for which current fishing pressure would result in steady-state profit < 0 are not fished). The second (rational reform) assumes that fisheries are reformed to maximize long-term food production (that is, adopt F_{MSY}, the fishing mortality rate that results in maximum sustain- able yield (MSY)), but only at prices for which reform results in greater future profit than that of current management. Importantly, adopting reform is associated with greater management costs for fisheries that are currently weakly managed. If a fishery is managed, its production changes, which alters the supply curve. Production occurs in a given fishery only if future profit > 0. The third supply curve (MSY) assumes that all fisheries are managed to maximize sustainable yield, regardless of the cost or benefit of doing so (Fig. 1.3). Supply curves under alternative cost assumptions yield results similar to those presented in Fig. 1.3 (Supplementary Fig. 1).

To construct supply curves for finfish and bivalve mariculture (which account for 83% of current production of edible animal products from mariculture (FAO 2020)), we use a previously published (Gentry et al. 2017) global suitability dataset at a resolution of 0.217°. Ecological conditions (that is, surface temperature, dissolved oxygen and primary productivity (bivalves only)) determine the suitability of different areas for production. We build on Gentry et al. (2017) by including economic considerations (for example, the capital costs of vessels and equipment and operating costs of wages, fuel, feed, insurance and maintenance; see Supplementary Information section 1.3, Supplementary Tables 5–7 for more details) to determine whether an ecologically suitable area is also economically profitable to farm at a given price. For any given price, we estimate the potential production and profitability of each pixel, and determine the global set of economically viable pixels for mariculture production of finfish and bivalves; we allow for production of both kinds of mariculture in the same pixel, provided the pixel is economically suitable for both. Summing production in this manner at the global level provides a point on the supply curve, at which farm design (Supplementary Table 4) is based on best practices for sustainable production (that is, stocking densities consistent with European organic standards (European Union 2008)). We then derive supply curves under different assumptions regarding mariculture policy and technological innovation, which affect the parameters of the supply model.

We estimate supply curves for finfish mariculture under three scenarios, all of which assume that wild fisheries are rationally managed; this pins down the potential supply of wild fish that can be used as feed in mariculture (Supplementary Table 8). We display three supply curves for fed mariculture (Fig. 1.3). The policy reforms scenario represents a future in which regulatory barriers are removed, unsustainable production is prevented and mariculture continues to use feed ingredients from wild fisheries at the current rate (that is, feed conversion ratios remain static, fishmeal and fish oil inclusion rates in feed remain the same, and feed availability depends on production from wild fisheries). This scenario represents the economically rational sustainable production given the current feed context. Two technological innovation scenarios represent policy reform plus a 50% and (a more ambitious) 95% reduction in fishmeal and fish oil requirements for fed mariculture production. The supply curve for bivalve (unfed) mariculture (Fig. 1.3) reflects production in the set of pixels for which unfed mariculture can be profitably produced at any given price.

5.2 Supply Meets Demand

To estimate how food from the sea might help to meet future increases in demand at the global level, we require estimates of the current and future demand curves of food from the sea. The intersection of future demand curves and our estimated sustainable supply curves provides an estimate of food from the sea in 2050. As a benchmark, we assume that the three sectors are independent, but that increases in demand are parametric, so each of the three sectors experiences a proportional increase in future demand—for example, as global population and per capita incomes rise (see Supplementary Information for detailed results, assuming all aquatic foods are perfect substitutes). We assume a straightforward structure in which each sector faces an isoelastic demand (for example, see Cai and Leung (2017), with own price elasticity = −0.382 (Muhammad et al. 2011); and sector-specific income elasticities estimated from Cai and Leung (2017)). Using these elasticities, the coefficient on current-demand curve in each sector (current, in Fig. 1.4) is tuned so the demand curve passes through the current price of seafood in that sector (averaged across fish from that sector) given the current global gross domestic product and population. Effectively, this approach assumes that all fish within a sector are substitutes. We do not explicitly estimate a current supply curve because it is not required to perform our calculations and—for reasons stated in the Article—we do not necessarily regard the current supply as sustainable. To project future demand at the global level, we develop two scenarios that we term future and extreme (Fig. 1.4). The future demand represents the demand curve for food from the sea in each sector given exogenous estimates of future population size and global income in 2050 (PwC 2017; United Nations 2017), which are entered as parameters in the demand curve (Supplementary Information). The extreme scenario doubles the quantity demanded at any given price in 2050, relative to the future scenario; we regard demand shifts larger than this amount as unlikely.

The Supplementary Information contains an extensive set of robustness checks and sensitivity analyses. One important alternative to the model in the Article is to allow all fish to be perfect substitutes in the future. Under that model, land-based fish production (aquaculture and capture) must be accounted for because those fish act as substitutes for food from the sea. Although this tends to increase the final estimates of food production from the sea, our qualitative findings are robust to this assumption and the Supplementary Information reports how this changes the model results described in the Article.

5.3 Reporting Summary

Further information on research design is available in the Nature Research Reporting Summary linked to this paper.

5.4 Data Availability

All datasets analysed during the current study are available in a Dryad repository at https://datadryad.org/stash/dataset/doi/10.25349/D96G6H.

5.5 Code Availability

All code used to conduct the study are available in a GitHub repository: https://github.com/emlab-ucsb/future_food_from_sea.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see our Editorial Policies and the Editorial Policy Checklist.

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a	Confirmed	
☒	☐	The exact sample size (*n*) for each experimental group/condition, given as a discrete number and unit of measurement
☒	☐	A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
☒	☐	The statistical test(s) used AND whether they are one- or two-sided *Only common tests should be described solely by name; describe more complex techniques in the Methods section.*
☒	☐	A description of all covariates tested
☒	☐	A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
☒	☐	A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
☒	☐	For null hypothesis testing, the test statistic (e.g. *F*, *t*, *r*) with confidence intervals, effect sizes, degrees of freedom and *P* value noted *Give P values as exact values whenever suitable.*
☒	☐	For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
☒	☐	For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
☒	☐	Estimates of effect sizes (e.g. Cohen's *d*, Pearson's *r*), indicating how they were calculated

Our web collection on statistics for biologists contains articles on many of the points above.

Software and code

Policy information about availability of computer code

Data collection	All data are from publicly available sources identified in the manuscript.
Data analysis	All data analysis was performed by the authors using our own code.

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

All datasets analyzed during the current study are available in a Dryad repository: https://datadryad.org/stash/share/1hAjS-Q3nwsUAgrShYfVm6yNZSTF9oJpGWrT1_J0NyU [Note: this is currently a private repo but we will provide a public link prior to publication]. All code used to conduct the study are available in a GitHub repository: https://github.com/emlab-ucsb/future_food_from_sea.

2 The Expected Impacts of Climate Change on the Ocean Economy

Steve Gaines, Reniel Cabral, Christopher M. Free, Yimnang Golbuu, Ragnar Arnason, Willow Battista, Darcy Bradley, William Cheung, Katharina Fabricius, Ove Hoegh-Guldberg, Marie Antonette Juinio-Meñez, Jorge García Molinos, Elena Ojea, Erin O'Reilly, and Carol Turley

Highlights

- The ocean is critically important to our global economy. Collectively, it is estimated that ocean-based industries and activities contribute hundreds of millions of jobs and approximately US $2.5 trillion to the global economy each year, making it the world's seventh-largest economy when compared with national gross domestic products. In addition, the nonmarket services and benefits provided by the global ocean are significant and may in fact far exceed the value added by market-based goods and services.
- Climate change is altering ocean climate, chemistry, circulation, sea level and ice distribution. Collectively, these system changes have critical impacts on the habitats, biological productivities and species assemblages that underpin many of the economic benefits of the sea.
- Swift efforts to reduce anthropogenic greenhouse gas emissions are needed to maintain a robust ocean economy. The recent Intergovernmental Panel on Climate Change report estimates that climate-induced declines in ocean health will cost the global economy $428 billion/year by 2050 and $1.98 trillion/year by 2100.
- Climate change is reducing the productivities and changing the spatial distributions of economically important marine species and their habitats. All countries stand to gain significant benefits relative to a business-as-usual trajectory by implementing climate-adaptive fisheries management reforms that address both changes in species' distributions and productivities due to climate change. Many countries could maintain or improve profits and catches into the future with effective adaptation.
- The potential of marine aquaculture (mariculture) is likely to remain high under climate change and, with careful planning, mariculture could offset losses in food and income from capture fisheries in those countries that will experience losses in that sector. Expanding the potential for marine aquaculture will require enhancing technical capacities, defining best practices, easing undue regulatory burdens, increasing access to credit and insurance, breeding stocks for faster growth and improving feed technology.
- The combined effects of ocean warming and acidification result in predictions of negative impacts on coral reef cover and tourism values for all countries, with magnitudes dependent on the strength of climate change. For a high emissions scenario (Representative Concentration Pathway 8.5), coral cover is expected to decline by 72–87%, causing on-reef tourism values to decrease by over 90% in 2100.
- Climate change impacts will differ by country and sector and solutions must be context-specific. By exploring climate change impacts at the country level for fisheries, aquaculture and reef tourism, countries can assess what they stand to gain or lose due to climate change and understand how they might capitalise on these predictions to inform their investments and actions.
- Implementing certain key strategies will help build socioecological resilience to climate change and ensure the continued, or improved, provision of functions and services from the ocean, especially for the most vulnerable coastal nations. These strategies include the following:
  - **A focus on equity.** Climate change is likely to cause and exacerbate global inequities, reducing resilience and thereby likely worsening outcomes under all climate change scenarios. It will thus be profoundly important to examine the equity implications of all new and existing management decisions across all three sectors.

- **Looking forward.** The future of the ocean economy is expected to drastically change given climate change, and the nature and magnitude of these changes can be highly variable. Each of these three sectors will need to work to understand risks and anticipate changes, and build precautionary and adaptive strategies into their management decisions.
- **Cooperating across boundaries.** As suitable habitats shift and change, marine species will move across jurisdictional boundaries and regional, national and international cooperative agreements will be necessary to ensure that these species are well-managed, and that the benefits are fairly distributed during and after the transitions.

1 Introduction

1.1 Overview

The ocean is critically important to our global economy. Collectively, it is estimated that ocean-based industries and activities contribute hundreds of millions of jobs and approximately US $2.5 trillion to the global economy each year, making it the world's seventh-largest economy when compared with national gross domestic products (GDPs) (Hoegh-Guldberg 2015; IPCC 2019). In addition, the nonmarket services and benefits provided by the ocean are significant and may in fact far exceed the value added by market-based goods and services (Costanza et al. 2014).

Anthropogenic climate change, driven by the exponential increase in emissions of greenhouse gasses (GHGs) since the industrial revolution, will continue to impact the ocean through a variety of channels. The severity of effects will depend greatly on the extent of warming reached through GHG emissions (IPCC 2018, 2019). The resulting changes to ocean processes and functioning have broad implications for our global economy that must be taken into account, both to inform adaptation efforts and motivate urgent mitigation strategies.

In this paper, we focus on those sectors of the ocean economy that are most in need of adaptation to ensure they can continue to provide valued functions as the climate changes: capture fisheries, marine aquaculture, and marine and coastal tourism. We also briefly discuss other marine-based sectors, some of which generate higher monetary value at a global scale, but either face less significant existential risks from the changing climate (e.g. shipping), or must be drastically transitioned to avoid worsening the climate crisis (e.g. oil and gas extraction). However, we leave deeper discussion of these important industries and the issues surrounding them to other Blue Papers (*Ocean Energy and Mineral Sources and Coastal Development*).

1.2 The Ocean Economy: Essentials

The ocean economy consists broadly of all ocean-based human activities that generate revenue, employment and other monetary and nonmonetary benefits (OECD 2016). Some of the ocean benefits, and the resources needed to generate them, are market-based in that they are traded on global markets and have market prices. Examples of market-based ocean benefits include the following: wild capture fisheries and marine aquaculture (also known as mariculture); pharmaceuticals; fossil fuel energy resources such as oil and gas; renewable energy resources such as wave, wind or thermal energy; the use of the ocean surface for transportation (shipping); ocean-based tourism; and emerging blue carbon markets. Following the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) framework, most of the marketable benefits mentioned are material contributions (e.g. food, energy sources, genetic resources), but other important marketable contributions to people are regulating services (e.g. carbon sequestration) and nonmaterial (e.g. tourism).

Many other ocean benefits are not traded on markets, and their values are thus far more difficult to assess. The set of nonmarket ocean benefits is very large (Polasky and Segerson 2009; Costanza et al. 2014) and ranges from different ecosystem services to the broader category of nonmaterial contributions to people. In terms of ecosystem services, nonmarket benefits include most of the ocean's cultural services (e.g. swimming, recreational fishing, observing sea life, the existence value of the ocean's diverse biota). In addition, ecosystem services include regulating services—the ocean's contribution to the global water, energy and chemical circulation systems, as well as the ocean's role in climate regulation, carbon dioxide (CO_2) uptake and coastal protection—which are typically not accounted for in existing markets. The IPBES framework further adds to the ocean's nonmaterial contributions by including learning and inspiration (i.e. education, scientific information), psychological experiences (i.e. relaxation, healing, aesthetic enjoyment), supporting identities (i.e. the basis for spiritual and social-cohesion experiences, myths and traditional knowledge) and maintenance of options for future generations and innovations and needs (Díaz et al. 2015, 2018).

1.2.1 The Market-Based Ocean Economy

The Organisation for Economic Co-operation and Development (OECD) projects that market-based ocean industries will expand at least as fast as the global economy as a whole over the next decade. The OECD (2016) outlines the ocean industries that contribute the most in terms of production value and employment (see Table 2.1).

The rankings of ocean industries are quite different for these two economic outputs. Energy production, shipping

Table 2.1 Ocean industries contributing most to the ocean economy

	% of production value	% of employment
1. Offshore oil and gas	34	6
2. Marine and coastal tourism	26	22
3. Port activities	13	5
4. Maritime equipment	11	7
5. Fisheries, marine aquaculture and fish processing	6	49
6. Ocean transportation	5	4
7. Shipbuilding and repair	4	6
8. Offshore wind	1	1

Source: OECD (2016)
Note: Data are from 2010

and tourism dominate production values, while nearly half of all ocean employment arises from food production. Therefore, the impacts of climate disruptions on these industries can have quite disparate social and economic consequences.

1.2.2 The Nonmarket Ocean Economy

Despite the complexities and theoretical challenges, a number of researchers have attempted to calculate the value of the diverse ecosystem services provided by the ocean. Although there is much debate, these assessments generally conclude that nonmarket services from the ocean are nearly comparable in value to the entire market-based gross global product (i.e. from the entire global economy). For example, a prominent evaluation by Costanza et al. (2014) assessed the value of global ocean ecosystem services to be almost $50 trillion in 2011. This translates to more than 80% of the gross global product in that year, or 30 times more than the ocean-based gross value added. Recent initiatives, such as IPBES, broaden the concept of valuation of nonmarket goods and ecosystem services even further to the more inclusive Nature's Contributions to People (NCP). The ocean provides a number of these important contributions, which arise from a diversity of human-ocean relationships, including those of indigenous people and local communities (Díaz et al. 2015; Pascual et al. 2017). Although we focus on measuring the impacts of climate change on the market ocean economy in this assessment, it is clear that solutions to those challenges could generate far larger returns from the added benefits they provide to these nonmarket components of the ocean economy.

2 How Rising Greenhouse Gasses Alter the Ocean

Climate change is altering ocean climate, chemistry, circulation, sea level and ice distribution (Brander 2010; García Molinos et al. 2016; IPCC 2019). Collectively, these system changes have critical impacts on the habitats, biotic productivities and species assemblages (Doney et al. 2012; Poloczanska et al. 2013; Pinsky et al. 2013; Visser 2016; Bryndum-Buchholz et al. 2019; Lotze et al. 2019) that underpin many of the economic benefits of the sea (Barange et al. 2018; Cheung et al. 2010; Free et al. 2019a; Lam et al. 2016; Sumaila et al. 2011). They also affect the risks of various human activities and developments (Gattuso et al. 2015; de Suarez et al. 2014; Barange et al. 2014). Unprecedented ocean changes are already occurring across all latitudes (Barange et al. 2018; Friedrich et al. 2012; Holbrook et al. 1997; IPCC 2019; Kleisner et al. 2017; Walther et al. 2002), with a high risk of negative impacts to many ocean organisms, ecosystems and services (Gattuso et al. 2015; IPCC 2019; Lotze et al. 2019). These impacts are likely to increase dramatically toward the end of this century, depending on the extent of future GHG emissions, with potentially direct consequences for ecosystem services, the ocean economy and human welfare (IPCC 2019; Pecl et al. 2017). Below, we describe these effects individually, but many of these influences may synergistically or antagonistically interact, potentially with additional consequences (see, for example, Rosa and Seibel 2008).

Throughout this paper, we rely on the Representative Concentration Pathways (RCPs) (van Vuuren et al. 2011) adopted by the Intergovernmental Panel on Climate Change (IPCC) in its Fifth Assessment Report to describe potential GHG emission trajectories and associated climate futures. The RCP scenarios are named according to the projected radiative forcing experienced in 2100 (2.6, 4.5, 6.0 and 8.5 Watts per square metre [W/m^2], respectively). They roughly correspond to projected increases in planetary surface temperatures relative to 1850–1900 of 1.6, 2.5, 2.9 and 4.3 °C, respectively, by the end of this century (IPCC 2019).

2.1 Altered Ocean Temperatures and Disturbances

Climate change has already contributed to substantial warming of the ocean over most of the globe. The ocean has absorbed ~93% of additional heat, leading to significant warming of the upper ocean (above 700 metres [m]) and warming of deeper waters (700–2000 m), increasing in strength since the 1980s (Cheng et al. 2017). Sea surface temperatures have increased by an average of 0.7 °C globally since 1900 (Barange et al. 2018; Jewett and Romanou 2017). RCP scenarios suggest that these trends, which already exceed the range in natural seasonal variability in subtropical areas and the Arctic, will continue (IPCC 2014, 2019). Future upper ocean warming is expected to be most pronounced in tropical and Northern Hemisphere subtropical regions, while deep water warming is expected to be more pronounced in the Southern Ocean (Barange et al. 2018;

IPCC 2019; Gattuso et al. 2015). By 2100, the ocean as a whole is likely to have warmed by two to four times (RCP 2.6) to five to seven times (RCP 8.5) as much as the warming observed since 1970 (IPCC 2019).

As these warming trends continue, the suitable distribution ranges of many marine species are expected to shift poleward. In general, species that are able to move to cooler waters, and have suitable habitats to move to, will do so (Barange et al. 2018; Cheung et al. 2010; IPCC 2019; Pinsky et al. 2013). Organisms and habitats that cannot move will either adapt to the new conditions caused by climate change or become extirpated, unless extensive transplantation or other initiatives are mounted to prevent this. Significant habitat losses are predicted in many areas, especially in the Arctic and coral reef ecosystems, resulting in altered community assemblages, predator-prey mismatches and local extinctions (Doney et al. 2014; Free et al. 2019a; Gattuso et al. 2015; Holbrook et al. 1997; IPCC 2019).

Warming waters, along with an increase in episodic 'marine heat waves', ocean acidification (discussed below) and the spread of diseases, will lead to mass coral bleaching and mortality throughout the ranges of most coral species (Donner et al. 2005; FAO 2018; Gattuso et al. 2015; Hoegh-Guldberg 1999; IPCC 2019; Kubicek et al. 2019; McClanahan et al. 2002). Intense reshufflings of current biodiversity patterns are also anticipated in biogeographical transition zones, where local populations of multiple species are at or close to their thermal tolerance limits. As a result of these movements, studies have predicted 30–70% average increases in potential fish production at high latitudes, and decreases of up to 40% in the tropics (Barange et al. 2018; Cheung et al. 2010). Indeed, ongoing rapid replacement of cold-affinity species by warm-affinity species has been recently documented in tropical-to-temperate (Kumagai et al. 2018; Verges et al. 2014) and boreal-to-Arctic (Fossheim et al. 2015) regions.

Furthermore, tropical cyclones, extreme sea level events including storm surges and flooding and precipitation over the ocean are predicted to increase in intensity and frequency through the first half of this century due to ocean circulation changes (discussed below) (Barange et al. 2018; Hartmann et al. 2013; IPCC 2014, 2019; Kirtman et al. 2013; Kopp et al. 2014; Ren et al. 2013). In addition, recent models and observational data indicate that recurring climate patterns such as the El Niño-Southern Oscillation are likely to increase in frequency and intensity as the ocean warms (Barange et al. 2018; Cai et al. 2014, 2015; IPCC 2019; Wang et al. 2017), with potentially important impacts on fishing, aquaculture and tourism operations. River flows and flooding may also change with increased snowmelt and more variable land-based precipitation, reducing salinity, increasing sedimentation and impacting productivity in nearshore waters (IPCC 2019; Jha et al. 2006; Pervez and Henebry 2015; Siderius et al. 2013; Loo et al. 2015). Finally, ocean warming leads to increased stratification of the water column and reduced water circulation and mixing (Barange et al. 2018; FAO 2018; IPCC 2019; Jacox and Edwards 2011; Oschlies et al. 2018).

2.2 Sea Level Rise and an Altered Distribution of Ice

Polar areas have seen drastic changes including shifts in the timing of the annual melt seasons, changes in snow cover and changes in ice sheet and glacier mass, which have resulted in sea level rise. Globally, mean sea level rose on average by 0.16 m from 1902 to 2015, and estimates indicate that by 2100, the global mean sea level will rise between 0.29 m and 0.59 m under RCP 2.6, and between 0.61 m and 1.1 m under RCP 8.5 (Barange et al. 2018; IPCC 2019; Kopp et al. 2014). The rate of increase varies across regions—in the western Pacific, sea level is increasing at three times the global average, while the rate of increase in the eastern Pacific is null or negative (Barange et al. 2018; Dangendorf et al. 2017). The economic consequences of global sea level rise will therefore also be highly heterogeneous across regions, as well as across sectors, with likely significant impacts stemming from the modification of coastlines, reduced coastal productivity as reefs and seagrasses are submerged and increased flooding (Barange et al. 2018; IPCC 2019).

In the Arctic, annual sea ice extent has decreased at a rate of 3.5–4.1% per decade, plummeting to a rate of −13% in September, the month marking the end of the melt season. This strong downward trend in extent is accompanied by a progressive loss of multiyear sea ice with over 50% of its extent lost during the period 1999–2017 (Kwok 2018; IPCC 2019). Meanwhile, mass lost from the Antarctic ice sheet tripled between 2007 and 2016 relative to the previous decade, leading to the lowest average monthly and yearly Antarctic sea ice extents on record in 2017 (IPCC 2019; Parkinson 2019). The Greenland Ice Sheet's mass loss doubled over this same period, and the rates of mass loss for both Greenland and Antarctic sea ice are expected to increase throughout the twenty-first century and beyond (IPCC 2019). Together, these two ice sheets are projected to contribute 0.11 m to global mean sea level rise under RCP 2.6, and 0.27 m under RCP 8.5 (IPCC 2019). While reductions in sea ice have opened new routes for international shipping, potentially reducing costs to this sector, these changes have also resulted in losses to sea ice–based travel and tourism, and pose risks to cultural livelihoods such as subsistence fishing and hunting for polar species (IPCC 2019). Glaciers and land-based ice sheets across the world have also shrunk (Barange et al. 2018; IPCC 2019) and their combined influence was the dominant source of sea level rise between 2006 and 2015 (IPCC 2019).

Sea level rise, combined with increased storm frequency and intensity, is expected to have significant negative impacts on ocean and coastal economy infrastructure, including damage to ports, aquaculture operations and offshore energy structures, and added risks and constraints on shipping (IPCC 2019). These impacts are likely to be among the costliest and potentially most disruptive of all the climate-driven ocean changes. For example, global annual flood costs from sea level rise under RCP 8.5 are estimated at $14 trillion/year (Jevrejeva et al. 2018). Furthermore, although there is uncertainty around exact numbers, sea level rise and other climate-related ocean changes will likely lead to the displacement of millions of people worldwide, with the poorest households facing the greatest risk (IPCC 2019). Low-lying island nations, such as Maldives, Marshall Islands, Tuvalu and Nauru, are especially vulnerable, with sea level rise threatening their entire economies and populations.

2.3 Altered Ocean Chemistry

Ocean acidity has increased by 26% since the industrial revolution, with regional variability in severity and rate of change (Barange et al. 2018; Gattuso et al. 2015; IPCC 2014, 2019; Jewett and Romanou 2017).

This increase has been driven primarily by the oceanic absorption of CO_2, which lowers ocean pH (by increasing bicarbonate and hydrogen ion concentrations) and carbonate ion concentrations, and increases the partial pressure of CO_2 and dissolved inorganic carbon. These changes can impact many marine organisms, particularly in early life stages, but are especially detrimental to corals and organisms that form carbonate shells (Barange et al. 2018; FAO 2018; Pörtner et al. 2014), and perhaps beneficial for some photosynthetic, non-calcifying taxa (Kroeker et al. 2013). Observed trends of declining ocean pH already exceed the natural seasonal variability throughout most of the open ocean, and they are expected to continue throughout this century (Barange et al. 2018; Gattuso et al. 2015; Henson et al. 2017; IPCC 2019).

By 2100, surface ocean pH is projected to decline by 0.036–0.042 pH units under RCP 2.6, or 0.287–0.29 pH units under RCP 8.5. High-latitude waters, deep waters and upwelling regions will be the first to see carbonate ion concentrations drop below the 'saturation point' (meaning below the point at which shell and reef formation is possible; the Arctic Ocean, the northeastern Pacific and the California upwelling system already experience seasonally undersaturated conditions), while the tropical ocean (where current carbonate ion concentrations are higher) will experience the largest absolute decreases in carbonate ion concentration and pH (Barange et al. 2018; Harris et al. 2013). Warm water corals will be impacted by decreased carbonate ion saturation levels even where waters do not become undersaturated (Hoegh-Guldberg et al. 2017).

Even if global warming is limited to 1.5 °C, warm water corals are likely to suffer significant negative impacts, including changes to community composition and diversity, local extinctions and reductions in range and extent (IPCC 2019). Coastal seawater acidification can be intensified by additional carbon from riverine input or through coastal productivity stimulated from land-based nutrient inputs, or nutrients released from sediments, aquaculture, sewage discharges and other point sources (Gattuso et al. 2015). These impacts will have significant negative effects on coral reef–related tourism and fishery operations as well as on shellfish aquaculture operations (although see below for a discussion of the potential for aquaculture adaptation and expansion).

Climate change is also impacting the dissolved oxygen content in ocean systems across the globe. Warming-driven stratification of the water column, exacerbated by other physical and biogeochemical processes, reduces the dissolved oxygen content in ocean water (Barange et al. 2018; Breitburg et al. 2018; Gattuso et al. 2015; IPCC 2019; Jacox and Edwards 2011; Oschlies et al. 2018). In recent decades, oxygen concentration in coastal waters and the open ocean has decreased, while the prevalence and size of 'oxygen minimum zones' (OMZs), areas where oxygen consumption by sediment bacteria exceeds the availability of oxygen, have increased, especially in the tropics, although it is difficult to conclusively attribute these shifts to human activity in these regions (Barange et al. 2018; Breitburg et al. 2018; IPCC 2019; Oschlies et al. 2018; Stramma et al. 2010; Levin 2002). These trends are expected to continue, with the whole-ocean oxygen inventory expected to decrease by 1.6–2% (RCP 2.6) to 3.2–3.7% (RCP 8.5), and the global volume of OMZs expected to increase by 7.0 ± 5.6% by 2100 under RCP 8.5 (Barange et al. 2018; Fu et al. 2018; Gattuso et al. 2015; IPCC 2019). Increased deoxygenation will likely lead to habitat compression, shifts in distribution and losses in species abundance and biodiversity (Breitburg et al. 2018; Stramma et al. 2010; Levin 2002). Furthermore, observed deoxygenation is generally worse than modelled results, which emphasises the need to improve our understanding of the processes driving deoxygenation to reduce the model uncertainty in our projections (Bopp et al. 2013; Oschlies et al. 2018).

Deoxygenation and OMZs affect species in different ways and to different degrees depending on varying oxygen tolerances. While some hypoxia-adapted species may benefit, impacts on most fish and invertebrates will be negative, and may include restricted vertical and horizontal migration, compressed habitats, alterations to predator-prey interactions and increased competition, impairment of reproductive capacity, reduced growth, vision impairments, increased disease incidence, epigenetic changes and death from asphyxiation (Barange et al. 2018; Breitburg et al. 2018; Eby and Crowder 2002; Gattuso et al. 2015; IPCC 2019; Oschlies et al. 2018). The combination of ocean warming, increased acidity and decreased oxygen availability is predicted to result in significant decreases in both the average size and abundance of many important fishery species (Breitburg et al. 2018).

2.4 Altered Circulation Patterns

Water circulation in the ocean, known as the 'global conveyor belt', is responsible for the redistribution of heat and freshwater, influencing local climates, productivity levels and ocean chemistry. A warming climate increases inflows of warm freshwater (from increased precipitation and melting glaciers and sea ice), which can reduce the formation of sea ice and sinking of cold salt water. This influx slows parts of global conveyor belt circulation (Barange et al. 2018; IPCC 2019; Liu et al. 2017). The Atlantic Meridional Overturning Circulation and Gulf Stream, which are responsible for a significant portion of the redistribution of heat from the tropics to the middle and high latitudes as well as of the ocean's capacity to sequester carbon, are showing signs of weakening (Caesar et al. 2018; IPCC 2019; Thornalley et al. 2018; Barange et al. 2018) and may continue to do so under all RCP scenarios (IPCC 2019). In the Atlantic, this weakening is driving lower sea surface temperatures in the subpolar Atlantic Ocean and a warming and northward shift of the Gulf Stream, which is expected to further weaken in the coming decades (Caesar et al. 2018; Thornalley et al. 2018; Barange et al. 2018; Liu et al. 2017). These changes could lead to dramatic shifts in weather and local and regional climate patterns (IPCC 2019), which would have significant impacts on the ocean economy (e.g. through damage to infrastructure) and society as a whole.

All western boundary currents other than the Gulf Stream are expected to intensify in response to tropical atmospheric changes and shifts in wind patterns resulting from climate change and GHG concentrations, likely strengthening coastal storm systems (Barange et al. 2018; Yang et al. 2016). The intensity of the eastern boundary currents, responsible for the major coastal upwelling zones and thus for some of the most productive waters in the world, will also likely change, although there is more uncertainty around the severity and direction of these changes, as well as around the resulting impacts (Bakun et al. 2015; Barange et al. 2018; Brady et al. 2017). As the land and ocean warm at different rates, stronger upwelling-favourable winds may strengthen these patterns; however, increased thermal stratification may restrict the depth of upwelling waters, and thus limit the amount of nutrients brought with them (Bakun 1990; Barange et al. 2018; Jacox and Edwards 2011; Rykaczewski et al. 2015; Sydeman et al. 2014; Wang et al. 2015). The impacts of intensified upwelling may result in a net increase in nutrient inputs and primary productivity or, alternatively, increase the presence of low oxygen and more acidic waters along the continental shelf (Bakun et al. 2015; Barange et al. 2018). Changes in either direction will have critical impacts for the many valuable marine capture fisheries located in and around upwelling zones. The most recent estimations at a global scale show a decrease in primary productivity of 7–16% by 2100 for RCP 8.5, largely driven by changes to circulatory and upwelling patterns as well as thermal stratification (IPCC 2019). However, the interaction and relative importance of these forces, as well as of regional processes and seasonal variability, will vary across geographies (Barange et al. 2018; IPCC 2019), and thus local data collection and modelling will be necessary to inform management.

3 Connecting the Links Between Climate Change and the Ocean Economy

3.1 Capture Fisheries

3.1.1 Importance of Capture Fisheries to the Ocean Economy

In 2016, the United Nations Food and Agriculture Organization (FAO) estimated that marine capture fisheries produced 79.3 million metric tonnes (mmt) of landings, representing 46.4% of global seafood production (170.9 mmt) and $130 billion in first sale value (FAO 2018). It also estimated that approximately 30.6 million people participated—either full time, part time, or occasionally—in capture fisheries, operating approximately 4.6 million fishing vessels. Small-scale fisheries are the backbone of socioeconomic well-being in many coastal communities (Bene 2004; Béné et al. 2007, 2010), especially in the developing tropics where the majority of fish-dependent countries are located (Golden et al. 2016). Fish and fish products are also among the most traded food commodities in the world. In 2016, approximately 35% of production entered international trade for either human consumption or nonfood uses (FAO 2018). The 60 mmt ($143 billion) of fish products exported in 2016 constituted a 245% increase relative to 1976 exports ($8 billion). Over this time period, the rate of growth of exports from developing countries surpassed that from developed countries (FAO 2018). Finally, the average annual increase in fish consumption (3.2%) has outpaced the average annual increase in human population growth (1.6%), and demand for fish is projected to increase as the human population continues to grow and become increasingly wealthy (FAO 2018).

3.1.2 Impacts of Climate Change on Capture Fisheries

Climate change is significantly altering the ability for marine fisheries to provide food and income for people around the world (IPCC 2019). These changes are commonly viewed as occurring through impacts on either the distribution of fish stocks (i.e. where fish can be caught and by whom) or the productivity of fish stocks (i.e. how much fish can be caught). In general, productivity is predicted to decrease in tropical and temperate regions and increase toward the poles (Lotze et al. 2019) as marine organisms shift their distributions to maintain their preferred temperatures (Pinsky et al. 2013; Poloczanska et al. 2013; Poloczanska et al. 2016). These regional shifts in productivity, range and fishing opportunity are likely to result in regional discrepancies in food and profits from fisheries (Lam et al. 2016), with tropical developing countries and small island developing states exhibiting the greatest vulnerability to the climate change (Allison et al. 2009; Blasiak et al. 2017; Guillotreau et al. 2012).

In the remainder of this Sect. 3.1.2, we detail how both retrospective and forward-looking studies have revealed the impact of climate change on the distributions and productivities of marine fisheries and the implications of these observations and predictions for adapting fisheries management to climate change. In Sect. 3.1.3, we present results from a new study (Free et al. 2019b) that demonstrate the country-level economic and food provisioning benefits of reforming fisheries management to account for shifting distributions and productivities. Finally, in Sect. 3.1.4, we outline how fisheries could implement climate-adaptive reforms along a gradient of scientific, management and enforcement capacities.

Marine fish and invertebrates are shifting distributions to track their preferred temperatures. Adaptive international agreements that prioritise equitable outcomes will be necessary to ensure that management remains sustainable and just as species shift in and out of management jurisdictions.

Observed changes: As the ocean has warmed, marine fish and invertebrates have shifted their distributions to track their preferred temperatures (Perry et al. 2005; Dulvy et al. 2008; Poloczanska et al. 2013; Pinsky et al. 2013). In general, this has resulted in shifts poleward and into deeper waters. At a mean rate of 72 kilometres (km) per decade, marine species have been moving an order of magnitude faster than terrestrial species (Poloczanska et al. 2013). These distribution shifts are already generating management challenges (Pinsky et al. 2018). For example, a 'mackerel war' erupted in 2007 when the northeast Atlantic mackerel stock shifted from waters managed by the European Union, Norway and Faroe Islands into Icelandic and Greenland waters. Disagreements over the drivers of the shift, the expected duration of the shift, and appropriate catch reallocations resulted in the stock becoming increasingly overfished (Spijkers and Boonstra 2017).

Forecasted changes: The rate of distribution shifts and associated management conflicts are anticipated to increase under climate change. All studies forecast generally poleward shifts in species distribution and productivity under continued warming (Lotze et al. 2019), often with a decrease in species diversity in equatorial regions, an increase in diversity in poleward regions and the subsequent formation of novel marine communities (García Molinos et al. 2016; Cheung et al. 2016). These shifts are likely to increase the risk of management conflicts over transboundary stocks. For example, 23–35% of exclusive economic zones (EEZs) are expected to receive a new stock by 2100 under strong greenhouse gas mitigation (RCP 2.6) to business-as-usual mitigation (RCP 8.5) scenarios, respectively (Pinsky et al. 2018).

Implications for adaptation: Establishing and strengthening international institutions and agreements to better manage stocks shifting in and out of jurisdictions will be important. These agreements will need to be both adaptive, to ensure that management remains effective under continued uncertainty, and inclusive of all impacted groups, to ensure that outcomes are equitable. As with management decisions made at the fishery and community scales, these international agreements must engender procedural, distributional and recognitional equity if they are to be truly resilient (Matin et al. 2018; Meerow et al. 2019). See Opportunity for Action #3 in Sect. 3.1.4 for more detail.

Climate change is reducing the productivity of marine fisheries globally. Regional impacts are especially pronounced, with some regions experiencing large gains in productivity while others experiencing large losses. Resilience to climate change can be enhanced by implementing adaptive, inclusive and transparent 'primary fisheries management', by accounting for shifting productivity in assessment and management and by rebuilding overfished stocks. Solutions should be developed through processes that ensure procedural, distributional and recognitional equity at all stages.

Observed changes: Free et al. (2019a) estimate that ocean warming has already driven a 4.1% decline in the maximum sustainable yield (MSY), the maximum amount of catch that can be harvested for perpetuity, of 235 of the largest industrial fisheries over the past 80 years. The North Sea, which supports large commercial fisheries, and four East Asian marine ecoregions, which support some of the fastest-growing human populations, have experienced losses in MSY of 15–35%. Meanwhile, the Baltic Sea and other regions have seen increases in MSY of up to 15%. Changes in productivity are driven by changes in growth, mortality or recruitment rates resulting from changing environmental conditions, phenologies (i.e. mismatches in the timing of juvenile recruitment and food availability), disease or food web structures, as well as changes in carrying capacities resulting from distribution shifts or habitat degradation (Hollowed et al. 2013). In general, well-managed fisheries have been the most resilient to these changes while overexploited fisheries have been the most vulnerable (Britten et al. 2016; Free et al. 2019a).

Forecasted changes: An ensemble of six marine ecosystem models (Bryndum-Buchholz et al. 2019; Lotze et al. 2019) forecasts decreases in marine animal biomass of 4.8, 8.6, 10.4 and 17.2% by 2100 under RCPs 2.6, 4.5, 6.0 and 8.5, which represent increasingly severe greenhouse gas emissions scenarios. The ensemble model and its constituent models consistently predict reduced productivity in tropical to temperate regions and increased productivity at the poles. For example, marine animal biomass is forecast to decline by 15–30% in the North/South Atlantic, North/South Pacific and Indian Ocean basins by 2100 while increasing by 20–80% in the polar Arctic and Southern Ocean basins (Bryndum-Buchholz et al. 2019). Regional disparities in marine animal biomass become increasingly pronounced under increasingly severe emissions scenarios. The redistribution of catch potential will drive a concomitant redistribution of revenues (Lam et al. 2016) and nutrition (Golden et al. 2016; Hicks et al. 2019).

Implications for adaptation: First and foremost, in both low- and high-capacity fisheries systems, implementing general fisheries reforms will enhance resilience to climate change as well-managed fisheries are the most ecologically (Free et al. 2019a) and socioeconomically resilient to climate change. In low-capacity fisheries systems, this can be achieved through 'primary fisheries management' (Cochrane et al. 2011), which uses the best available science to inform precautionary management while building institutional capacity for adaptive and participatory co-management. To do so, adaptation policy should target the most vulnerable communities, which in fisheries are typically women and migrant fishers; those with highly fisheries-dependent livelihoods in terms of nutrition and income; and the agency of these individuals to adapt (Cinner et al. 2018). In high-capacity fisheries systems, this will involve accounting for shifting productivity in fisheries stock assessments and management procedures. See Opportunities for Action #1–2 and #4–5 in Sect. 3.1.4 for more detail.

3.1.3 Ability for management to mitigate the impacts of climate change

Most forecasts of the impacts of climate change on fisheries compare the maximum biological potential for food production today with that in the future (Cheung et al. 2010; Lam et al. 2016). While this is useful for understanding the biological limits of the ocean under climate change, it fails to consider the effects of alternative human responses (Barange 2019), which could either limit or exacerbate the impacts of climate change on society. The actions of fishers, management institutions and markets all influence the benefits derived from fisheries (Costello et al. 2016) and could mitigate many of the negative impacts of climate change (Gaines et al. 2018). *Thus, we present a recent analysis* (Free et al. 2019b)[1] *that documents the benefits countries stand to gain by implementing climate-adaptive fisheries management reforms that address both changes in species distribution and productivity due to climate change.*

Methods: Free et al. (2019b) forecasted the distributions and productivities of 779 harvested marine species out to 2100 under three greenhouse gas emissions scenarios (RCPs 4.5, 6.0 and 8.5), and compared the status of these fisheries and the amount of catch and profits derived from them under both climate-adaptive management and business-as-usual management. Under climate-adaptive management, fisheries management dynamically updates economically optimum harvest rates to match shifts in productivity, and transboundary institutions maintain management performance as shifts in distribution move stocks into new management jurisdictions. Under business-as-usual management, current (rather than economically optimal) harvest rates are initially applied and are gradually transitioned to open access as stocks shift into new management jurisdictions (see Free et al. 2019b for details on the management scenarios). Free et al. (2019b) then measured the extent to which climate-adaptive management could maintain catch and profits into the future and generate catch and profits relative to business-as-usual management.

Results: Even countries experiencing declines in fisheries productivity and catch potential would derive more catch and profits through climate-adaptive management than through business-as-usual management (Fig. 2.1). Furthermore, in many countries, adaptive management would not only reduce the impacts of climate change, but actually increase catch and profits relative to today (Fig. 2.1). Climate-adaptive fisheries management results in greater cumulative profits than business-as-usual management for 99% of countries under RCPs 6.0 and 8.5. It results in greater cumulative catches than business-as-usual management in 98% and 67% of countries in RCPs 6.0 and 8.5, respectively. Furthermore, under adaptive management, 71% and 45% of countries derive more catch and profits from fisheries in 2100 relative to today under RCPs 6.0 and 8.5, respectively. The impacts of climate change on fisheries and the opportunities and benefits of climate-adaptive fisheries management reforms can be explored for specific countries in an interactive web application created by the Sustainable Fisheries Group at the University of California, Santa Barbara (UCSB 2019).

[1] This paper is currently under peer review but a pre-print is publicly available on BioRxiv here: https://www.biorxiv.org/content/10.1101/804831v1.

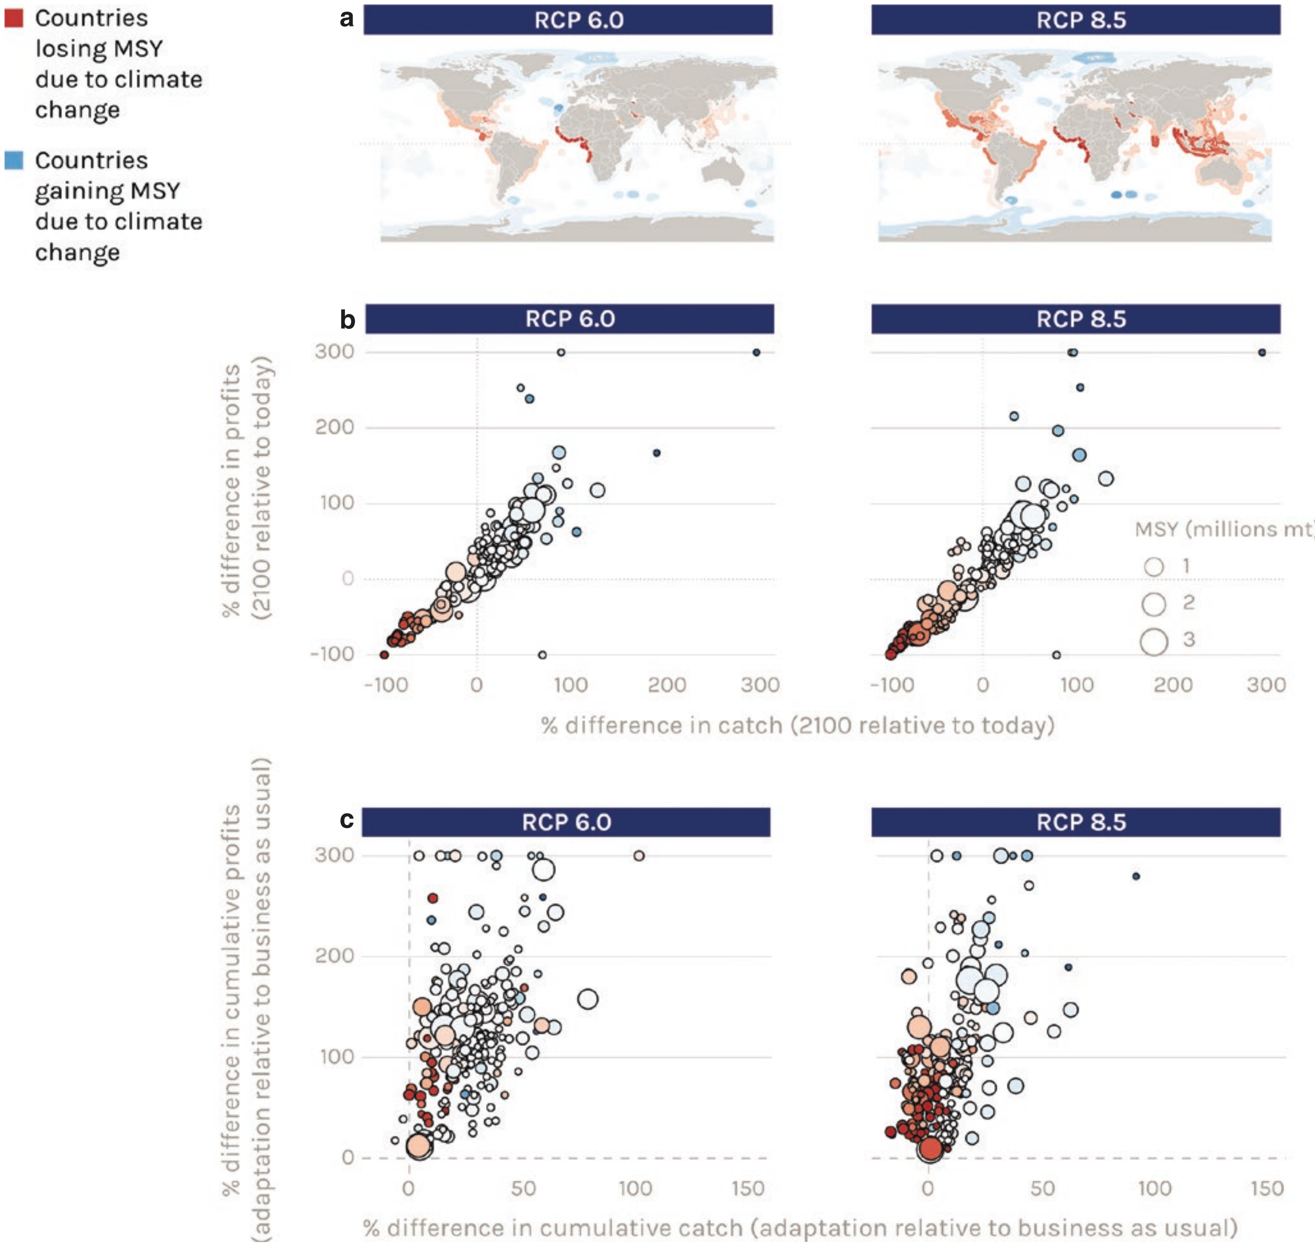

Fig. 2.1 Ability for adaptive fisheries management to mitigate impacts of climate change. *Notes:* (**a**) *shows that maximum sustainable yield (MSY) is forecast to decrease in equatorial exclusive economic zones (EEZs) and increase in poleward EEZs through 2100.* (**b**) *shows that adaptive management results in higher catch and profits in 2100 relative to today for many, but not all, EEZs despite climate change.* (**c**) *shows that adaptive management nearly always yields more cumulative profits than business-as-usual management and frequently yields more cumulative catches than business-as-usual management. In all panels, deeper reds show countries losing MSY and deeper blues show countries gaining MSY under climate change.* (Source: Adapted from Free et al. 2019b)

Implications for adaptation: Fisheries management that accounts for shifts in species distributions and productivities due to climate change will generate better outcomes than business-as-usual management in all countries, even those hardest hit by climate change.

Challenges for improving management include the lack of financial and technical capacity for monitoring and evaluating fisheries in many regions of the world, both for small-scale and industrial fisheries, and the conflicts emerging in fisheries due to climate change and other drivers (Spijkers et al. 2019). In the next section, we detail five key opportunities for action for implementing such reforms.

3.1.4 Opportunities for action and key conclusions

Building a socioecological system that is resilient to climate change is key to ensuring healthy, productive fisheries in the future. Below are five overarching, high-priority opportunities for designing fisheries management approaches in the context of a changing climate along a gradient of scientific, management and enforcement capacities:

1. **Implement best practices in fisheries management.** Historically, well-managed fisheries have been among the most resilient to climate change (Free et al. 2019a), and our results predict that well-intended, albeit imperfect, management will continue to confer climate resilience. Together, these results indicate that the wider implementation of best practices in fisheries management will mitigate many of the negative impacts of climate change.

   In higher-capacity systems, best practices include scientifically informed catch limits, accountability measures, regional flexibility in policy practices and the protection of essential fish habitats (Miller et al. 2018b). In the United States, such measures have contributed to dramatic declines in overfishing, increases in biomass and maintenance of catch and profits (NOAA 2018).

   In lower-capacity systems, best practices include implementing 'primary fisheries management' (Cochrane et al. 2011)—which uses the best available science and precautionary principles to manage data-poor and capacity-limited fisheries—and establishing local, rights-based management (Ojea et al. 2017) to incentivise sustainable stewardship.

   Rights-based management systems include catch share programmes, such as Individual Transferable Quotas (ITQs) and Territorial Use Rights in Fisheries (TURFs), which define property rights over catch and space, respectively (Costello et al. 2010). By giving users ownership of the resource, well-designed, rights-based management systems incentivise long-term stewardship and have been shown to promote compliance, prevent overfishing and increase profits (Costello et al. 2016; Costello et al. 2008; Melnychuk et al. 2011). Enforcement and the strength of fishing pressure limits are also key for successful fisheries management (Melnychuk et al. 2017) and contribute to a precautionary approach in the face of climate change. Overall, fisheries best practices confer ecological resilience by maintaining healthy stock sizes, age structures, and genetic diversity and building socioeconomic resilience by providing a portfolio of options to fishers and a buffer against climate-driven losses in any one target stock.
2. **Be dynamic, flexible and forward-looking.** Adapting to climate change will require dynamic, flexible and forward-looking management. This can be achieved by aligning management policies with the spatiotemporal scales of climate change, ecosystem change and socioeconomic responses (Holsman et al. 2019). In higher-capacity systems, this could involve four broad strategies. First, managers can envision and prepare for alternative futures using tools such as forecasts (Hobday et al. 2016), structured scenario planning (Moore et al. 2013), holistic ecosystem models (Gaichas et al. 2016), risk assessments (Holsman et al. 2017) and climate vulnerability analyses (Hare et al. 2016). Second, the proliferation of near real-time biological, oceanographic, social and/or economic data can be harnessed for proactive and dynamic adjustments in spatial and temporal management actions (Hazen et al. 2018).

   Third, developing harvest control rules that account for or are robust to changing environmental conditions affecting productivity can increase catch while reducing the probability of overfishing (Tommasi et al. 2017). Finally, all of these management procedures should be simulation tested through management strategy evaluations (Punt et al. 2016) to measure the efficacy of alternative strategies and their robustness under different climate scenarios (Punt et al. 2014).

   In lower-capacity systems, forward-looking fisheries management could include precautionary management to buffer against uncertainty (Richards and Maguire 1998) as well as management strategies that preserve a population's resilience, age structure and genetic diversity. For example, size limits, seasonal closures and protected areas can be used to protect the big, old, fecund females (BOFFs) that disproportionately contribute to reproductive output (Hixon et al. 2014) and to maintain the genetic diversity required to promote evolutionary adaptations to climate change.
3. **Establish and strengthen international institutions and agreements to better manage stocks shifting in and out of jurisdictions**. Shifting distributions are already generating management challenges and the rates of these shifts and associated conflicts are expected to increase with climate change (Pinsky et al. 2018; Spijkers and Boonstra 2017; Spijkers et al. 2019). New or strengthened international institutions and agreements will be necessary to ensure that management remains sustainable as stocks shift between jurisdictions.

   First, this will require sharing data between regional fisheries management organisations or countries to identify, describe and forecast shifting stocks. Second, it will require a commitment to using these shared data to inform collaborative management. For example, these data could be used to regularly and objectively update national allocations of catch or effort based on changes in distribution rather than historical allocations (e.g. Havice 2013; Aqorau et al. 2018). An alternative approach could be to develop fisheries permits that are tradeable across political boundaries, which would provide future resource users access to fisheries not yet in their waters and incentivise good management (Serdy 2016). Finally, incentivising the cooperation necessary to establish data sharing and collaborative management will require overcoming prevailing management mentalities that one party 'wins' while the other 'loses' when stocks shift across boundaries. This could involve broadening negotiations to allow for alternative avenues of compensation or 'side payments' (Miller and Munro 2004). In cases where establishing international cooperation proves difficult, marine protected areas (MPAs) placed along country borders could buy time for negotiations by protecting stocks as they shift across borders (Roberts et al. 2017). A more precautionary approach would be to put new fishing areas on hold until adaptive management can be put in place, as illustrated by the Central Arctic Ocean Fisheries Agreement (Schatz et al. 2019).

4. **Build socioeconomic resilience.** The impact of climate change on fishing communities can be reduced through measures that increase socioeconomic resilience and adaptive capacity to environmental variability and changing fisheries (Cinner et al. 2018; Charles 2012; Fedele et al. 2019). Across low- to high-capacity systems, these measures include policies that do the following:
   (a) facilitate flexibility, such as by supporting access to multiple fisheries and alternative livelihoods
   (b) provide better assets, such as the enhancement of fisheries technology and capacity
   (c) provide better organisation in the system, including through multilevel governance, community-based management and other governance structures (Holsman et al. 2019; Ojea et al. 2017)
   (d) promote agency and learning (Cinner et al. 2018)

   For example, policies that promote access to multiple fisheries provide fishers with a portfolio of fishing opportunities that can buffer against variability (Kasperski and Holland 2013; Cline et al. 2017), while policies that help diversify livelihoods reduce reliance on fisheries (Cinner et al. 2009; Daw et al. 2012). Increased mobility through technological enhancements can increase social resilience by allowing fishers to follow shifting stocks (Cinner et al. 2018), but can also result in the migration of fishers. Multilevel governance promotes flexibility in resource governance by matching ecological resilience and management across scales (Hughes et al. 2005).

   Community-based management can increase adaptive capacity by incorporating local knowledge and can improve sustainability by fostering a sense of stewardship (Gutiérrez et al. 2011). Spatial rights-based approaches such as TURFs may confer social resilience insofar as they are often community managed and allow fishers to generate revenues through other compatible activities such as tourism, recreation and aquaculture (Moreno and Revenga 2014). On the other hand, ITQs may confer a different kind of resilience because rights are defined over fish catches, not spatial areas, so they may be more resilient to range shifts arising from climate change. Furthermore, all of these measures can be designed to reduce fishing pressure and promote ecological resilience to climate change.

5. **Use principles of fairness and equity to drive policy decisions.** The challenges of maintaining fairness and equity, such as adequately including the representation and needs of vulnerable marine livelihoods (i.e. those of women, migrants, indigenous peoples), are likely to be created or amplified by climate change. For example, on a regional level, we expect to see greater impacts in the equatorial region, which could exacerbate existing patterns of food insecurity and poverty. In the case of more informal or unregulated economies and fishing activities (e.g. shellfish gathering, fish processing), which are most times performed by women (Harper et al. 2017) and marginalised groups (Barange et al. 2018), there is a risk to being left out from regulations, leading to maladaptation.

At a more local level, climate change can shift the distribution of resources, thereby changing the impact on human populations from past patterns. Without an adequate response, these impacts could lead to inequalities, unrest and severe social disruption, thus likely worsening outcomes in the face of climate change. Addressing the inequities created by climate change is valuable in its own right to stem these potential negative consequences and deliver increased social resilience and stability. At the same time, using fairness and equity to guide policies can also help foster important buy-in to policies necessary for addressing climate change effects so that adoption is swifter and more complete. Finally, developing equitable solutions can help uncover and target the underlying drivers of both existing inequities and climate change itself, thereby allowing for wholesale system transformation when it is necessary to create equitable resilience (Cohen et al. 2019; Matin et al. 2018; Meerow et al. 2019; Mikulewicz 2019). Thus, equity is not just a valuable goal of management and policy reform; it is also a critical input into these decisions as it serves as a functional driver of climate resilience.

3.2 Marine Aquaculture

3.2.1 Importance of Mariculture to the Ocean Economy

Aquaculture, the cultivation of aquatic animals and plants, is one of the fastest-growing industries in the world and now produces more seafood than wild capture fisheries (FAO 2018). Although marine aquaculture, hereafter called 'mariculture', currently represents only one-third of total aquaculture production (freshwater/inland aquaculture represents the remainder), this proportion is increasing. In 2016, mariculture produced 38.6 mmt of seafood worth $67.4 billion at first sale. Over half of this production was shelled molluscs (58.8%), while finfish and crustaceans represented 23% and 17% of production, respectively (FAO 2018). When converted to edible food equivalents, finfish mariculture provides the most food by volume (Edwards et al. 2019). Additionally, fed aquaculture (including finfish and crustaceans), which requires feed inputs, is growing faster than unfed bivalve aquaculture due to increasing demand for these commodities (Tacon et al. 2011; Hasan 2017).

3.2.2 Impacts of climate change on mariculture

Mariculture production is vulnerable to climate change through impacts both on the cultivated organisms as well as on the cost and infrastructure of conducting mariculture operations. Like wild marine species, cultivated marine species are impacted by changing environmental conditions (Weatherdon et al. 2016), but unlike wild species, humans can induce accelerated adaptation in cultivated species through selective breeding (Sae-Lim et al. 2017). Unlike most wild capture fisheries, mariculture operations require a significant amount of shore- and ocean-based infrastructure for cultivating marine species through multiple life stages. Both shore- and ocean-based infrastructure are vulnerable to storms, which are expected to increase in frequency and intensity under climate change (IPCC 2019), and ocean-based infrastructure such as lines, cages and pens must be actively moved in response to poor environmental conditions such as harmful algal blooms, hypoxia, or changing salinity or temperature, which increases costs and disproportionately impacts farmers unable to relocate (Dabbadie et al. 2018). As with capture fisheries, the impacts of climate change on aquaculture are expected to vary by location, species and method of production (Soto et al. 2018). The primary threats to unfed bivalve aquaculture and fed finfish and crustacean aquaculture are the following:

1. **Ocean warming** is expected to raise mortality rates and lower productivity for higher-trophic-level species (bivalves, finfish, crustaceans) (Rosa et al. 2014).
2. **Sea level rise** will increase the intrusion of saline water into deltas and estuaries compromising brackish-water aquaculture (De Silva 2012; Garai 2014), and shifting shoreline morphology could reduce habitat availability (bivalves, finfish, crustaceans).
3. **Increasing storm strength and frequency** pose risks to infrastructure (De Silva 2012), and increased weather variability has been associated with lower profits (bivalves, finfish, crustaceans) (Li et al. 2014).
4. **Ocean acidification** impedes the calcification of mollusc shells (Gazeau et al. 2013) resulting in reduced recruitment, higher mortality (Barton et al. 2012; Green et al. 2013) and increased vulnerability to disease and parasites (bivalves).
5. **Increasing rainfall** will raise the turbidity and nutrient loading of rivers, potentially causing more harmful algal blooms (HABs) that reduce production and threaten human health (bivalves, finfish, crustaceans) (Himes-Cornell et al. 2013; Rosa et al. 2014).
6. **The emergence, translocation and virulence of disease, pathogens and parasites** are impacted by climate change. For example, warming can increase susceptibility to disease, promote the influx of new pathogens (Rowley et al. 2014) and increase the toxicity of common pollutants (bivalves, finfish, crustaceans) (Fabbri and Dinelli 2014).
7. **Reduced feed availability** resulting from climate change and/or overfishing could challenge the growth potential for fed aquaculture (finfish, crustaceans) (Froehlich et al. 2018a).

3.2.3 Potential for mariculture production to grow under climate change

While marine capture fisheries production has stagnated over the past three decades, mariculture production has expanded rapidly, and is likely to become the source of new seafood production as the human population and demand for seafood grow (FAO 2018). However, the extent to which climate change could impede the ability for sustainable mariculture to meet growing food demand is unknown (IPCC 2019). **Although there are no global-scale estimates of how climate change is likely to impact mariculture profitability and productivity, four recent studies collectively suggest that the potential for sustainable and profitable mariculture is likely to remain high under climate change.**

First, Gentry et al. (2017) mapped the biological potential for mariculture and estimated that bivalve and finfish mariculture could respectively generate 767.7 mmt and 15.6 billion mt of production per year (>700 times more production than today). Second, the Blue Paper *The Future of Food from the Sea* (Costello et al. 2019) refined this analysis to account for economic feasibility and the limited availability of feed for fed finfish aquaculture, and estimated that bivalve and finfish mariculture could respectively generate 483.0 mmt and 10.5 mmt of production per year under current prices and feed compositions (~21 times more production than today). Third, Froehlich et al. (2018b) forecasted mariculture production potential under a high emissions scenario (RCP 8.5) and found only slight declines in suitable habitat and production potential across continents.

Finally, Klinger et al. (2017) suggest that breeding a larger proportion of mariculture stocks for fast growth could, on its own, more than offset the forecasted declines in productivity. In the remainder of this Sect. 3.2.3, we provide a brief overview of this chain of evidence.

1. **Enormous areas of the ocean are suitable for bivalve and finfish mariculture and the vast majority of countries would need to farm less than 1% of their exclusive economic zones to match current levels of seafood consumption.** Gentry et al. (2017) mapped the biological production potential for finfish and bivalve mariculture based on the growth potential of 180 mariculture species (120 finfish, 60 bivalves) constrained by their temperatures, dissolved oxygen levels, primary production tolerances and existing human uses (i.e. protected areas, shipping lanes and oil rigs). Overall, they estimated an enormous untapped potential for mariculture: bivalve and finfish mariculture could generate 767.7 mmt (over 2.5 million square kilometres [km^2] of suitable habitat) and 15.6 billion mt per year (over 11.4 million km^2), respectively. By comparison, bivalve and finfish mariculture currently produce only 15.3 and 7.7 mmt per year, respectively (FAO 2018). However, their analysis did not consider the economic feasibility of this production or the limited availability of feed for fed mariculture.
2. **Current mariculture production is far under capacity even after accounting for economic feasibility and limited feed availability. Advancements in feed technology would dramatically expand the production potential of finfish mariculture.** In their Blue Paper, Costello et al. (2019) refined the Gentry et al. (2017) analysis by calculating the cost and feed demand of their production estimates and assuming that mariculture production will occur only in profitable areas and that finfish mariculture production is capped by feed availability. They show that global- and country-level mariculture production is significantly under capacity. Bivalve production of 483.0 mmt should be possible at today's prices for maricultured bivalves ($1400 per mt of blue mussels). This is 467.7 mmt (>3000%) more than the current production of 15.3 mmt. Additionally, 10.5 mmt of finfish production should be possible at today's prices for maricultured finfish ($7000 per mt of Atlantic salmon) and today's feed composition. This is 2.8 mmt (36%) more than the current production of 7.7 mmt. However, technological advances resulting in a 95% reduction in the reliance of feed on fish ingredients (Oliva-Teles et al. 2015) would unlock a 209.6 mmt (>2700%) increase in finfish production to 217.3 mmt. The majority of these underages in mariculture production occur in equatorial countries (Fig. 2.2 on the following page), suggesting that mariculture expansion could mitigate the losses in capture fisheries productivity expected for these regions, potentially offsetting some of the inequities associated with these climate change impacts. Furthermore, mariculture operations can provide a critical source of jobs and income to local communities, especially to vulnerable groups such as unskilled workers (Irz et al. 2007) who might otherwise be made significantly worse off by climate change.
3. **Although climate change is expected to reduce mariculture production potential, the magnitude of this reduction is small relative to the sheer potential for production.** Froehlich et al. (2018b) extended the work of Gentry et al. (2017) to predict how finfish and bivalve mariculture will change from now to 2090 under the warming, acidification and primary productivity shifts associated with a high emissions scenario (RCP 8.5). They forecast a global increase in the suitable habitat available for finfish mariculture, particularly in polar and subpolar regions. Conversely, they forecast a global decrease in the suitable habitat available for bivalve mariculture due to the negative impact of ocean acidification. In both sectors, the growth and production potential of the suitable habitat decreases over time. As a result, global mariculture production is likely to decline by mid-century, with the greatest certainty around bivalve declines. However, the relevance of these declines is unclear, because Froehlich et al. (2018b) do not publish the nominal production potential (i.e. metric tonnes of food) for 2090. Even if climate change reduced the 495.5 mmt of mariculture production estimated to be economically feasible with today's feed technology (Costello et al. 2019) by 90%, mariculture would still be 28% more productive than it is today (49.4 mmt versus 38.6 mmt).
4. **Breeding a larger proportion of mariculture stocks for fast growth could more than offset the negative impacts of climate change on mariculture production potential.** Klinger et al. (2017) mapped the production potential of three important finfish mariculture species—Atlantic salmon (*Salmo salar)*, gilthead seabream (*Sparus aurata*) and cobia (*Rachycentron canadum*)—under a

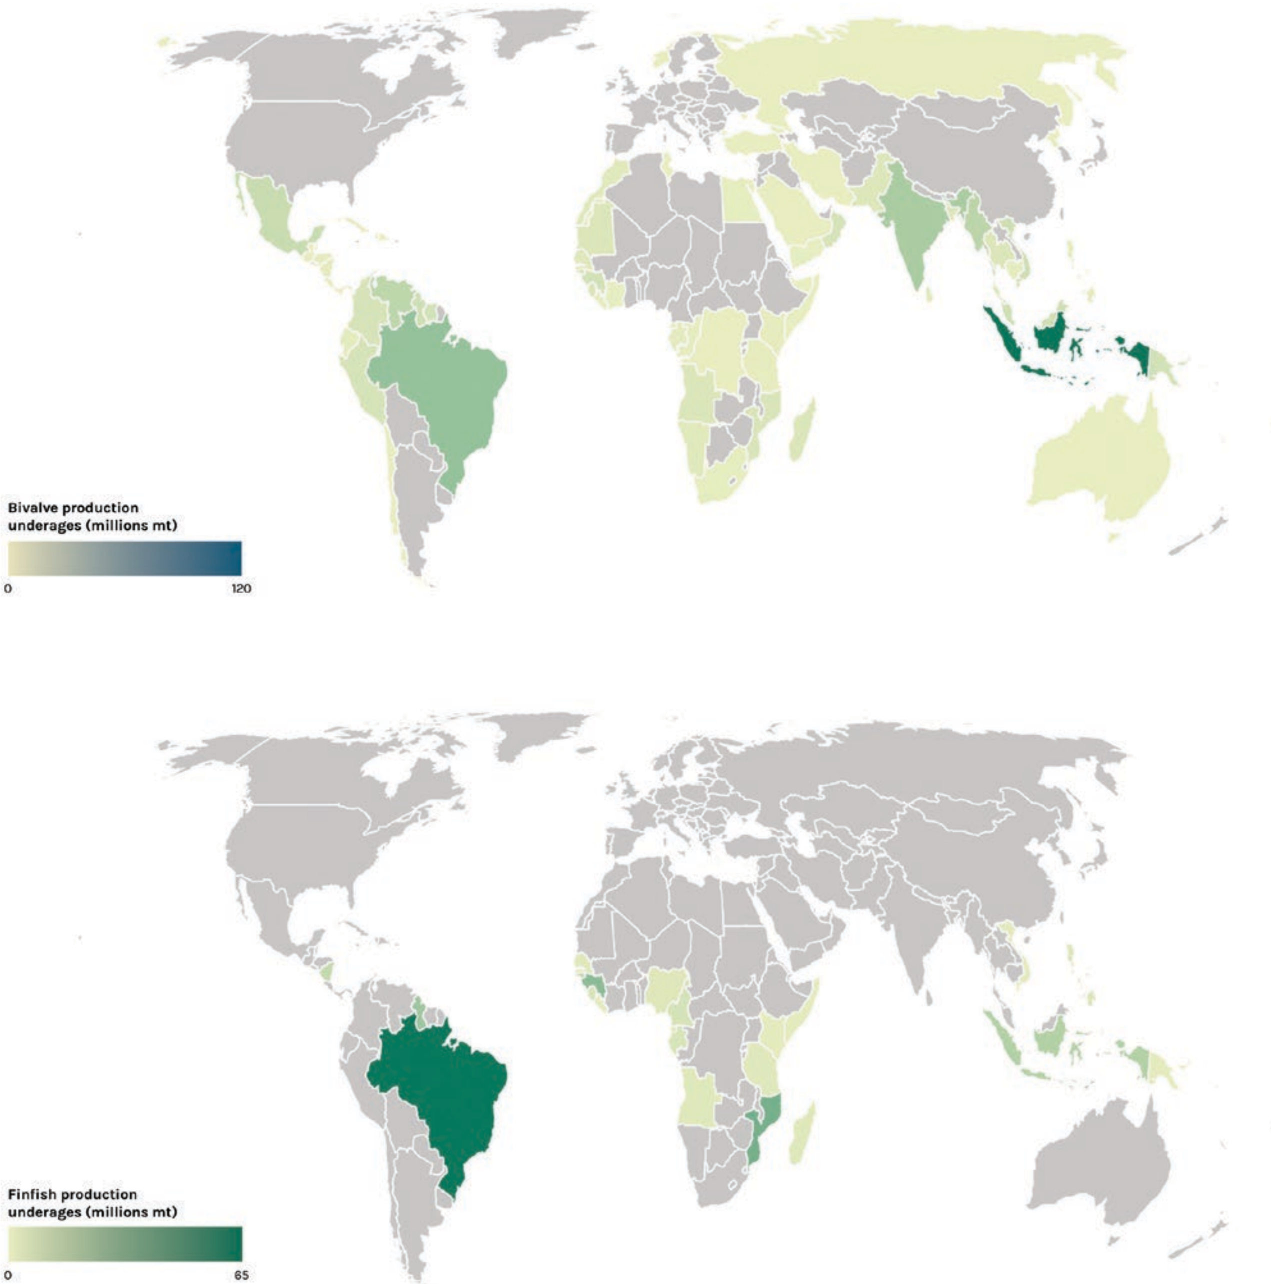

Fig. 2.2 Mariculture production underages for bivalves and finfish. *Notes: Mariculture production underages for bivalves at current prices ($1700/mt for blue mussels) (top map) and finfish at current prices ($7000/mt for Atlantic salmon) with a 95% reduction in the reliance of feed on fish ingredients (bottom map).* (Source: Adapted from Costello et al. 2019)

high emissions scenario (Geophysical Fluid Dynamics Laboratory Climate Model version 2.5 and estimated that increases in annual growth rates of 25–41% would be required to offset warming-induced declines in annual growth rates. They found that selective breeding programmes for faster growth in these species would increase growth rates by 10–15% per generation or by 100–200% over multiple generations—more than enough to offset the negative impacts of climate change. Given that only 10% of global mariculture production is currently derived from selectively bred stocks (Gjedrem et al. 2012), breeding a larger proportion of stocks for fast growth could, on its own, offset the negative impacts of climate change predicted by Froehlich et al. (2018b).

Although these four studies collectively present a chain of evidence to suggest that mariculture potential will remain high under climate change, they do not consider the social

(Froehlich et al. 2017), regulatory (Abate et al. 2016) or capacity barriers to mariculture development (Gentry et al. 2019); the challenges posed by climate-driven increases in HABs, diseases and storm frequency (IPCC 2019); or the environmental impacts of mariculture (Clavelle et al. 2019). In the next Sect. 3.2.4, we detail these challenges.

3.2.4 Barriers and Trade-Offs in the Expansion of Mariculture

If the potential for mariculture production is so large, why is current production so low? This gap is likely driven by two factors: a lack of expertise and capacity for conducting mariculture operations in many developing countries; and challenging regulatory barriers for developing mariculture operations in many developed countries. First, countries with low or crashed mariculture production exhibit lower GDPs and business friendliness scores than countries with stable or increasing mariculture production (Gentry et al. 2019). In Palau, for example, many mariculture operations have been initiated with outside funding but failed once the initial funding period ended. The longest-running mariculture operation in Palau is a government subsidised clam hatchery that would be unprofitable without government support (Y. Golbuu, personal communication). Second, countries with stricter environmental regulations have exhibited lower production and production growth than countries with more lenient regulations (Abate et al. 2016). For example, despite having one of the largest EEZs and longest coastlines, the United States produces only 1% of global mariculture (FAO 2018) due to precautionary regulations on mariculture zoning (Wardle 2017; Sea Grant California et al. 2019).

Mariculture operations can also pose a risk to marine ecosystems and the wild capture fisheries supported by these ecosystems (Clavelle et al. 2019). They can degrade habitats (Richards and Friess 2016), reduce water quality (Price et al. 2015), spread disease (Lafferty et al. 2015), hybridise with wild species (Lind et al. 2012) and introduce invasive species (Diana 2009). The expansion of mariculture should depend on adopting best practices for preventing or reducing these impacts (Klinger and Naylor 2012) including by doing the following:

1. using marine spatial planning to site mariculture in productive and profitable areas that minimise impacts on ecosystems
2. conducting offshore or integrated multitrophic mariculture to reduce eutrophication risk
3. expanding unfed bivalve mariculture, which has lower environmental impacts compared with fed finfish mariculture

See the Blue Paper *The Future of Food from the Sea* (Costello et al. 2019) for more details regarding the ecosystem impacts of mariculture and the opportunities for adaptation to reduce these impacts.

3.2.5 Adapting marine aquaculture to climate change

Selective Breeding for Fast Growth

Although selective breeding—the breeding of cultivated plants and animals to inherit specific traits—has historically been implemented less in aquaculture than in terrestrial farming (Gjedrem et al. 2012), aquaculture species are increasingly being bred to increase productivity and disease resistance (Gjedrem and Baranski 2009). The majority of breeding programmes have focused on increasing growth rates and maximising productivity and have been met with success. For example, Atlantic salmon breeding programmes have increased harvest weight by 12% per generation with cumulative genetic gains of ~200% over multiple generations (Janssen et al. 2016). Similarly, seabream breeding programmes have increased harvest weight by 10–15% per generation with cumulative genetic gains of ~100% over multiple generations (Janssen et al. 2016). These cumulative gains exceed the 25–41% total increase in annual growth rate thought to be necessary to offset the most extreme climate-induced decreases in mariculture productivity (Klinger et al. 2017); thus, selective breeding for fast growth rates alone could be sufficient to offset many of the negative impacts of climate change on mariculture.

Selective Breeding for Temperature Tolerance

Selective breeding for fast growth rates at elevated temperatures could further offset the impacts of climate change on mariculture but has yet to be widely implemented (Gjedrem et al. 2012) and has been met with mixed success (Gjedrem and Baranski 2009; Sae-Lim et al. 2015). Some selective breeding programmes have successfully resulted in increased temperature tolerances (Sae-Lim et al. 2017), but these breeding programmes can be costly (Ponzoni et al. 2008; Gjedrem et al. 2012). Furthermore, the use of selectively bred fish can pose risks to wild populations and ecosystems (Lind et al. 2012). Cultured fish frequently escape from aquaculture facilities (Jensen et al. 2010) and can interbreed with wild fish, leading to reduced genetic variability and a reduction in fitness in wild populations (Hutchings and Fraser 2008). However, in tropical countries where wild populations are projected to diminish (Lotze et al. 2019), this risk may be inherently reduced or deemed acceptable under climate change.

Risk-Based Planning and Environmental Monitoring Systems

The siting of mariculture farms based on risk-based zoning coupled with the active monitoring and responsive relocation of pens, cages and lines could help to minimise the impacts of both climate change and climate variability on mariculture production potential (Soto et al. 2018). To date, most mariculture site selections have been ad hoc, but a growing number of national and regional authorities are beginning to plan mariculture zoning using risk analysis (Aguilar-Manjarrez et al. 2017; Xinhua et al. 2017; Lester et al. 2018; Sainz et al. 2019). After siting mariculture farms in locations forecast to experience low climate risk, environmental monitoring systems could be used to track changes in environmental conditions, provide early warnings about oncoming environmental risks (e.g. HABs) and give farmers the opportunity to prepare for adverse conditions or relocate cages, pens and lines if logistically feasible (Soto et al. 2018).

Access to Affordable Credit and Insurance

Policies that increase mariculture farmers' access to credit and insurance options will also help promote the development and expansion of mariculture in the face of climate change (Soto et al. 2018). Access to affordable credit is necessary for funding both the upfront capital costs of establishing a mariculture farm as well as the annual operating costs required to adapt to or recover from climate-induced stressors (Karim et al. 2014). Increased access could be promoted through microfinance schemes or loan guarantee funds (Soto et al. 2018). Similarly, increasing storm frequency and intensity will necessitate providing more insurance options for mariculture farmers. Pilot programmes in China and Vietnam indicate that insuring small-scale farms, which are particularly vulnerable and also major contributors to food security, is a profitable investment (Nguyen and Pongthanapanich 2016; Xinhua et al. 2017).

The expansion of mariculture depends on it becoming a more efficient and lower-risk business endeavour and the insurance-pooled model used in these pilot programmes has helped raise production efficiencies while reducing production and market risks.

Reducing Feed Limitations for Fed Mariculture

Innovations in feed technology could greatly enhance the potential for fed mariculture (Costello et al. 2019; Froehlich et al. 2018a) and increase the opportunities for production under climate change. The amount of feed available for mariculture can be increased through a variety of mechanisms including the following:

1. ending over- and underfishing of the forage fish fisheries targeted for the production of fish meal (FM) and fish oil (FO) from whole fish (Froehlich et al. 2018a)
2. processing a larger proportion of landings for trimmings and diverting these by-products to the production of FM and FO (Jackson and Newton 2016)
3. reducing the amount of FM and FO used in the diets of non-carnivorous aquaculture species such as carp and other freshwater fishes, and terrestrially farmed species such as pigs and chickens (Froehlich et al. 2018a)
4. replacing fish ingredients with alternative sources of protein
5. increasing feed conversion rates

3.2.6 Opportunities for action and key conclusions

1. **Mariculture can provide food and income in countries losing access to capture fisheries.** Current mariculture production is far below potential production in many countries and the continued development of mariculture could provide food and employment in countries with climate-driven declines in capture fisheries.
2. **Expanding mariculture will require preventing, reducing and accepting the environmental trade-offs of mariculture.** Mariculture poses risks to marine ecosystems and capture fisheries and its expansion has frequently been impeded by these concerns. Expanding mariculture will depend on preventing and reducing these risks and establishing clear best practices that will help ease the regulatory burden.
3. **Finfish mariculture could generate more food and income through advancements in feed technology.** The production potential of finfish mariculture is challenged by the availability of fishmeal and fish oil from capture fisheries. Optimally managing forage fisheries, processing by-products for FM and FO, removing FM and FO from the diets of non-carnivorous fish and terrestrially farmed animals and replacing fish ingredients with alternative sources of protein would increase the viability of finfish mariculture.
4. **Mariculture species should be selectively bred for fast growth and robustness to climate change.** Despite the advantages of selective breeding, only 10% of global mariculture production is currently derived from selectively bred stocks (Gjedrem et al. 2012). Breeding a larger proportion of aquaculture stocks for fast growth could, on its own, offset the negative impacts of climate change on mariculture (Klinger et al. 2017). However, this will also necessitate increased efforts to reduce escapement, minimise pollution and mitigate other potential negative environmental impacts of mariculture.
5. **Increase access to financial services such as credit and insurance.** Mariculture is expected to become more expensive and riskier under climate change; increased access to credit and insurance for mariculture farmers will be necessary to assist with these costs and risks.
6. **Siting mariculture farms in low-risk areas and actively monitoring and responding to changing environmental conditions can enhance resilience to climate change.**

3.3 Marine and Coastal Tourism

3.3.1 Importance of marine tourism to the ocean economy

Marine and coastal tourism, referred to collectively as ocean tourism in this report, was the second-largest ocean-related economic sector in 2010, next to offshore oil and gas (OECD 2016). Ocean tourism is projected to be the top contributor of ocean industries by 2030 in terms of production value, when it will account for 26% of the ocean-based economy, compared with 21% for oil and gas (OECD 2016). Ocean tourism dwarfs the contribution of industrial capture fisheries, which constitute only 1% of ocean-based industries' production value (not accounting for artisanal fisheries, which are a critical component of the economies of Asia and Africa). The range of ocean tourism activities include beach tourism, recreational fishing, swimming, snorkelling, diving, whale watching, and taking cruises, among others. Ocean tourism's global direct value added was estimated at $390 billion in 2010, directly providing seven million full-time jobs. In addition, the ocean is a source of recreation for millions of people in the developed and developing worlds (Ghermandi and Nunes 2013; Arlinghaus et al. 2019). For comparison, the global value added of industrial capture fisheries was $21 billion in 2010 (OECD 2016), providing 11 million full-time jobs (artisanal fisheries not included).

Ocean tourism directly supports the livelihoods of millions of people and the economies of the developing tropics and many small island developing states. For example, coral reef tourism alone contributes over 40% of the gross domestic products of Maldives, Palau and St. Barthélemy (Spalding et al. 2017; Siegel et al. 2019). Despite the importance of ocean tourism in the economy, data and research on the impacts of climate change in the tourism sector are limited (Scott et al. 2012). Because coral reef tourism is one of the best-studied sectors (Scott et al. 2012), and potentially one of the most valuable ocean tourism options for many coastal nations, we focus our analysis on this sector.

Coral reef tourism is worth $35.8 billion globally every year (Spalding et al. 2017). We present a first- of-its-kind analysis of how climate change will affect coral reef tourism values at a country/territory level and explore options for nations and local communities to best prepare for the impacts of climate change.

3.3.2 Impacts of climate change on marine tourism

Weather conditions and attractiveness/uniqueness of the environment are key factors drawing people to ocean tourism (Moreno and Amelung 2009), and climate change impacts both. Understanding the potential impacts of climate change on tourism requires understanding how climate change will impact the physical and ecological resources on which tourism depends.

Marine heatwaves, or periods of extremely high ocean temperatures, have affected marine organisms and ecosystems (e.g. fisheries, coral reefs) in the last two decades and are expected to increase in frequency, intensity, duration and spatial extent (IPCC 2019). Marine heatwaves have critical impacts over habitat formation species (e.g. seagrasses, corals, kelps) that can disrupt the provision of ecosystem services (Smale et al. 2019). Future ocean warming will increase the frequency, intensity and spatial extent of bleaching events (Donner et al. 2005; IPCC 2019) that cause coral reef mortality (e.g. Arceo et al. 2001) and a subsequent reduction in reef fish diversity and numbers (e.g. Graham et al. 2007) that on-reef tourism depends on. Storms and storm surges are also expected to increase in intensity and become more frequent (IPCC 2019), causing a reduction in the desirability of a place for tourism, disrupting transportation (flights and ferries), and potentially destroying the coastal infrastructure that supports tourism. Sea level rise impacts coastal integrity and coastal assets and, together with extreme events, causes coastal erosion that, if constrained by urbanisation, can lead to coastal squeeze (Toimil et al. 2018; Scott et al. 2012). This has a known negative impact on visitors' perceptions and associated economic impacts (Scott et al. 2012). Ocean warming also affects fisheries productivity (Free et al. 2019a) and the migration patterns of species that are major draws for tourism (e.g. whales, sharks, turtles) (e.g. Lambert et al. 2010).

Climate change interacts with coral reef tourism through its direct impact on the following:

1. coral reefs and associated species on which some reef tourism directly depends (e.g. snorkelling, diving, recreational fishing)
2. weather conditions that drive a user's preference for the place
3. coastal infrastructure that supports tourism

For ocean tourism that directly depends on healthy coral reef ecosystems, such as diving and snorkelling (on-reef tourism), changes in reef conditions are expected to impact tourists' preferences and coral reef tourism's economic values. While activities that do not directly depend on reefs (i.e. reef-adjacent activities such as white sand beaches and sunbathing) are also expected to be affected by climate change (directly and indirectly through processes such as the wave attenuation role of reefs and coral reefs as a source of white sand), the magnitude of the impact is hard to measure.

3.3.3 Economic Impacts

Economic Impacts on Coral Reef Tourism

We use the coral reef tourism values per country and territory reported by Spalding et al. (2017) to represent current coral reef tourism values. These values are composed of on-reef and reef-adjacent tourism values.

Chen et al. (2015) performed a meta-analysis of how climate change impacts, in the form of changes in sea surface temperature (SST) and ocean acidification (using atmospheric CO_2 levels as a proxy), have affected and will continue to affect coral reef health and coral reef tourism values at the regional and global levels. We used their model to project how changes in SST and ocean acidification will change coral cover at the country level and how these changes in reef conditions would translate to changes in tourism values.

We project per-country future tourism value changes (with 2019 as a baseline) using the SST and CO_2 projections for RCP 2.6, 4.5, 6.0 and 8.5 climate scenarios from the CMIP5 Coupled Model Intercomparison Project (Taylor et al. 2012). For this report, we present the results for 2100 only to be consistent with the fisheries and aquaculture projections. These are the model's assumptions about how ocean warming and acidification affect coral reef cover and tourism values:

SST effect

- When the annual mean SST is less than 22.37°, a 1% increase in SST leads to a 0.67% increase in live coral coverage (relative to the percent of live corals available prior to changes in temperature).
- When SST is between 22.37° and 26.85°, a 1% increase in SST leads to a 1.59% increase in live coral coverage.
- When SST is greater than 26.85°, a 1% increase in SST leads to a 2.26% decrease in live coral coverage.

Ocean acidification effect

- Using atmospheric CO_2 as a proxy (Table 2.2), a 1% increase in CO_2 decreases live coral coverage by 0.61%.

Effect of changes in coral cover to coral reef tourism values

- A 1% decline in coral cover decreases coral reef value by 3.81%. We limit the effect of climate change to on-reef tourism values only.

Other factors not accounted for in the model above are the effects of climate change–associated increases in ocean disturbances such as storms, mass bleaching events that cause extensive reef mortality (Donner 2009; Frieler et al. 2013; Hughes et al. 2017, 2018), heat waves (Smale et al. 2019), sea level rise (Gattuso et al. 2018), algal blooms, jellyfish blooms, climate change–related diseases (Sokolow 2009) and water and electricity supply disruptions (Weatherdon et al. 2016). Also important and not included is the confounding effect of local stressors such as nutrient pollution and illegal and destructive fishing, which negatively impact tourism values.

Table 2.2 Global atmospheric CO_2 concentrations (ppm) for different RCPs using CMIP5

Year\RCP	2.6	4.5	6.0	8.5
2019	409.80	408.88	407.40	412.82
2030	430.78	435.05	428.88	448.83
2050	442.70	486.54	477.67	540.54
2100	420.90	538.36	669.72	935.87

Notes: PPM stands for parts per million, RCP for Representative Concentration Pathway and CMIP5 for Coupled Model Intercomparison Project 5

Nutrient enrichment has been shown to increase the susceptibility of coral reefs to bleaching (Wiedenmann et al. 2013), increase the severity of coral diseases (Bruno et al. 2003) and increase the vulnerability of coral reefs to ocean acidification (Silbiger et al. 2018). Furthermore, the poleward movement (Price et al. 2019), potential thermal evolution/adaptation (Speers et al. 2016; Donner 2009) and species-specific responses of corals (Fabricius et al. 2011) are not accounted for in our projections. All these additional climate change–induced stressors and the confounding effect of local stressors impact local and national economies (Hoegh-Guldberg et al. 2018).

The combined effect of warming (SST) and ocean acidification as factors affecting coral reef cover and tourism values results in predictions of negative effects for all countries, with magnitudes dependent on the climate pathways (Fig. 2.3, Table 2.3).

For the high-emissions scenario of RCP 8.5, which is characterised by considerable increases in greenhouse gas emissions, coral cover is expected to be reduced by 72–87% (relative to the present coral cover) and on-reef tourism values by over 90% from 2019 to 2100 due to combined ocean warming and acidification. The reduction will be less severe under a stabilisation scenario of RCP 4.5 with an expected reduction of 12–28% and 36–66% in coral cover and on-reef tourism values, respectively. Note that the reduction in coral cover is still conservative as other factors such as bleaching events, storms and other climate stressors, which are expected to intensify and become more frequent, are not included in the model.

Brander et al. (2012) projects that ocean acidification will cause a 27.5% reduction in global coral cover by 2100 under RCP 8.5 (with 2000 as the baseline year). This value is in line with Chen et al. (2015), which our projections are based on,

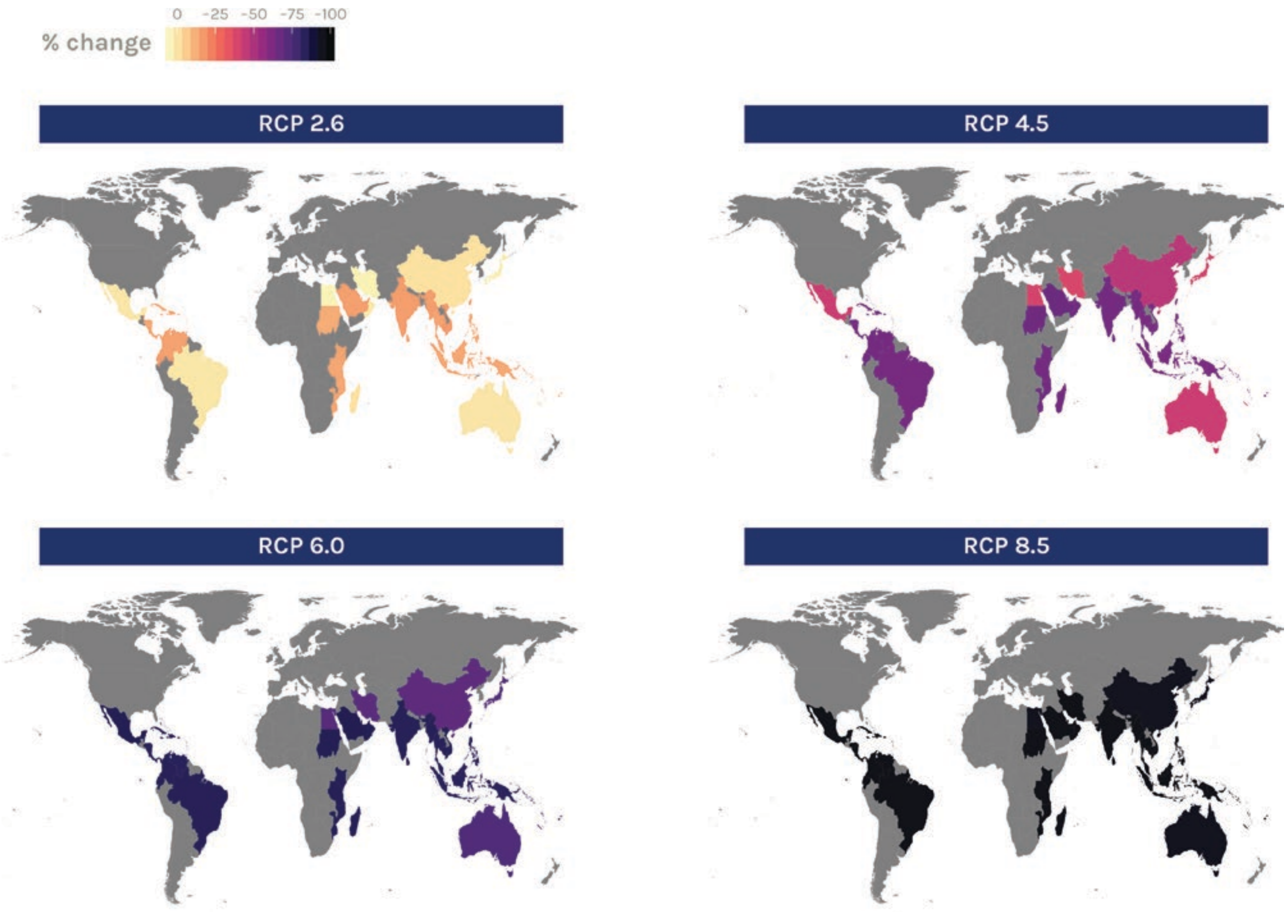

Fig. 2.3 Percent change in coral reef tourism values in 2100 for different climate projections. *Notes: Values in 2100 are relative to those in 2019. See* Table 2.3 *for country values*. (Source: Model adapted from Chen et al. 2015)

Source: Country-level tourism values data provided by M. Spalding. Model for change in coral cover adapted from Chen et al. (2015)
Notes: Climate change effect. Summary table for all countries and territories with over 50 square kilometres of reef, and total reef-related expenditures of more than $10 million per year. On-reef tourism value pertains to in-water activities such as diving, snorkelling and glass-bottom boats. Adjacent-reef tourism value captures a range of indirect benefits from coral reefs, including the provision of sandy beaches, sheltered water, seafood and attractive views

which indicates a coral cover reduction of ~31% due to ocean acidification and ~28% due to ocean warming (for RCP 8.5). Our projections have not incorporated the effects of bleaching, which is expected to be more frequent in the future and can be a greater driver of coral mortality under climate change. Speers et al. (2016) modelled the effects of combined ocean warming, acidification and intensifying bleaching on changes in coral cover and projects that current global coral cover will be reduced by 92% by 2100 under RCP 8.5.

The top five countries with the highest coral reef tourism values are Egypt (~$7 billion/year), Indonesia (~$3.1 billion/year), Mexico (~$3 billion/year), Thailand (~$2.4 billion/year) and Australia (~$2.2 billion/year). These five countries have 45–86% of their coral reef tourism values based on on-reef activities (e.g. snorkelling and diving), and climate change impacts (ocean warming plus acidification) will reduce on-reef tourism values by over 90% in 2100 for RCP 8.5 (39–63% for RCP 4.5).

The projections above should be interpreted as the effect of climate change on future potential tourism values, holding all other factors equal. Our projections indicate that the degree of climate change impacts depends on the emissions pathways taken in the future, although any of the emissions scenarios would still negatively impact reef tourism values.

When most of a country's coral reef tourism value comes from reef-adjacent activities, climate change may not severely affect that country. The reef-adjacent values, however, will be affected by increased extreme weather events in the area, algal blooms and coastal erosion, which we have not yet incorporated into the current calculations.

We reported here how climate change impacts coral cover and the corresponding on-reef tourism values of several national economies. While the coral reef tourism values of all nations are projected to be negatively affected by climate change, nations can still incur positive tourism values in the future as our estimate has not accounted for increases in tourism demand and arrivals in the future—international arrivals are expected to increase 3–5% per year (UNWTO 2016; Lenzen et al. 2018). In accounting for the improvements in tourism values due to an increase in tourist arrivals, it should be noted that the tourism value is a hump shape, or concave function, of tourism arrivals. Additional arrivals increase tourism values up to some point after which the desirability of a place for tourism decreases as tourist numbers further increase. Future research can incorporate the Shared Socioeconomic Pathways (SSPs) to future projections of tourism under climate change to account for not only ecosystem changes, but also changes in the demand for tourism.

Economic Impacts in Other Systems

Coral reef tourism is not the only tourism sector that will be impacted by climate change. Other non-reef coastal attractions such as the coastal glaciers in Ilulissat Icefjord, Denmark, a UNESCO World Heritage site, and places such as coastal cities like Venice, Italy (Moreno and Amelung 2009) or Alexandria, Egypt (Scott et al. 2012) will also be heavily affected by climate change. Beach tourism in tropical and temperate areas is expected to be significantly affected by climate change, especially due to the effect of sea level rise and storms on shoreline erosion (Scott et al. 2012). For example, in the Mexican Caribbean, the estimated total beach replenishment cost for the main five ocean tourism cities under a future 1 m sea level rise scenario is $330 million (Ruiz-Ramírez et al. 2019), and in the United States, the total beach nourishment cost for 2060 based a 0.32 m scenario amounts to $20.40 billion (Scott et al. 2012). The breaking of ice in the polar region also poses potential danger to cruise ships and navigation. For all these systems, 'last chance tourism' is emerging, attracting people to the most vulnerable areas (IPCC 2019).

Consequences need to be further explored to understand the implications and dimensions of this trend.

Quantifying the impacts of climate change on other ocean tourism activities and beyond will provide a more complete picture of the impacts of climate change on local and national economies, which could potentially motivate local, national and global actions.

Ocean Tourism and Equity

Ocean tourism has the potential to alleviate poverty, especially in coastal fishing and farming communities where poverty incidences are high. It can boost local and national economic development and improve local welfare. However, unregulated ocean tourism development can bring in several unwanted consequences, such as the degradation of the environmental resource base that the tourism industry depends on, destruction of local cultures and traditional livelihoods and inequitable distribution of economic benefits (Cabral and Aliño 2011). Actions that ensure an equitable and sustainable tourism industry include proper planning of tourism developments, promotion of ecotourism activities that respect local cultures and traditions (including indigenous peoples' rights over ancestral domains) and implementation of policies that ensure that economic benefits from tourism activities accrue locally (i.e. provide local opportunities).

3.3.4 Opportunities for action and key conclusions

1. **Enhance coral reef resilience to climate change.** Reducing the negative impacts of climate change and associated ocean disturbances to coastal economies requires improving the resilience of marine and coastal ecosystems to climate change (Gattuso et al. 2018; James et al. 2019; Weatherdon et al. 2016). Establishing marine protected areas and MPA networks can help improve the

ecological resilience of coral reefs. MPAs protect marine ecosystems and their services from environmental uncertainties (Roberts et al. 2017), help minimise the footprints of human activities such as fishing (Lester et al. 2009), secure the continuous supply of genetic materials and serve as climate refugia when sited in cooler, less-impacted areas (Roberts et al. 2017; Mcleod et al. 2009). Furthermore, MPAs help ensure that coral reefs and associated species that are important draws for tourism are protected.

However, conventional management approaches that include MPAs may be insufficient to protect global coral reefs under warming and acidifying ocean conditions (Anthony et al. 2017). Assisted relocation and evolution (van Oppen et al. 2017) together with new biotechnology practices can enhance the resilience of coral reefs, but with associated costs. Protection should prioritise ecosystem connectivity—while there are preferences for some physical attributes of coastal tourism, like white sand, and there is a tendency to alter the ecosystem to favour some components (e.g. removing mangroves to access sandy beaches) (e.g. Cabral and Aliño 2011), it is important to recognise the huge role these ecosystems play in maintaining coastal integrity. For example, protecting mangroves and seagrass beds—which serve as nursery areas for a number of coral reef fish species and protect coral reefs by trapping sediments—enhances reef health and productivity.

2. **Protect and regenerate natural habitats.** Preserving and restoring natural coastal habitats such as coral reefs, beaches and mangroves increases the resilience of coastal areas to climate change (James et al. 2019), providing an alternative to hard infrastructure that allows for wave attenuation and shoreline stabilisation (James et al. 2019; Gattuso et al. 2018), as well as providing additional protections from storm surges and excess flooding (Ruiz-Ramírez et al. 2019). Traditional infrastructures for tourism such as urbanised beach fronts are expected to suffer shoreline erosion (coastal squeeze) due to climate change (Toimil et al. 2018; Scott et al. 2012). In these cases, coastal natural habitats can allow for landward retreat; otherwise, beach nourishment will be required to maintain tourism in heavily urbanised areas at very high costs (Scott et al. 2012). The quality of nearby sand habitats can be important to reduce those costs (Ruiz-Ramírez et al. 2019).
3. **Diversify development portfolios.** Diversifying tourism activities and investments to include linked ecosystems will help maintain diverse ecosystem functions, while simultaneously capturing the tourism potential of various ecosystems. Ecotourism, or tourism activities that support nature conservation and education, should be prioritised. Pressures on and drivers of reef health are often associated with governance and the socioeconomic needs of the people dependent on reefs. Linking fisheries, aquaculture and tourism to local food and livelihood security will improve the portfolio of policies that can be applied to reduce climate change's impacts on local and national economies. Marine spatial planning will play a key role in maintaining healthy reefs by strategically siting activities in the ocean so that negative interactions can be reduced. Actions include properly siting tourism infrastructure and making investments that account for potential future coastal and ocean changes. Management plans should explicitly address the role of natural habitats functioning as buffers to climate change on tourism (Ruiz-Ramírez et al. 2019). Communities that directly depend on coral reef tourism for their livelihoods need to increase their adaptive capacities, as this sector is expected to be negatively impacted by the changing climate in all countries. Local governments, private investors and development agencies can help by improving and developing social and institutional arrangements that allow for learning (i.e. technical education and skills development) and diversifying livelihoods and income sources (Cinner et al. 2018) while incorporating local and indigenous knowledge into the planning and decision process.
4. **Ensure that waste is properly disposed of and that waste treatment facilities are included in coastal tourism infrastructure.** As described above, nutrient enrichment exacerbates ocean acidification.

   Controlling nutrient input from coastal and terrestrial activities will help reduce the impact of climate change on coral reefs and reef tourism. Strategies can include ensuring that waste management, such as waste treatment facilities/recycling, is included in tourism development plans. Pollution combined with overfishing that degrades coral reefs caused the Caribbean to lose \$95–140 million/year in net revenue from coral reef–associated fisheries, \$100–300 million/year in reduced tourism revenue and \$140–420 million/year in reduced coastal protection (Burke et al. 2011).
5. **Reduce the environmental footprint of tourism through ecotourism and clean energy investments.** While climate change will inevitably affect tourism, tourism is also a major contributor of greenhouse gas emissions (Scott et al. 2012). It is estimated that tourism contributes 8% of global GHG emissions, with transport, shopping and food as major contributors (Lenzen et al. 2018). With tourism expected to grow 3–5% per year, it is important to ensure that the environmental footprint of tourism is minimised. Future increases in international arrivals do not necessarily translate to economic benefits for countries; hence, policies that ensure optimal benefits

for national economies while reducing tourism's footprint, such as those that promote ecotourism activities, should be prioritised. Furthermore, investments in clean and efficient energy in the tourism sector help reduce tourism's environmental footprint.

3.4 Improving the Energy Efficiency of the Ocean Economy

Improving the energy efficiency of ocean-related industries, especially shipping/transportation, would generate climate change benefits as well as benefits to the industries themselves. While significant improvements to the offshore oil and gas industry would require extensive transitioning of investments away from exploration and extraction of fossil fuels and into renewable energy (Allison and Bassett 2015), the shipping industry can make relatively large energy efficiency gains using existing technologies (Allison and Bassett 2015; Ash and Scarbrough 2019; Hoegh-Guldberg et al. 2019). For example, switching international shipping to solar-generated, ammonia-based fuel would allow for significant reductions in greenhouse gas emissions (Ash and Scarbrough 2019). Related topics are discussed in more depth in the Blue Papers *Ocean Energy and Mineral Sources* and *Coastal Development*. Fisheries and aquaculture are already relatively energy efficient, especially when compared with the terrestrial production of animal protein (Allison and Bassett 2015; Hoegh-Guldberg et al. 2019), but there is great potential in the expansion of carbon- and energy-efficient shellfish aquaculture as well as in the reduction of overcapacity in fisheries (Allison and Bassett 2015). Finally, the tourism sector involves a diverse array of opportunities for improving energy efficiency—from increasing fuel efficiency and using carbon offsets for various modes of travel to improving the energy efficiency of hotels and other tourism destinations around the world (Allison and Bassett 2015).

4 Impacts of Climate Change Mitigation in the Sea

Global efforts to mitigate climate change include a variety of approaches that may themselves have impacts on ocean ecosystems, species assemblages and the ocean economy. Here, we discuss the potential marine impacts and opportunities of four major categories of climate change mitigation methods that directly affect the ocean: efforts to conserve and increase 'blue carbon' storage; expansion of ocean-based renewable energy generation; deep-sea mining to meet demand for rare earth elements; and geoengineering techniques. We limit our discussion of the three latter topics to their direct impact on the ocean.

4.1 Conserving and Expanding Blue Carbon

The term 'blue carbon' refers to the capacity of marine ecosystems to store organic carbon over centuries or millennia (Serrano et al. 2019). The ocean is the largest carbon sink on Earth; it has already absorbed more than 90% of Earth's additional heat and captured nearly one-third of all atmospheric CO_2 emissions since the 1700s (Gattuso et al. 2015). Through a process known as the 'biological pump', marine organisms convert CO_2 into biomass (referred to as carbon 'fixation') through photosynthesis. A portion of this carbon is deposited and buried on the seafloor, thus removing it from the atmospheric carbon cycle on a long enough time scale to constitute a carbon sink (at which point this carbon is referred to as having been 'sequestered') (Barange et al. 2017; Duarte et al. 2013; Mcleod et al. 2011; Serrano et al. 2019; Vaughan and Lenton 2011). Marine carbon sequestration occurs both in the open ocean and along the coast, and there are opportunities to increase the sequestration capacity and contribute to climate change mitigation in both areas. These opportunities are becoming an important sector of the ocean economy as efforts mature to quantify and monetise (e.g. with carbon pricing) marine ecosystem restoration and management for carbon sequestration (Alongi et al. 2016; Lavery et al. 2013; Lovelock et al. 2017; Mcleod et al. 2011; Pendleton et al. 2012). As this sector develops, it is critical to consider the implications for vulnerable and marginalised groups, including small-scale fishers, who may be overlooked in blue carbon decision-making (Cohen et al. 2019).

Vegetated coastal ecosystems—primarily seagrasses, mangrove forests and tidal marshes—occupy only 0.2% of the global ocean surface, but have an outsize capacity for carbon sequestration, contributing up to 50% of carbon burial in marine sediments (Duarte 2017; Duarte et al. 2013; Hoegh-Guldberg et al. 2019; Mcleod et al. 2011; Serrano et al. 2019), far outpacing the capacity per unit area of terrestrial habitats (Hoegh-Guldberg et al. 2019; Serrano et al. 2019). Kelp and other macroalgal beds have also recently been identified as contributors to global blue carbon storage (Serrano et al. 2019), and although there is significant debate around whether coral reefs act as carbon sources or sinks, the presence of coral reefs adjacent to seagrass beds and mangrove forests may improve the blue carbon efficacy of the system as a whole (Watanabe and Nakamura 2019).

While the capacity to expand the existing inventories of fixed and sequestered carbon in vegetated coastal ecosystems is limited, there is a critical need to protect them from degradation and conversion to alternative land uses (Allison and Bassett 2015; Hoegh-Guldberg et al. 2019). These ecosystems are among the most threatened habitats on Earth, and their current and projected loss not only reduces global CO_2 uptake, but also releases large amounts of carbon currently stored in their biomass and soils (Allison and Bassett 2015; Duarte 2017; Gattuso et al. 2015; Hoegh-Guldberg et al. 2019; Serrano et al. 2019). There may be sizable blue carbon potential in the restoration of marine vegetation where large portions of the coastline have been lost to development, as well as in the expansion of macroalgae aquaculture (Duarte 2017). In addition to their carbon sequestration capacity, vegetated marine ecosystems provide coastal protection and sea level rise mitigation services, regulate water quality, provide critical habitat for many marine species including commercially important fishery targets and enhance system biodiversity and resilience (Serrano et al. 2019). Thus, their protection and restoration would have multiple synergistic benefits (Allison and Bassett 2015).

There are also potential opportunities to increase the open ocean's capacity to sequester carbon where the biological pump moves biogenic carbon to depths of 1000 m or more, capturing it for centuries or longer (Burd et al. 2016). The main sources of this biogenic carbon are faeces, mucus and dead organisms.

Researchers have recently suggested that fisheries could be managed to have higher standing stock biomass, even in the face of climate change (Gaines et al. 2018; Hilborn and Costello 2018), which could theoretically increase the input of organic matter (including carbon) to the biological pump, especially when cascading ecosystem impacts of increasing standing stock biomass are considered (Roman and McCarthy 2010). Fostering the recovery of larger, deeper-diving fish and marine mammals could also increase upward fluxes of fixed nitrogen and other limiting nutrients from the deep ocean, thereby spurring additional primary productivity and subsequent CO_2 fixation (Aumont et al. 2018). These potential deep-sea carbon sequestration opportunities have thus far been inadequately studied, and would benefit from further exploration.

4.2 Expanding Ocean Renewables

Marine renewable energy sources have significant potential for reducing human demand for fossil fuels and reducing climate-changing GHGs (Boehlert and Gill 2010; Hoegh-Guldberg et al. 2019). Technologies capable of producing energy from the ocean are vast and expanding, with most taking advantage of wind, waves, currents, tides or thermal gradients, collectively referred to as offshore renewable energy developments, or ORED (Boehlert and Gill 2010). As these technologies expand, they will impact the ocean both above and below the water's surface through the following six channels, discussed in depth in Boehlert and Gill (2010):

1. **Physical presence**: Stationary structures such as support pillars and cables will alter pelagic habitats and bottom communities. Structures not treated with anti-fouling chemicals will create new settlement habitats, essentially forming artificial reefs and de facto 'fish aggregation devices'. ORED structures may also create barriers to species migration above and below the water.
2. **Dynamic effects**: Structures with moving parts (e.g. wind energy devices and below-water turbines) may be especially hazardous to migratory birds, cetaceans and fish. Oscillating structures, such as buoys and rotors, will modify water movement, turbulence and stratification, potentially altering the associated movements of marine species.
3. **Chemical effects**: Anti-fouling and other chemicals used on ORED technologies can leach into the surrounding water. Constructing, servicing and decommissioning structures brings additional risk of chemical spills. Furthermore, the movement of deep water to the surface during ocean thermal energy conversion can change chemical conditions through the increased input of nutrients, heavy metals and carbon dioxide, which can also outgas to the atmosphere.
4. **Acoustic effects**: Acoustic ORED impacts will be most severe during survey and construction phases, but noise from moving ORED structures may impact marine species during the operational phase as well.
5. **Electromagnetic field effects**: The transmission of electricity from ORED structures to shore generates low-frequency electromagnetic fields in the surrounding water, which may change the behaviours of marine species that use natural electric and/or magnetic fields for a variety of behaviours. Electricity-transmitting cables may also increase the temperature of the surrounding water and sediment, but the effects of this are still unknown.
6. **Effects of the energy removal itself**: Removing energy from the water can change local water movement (e.g. seasonal or tidal opening and closing of estuary systems), more distant current patterns, tidal ranges and thermal regimes. All of these changes may impact productivity patterns and species movement.

Each of these impacts must be evaluated throughout the stages of development, and across spatial and temporal scales (i.e. local versus far-reaching, and short- versus long-term impacts). The cumulative impacts of multiple adjacent developments must also be understood (Boehlert and Gill 2010). In addition, both the feasibility and the potential impacts of marine renewable energy technologies may be altered by the effects of climate change, including sea level rise, increased storms and extreme events, and changes to wave and circulatory energy patterns. These eventualities will need to be considered, and operations will need to be designed for climate resilience if they are to be successful and sustainable.

4.3 Expanding Deep-Sea Mining to Meet Demand for Rare Earth Elements

Rare earth elements (a group of 17 elements comprised of 15 lanthanides, plus yttrium and scandium) are critical to the development and operation of a variety of renewable energy technologies, including solar cells, wind turbines and electric vehicles (Dutta et al. 2016), but current land-based supply streams may not meet growing demand (Dutta et al. 2016; Miller et al. 2018a). The deep-sea floor, especially areas around hydrothermal vents, contains relatively vast quantities of rare earths that could help to meet this demand, and mining contracts for deep-sea resources including rare earths have been awarded to a number of countries and companies (Kato et al. 2011; Miller et al. 2018a). However, the costs associated with extracting rare earth elements are thus far prohibitive, and no commercial-scale mines are as yet operational (Miller et al. 2018a).

In addition to the usual risks associated with mining and other extractive industries in the ocean (including the potential for the release of toxic elements, contamination from dredge spoils, increased noise, heat and light pollution, and loss of biodiversity), these deep-sea mining operations carry risks related to impacts to the fragile marine ecosystems and unique and endemic species communities found on the deep-ocean floor, many of which have been recognised as vulnerable (Miller et al. 2018a; Van Dover et al. 2017). Furthermore, impacts may extend many kilometres away from mining sites and the long-term impacts will be much more significant than in shallow water because deep-sea habitats can take decades to millennia to recover (Miller et al. 2018a). Finally, deep-sea mining carries additional challenges, such as the potential for conflict with other marine uses and the legal and political complexities of operating under international waters in the open ocean (Miller et al. 2018a).

4.4 Geoengineering Solutions

A variety of ocean-based geoengineering concepts have been suggested to help mitigate climate change including 'cloud brightening', by mechanical or biological means, to increase atmospheric albedo; fertilising patches of the ocean with limiting nutrients (iron, nitrogen or phosphorus) to enhance primary productivity and sequestration of carbon (see blue carbon discussion above); inducing upwelling to do the same; inducing downwelling to increase the sinking of CO_2-rich waters; and 'enhanced weathering', wherein materials such as carbonate or silicate are added to the water to increase alkalinity, thereby stimulating removal of CO_2 from the atmosphere (Allison and Bassett 2015; Vaughan and Lenton 2011). Together, these efforts could theoretically reduce global radiative forcing by an estimated ~4.2 W/m^2, with cloud brightening contributing the bulk of that reduction (Vaughan and Lenton 2011).

While the costs of implementing any of these techniques are currently prohibitive, and the carbon-balance effects are highly uncertain (Allison and Bassett 2015; Vaughan and Lenton 2011), even if they prove cost-effective and sequester substantial amounts of carbon they may result in unwanted ocean impacts. For example, ocean fertilisation could lead to increased deoxygenation and eutrophication, and making adjustments to natural upwelling and downwelling patterns could alter primary productivity and change community structures and functions (Vaughan and Lenton 2011). Increasing cloud cover could generate unwanted weather patterns (Irvine et al. 2010; Jones et al. 2009) and address only global temperature changes without reducing other impacts, such as ocean acidification (Gattuso et al. 2015; Vaughan and Lenton 2011; Williamson and Turley 2012). Each of these impacts could have significant consequences for other sectors of the ocean economy, as discussed above. Finally, there may be important ethical implications associated with many of these geoengineering options related to the uneven distribution of impacts (Allison and Bassett 2015; Jones et al. 2009; Vaughan and Lenton 2011). Thus, near-term efforts should be focused on drastically reducing CO_2 emissions while research into the risks and benefits of these geoengineering technologies continues.

5 Conclusions and Opportunities for Action

The ocean is critically important to the global economy. Collectively, it is estimated that ocean-based industries and activities contribute hundreds of millions of jobs and approximately $2.5 trillion to the global economy each year, making it the world's seventh-largest economy when compared with national GDPs (Hoegh-Guldberg 2015; IPCC 2019). In this paper, we reviewed the impact of climate change on the three key components of the ocean ecosystem economy—fisheries, marine aquaculture and coral reef tourism—and the opportunities for effective institutions and markets to reduce these impacts.

Building on existing work, we developed three models to forecast the economic impacts of climate change and potential benefits of adaptation in each sector for every coastal country under diverse climate scenarios. For capture fisheries, we find that all countries would benefit from implementing climate-adaptive reforms and that many countries could maintain current profits and catches into the future with adaptation. For aquaculture, we show that production is under capacity in many countries and the negative effects of climate change could be more than offset by developing and expanding sustainable mariculture. For ocean tourism, we find that all countries will be negatively impacted, and both local and global actions that reduce the magnitude of climate change effects would help lessen the economic impacts.

Maintaining a robust ocean economy will depend on swift efforts to reduce greenhouse gas emissions. The recent IPCC (2019) report estimates that climate-induced declines in ocean health will cost the global economy $428 billion/year by 2050 and $1.98 trillion/year by 2100. The magnitude and inequity of these losses is highly sensitive to future greenhouse gas emissions across sectors of the ocean economy. The ability for climate-adaptive fisheries management to mitigate losses under climate change deteriorates under increasingly severe emissions scenarios. The ability for mariculture to be a viable substitute for declining capture fisheries is also diminished under increasingly severe climate futures. Finally, the magnitude of losses in marine and coastal tourism increases dramatically under increasingly severe emissions scenarios. In all cases, these impacts are especially pronounced in the tropical developing countries, which have contributed the least to growing greenhouse gas emissions. Thus, it will be the responsibility of the industrial nations to take a leadership role in curbing emissions and reducing the impacts of climate change on the ocean economy.

Since climate change impacts differ by country and sector, possible solutions will be context-specific. By exploring the climate change impacts at the country level for fisheries, aquaculture and reef tourism as described in this report, countries will be able to assess what they stand to gain or lose due to climate change. Below, we outline solutions for each sector based on whether a country will experience gains, no change or losses.

5.1 Capture Fisheries

An interactive web interface developed by the Sustainable Fisheries Group at the University of California, Santa Barbara, summarises the impact of climate change on marine fisheries around the world and the opportunities for countries to mitigate these impacts through climate-adaptive fisheries management reforms (UCSB 2019). It illustrates how the health of fisheries and the catches and profits provided by them will change under four increasingly severe climate change scenarios (+0.3 °C, +0.9 °C, +1.2 °C and +2.3 °C increases in sea surface temperature by 2100) with and without climate-adaptive fisheries reform. This tool can be used to determine whether a country is likely to experience negative, positive or neutral impacts of climate change.

1. **Lower-capacity countries** (often tropical, developing countries experiencing negative impacts of climate change) should implement or strengthen their fisheries management (see Cochrane et al. 2011) to enhance resilience to the negative effects of climate change.
2. **Higher-capacity countries** (often temperate, developed countries experiencing mixed impacts of climate change) should account for shifting productivity in fisheries stock assessments and management procedures (see Pinsky and Mantua 2014) to capitalise on the positive effects of climate change and mitigate the negative effects.
3. **All countries** will derive benefits from international cooperation that both ensures that management does not degrade as stocks shift distributions and results in fairness and equity in fisheries outcomes under climate change.

5.2 Aquaculture

1. **In countries with underdeveloped mariculture potential** (Fig. 2.2), the negative effects of climate change can be offset by both sustainably expanding current mariculture operations and investing in science and technologies that enhance mariculture efficiency and productivity amidst a changing climate.
2. **In countries with fully developed mariculture potential** (Fig. 2.2), mariculture production can be maintained by selectively breeding for fast growth or heat tolerance or by shifting portfolios of mariculture species to match the new thermal regime.
3. **In all countries**, studying the impact of large-scale mariculture on marine ecosystems will be essential to identifying and promoting best practices in sustainable mariculture. Making strategic investments and expanding mariculture operations can boost local food supply without interacting negatively with other ecosystem services.

5.3 Ocean Tourism

Climate change will reduce the potential of ocean tourism to boost the local economies of countries with coral reefs. The magnitude of the impact will depend on the realised global emissions pathways, confounding effects of local stressors, dependency of the local economy to ocean tourism and type of ocean tourism. While on-reef tourism (e.g. snorkelling and diving) will be more vulnerable than reef-adjacent tourism (e.g. sunbathing, white sand), the latter will also likely be affected, although the magnitude of the impact is uncertain. Table 2.3 summarises the predicted changes in coral cover and reef tourism values given climate change as well as the current on-reef and reef-adjacent tourism values of each coastal country with coral reefs.

1. **In countries with a high proportion of their local economy dependent on tourism**, such as Maldives, Palau and St. Barthélemy (i.e. over 40%of their GDPs are from reef tourism), options include slowly diversifying to other

industries, such as mariculture, and creating opportunities for alternative forms of tourism, such as wreck diving and other novel activities, while at the same time increasing investments in the management of and improvements to reef ecosystems, fisheries and ocean tourism.

2. **In countries with high reef-adjacent values and where ocean tourism is important**, it is still imperative to improve and maintain coral reef health to secure the continuous provision of many of the ecological processes and services that support reef-adjacent activities (e.g. white sand from corals, wave attenuation function of coral reefs).
3. **For countries with disproportionately high on-reef tourism values**, investments in reef-adjacent tourism activities and ecotourism activities can both enhance the economic potential of coral reefs and motivate more investments in protecting reef health.
4. **Coral reef tourism can be a viable industry in countries that are expected to experience losses in aquaculture and capture fisheries**. Although climate change will hinder countries' abilities to tap into the full potential of ocean tourism, that does not mean that coastal tourism cannot improve the local economy.
5. **Given that current ocean tourism activities impact future ocean tourism economic output and ecosystem health** (feedback loops), all countries must aim to efficiently enhance ocean tourism gains by prioritising high-economic-gain activities while reducing the ecological footprints of ocean tourism activities (i.e. by investing in ecotourism and clean and efficient energy).

Across each of the above sectors of the ocean economy, the recommendations to build socioecological resilience to climate change and ensure the continued, or improved, provision of valued functions and services can be captured in three high-level mandates:

(a) **Be forward looking:** The future of the ocean economy is expected to drastically change given climate change, and the nature and magnitude of these changes can be highly variable. It will no longer be appropriate (or possible) to make predictions based on historical benchmarks or to assume that our usual metrics for measuring outcomes will remain stable. As the climate changes, each of the above-discussed ocean sectors will need to work to understand risks, anticipate changes and make decisions aimed at improving ecosystem health. In many cases, the risks and changes will become increasingly uncertain, which means that all management decisions need to factor in the likelihood of increasing surprises by being a bit more precautionary. **For wild-capture fisheries**, looking forward will entail things like scenario planning and management strategy evaluation, while stock assessments, harvest controls, allocation systems and even marine protected areas will all need to be more flexible, adaptive and precautionary. **Mariculture operations** will need to invest in things like selective breeding, improvements to feed conversion ratios, and technologies that continue to reduce risks from increasingly frequent and stronger storms. **Ocean tourism operations** may need to engage in practices aimed at building ecosystem resilience and health and be efficient by catering to tourism activities that provide high economic returns and have smaller ecological footprints. The designs of spatial management systems should account for future shifts in species ranges and productivities to both facilitate the successful movement of species to other areas and enhance marine population resilience to environmental and social changes.

(b) **Cooperate across boundaries**: It will also be critical to expand the current boundaries of our management decisions to allow for effective systems-level problem identification and solution development. As suitable habitats shift and change, marine species will move across jurisdictional boundaries and regional, national and international cooperative agreements will be necessary to ensure that these species are well-managed, and that the benefits are fairly distributed during and after the transitions. **For mariculture**, it will be critical to incorporate other marine uses and sectors in the planning and implementation of operations. Whole-systems thinking would also benefit tourism by ensuring the durability of this sector into the future as well as taking advantage of tourism opportunities that emerge in new areas (i.e. for the case where new coral reefs may establish in subtropical areas). In addition, it will be critical to share lessons learned and tools applied across and between sectors and jurisdictions to ensure lower-capacity regions will not fall behind in the implementation of solutions.

(c) **Focus on equity**: Finally, it will be profoundly important to examine the equity implications of all new and existing management decisions across these sectors, as climate change is likely to cause and exacerbate global inequities. Inequity reduces resilience, thereby likely worsening outcomes under all climate change scenarios.

Furthermore, equity considerations should be an input to decision-making in terms of both the design and implementation of management reforms and the creation and execution of new international agreements. Equitable solutions are more likely to garner buy-in from impacted groups and will thus be more likely to be effectively implemented. Focusing on equity can also lead to the development of more effective solutions that target the underlying system dynamics and power differentials that are, in fact, the root drivers of climate change. These solutions should consider equity issues in access and participation in the blue economy, including through the provision of no-cost skills development opportunities, and they must involve different world views and knowledge systems, integrating local and indigenous knowledge and avoiding poverty traps and the marginalisation of already vulnerable groups.

Truly inclusive, representative, participatory decision-making processes are needed in all sectors to ensure procedural equity in all policy and management decisions. In addition, new solutions and interventions must seek to ensure distributional equity (i.e. equitable access to benefits and exposure to risks stemming from decisions) and to engender recognitional equity (i.e. recognition of and respect for differences within and between groups, and understanding of how these differences alter the perception and experience of impacts) if systems are to become equitably resilient to climate change.

It is imperative that countries explore the synergistic impacts of climate change across all three economic sectors (fisheries, mariculture and ocean tourism) and identify whether they are vulnerable to universally negative impacts, have options to offset negative impacts in some sectors through adaptation or could benefit from potentially positive impacts in other sectors. Countries should also note the magnitude of climate change impacts to the three major components of their ocean ecosystem economies to best plan their investments for climate change adaptation and mitigation strategies. While the solutions we put forward above are targeted to individual economic sectors, the three marine ecosystem economies are connected ecologically and socioeconomically, and positive actions to one sector often act synergistically with other sectors, especially when the actions are aimed at maintaining and enhancing ecosystem health.

Unregulated economic developments in fisheries, aquaculture and tourism have brought many unintended environmental and social consequences, including the degradation of non-use values and the provision of many other ecosystem services, both in developing and developed nations. While investments in these three sectors could improve national and local food and livelihood security amidst the challenges brought by anthropogenic climate change, sustaining the development and benefits they bring requires a development path that promotes and maintains a healthy ocean ecosystem. After all, the productivity and resilience of aquaculture, tourism and fisheries depend on clean water, intact habitats (e.g. mangroves and seagrass beds that serve as nursery grounds for commercial marine species) and diverse marine organisms, among others. Since this paper primarily focuses on ocean ecosystem sectors, the majority of the outlined recommendations and actions drive sustainable improvements in the ocean economy and, therefore, can provide positive synergistic effects for the underlying natural resource and its nonmarket values. Faster development and greater economic values in these three sectors can be realised if trade-offs between use and non-use values, which vulnerable communities often directly depend on, are avoided.

We expect that the variable directions of impacts of climate change across the three economic sectors for each country will draw new investments in some sectors while other sectors are expected to continually suffer.

It is imperative that developments are well-planned and properly regulated to avoid unwanted environmental impacts, degradation of local cultures and livelihoods, and the inequitable distribution of benefits. For instance, including access to technical education and skills development will ensure that resources are available for people to transition from one form of livelihood to another, hence ensuring that the economic benefits of local developments accrue locally. There is also huge potential for local investments in renewable energy and energy-efficient technologies that can improve local livelihoods, enhance local economic benefits and reduce the carbon footprints of human activities. Finally, we envision that our results will ultimately help guide new ocean investments and positive conservation actions by governments, nongovernmental organisations, development agencies, philanthropies and international communities.

Acknowledgements The authors thank Jane Lubchenco, Merrick Burden and Kate Bonzon for helpful comments on earlier drafts of this Blue Paper and Mark Spalding for reef tourism data. The paper's technical reviewers, Manuel Barange, Sarah Cooley, Salif Diop, Silvia Patricia González Díaz and Boris Worm, as well as its arbiter, Andreas Merkl, all provided helpful technical comments. The authors also thank World Resources Institute for providing support as the Ocean Panel Secretariat.

While our colleagues were very generous with their time and input, this report reflects the views of the authors alone. The authors thank Sarah DeLucia for copyediting and Jen Lockard for design.

About the Authors

Co-authors

Steven Gaines is the dean and a distinguished professor at the Bren School of Environmental Science & Management at the University of California, Santa Barbara (USA).

Reniel Cabral is an assistant researcher at the Bren School of Environmental Science & Management at the University of California, Santa Barbara (USA).

Christopher M. Free is a postdoctoral scholar at the University of California, Santa Barbara (USA).

Yimnang Golbuu is the CEO of the Palau International Coral Reef Center (Palau).

Contributing Authors

Ragnar Arnason is a professor of economics at the University of Iceland (Iceland).

Willow Battista is the manager of research, design, and engagement in the Fishery Solutions Center at the Environmental Defense Fund (USA).

Darcy Bradley is a lead scientist at the Environmental Market Solutions Lab at the University of California, Santa Barbara (USA).

William Cheung is a professor at the Institute for the Oceans and Fisheries at the University of British Columbia and the director of science for the Nippon Foundation-UBC Nereus Program (Canada).

Katharina Fabricius is a senior principal research scientist at the Australian Institute of Marine Science (Australia).

Ove Hoegh-Guldberg is a professor of marine science and director of the Global Change Institute at the University of Queensland (Australia).

Marie Antonette Juinio-Meñez is a professor at the Marine Science Institute at the University of the Philippines (Philippines).

Jorge García Molinos is an assistant professor at the Arctic Research Center at Hokkaido University (Japan).

Elena Ojea is a senior researcher at the Future Oceans Lab, CIM- UVigo, at the University of Vigo (Spain).

Erin O'Reilly is the projects and operations coordinator at the Environmental Market Solutions Lab at the University of California, Santa Barbara (USA).

Carol Turley is a senior merit scientist at the Plymouth Marine Laboratory (UK).

Highlights

- This paper analyses the underlying tension between the need for rapid decarbonisation, including that required for scaling up ocean-based renewable energy, and the resource and environmental implications related to that metal demand, with particular attention on current proposals to mine the deep seabed.
- Building a sustainable global energy system is intimately linked to both scaling up renewable energy and finding a way to source and use rare minerals in a more sustainable way. Questions remain as to whether deep-seabed mining should be heralded as the key to a transition to a sustainable energy sector, based on whether it can be accomplished in a way that appropriately ensures a healthy and resilient ocean.
- Rapid transformation of our energy systems is required if we are to achieve the goals of the Paris Agreement and limit the global average temperature rise to 1.5 °C, or even 2 °C, above pre-industrial levels. In addition to expanding land-based renewable energy, the ocean offers significant potential for supporting this transition. However, new technologies must be implemented in a

J. Lubchenco, P. M. Haugan (eds.), *The Blue Compendium*, https://doi.org/10.1007/978-3-031-16277-0_3

sustainable way in order to avoid unintended consequences that could undermine other aspects of ocean health.

- Ocean-based renewable energy sources include offshore wind (near-surface as well as high-altitude), floating solar, marine biomass and ocean energy, which encompasses tidal range, tidal stream, wave, ocean thermal energy conversion (OTEC), current and salinity gradient.
- Offshore wind (near-surface, i.e. based on bottom- fixed or floating support structures) is presently more developed than other marine renewable energy and has reached cost parity with fossil sources of electricity.
- The trend for newer multi-megawatt wind turbine generators is to use direct-drive systems with permanent magnet generators. Since most other ocean-based renewable energy technologies are still in early phases of development with little deployment, few studies have been completed on what materials will be needed to scale up the use of these technologies. If these technologies have similar metal requirements to modern wind turbines, which is likely, implementation will rapidly increase the demand for many metals, such as lithium, cobalt, copper, silver, zinc, nickel and manganese, and rare earth elements (REEs).
- The demand for specific metals to serve the global energy transition is highly dependent on their cost. Often, alternatives to specific metals can be found. The industry is continually developing solutions that can use cheaper and more abundant resources avoiding specific costly metals.
- Selected metals and minerals are increasingly difficult to find in large quantities or high grades on land, but are present in higher concentrations in some parts of the deep seabed. As such, the deep seabed resource potential has attracted interest in mining for copper, cobalt, nickel, zinc, silver, gold, lithium, REEs and phosphorites.
- The potential to mine the deep seabed raises various environmental, legal and governance challenges, as well as possible conflicts with the United Nations Sustainable Development Goals.
- Greater knowledge of the potential environmental impacts and measures to mitigate them to levels acceptable to the global community will be crucial.
- Full analysis of the perceived positive and negative impacts is required before there can be confidence that engaging in industrial-scale deep-seabed mining would achieve a global net benefit.

1 Introduction

Scenarios for sustainable transformation of the global economy to near zero greenhouse gas emissions in 2050 in line with the Paris Agreement and the UN 2030 Agenda for Sustainable Development rely strongly on renewable energy. Offshore wind shows potential to become a globally significant supplier of electricity in these scenarios. Floating solar energy and direct ocean energy sources, such as wave, tidal and ocean thermal energy, may also contribute significantly in a range of locations, but require more policy support and understanding of potential environmental impacts in order to become significant in the transition to a sustainable global energy system.

The expanding use of batteries to electrify the transport sector is leading to increasing demand for a range of rare minerals. Renewable energy technologies, such as solar panels and wind turbines, along with electronic products and cell phones, also use these various minerals. One potential new source of minerals is the deep seabed. But the mining of these minerals raises potentially serious environmental, legal, social and rights-based challenges, as well as potential conflicts with UN Sustainable Development Goals 12, 13 and 14.

This Blue Paper focuses on the extent to which a selected subset of ocean resources, ocean-based renewable energy and deep-seabed minerals can contribute to sustainable development. Options for harvesting ocean-based renewable energy and the needs for ocean-based minerals are reviewed with a focus on scenarios where anthropogenic global warming in the twenty-first century is limited to 1.5–2 °C – in other words, where decarbonisation of the global economy has to happen fast. The deep-seabed minerals case is discussed in some detail in order to spell out the steps that would be required if deep-seabed mining were to be developed, and to weigh up the benefits, risks and alternatives.

The introductory section briefly explains the basic characteristics of ocean-based renewable energy, discusses the expected demands for minerals from ocean-based renewable energy and global energy system transformation, and ends with an introduction to deep-seabed mining. In Sect. 2, 1.5 °C scenarios, both with and without carbon capture and storage (CCS) and negative emissions in the later part of the century, are described. In Sect. 3, ocean-based renewable energy options, their technological and cost status, and projections for future development are reviewed. In Sect. 4, deep-seabed minerals and the motivations for mining them are addressed. Section 5 focuses on sustainability, including the environmental impacts of ocean-based renewable energy and deep-seabed mining. Section 6 deals with governance issues, before moving into the opportunities for action in Sect. 7.

1.1 What is Ocean-Based Renewable Energy?

Ocean-based renewable energy sources (often called marine renewable energy) include offshore wind (near-surface as well as high-altitude), floating solar, marine biomass and ocean energy, which encompasses tidal range, tidal stream, wave, ocean thermal energy conversion (OTEC), current and salinity gradient. All of these are considered in this paper except marine biomass. Harvesting of naturally growing marine biomass, as well as industrial production, is ongoing in several locations, mostly motivated by demands for food, feed or pharmaceuticals. The by-products of such production may be combusted for energy purposes, and thereby reduce the need for other energy sources. However, based on current knowledge, the global long-term significance as an energy source is believed to be limited.

Offshore wind (near-surface, i.e. based on bottom-fixed or floating support structures) is presently much more developed than the others and has reached cost parity with fossil sources of electricity in recent contracts. Offshore wind is therefore dealt with separately in Sect. 3.1. Of the others, technology for exploiting tidal range is well developed in some locations, tidal stream is developing rapidly now, and wave energy has a long history of research but no clear technology winner. OTEC, which has potential in the tropics, requires significant investment in order to capitalise on the economy of scale. Salinity gradient, which has potential where fresh water meets saline seawater, has only seen experimental-scale testing. Ocean currents, exploiting the energy contained in large-scale thermohaline ocean circulation, has considerable potential, but has challenges relating to proximity to demand, in combination with the early stage of technology. Floating solar has so far been mostly developed in fresh water for reservoirs and dams but has clear potential for ocean scale-up. High-altitude wind can be scaled up offshore once key technology has been validated, presumably first onshore. These energy sources are further described in Sect. 3.2.

1.2 Renewable Energy and the Demand for Metals

Key elements of a low-carbon emissions future are the accelerated use of wind power, solar energy and the electrification of the energy sector, including use of electric vehicles.

Construction of offshore wind turbines requires significant amounts of conventional materials, in particular steel. However, rare earth elements (REEs) are also needed, in particular in the construction of the direct-drive permanent magnet generators that are currently preferred. For offshore wind, it is the use of REEs in the generators that appears to be the biggest potential challenge when it comes to supply of minerals. Wilburn (2011) states that each megawatt (MW) of installed capacity needs 42 kilograms (kg) of neodymium and 3000 kg of copper.

Stegen (2015) provides an overview of REEs and permanent magnets in connection with renewable energies. Stegen notes that present wind turbines using direct-drive permanent magnet generators are favoured over conventional heavy gearboxes since the latter require more steel and concrete. The reduced weight of permanent magnet generators and increased reliability and efficiency is particularly attractive offshore. Permanent magnets typically use neodymium, dysprosium, praseodymium and terbium. For turbines above 10 MW, which are now beginning to be applied offshore, superconducting generators may be preferred over permanent magnet generators, again because of costs and weight. However, greater deployment of superconductors will increase demand for yttrium, another element typically considered together with REEs (included in REEs or expressed as REY, rare earths and yttrium).

Pavel et al. (2017) discuss substitution strategies for REEs in wind turbines, noting the variety of designs that are being considered and the potential for material efficiency. They do not consider the deep seabed as a source, but still conclude that the wind industry is well prepared for potential shortages in REEs in both the short and medium term. For the longer term, superconductors are being considered. A considerable amount of REEs, including yttrium at high concentration in seafloor mud, was recently documented in the Japanese exclusive economic zone (EEZ) (Takaya et al. 2018).

Goodenough et al. (2018) note that very little mineral-processing research on REEs took place outside of China during the 1980s, 1990s and 2000s, but this research has been accelerating in recent years after China introduced export restrictions. It remains a challenge to develop the value chain from mining through processing and separation to end-uses. Goodenough et al. (2018) also note that, within 10 years, new technological developments are likely to drive substantial changes in both processing of, and demand for, REEs.

Moving to the further requirements from the energy sector as a whole, a recent IPCC report indicates that 70–85 percent of all electricity must be from renewable sources by 2050 to limit global warming to 1.5 °C (IPCC 2018). Implementation of these renewable technologies will rapidly increase demand for many metals, including lithium, cobalt, copper, silver, zinc, nickel and manganese, and REEs and others (Arrobas et al. 2017; Sovacool et al. 2020). The projected metal demand varies greatly for the different energy sources under scenarios involving different amounts of renewable energy at different rates over the next 30 years (Arrobas et al. 2017; Dominish et al. 2019). For example, the demand for metals, such as aluminium, cobalt, nickel, lithium, iron and lead, coming from solar and wind will be twice as high under a 2 °C warming scenario than under a 4 °C scenario, but the demand from batteries would be more than 10 times higher. Offshore wind energy generation requires more metals than onshore wind due to the use of magnets; differing solar technologies use different amounts of silver, zinc and indium; and for cars, fully electric, hybrid and hydrogen fuel cells differ in their demands for lithium, lead and platinum (Arrobas et al. 2017). There is general agreement that electric car batteries will be the greatest source of increased metal demand.

Deetman et al. (2018) study scenarios for copper, tantalum, neodymium, cobalt and lithium demand up to 2050 and find that in a stringent climate policy scenario (1.5–2 °C), the demand from cars rises more rapidly than that from appliances and energy technologies. In particular, this applies to cobalt and lithium. Boubault and Maizi (2019) extend the well-known TIMES energy system model tool for electricity generation to metal need is expected to diminish as the industry transitions to even larger turbines with superconductors. The energy sector as a whole has a wider set of mineral needs but also larger flexibility to switch between alternative technological solutions. Trends and demands for the coming decade can be estimated, but it is very difficult to deduce a minimal set of required metals to enable energy system transition to a 1.5–2 °C global temperature rise requirements for the power sector using a life cycle approach. Cost-optimal deployments of different electricity generation sources in a 2 °C scenario to 2100 provide corresponding metal needs. In comparison with the baseline scenario, cobalt and aluminium are among those that increase the most.

Limiting the global average temperature rise to 1.5 °C using 100 percent renewable energy is projected to increase demand in 2050 to more than four times the existing reserves for cobalt, almost three times the reserves for lithium, and slightly more than the existing reserves for nickel (Dominish et al. 2019). Cobalt and nickel, whose demand could exceed current production rates by 2030, are driving the rapidly rising interest in mineral mining on the deep seafloor. Cobalt in particular has highly concentrated production and reserves (especially in the Democratic Republic of the Congo) and thus poses the greatest supply risk; cobalt contamination also causes severe health impacts for miners and surrounding communities (Dominish et al. 2019).

Attempts to compare various modelling studies of energy systems and metal needs (Boubault and Maizi 2019) are complicated by the different choices made in terms of scenarios, assumptions and the degree of resolution in the metals covered by each model. In conclusion, there are large uncertainties about metal needs over time horizons of longer than a decade. A hot topic for offshore wind is REEs for permanent magnets. However, this across the timeframe of 2050 to 2100. Integrated energy system models that include metal needs in a life cycle approach (Hertwich et al. 2015) are useful tools but rely on bottom-up estimates of costs of energy sources and energy conversion processes. The search for alternative technologies is intense, driven by actual costs as well as projections of future costs.

The increase in metal mining needed to address climate change (and the transition to renewable energy) is drawing increasing attention (Arrobas et al. 2017) and has led to a proposal that nationally determined contributions under the Paris Agreement identify critical minerals for energy security options and identify sourcing challenges (Sovacool et al. 2020). Population growth and rising consumption associated with an increased standard of living globally creates additional increased demand for metals, independent of climate change (Graedel et al. 2015; Ali et al. 2017).

1.3 Minerals on the Deep Seafloor

Metals and minerals of interest on the deep seafloor include primarily copper, cobalt, nickel, zinc, silver, gold, lithium, REEs and phosphorites (see Sect. 4). Many of the metals are found in polymetallic nodules on abyssal plains (covering 38 million square kilometres (km^2) at water depths of 3000–6500 metres (m)), on cobalt-rich crusts which occur on seamounts (covering over 1.7 million km^2 at 800–2500 m), and in polymetallic sulphides near mid-ocean ridges and in back-arc basins (covering 3.2 million km^2) (Fig. 3.1) (Levin et al. 2016; Miller et al. 2018; Hein and Koschinsky 2014; Petersen et al. 2016). Phosphorites, of interest for fertiliser, occur as modern deposits or fossil beds along productive continental margins (slopes) (Baturin 1982). These resources occur both within and beyond national jurisdictions (Fig. 3.1), with the exception of phosphorites, which are targeted only within EEZs. However, while 42 percent of areas with massive sulphides and 54 percent of areas with cobalt-rich crusts fall within EEZs, only 19 percent of known polymetallic nodules are within EEZs. More information on their formation and distribution is provided in Fig. 3.1 and by Petersen et al. (2016) and Jones et al. (2017).

Mining of the deep seabed (below 200 m) has not yet taken place. Extraction of minerals from the seafloor is planned to involve either modified dredging (for nodules) or cutting (for massive sulphides and crusts), and transport of the material as a slurry in a riser or basket system to a surface support vessel (Fig. 3.2). The mineral-bearing material will be processed on board a ship (cleaning and dewatering—with the waste water and sediment being returned to the ocean) and transferred to a barge for transport to shore where it will be further processed to extract the target metals (Collins et al. 2013; Brown 2018) (Fig. 3.2). Relative to mining on land, there is less overburden to remove and no permanent mining infrastructure required for deep-seabed mining (Lodge and Verlaan 2018).

However, there is likely to be solid waste material left after metal extraction, and disposal mechanisms for this

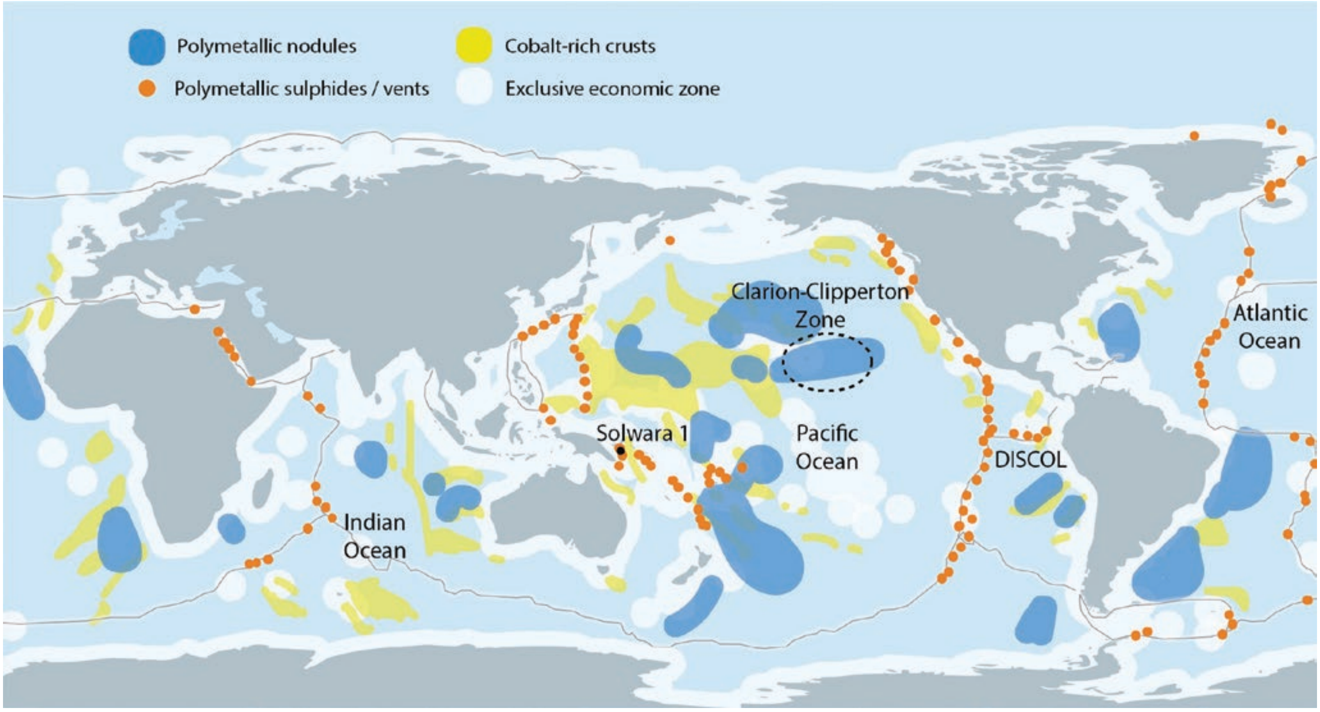

Fig. 3.1 Distribution of Polymetallic Nodules, Polymetallic Sulphides and Cobalt-Rich Crust Resources in the Deep Sea. (Note: The white area around Antarctica is not an exclusive economic zone but rather governed by an international commission. Source: Miller et al. 2018; Hein et al. 2013)

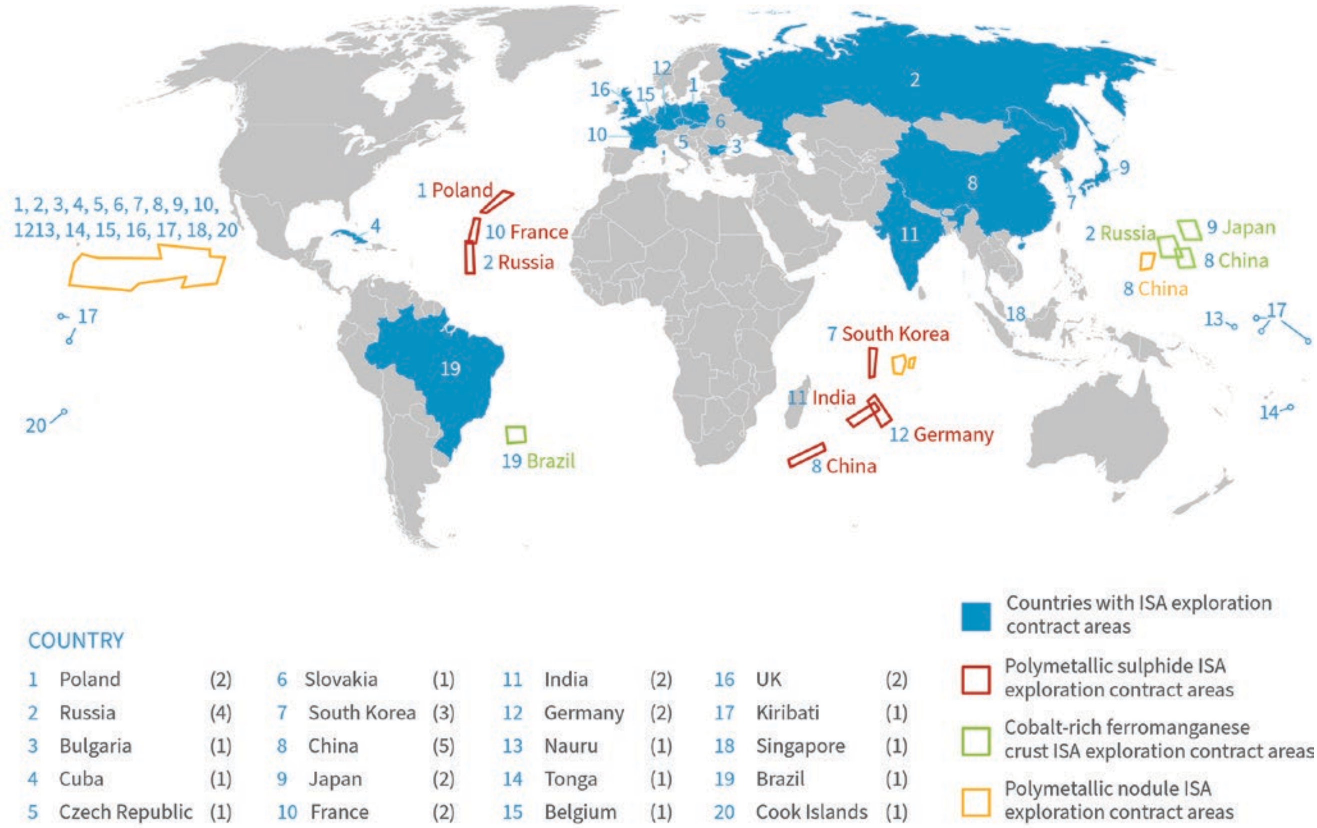

Fig. 3.3 International Exploration Contracts from the ISA. (Note: Countries with international exploration contracts from the ISA are shown in blue, the number of contracts per country (as of 2019 is depicted in the legend), and the general location of contracts in the Area is shown schematically for different resources. Source: Authors)

waste could be comparable with those used for terrestrial mine tailings, some of which are introduced into the deep ocean via pipe (Ramirez-Llodra et al. 2015; Vare et al. 2018).

The current governance structure under the UN Convention on the Law of the Sea (UNCLOS; UN 1982) gives the International Seabed Authority (ISA) regulatory responsibility for both the minerals on the seafloor in international waters (the Area) *and* the protection of the marine environment from the effects of mining in the Area. The minerals of the Area are designated as "the common heritage of [hu]mankind" (UN 1982). Since 2001, 30 *exploration* contracts for deep-seabed minerals in the Area have been approved. These were granted initially for 15 years each, and those contracts which have expired have been renewed for a 5-year extension. Seventeen of the ISA contracts are for polymetallic nodules in the Clarion-Clipperton Zone (CCZ) and two are for nodules elsewhere; others are for crusts and seafloor massive sulphides, and occur on West Pacific Seamounts (in the Prime Crust Zone), the Mid-Atlantic and Southwest Indian Ridges, the Rio Grande Rise off Brazil,[1] and in the Central Indian Ocean (Fig. 3.3). The exploration contract areas are granted to individual states, consortia of states, state-owned enterprises or companies working with states. At the time of writing this paper, the contracts cover more than 1.3 million km^2 (or 500,000 sq. miles), equivalent to about 0.3 percent of the abyssal seabed (Petersen et al. 2016). No contracts for mineral *exploitation* in the Area exist. Regulations for the exploitation of seabed minerals and for associated environmental management are currently under development by the ISA.

Roughly 70 percent of the 154 coastal states have significant deep ocean within their EEZs; many of these contain mineral resources. Licences for deep-seabed mineral exploitation within national jurisdictions have been granted by Papua New Guinea (to Nautilus Minerals) and by Sudan/Saudi Arabia (Diamond Fields International) (Miller et al. 2018). Additionally, New Zealand, the Kingdom of Tonga, Japan, Fiji, the Solomon Islands and Vanuatu have permitted research to assess the mining viability or issued exploration permits for national seafloor polymetallic sulphides, although some of them have lapsed. Exploration for polymetallic nodules in the Cook Islands (Cook Islands News 2018), cobalt crusts and polymetallic nodules in Brazil (Marques and Araújo 2019), and phosphorites in Namibia and South Africa (NMP n.d.; Levin et al. 2016) are also under consideration.

Sand is another resource mined in the ocean. Demand for sand, used in building and transportation, has increased

[1] Brazil has more recently indicated that the site in question falls within national jurisdiction (not the ISA's jurisdiction), according to an extended continental shelf claim, lodged by Brazil subsequent to the award of their ISA contract.

23-fold from 1900 to 2010, and is now seen as a scarce resource, the extraction of which can cause environmental degradation, health risks and social disruption (Torres et al. 2017). Sand occurs in shallow marine waters, is not closely tied to energy industries and is not a mineral per se, so will not be considered further here.

2 Transition to a Sustainable Global Energy System—1.5 °C Scenarios

2.1 Characteristics of 1.5 °C Scenarios

A recent special report from the Intergovernmental Panel on Climate Change (IPCC 2018) describes two main pathways to a 1.5 °C global average temperature rise by 2100. In the first pathway, global warming stabilises and stays at or below 1.5 °C. The second pathway sees some overshoot around mid-century before returning to a 1.5 °C rise. Scenarios with long and large overshoot typically rely heavily on technologies for removing CO_2 from the atmosphere. Such negative emission scenarios are treated in Sect. 2.2, but it should be noted that related technologies have not yet been deployed at scale and it remains to be seen if they will be applicable and cost-competitive. For example, Reid et al. (2019) raise a series of issues with bioenergy and argue against a path dependency and lock-in that would be implicated by substituting bioenergy for fossil fuel in scenarios involving bioenergy with carbon capture and storage (BECCS). Scenarios that do stay continuously below a rise of 1.5 °C typically require more rapid and larger deployment of renewable energy, as well as stronger energy efficiency and demand-side measures. Such scenarios are characterised by electrification of the global energy system and the stabilisation in or even reduction of global final energy use, despite delivering modern and sufficient energy to a growing world population (IPCC 2018). They are therefore low energy demand (LED) scenarios compared with fossil-based business-as-usual scenarios even if they deliver the same energy services.

IPCC LED scenarios (IPCC 2018) typically see a reduction in final energy use of 15 percent in 2030 and 30 percent in 2050, compared with 2010. Renewables deliver approximately 60 percent of electricity in 2030 and 80 percent in 2050. This translates to an increase of more than 400 percent in non-biomass renewables from 2010 to 2030 and more than 800 percent from 2010 to 2050 (IPCC 2018). IPCC LED scenarios (IPCC 2018) with no overshoot show 10–15 percent reduction in the global use of biomass renewables for energy, and employ a limited amount of afforestation but use no other carbon dioxide removal (CDR) technologies.

Jacobson and colleagues in a series of publications (most recently Jacobson et al. 2017, 2018, 2019) construct scenarios requiring 100 percent of global energy to come from wind, water (including ocean energy, hydropower and geothermal) and solar energy by 2050 (Fig. 3.4).

Jacobson et al. (2017) provide detailed specifications of their modelled contributions from different energy sources and grid components, such as batteries, heat and cold storage and heat pumps. Jacobson et al. (2018) confirm that the energy systems modelled provide stable energy services, despite relying heavily on variable wind and solar. While the scenarios by Jacobson et al. (2017, 2018) have previously

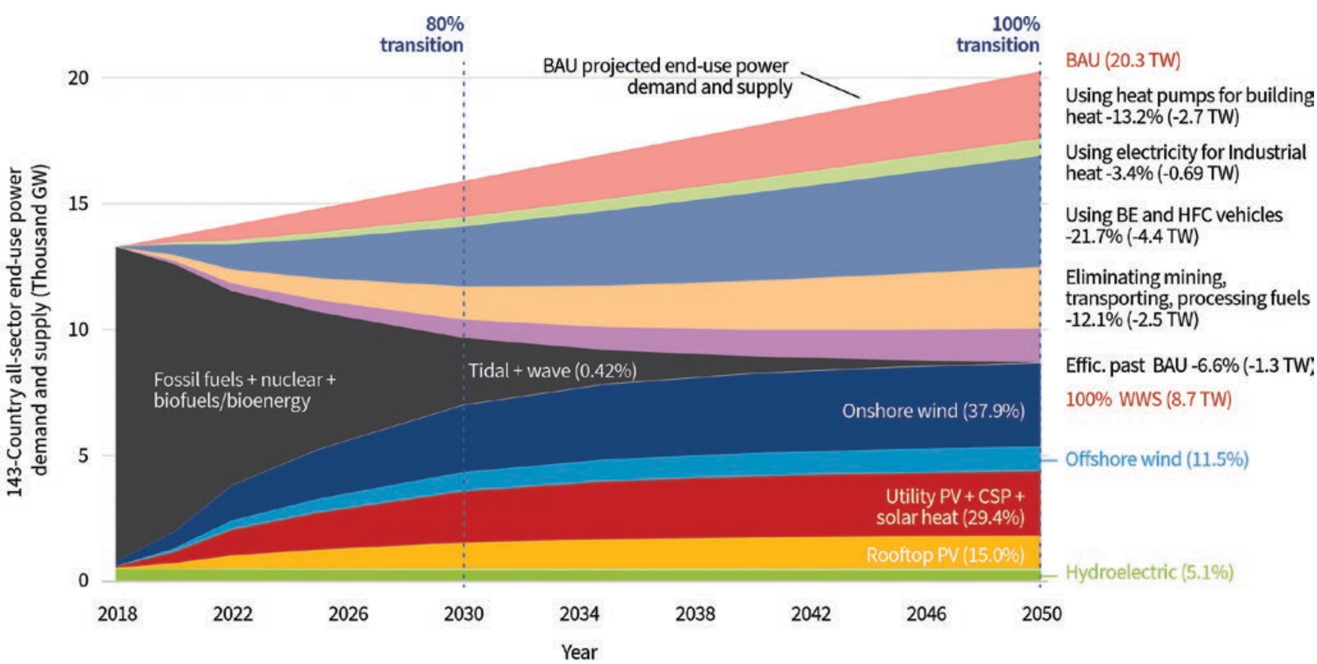

Fig. 3.4 Development of Wind, Solar and Other Energy Sources in a Low Energy Demand Transition to 100 Percent Wind, Water and Solar. 143-Country all-sector end-use power demand and supply (Thousand GW). (Note: An earlier study (Jacobson et al. 2017) gave less drastic reductions in final energy use to 11.8 TW in 2050, of which 13.6% or 1.6 TW was offshore wind. Source: Jacobson et al. 2019)

been considered extreme and have been criticised (Clack et al. 2017), other recent studies, notably Grubler et al. (2018) with a different modelling approach, achieve even larger reduction in global final energy demand in 2050, based on improved service efficiencies and demand-side transformation. Beneficial effects on other UN Sustainable Development Goals (SDGs) include better health via reduced pollution (SDG 3), reduced bioenergy and larger forest areas (SDG 15) and reduced ocean acidification (SDG 14). Environmental impacts are discussed in Sect. 5. Grubler et al. (2018) allow for some bioenergy, fossil fuel and nuclear energy. Their requirements for solar and wind energy are therefore lower than those of Jacobson et al. (2017, 2018, 2019), even though they deal with all countries and regions of the world.

Solar photovoltaic (PV) and wind energy are particularly implicated in use of certain minerals (Sect. 1.2). The installed capacities (i.e. nameplate capacities or full-load outputs) of solar PV and wind in 2050 from Jacobson et al. (2018) of approximately 30 and 17 terawatts (TW), respectively, are assumed to be upper bounds on the possible demands for installed solar PV and wind in a sustainable energy future. This includes onshore and offshore installations. The installed offshore wind capacity is estimated at about 4 TW. Note that these installed capacities are 2.5 to 6 times larger than the average utilised capacities in Fig. 3.4, reflecting a varying capacity factor (ratio between the energy delivered over a time period and the energy that would have been delivered if the turbine was running at maximum, i.e. installed capacity) due to variable winds and sun. In comparison, Teske et al. (2015), in their Advanced Energy [R]evolution scenario (ADV ER) arrive at approximately 9 TW installed capacity for solar PV and 8 TW installed capacity for wind in 2050. Teske et al. (2016) claim that this scenario is ambitious and may not guarantee to keep the global temperature rise below 1.5 °C, but may be the maximum transformation that is realistically achievable.

IEA (2019a) presents two scenarios, a stated policy scenario (SPS) and a sustainable development scenario (SDS). In the two cases, the global installed capacity of offshore wind in 2040 is estimated to be 340 and 560 gigawatts (GW), respectively. With a significant improvement in the capacity factors over the coming 20 years, the annual energy contribution from offshore wind in 2040 is estimated to be 1400 and 2350 terawatt-hours (TWh) per year for the two scenarios respectively.

2.2 Negative Emissions and Carbon Capture and Storage

As mentioned in Sect. 2.1, many of the scenarios in the IPCC report (IPCC 2018) rely on negative emissions in the later part of the present century in order to repair the overshoot and get back to a global temperature rise of less than 1.5 °C. Overshoot would imply potentially damaging impacts on the ocean and its ecosystems.

Geoengineering through solar radiation management would, if successful, limit global warming, but to avoid ocean acidification atmospheric CO_2 needs to be limited too. Several CDR technologies which would capture CO_2 from the air have been proposed. However, IPCC (2018) states, with high confidence, that: “CDR deployment of several hundreds of $GtCO_2$ is subject to multiple feasibility and sustainability constraints.” Afforestation and BECCS are the options most widely studied.

BECCS consists of harvesting biological material, burning it for energy purposes in an energy plant (power or combined heat and power) and adding facilities for CCS. A few BECCS pilot plants exist (IPCC 2018). More research experience is available on CCS from fossil fuel power plants and some from transport and storage of CO_2 for other purposes or from other sources (IPCC 2005). Storage of CO_2 is taking place also in the subseabed, notably for more than two decades on the Norwegian continental shelf (Furre et al. 2017). While CCS research and application has been promoted in several countries over the past decades, questions still remain on the practicality and cost-competitiveness. In Europe, developments in new renewable energy, notably wind for production of electricity, mean that it is steadily becoming cheaper and is already cost- competitive with fossil fuel without CCS.

With CCS, there is the added investment in capture facility, transport and storage, and the related energy penalty (increase in energy and fuel use for running the CCS process) which tends to sit around 20–25 percent (IPCC 2005). Research and development continues, however. Active projects in Norway are directed at CO_2 from other industries like cement and incineration of waste. There are also studies on the separation of CO_2 from natural gas and on delivering hydrogen for energy purposes. Related efforts may lead to an increase in the interest in storing CO_2 offshore in the subseabed and development of technology that could be transferred to BECCS. However, the energy penalty (use of more biological material to provide energy to run the process) and investments in facilities cannot be avoided. In view of the diminishing costs of electricity based on renewables, competition on cost appears to be difficult. Furthermore, the carbon capture process is never 100 percent effective so some CO_2 release has to be accepted. In a sustainable energy future with very tight restrictions on CO_2 emissions, it appears that non-biomass renewables—wind, water, solar and in some locations geothermal—have to replace the lion’s share of the energy services presently served by fossil fuel.

Overshoot in itself may lead to irreversible damage to the climate system. No CDR technologies have yet been scaled up. Costs and environmental implications are uncertain. The modelling approaches used in scenario calculations assume learning curves and discount rates that tend to favour shifting of costs to the distant future. Ethical and hard science aspects of these questions are interlinked and hotly debated in the popular media as well as scientific forums (Anderson and Peters 2016). It appears that relying on negative emission technologies in the future is optimistic and could be deemed irresponsible. In the context of this report, the 1.5 °C scenarios discussed in Sect. 2.1. are those considered to be representative of a sustainable future.

3 Ocean-Based Renewable Energy

The status and costs of the various technologies—in other words, their technical and economic potential—are addressed in this section, while the environmental impacts and wider sustainability issues are discussed in Sect. 5. Since offshore wind is considerably further advanced in its implementation than the other technologies, offshore wind is treated separately.

3.1 Offshore Wind

3.1.1 Technical Potential

When considering the available wind energy resources across the global ocean, a geophysical potential may be estimated from knowledge of the global wind field. This global potential remains theoretical, however, and of little practical interest. For example, it is considered unrealistic to deploy wind turbines in the Southern Ocean, not only because of the difficult operating conditions, but also because of the distance to users of the electricity. The cost and even the energy expenditure associated with the manufacturing and laying of electric cables, the deployment of floating turbines at great ocean depths and the loss in transmission would prohibit any such project. A more interesting consideration is the technical potential (Fig. 3.5). The technical potential takes into account technical limitations and excludes inaccessible resources. What these technical limitations are will depend on technology developments and trends. Assessments therefore vary depending on the assumptions made.

Bosch et al. (2018) estimate the global and regional offshore wind power potential. They consider three different water depth ranges (0–40 m, 40–60 m and 60–1000 m) within the EEZ of each country. Various exclusion zones are accounted for. They find that the worldwide technical potential for power production from offshore wind amounts to about 330,000 TWh/year as compared with the world's electric energy production in 2018 of about 26,700 TWh/year (IEA 2018) and the modelled offshore wind contribution in 2050 in Fig. 3.4 which corresponds to 9000 TWh/year. Bosch et al. (2018) also review resource estimates made by others. The global total estimates range from 157,000 TWh/year to 631,000 TWh/year, depending upon the assumptions made.

A similar study performed by Eurek et al. (2017) estimated the global potential for offshore wind deployment while including various exclusion zones related to water depth, distance to shore, protected areas and sea ice. They ended up with an estimated potential of 315,000 TWh/year using a capacity factor of 0.285.

IEA (2019b) has also made estimates on the technical potential for offshore wind, using somewhat different criteria for exclusion zones. The results are summarised in Table 3.1. The total global technical resources are found to be about 420,000 TWh/year.

The above estimates for the global potential for offshore wind are 6 to 23 times the present global electricity consumption. Most of the estimates also exceed the pres-

Table 3.1 Offshore Wind Potential (TWh/year)

"Near shore" denotes sites less than 60 km from the shore and "far shore" denotes sites at a distance of 60–300 km from the shore. Source: IEA 2019b

Fig. 3.5 Geophysical, Technical, Economic and Social/Political Potential of Wind or other Energy Resources across the Global Ocean. (Source: Adapted from Hoegh-Guldberg et al. 2019)

ent global total primary energy consumption (14,314 million tonnes of oil equivalent (Mtoe) = 166,470 TWh in 2018; IEA (2019b)). The above estimates do not consider limitations due to costs and make some assumptions on technological elements. The economic potential depends on the costs (see next section) of these technologies in relation to competing technologies. The economic potential will be smaller than the technical potential. Figure 3.4 shows one example of an estimate of economic potential given certain assumptions. Social/ political and environmental considerations discussed in Sect. 5 may limit the potential further (Fig. 3.5).

3.1.2 Status of Technology and Costs

While there is abundant technical potential for offshore wind energy generation, the economics of deploying energy offshore limit the capacity that might be installed. In future low-carbon scenarios, technologies with similar GHG mitigation potential compete. A conservative approach based on a range of earlier published scenarios was chosen by Hoegh-Guldberg et al. (2019), resulting in an estimate of up to 3500 TWh/year in 2050 from offshore wind. The 1.6 TW yearly average offshore wind power from Jacobson et al. (2017), corresponding to approximately 14,000 TWh/year, and the 1.0 TW figure (Jacobson et al. 2019) corresponding to approximately 9000 TWh/year (Fig. 3.4), are estimates of the economic potential for offshore wind in a future low-emission scenario. While the numbers cited in Sect. 3.1 do take into account areas that would be unavailable for offshore wind, they are still theoretical and not likely to ever be achieved. However, theoretical estimates are at least an order of magnitude larger than those of Jacobson et al. (2017), indicating that there are no resource constraints on offshore wind installations.

By the end of 2018, the total worldwide installed capacity of wind energy amounted to 564 GW, of which only 23 GW were offshore (IRENA 2019c). The yearly electrical power production from offshore wind amounted to about 77 TWh (IEA 2018). For offshore wind turbines, bottom-fixed turbines in shallow water depth (< 40 m water depth) dominate. Deep-water, floating support structures are used in one wind farm only, a 0.03 GW wind farm on the east coast of Scotland. This wind farm was installed in 2017. Europe presently has the majority of the offshore wind installations, with an installed capacity of 18.5 GW, while Asia has 4.6 GW. It has been anticipated that China will have more installed capacity than Europe by 2021 (Backwell 2019). However, according to IEA (2019a) estimates, China will overtake Europe in the early 2030s. It is expected that North America will be number three after Asia and Europe.

As the wind conditions in general are better offshore – the wind is more stable—the utilisation of the installed generator capacity is generally higher than onshore.

In Europe, the capacity factor for offshore wind farms commissioned in 2018 was 43 percent, increasing from 38 percent in 2010. Onshore, the comparable global averages are 34 percent and 27 percent, respectively (IRENA 2018a, b). IEA (2019b) expects that, by 2040, the capacity factors for good offshore sites will move towards 60 percent, while the worldwide average will be close to 50 percent. Over the last decade, the cost per MW of installed power has been reduced and the capacity factor for new installations has increased. The operation and maintenance costs per produced megawatt-hour (MWh) are also expected to decline as the turbines are designed to be more robust and fit for the offshore environment. All three factors contribute to a reduced levelised cost of electricity (LCOE; the ratio between the discounted costs over the lifetime of an electricity-generating plant and the sum of actual energy amounts delivered). However, the single most important factor to reduce LCOE is the cost of capital or the discount rate. Reduced project uncertainties and favourable financing terms will contribute to a reduced LCOE. IEA (2019a) shows that using an average discount rate of 4 percent rather than 8 percent may reduce the LCOE for offshore wind projects from US $140/MWh to $100/MWh. As the number of shallow-water, bottom-fixed support structures, mainly monopiles, has increased, the cost reduction due to mass production has been significant. Bottom-fixed offshore wind turbines are thus considered mature and have reached commercial scale. The costs have reached parity with fossil sources of electricity in recent contracts, down towards $50/MWh, without transmission costs. The Dogger Bank Creyke Beck A wind farm won a UK government auction for renewable power in September 2019, with a strike price of $51/MWh (IEA 2019a; Dogger Bank Wind Farms 2019).

IRENA (2019b) shows similar LCOE figures. Stehly et al. (2018) found that the 2017 average in the United States was $124/MWh for bottom-fixed and $146/MWh for floating. In Europe, the LCOE for projects commissioned in the period 2010–2015 shows very moderate decline. However, after that, a significant drop in LCOE for new projects is observed. In 2012, the European Union set an ambitious aim of LCOE of $110/MWh in 2020. This aim has already been achieved for several projects. For projects commissioned in 2018, the European average was $134/MWh and for projects in China $105/MWh (IRENA 2019b). However, contracts with record low costs have been signed in the Netherlands ($55/MWh to $73/ MWh) and Denmark ($65/MWh) for a near-shore project, excluding grid connection costs. No data are available for floating systems as only one small wind farm has been realised. Ørsted (2019) indicates a cost reduction in offshore wind of 18 percent per doubling of capacity.

Bottom-fixed support structures are designed for site-specific conditions. Worldwide, there are limited large, shallow-water areas suitable for wind-power development. Bosch et al. (2018) estimate the potential wind power production from shallow-water areas (<40 m) to be less than one-third of the potential production from the deeper areas (60–1000 m water depth). IEA (2019a) estimates the shallow-water areas (<60 m water depths) to be about 20 percent of the total areas available (see Table 3.1). Deep water requires floating support structures. Such solutions are less mature than the bottom-fixed solutions and are presently more expensive than the shallow-water bottom-fixed support structures. Floating support structures are well suited for standardisation and mass production as they do not depend upon site-specific conditions at sea bottom. In a scenario with large-scale deployment of floating offshore wind turbines, it is thus expected that the LCOE will be comparable with that of bottom-fixed support structures.

The increased size of turbines and wind farms, as well as the learning rate of the offshore wind industry, have all contributed to reduced LCOE. However, moving into deeper water and farther from shore has partly outweighed the cost reductions. In Fig. 3.6, an approximate split of the capital costs of offshore wind turbines completed in 2018 is given.

3.1.3 Future Development Scenarios

According to IRENA (2019c), the rate of wind energy deployment (2017–18) is 54 GW/year globally. To achieve the required energy transformation (increased electrification, reduced emissions) a significant speed-up in wind energy installations is required. IRENA (2019c) indicate 200 GW/year in 2030, increasing to 240 GW/year in 2050 worldwide. How much of this growth can be taken offshore is uncertain. However, the resources are not a limitation.

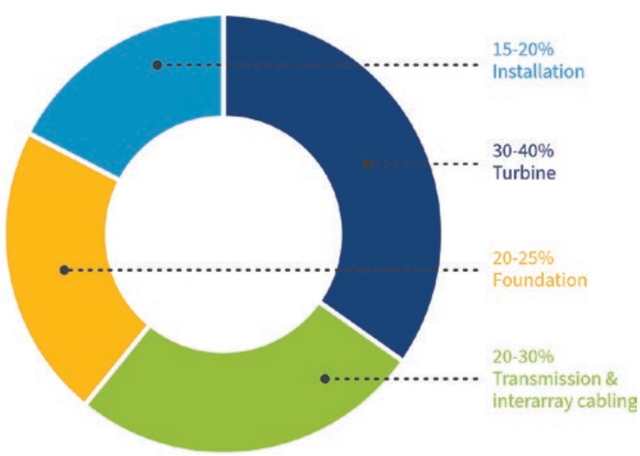

Fig. 3.6 Approximate Split of the Capital Costs of Offshore Wind Turbines Completed in 2018. (Source: IEA 2019b; IEA analysis based on IRENA 2019a, IJGlobal 2019 and BNEF 2019)

According to IEA (2017), offshore wind generation has grown five-fold over the period 2010–2015 and is expected to double over the period 2015–2020. IEA (2019b) in their SDS has a compound annual growth rate (CAGR) of 16.9 percent for the global offshore wind market in the period 2018–2040, while Bloomberg (2019) forecasts growth at a CAGR of over 18 percent over the period 2019–2023. Between 2020 and 2025, offshore wind generation needs to triple to be fully on track with the 2 °C target. By 2025 about 2785 TWh/year of electricity should be produced from offshore wind to be in line with the SDS. The corresponding figure for 2040 is 6950 TWh/year. It is indicated that in 2040 the electric energy produced from other ocean-based renewable energy sources could contribute more than 1200 TWh/year.

Assuming that it comes from offshore wind alone, this requires an installed capacity of about 326 GW of offshore wind in 2040. To achieve this, 15 GW of offshore wind has to be installed every year for 20 years. Using the Jacobsen et al. (2017) figures, the contribution from offshore wind is larger. To achieve 3800 GW of installed offshore wind capacity (corresponding to 1600 GW average power) in 2050, an installation rate of 127 GW/year is required over 30 years. In other words, the 2 scenarios require substantially different installation rates, almost 10 times greater for the Jacobsen et al. (2017) scenario. This difference is mainly due to differences in the assumptions regarding the future contribution of offshore wind to the electricity supply. Both scenarios require an accelerated development of new ocean areas for offshore wind. Development of deep-water areas with floating wind turbines can make a significant contribution to achieve this goal. Even further acceleration would be needed to ensure only a global temperature rise of 1.5 °C. It is to be noted that the European Commission (2018) presents a strategic roadmap which would lead to an even larger contribution of offshore wind in their region.

3.2 Other Ocean-Based Renewable Energy

3.2.1 Technical Potential

There are several other renewable energy technologies which exploit the available resources of the offshore environment. The technologies that harness energy directly from the ocean itself (i.e. water-based technologies) have particular advantages, such as the power density of moving water (much larger than that of air), the predictability and consistency of the resource (notably tides), and the fact that the resource can typically deliver at times when other renewable energy resources do not. Floating solar photovoltaics and high-altitude wind have different characteristics. The range of other ocean-based renewable energy technologies, summarised in Table 3.2, include:

Table 3.2 Geophysical and Technical Potential Estimates for Ocean-Based Renewable Energy Technologies, with Technology Readiness Levels Estimated

Technology	Geophysical energy potential (TWh/year)	Technical potential (TWh/year)	Technology readiness level
Tidal range	26,000	6000	9
Tidal stream	–	150	8
Wave	32,000	1750–5550	7
OTEC	38,000	–	4
Salinity gradient	–	1650	3
Ocean current	–	–	3
Floating PV	700,000,000	–	7*
High-altitude wind	–	–	6

Note: The technology readiness level (TRL) scale used here is based on the guidance principles for TRLs for ocean-based energy technologies, as defined by the European Commission (Appendix A in Magagna et al. 2018), ranging from TRL 1 (Basic principles observed), to TRL 9 (Actual system proven in operational environment). The actual assessment of TRLs for each technology is our own. Offshore wind would appear with TRL 9

** Very recent developments (Oceans of Energy 2020) could justify lifting the TRL of floating PV to 8*

- **Tidal range energy:** Tidal range energy technologies include tidal barge energy systems and tidal lagoon energy systems. Tidal range systems represent the bulk of existing installed ocean-based renewable energy, having been in operation for decades.

  Tidal range technologies act effectively as low-head 0.22 percent of the world ocean. Taking into account the impracticality of ice-covered regions, the global annual potential energy from tidal range technologies is approximately 6000 TWh, with 90 percent distributed across five countries (O'Neill et al. 2018).
- **Tidal stream energy:** With the rise and fall of tidal water elevation that occurs twice a day, tidal currents are generated. Tidal stream energy converters harvest the energy of these currents and convert it to electrical energy. Many technologies are in development, but convergence towards horizontal axis turbines has occurred. These tidal energy converters are intended to be modular, to be deployed in subsurface arrays. No reasonable estimate for the total global geophysical tidal stream potential is known, but best estimates of the total global technical tidal stream energy potential is approximately 150 TWh/year (with high uncertainty; Yan 2015).
- **Wave energy:** Wave power converts the kinetic and potential energy of the surface wind-waves of the ocean into electrical energy (or some usable commodity, such as desalinated water). Wave energy converters are designed to be deployed in arrays, similar to wind farms. Many concepts are in development, with little to no convergence in technologies. The total geophysical wave energy potential is estimated to be 32,000 TWh/year (Mørk et al. 2010), with estimates of the global technical potential ranging from 1750 (Sims et al. 2007) tohydropower systems—in their simplest form, water is constrained on the high tide (by barrage or lagoon) and powers a water turbine on release. The estimated global annual geophysical tidal range potential is around 25,880 TWh (constrained to regions with water depth < 30 m, and a reasonable threshold for energy output). The distribution of this resource, however, is confined to just 5550 (Krewitt et al. 2009) TWh/year.
- **Ocean thermal energy conversion (OTEC)**: OTEC exploits the temperature gradient between the cold deep ocean and the warmer surface waters and converts it into electricity or other commodities, such as desalinated water, heating and cooling, or nutrient supply for other marine applications. A temperature gradient in excess of 20 degrees is required, which constrains interest in OTEC to the tropics (+/−20 degrees latitude). An upper limit of the long-term steady-state global resource has been estimated to about 38,000 TWh/year (Nihous 2018). This is from a theoretical study assuming all OTEC facilities have optimal discharge depth and efficient generators. The technical potential is very uncertain.
- **Salinity gradient energy**: This technology converts energy produced from the chemical pressure that results from the difference in salt concentration between freshwater and saltwater. It can be exploited at river mouths where freshwater and saltwater meet. The technical potential for power generation has been estimated at 1650 TWh/year (Lewis et al. 2011).
- **Ocean current energy**: These technologies operate along a similar concept to tidal stream energy, harvesting the flow of water in motion. However, the targeted ocean currents for these technologies are the deep-water currents of the thermohaline circulation (e.g., the western boundary currents such as the Kuroshio, the Gulf Stream and the East Australian current). These currents have less variability than the tidal currents but are less accessible. No estimate of technical potential has been made, but it is an area of interest for innovators.
- **Floating solar photovoltaics (PV)**: Over the past three years, the installed capacity of floating solar (e.g., PV panels deployed on floating platforms) has increased at a CAGR of 168 percent, to a total capacity of 1.3 GW (World Bank Group, ESMAP and SERIS 2019). This is predominantly on inland waterways (reservoirs, canals, etc.), with the offshore market still nascent. While there are unique challenges for offshore, the available resource presents an opportunity for a growing market. No global estimate of the offshore solar resource is available. However, with the ocean representing 70 percent of the

earth's surface, a very rough estimate of the geophysical potential is 70 percent of the almost 1 billion TWh (WEC 2013) of solar radiation reaching the earth's surface each year, which represents an abundant resource**.**

- **High-altitude wind:** Technologies exploiting wind at high altitudes are under development, notably using kites (Lunney et al. 2017). One advantage of kites compared with conventional turbines is their low demand for materials. Testing in offshore environments has recently begun from a floating platform (Norwegian Offshore Wind Cluster n.d.). Since most ocean-based renewable energy technologies are still in early phases without much deployment, few studies have been done on life cycle and material needs assessment (Uihlein 2016). It seems that the major metal requirements of these technologies would be similar to those of offshore wind. Specific requirements for floating solar PV would be similar to those for land-based PV (Arrobas et al. 2017).

3.2.2 Status of Technology and Costs

At the end of 2018, the total installed capacity of ocean-based energy technologies was 532.1 MW (IRENA 2019a), consisting mainly of tidal barrage technology at two sites. Installed capacity in 2016 was 523.3 MW, which generated 1023.3 GWh electricity (IRENA 2019a), implying a mean capacity factor of 0.23 across the sector. Estimates of the LCOE are subject to a range of parameters, including the local conditions which increase costs. The estimated LCOE for wave energy is in the range of \$360–690/MWh (IRENA 2014). Tidal stream energy LCOE is presently in the range of \$275–520/MWh (IRENA 2014b), contingent upon sufficient current speeds. LCOE of OTEC is in the range of \$600–940/MWh (IRENA 2014c). Learning rates for ocean-based technologies are typically assumed at around 15 percent (OES 2015), with average LCOEs for wave energy and tidal energy of \$165–220/MWh by 2030 (Cascajo et al. 2019; SI Ocean 2013). Due to the capital intensity of OTEC, interest and discount rates have a high impact on LCOE estimates. Economies of scale are anticipated to bring LCOE into a range of \$70–190/MWh for installed capacities exceeding 100 MW (IRENA 2014c; OES 2015).

3.2.3 Future Development Scenarios

Electricity generation from marine technologies increased an estimated 3 percent in 2018 (IEA 2019c). This rate of growth is not on track to meet the IEA SDS target for ocean-based technologies of 15 TWh/year in 2030 (IEA 2019c), which would require an annual growth rate of 24 percent to meet. The IEA SDS corresponds with an emissions target of approximately 25 GT CO_2e by 2030. By 2050, the range of projected power generation from ocean-based technologies for various scenarios (reference technology scenario/two degrees scenario/beyond two degrees scenario) is 108/536/637 TWh/year (2050 emissions 40/13/4.7 GT CO2e), corresponding to annual growth rates from present of 15/21/22 percent (IEA 2019c). The full range of projections currently being put forward for other ocean-based technologies extends up to a max of 1943 TWh/year (Teske et al. 2010).

4 Motivations for Deep-Seabed Mining

As mentioned above (Sect. 1.2), there is increased global demand for metals and REEs from emerging technology industries (Table 3.3). For example, renewable energy production requires significant amounts of a range of metals, generally more than required for production of energy from fossil fuels (IRP 2019; Giurco et al. 2019). Many of the required metals and elements occur together—not only in large amounts but also at higher concentrations than on land—in minerals precipitated in the deep ocean. The higher concentration makes them attractive for mining operations and contributes to their resource potential (Petersen et al. 2016).

Mining on land has significant environmental and social impacts (IRP 2019). Among these, displacement of communities, contamination of rivers and groundwater from tailings, damage to communities from tailings slides, violation of land rights, mining community repression and unfavourable child labour/slavery practices (Church and Crawford 2018; Sovacool et al. 2020) have all provided the incentive to look to the ocean as a source of minerals (Batker and Schmidt 2015; IRP 2019). A large fraction of the minerals required for renewable energy technologies are produced in states with corrupt or fragile governance (Church and Crawford 2018). The social impacts of deep-seabed mining is a topic less considered, although concerns have been expressed in the Pacific region about the potential for deep-seabed mining to interfere with local traditional practices, local communities' property, food sources and lifestyle, and that deep-seabed mining could exacerbate social tensions and even lead to political instability (SPC 2012; Aguon and Hunter 2018). Also, the extraction of deep-seabed minerals from offshore sites should not be considered in isolation from the infrastructure development, and the transfer and processing of ore, which would occur on land and could also have impacts similar to mining on land (SPC 2013).

Table 3.3 Major Uses, Production and Potential Supply in Selected Seabed Deposits Relative to Land-Based Reserves for Metals Targeted for Deep-Seabed Mining

Metal	Uses	Deep-sea sources	Annual production in 2017 in thousands of metric tonnes (top 3 land producers)	Annual projected demand in 2050 in Thousands of metric tonnes from low-carbon energy technology	Metal supply in the clarion-clipperton zone in thousands of metric tonnes (% of land-based reserves)#	Metal supply in the prime crust zone in thousands of metric tonnes** (% of land-based reserves)#	Inferred metal supply in seafloor massive sulphides in thousands of metric tonnes*** (% of land-based reserves)#
Copper (Cu)	Used in electricity production and distribution – wires, telecommunication cables, circuit boards. Non- corrosive Cu-Ni alloys are used as ship hulls	Polymetallic sulphides at hydrothermal vents, polymetallic nodules on abyssal plains	19,700 (Chile, Peru, USA)	1378	226,000* (23–30% of land-based reserves)	7400 (0.7% of land-based reserves)	21,600 (2% of land-based reserves)
Cobalt (Co)	Used to produce high-temperature super alloys (for aircraft gas turbo-engines, rechargeable lithium-ion batteries)	Cobalt-rich crusts on seamounts, polymetallic nodules on abyssal plains	110 (Democratic Republic of Congo, Australia, China)	644	44,000 (340–600% of land-based reserves)	50,000 (380% of land-based reserves)	N/A
Zinc (Zn)	Used to galvanise steel or iron to prevent rusting, in the production of brass and bronze, paint, dietary supplements	Polymetallic sulphides at hydrothermal vents	12,800 (China, Peru, Australia)	N/A	N/A	N/A	47,400 (21% of land-based reserves)
Manganese (Mn)	Used in construction for sulphur fixing, deoxidizing, alloying properties	Cobalt-rich crusts on seamounts, polymetallic nodules on abyssal plains	16,000 (China, Australia, South Africa)	694	5,922,000 (114% of land-based reserves)	1,714,000 (33% of land-based reserves)	N/A
Silver (Ag)	Used in mobile phones, personal computers, batteries. Also in mirrors, jewellery, cutlery and for antibiotic properties	Polymetallic sulphides at hydrothermal vents	25 (Peru, China, Mexico)	15	N/A	N/A	69 (4.3% of land-based reserves)
Gold (Au)	Used in jewellery, electrical products (metal-gold alloys)	Polymetallic sulphides at hydrothermal vents	2.5–3 (China, Australia, USA)	N/A	N/A	N/A	1.02 (0.002%
Lithium (Li)	High-performance alloys for aircraft; electrical, optical, magnetic and catalytic applications for hybrid and electric cars	Cobalt-rich crusts on seamounts, marine sediments	43 (Chile, Australia, China)	415	2800 (25% of land-based reserves)	20	N/A
Nickel (Ni)	Stainless steel (automobiles, construction), weapons, armour	Cobalt-rich crusts on seamount, polymetallic nodules on abyssal plains	2100 (Russia, Indonesia, Canada)	2,268	274,000* (180–340% of land-based reserves)	32,000 (21% of land-based reserves)	N/A

Note: The land-based reserves are known with enough certainty that they can be mined economically whereas the seafloor estimates are far from this level of certainty

** India's 75,000 km2 nodule claim in the Indian Ocean contains another 7000 thousand metric tonnes of Cu and Ni*

*** Based on 7,533,000 thousand metric tonnes in the Prime Crust Zone*

**** Based on 600,000 thousand metric tonnes in the neovolcanic zone with grades determined as averages of analysis of surface samples. Source: Compiled from Hein et al. 2013; Petersen et al. 2016; Miller et al. 2018; Hannington et al. 2010; Fleming et al. 2019; Sovacool et al. 2020*

4.1 Will Deep-Seabed Mining Help Address Climate Change?

Deep-seabed mining could lead to an increased global supply of cobalt, copper, nickel, silver, lithium and REEs (Hein et al. 2013), which could make solar energy, wind turbines and electric cars more affordable and/or prevalent, potentially aiding the transition to renewable energy (Dominish et al. 2019). Mining deep-sea polymetallic nodules is calculated to release less CO_2 per kg than mining on land (Van der Voet et al. 2019). A recent report commissioned by a deep-seabed mining company involved with three exploration tenements in the CCZ suggests that extracting half of the CCZ nodules would provide the manganese, nickel, cobalt and copper needed to electrify 1 billion cars, while releasing only 30 percent of the greenhouse gases of land mining (Paulikas et al. 2020).

This conclusion has been questioned under various future global energy scenarios. Teske et al. (2016) conclude that an energy revolution, required to combat climate change, could take place without deep-seabed mining. Increasing mineral production rates in combination with more recycling (e.g., of lithium-ion batteries) and research into alternative technologies that reduce or completely eliminate the use of lithium, silver, neodymium and dysprosium – the critical elements under the greatest resource pressure – would advance this option. Recycling costs and thus incidence is a function of energy and raw material costs, which are affected by collection and transportation efficiency; in many cases, where the mass of the desired mineral is small in the waste stream, product redesign would be required for recycling to become effective.

4.2 Can Metal Demand Be Reduced to Avoid Deep-Seabed Mining?

Key to reducing metal demand is the concept of a circular economy, which acts through improved product design, reduced demand, reuse, recycling, reclassification of materials and use of renewable energy for production (Ghisellini et al. 2016). With REEs and metals, it is particularly hard to achieve economies of scale in recycling and reuse, because of the limited quantity of elements contained, the long lifespan of some products using these elements, and metal separation issues requiring complex and energy- intensive processes (Schüler et al. 2011). The materials added to improve product quality and durability can make metal recovery from electronic products even more difficult (Tansel 2017).

Models for increasing metal demand often assume growth in demand based on recent rates of increase, or based on current technology status, which may in fact become obsolete quickly. Commodity price forecasts are notoriously inaccurate. As an example: it is reported that Massachusetts Institute of Technology, commissioned by the ISA to undertake financial modelling for nodule mining in the CCZ, in the space of several months revised its estimate of the likely value of a metric tonne of one target metal in nodules (electrolytic manganese metal) from $3500 to $1561 (Africa Group 2019). Future demand for resources could be lower than expected, including through saturation in material use as countries move through stages of development (Bleischwitz et al. 2018). This has been documented for copper in the United States, United Kingdom, Japan and Germany, and may be especially relevant for emerging economies, such as China, that are undergoing changing growth patterns that could stabilise demand in the future (Bleischwitz et al. 2018).

5 Sustainability Challenges and Enabling Conditions

5.1 Environment, Vulnerabilities and Costs

5.1.1 Environmental effects of ocean-based renewable energy deployment

The potential benefits of ocean-based renewable energy to contribute to future low-carbon energy generation have been specified in the sections above. However, given the early stages of development of these technologies, there remain environmental risks to the marine environment from their deployment, particularly when considered at the scale required to make a decisive contribution to the future energy system.

As offshore wind is a more mature technology, with greater installed capacity, the risks it poses are slightly better known than for the less mature ocean-based technologies. However, there are still large knowledge gaps in the field of environmental impacts of offshore wind. Considerable lack of baseline data may be a key limitation when evaluating impacts, depending on location and whether there have been any prior studies in the area for other purposes such as oil and gas or fisheries. Baseline data provide information on the state of the marine environment prior to construction, and are used as a basis for comparison over time during the construction and operational phases. Such data may include information on distribution of important and vulnerable species and habitats, and migration routes for marine mammals, fish and birds. Baseline research on species abundance and distribution over annual cycles, population structures and status, and assessment of ecosystem dynamics are necessary.

The literature on the environmental impacts of ocean-based renewable energy was very limited before 2000, but it has increased considerably in the last 20 years (Mendoza et al. 2019; Zydlewski et al. 2015). Boehlert and Gill (2010) provide an early overview of literature with recommendations for needed environmental research on ocean-based renewable energy developments including offshore wind. Impacts range from effects on bird migration, physical habitat change on the seafloor, chemical spills and sound (in air and water) to electromagnetic disturbance from submarine power cables.

The primary environmental concerns of ocean-based renewable energy deployment are typically common to both offshore wind and most of the other ocean- based technologies. Key concerns relate to possible interactions between aspects of the energy conversion systems (turbines, anchors, foundations, mooring lines, etc.) and marine ecosystems. As the installed capacity of these offshore energy systems increases, additional concerns relating to ecosystem processes may arise, such as concerns over changes to atmospheric mixing and climate implications from offshore wind (Wang and Prinn 2011) or concerns around changes in sediment transport and coastal stability implications from other ocean-based technologies (Contardo et al. 2018). OTEC is rather different from the other ocean-based energy technologies. Water discharged in the upper part of the water column would cool and change the environment and may cause concern well before reaching a new steady state consistent with the maximum geophysical potential of OTEC (Nihous 2018).

Regulators and other stakeholders for ocean-based energy projects have identified several possible interactions and potential effects of ocean-based energy devices. These include some that have been evaluated and deemed less critical, such as release of chemicals from coatings or oil spills from devices. As the evidence base grows, there has also been progress towards "retiring" some of the environmental concerns that have been assigned to ocean-based energy developments, such as the effects of electromagnetic fields on marine organisms (Copping et al. 2019). Noise and fauna–device interactions, however, remain key environmental concerns.

Environmental impacts will vary among the technologies. For bottom-fixed offshore wind, noise from piling during construction is of particular concern. Noise associated with pile-driving of foundations can lead to changes in the behaviour of a range of sea animals. For example, porpoise populations have been found to temporarily migrate during construction of offshore wind farms, with population density returning to normal following construction (Carstensen et al. 2006). Based on measurements from wind farms in the German Bight, Brandt et al. (2018) find that harbour porpoises avoid the construction site for up to two days after piling activities, and observable declines in porpoise detections are found up to 17 km away during actual piling activities.

Noise mitigation systems have reduced the impacts and such systems are being further developed.

Noise also affects fish. Hammar et al. (2014) studied impacts on cod in an area between Sweden and Denmark addressing impacts from pile-driving, working vessels and cable-trenching during construction, as well as from turbine noise, turbine lubricants and cable electric fields during operation. They found that noise from pile-driving was the most significant stressor and that ecological risks can be significantly reduced by avoiding particular construction events during the cod recruitment period.

While sound intensities of noise from shipping and installation of wind turbines, notably pile- driving, will be considerably higher than during operation, noise from operation of wind turbines is also of concern.

During the operation phase, the noise from the wind turbines varies with the strength of the wind. Noise arises in the turbine gearbox and generator, and is transmitted through the structure to the water and to the ground. Clearly the noise will depend on the type of gearbox and on the fundament or anchoring.

During the operational phase, the noise from ocean- based energy technologies might be considered comparable with other offshore industries; however, the characteristics of the sound will differ from the sound from other industries (e.g., slower rotational speeds). For subsurface technologies (e.g., wave and tidal devices), marine mammals may be disturbed by certain frequencies of noise and potentially avoid the area.

Wahlberg and Westerberg (2005) review pertinent aspects of underwater sound and hearing abilities of fish, noting that despite decades of increasing anthropogenic noise in the ocean due to maritime traffic and other human activities, the knowledge about fish response to noise is very limited. They conclude that fish can detect offshore wind turbines and that the noise may have a significant impact on the maximum acoustic signalling distances by fish within a range of a few tens of kilometres. The noise level and characteristics are expected to vary between types of wind turbine and fundament, and the hearing abilities at different sound frequencies vary among fish species.

Despite considerable efforts on understanding the impacts of noise from seismic investigations for offshore oil and gas, marine noise management in general is still in its infancy. De Jong et al. (2018) provide experimental evidence for the negative effects of noise on acoustic communication and spawning success for fish. But it remains to be investigated in the field and with noise characteristics from offshore wind activities. Electrification of the service vessels in the wind farm will reduce the noise level and other ship traffic will be minimised in the wind farm area. A risk-based approach integrating noise from different human activities (Faulkner et al. 2018) is proposed as a component of marine spatial planning. Offshore infrastructure may also create habitats acting as artificial reefs that enhance biodiversity and protect the area against heavy fishing including bottom trawling. Current regulations for the North Sea oil and gas installations require decommissioning at end of life, but complete decommissioning is not favoured by most experts (Fowler et al. 2018), neither for oil and gas nor for offshore wind installations. Both with respect to reef effects and noise, it is worth remembering that the distance between individual turbines in an offshore wind farm is in the order of 6–10 rotor diameters. For state-of-the-art turbines with a rotor diameter of 160–220 m, the distance between the turbines will be in the range of 1–2 km.

Collisions with offshore wind turbines are a notable risk for some seabird species, if turbines are placed such that they disconnect important roosting and feeding sites, or in migratory routes. However, recent research, spanning a two-year monitoring period at the Vattenfall Thanet offshore wind farm (one of the United Kingdom's largest offshore wind farms) has shown the risk of seabirds colliding with offshore wind turbines is lower than previously predicted (Skov et al. 2018), with six strikes recorded during the two-year monitoring period. For other ocean-based energy technologies, collision between devices and marine mammals is a key concern (Copping et al. 2016).

With increasing deployment of offshore wind, the potential environmental risks associated with offshore wind are much more clearly understood and there is growing consensus towards the position that offshore wind farms can be constructed without significantly damaging the environment. However, to achieve this requires proper planning and putting in place mitigation measures (WWF 2014). Other ocean-based technologies, being less mature, with fewer deployments from which to monitor potential risks, have much greater scientific uncertainty surrounding the probability of occurrence, and/or the severity of consequences, specified as the potential risk.

The combination of collecting proper baseline data, careful monitoring of interactions, effective device design and proper marine spatial planning for projects will be required to ensure that potential risks are mitigated. Ecosystem modelling is being used to determine impacts on ecosystem indicators (Raoux et al. 2018). Various approaches and methods for marine spatial planning with specific focus on offshore wind have been proposed (Pinarbasi et al. 2019).

No wind energy projects in the high seas have been proposed up to now. However, the resource is considerable and may be of interest in the future. Elsner and Suarez (2019) make the point that important justice questions remain concerning access and benefits. Even if the UN Convention for the Law of the Sea (UNCLOS; UN 1982) is recognised as the legal basis for any offshore wind deployments in the high seas, there is a danger that flag states may undercut environmental and safety standards for offshore wind energy installations (Elsner and Suarez 2019). Marine spatial planning approaches and the establishment of cooperative mechanisms are needed to safeguard against such developments.

5.1.2 Environmental Effects of Deep-Seabed Mining

Environmental unknowns, vulnerabilities and costs are some of the most challenging aspects of deep-seabed mining (Thompson et al. 2018). The remoteness of most of the deep ocean combined with the harsh operating conditions (high pressure, low temperatures and darkness), requiring expensive and highly technical equipment, have resulted in limited exploration and scientific research. These constraints, and the vastness of the area in question, mean that the majority of the deep ocean, both within and beyond national jurisdictions, are poorly characterised and understood, or still completely unexplored.

Of the three habitat types vulnerable to mining – abyssal plains with polymetallic nodules, hydrothermal vents with massive sulphides and seamounts with cobalt-rich ferromanganese crusts, the last – especially in the Prime Crust Zone (an area in the West Pacific identified as of the greatest economic interest for mining cobalt-rich crusts)— are the least explored, hence their biodiversity has not yet been characterised (Morgan et al. 2015). Even in polymetallic nodule zones, thought to be bereft of life only 40–50 years ago when UNCLOS Part XI was crafted, four decades of research by contractors and scientific organisations in the nodule-rich CCZ show that environments and associated biodiversity remain largely undiscovered or unidentified. For example, in the eastern CCZ, over 50 percent of species over two centimetres (cm) in size collected by Amon et al. (2016) in 2013, and 34 of the 36 species of xenophyophores (large single-celled organisms) collected by Gooday et al. (2017) in 2015, were new to science. And while hydrothermal vents are the most characterised and understood of the three habitats, many species at vents appear to be rare (comprising <5 percent of the total abundance in samples), and poorly known (Van Dover et al. 2018). Finally, the connections of these habitats to the wider global functioning is poorly understood, although new studies have begun to shed some light on this (Sweetman et al. 2019; Ardyna et al. 2019)

5.1.3 The Impacts of Deep-Seabed Mining Remain Unknown

Deep-seabed mining is expected to create environmental impacts that involve the following (Van Dover 2014; Levin et al. 2016; Vanreusel et al. 2016; Gollner et al. 2017; Boetius and Haeckel 2018):

- Direct removal of the resources which act as a substrate for specialized faunal communities, including at least half of the species larger than 0.5 millimetres (mm) in size inhabiting these ecosystems – as a result, the animals will be killed or crushed.
- Changes to the geochemical and physical properties of the seafloor.
- Sediment plumes created from the disturbance on the seafloor as well as from the return waterdeposited in the water column that may smother or clog feeding apparatus and limit visibility.
- Contaminant release and changes to water properties.
- Increases in sound, vibration and light.

Several large programmes (such as MIDAS and JPI Oceans Mining Impact) have addressed likely mining impacts, but in the absence of disturbance studies on appropriately large scales (across space and time), the intensity, duration and consequences of the impacts of commercial mining remain speculative. Regulators can set rules designed to minimise environmental impacts, such as requiring processed water and sediment to be returned to the ocean at certain depths in order to minimise the creation of a sediment plume in the water column. However, deep-seabed mining poses a risk for biodiversity loss, forced species migrations and loss of connectivity, potentially leading to species extinctions in the deep ocean (Van Dover et al. 2017; Niner et al. 2018). This is of particular concern as many deep-sea species may have genetic compounds that could have biotechnical or pharmaceutical use in the future. There could also be impacts to ecosystem services, such as to fisheries, climate regulation, detoxification and nutrient cycling, but the potential risks have not yet been quantified (Le et al. 2017).

Another poorly understood issue is the length of time that biological communities affected by deep-seabed mining will take to recover. There have been no tests undertaken on a scale that would replicate commercial mining in any of the three habitats, and it is likely that recovery times will differ among ecosystems. However, information gleaned from small-scale experiments, as well as from other industries such as deep-sea trawling, point to lengthy recovery times in each system. Bluhm (2001), Vanreusel et al. (2016), Jones et al. (2017) and Miljutin et al. (2011) have shown that, while there is always some recovery in faunal density and diversity, communities have still not returned to baseline conditions two decades after tests in nodule areas. Simon-Lledó et al. (2019) echoed these findings, showing that, in disturbed areas of the Peru Basin, both the presence of suspension feeders (corals, sponges, etc.) and diversity generally remained significantly reduced after 26 years. Instead, the community was dominated by deposit feeders and detritivores. They concluded that, if the results of the DISCOL experiment in the Peru Basin could be extrapolated to the CCZ, the impacts of nodule mining (taking into account the area directly impacted, as well as the plume deposition area) may be greater than expected, and could lead to an irreversible loss of some ecosystem functions. As nodule mining will remove the nodules, which take millions of years to form, full-scale recovery will likely take a period of time on that scale. Sites identified as being the most favourable for nodule mining are estimated to span 38 million km^2 (Petersen et al. 2016); individual nodule exploration contracts, of which there are 19 in international waters, each cover 75,000 km^2.

On seamounts, where cobalt-rich ferromanganese crusts are located, cold-water corals and other sessile suspension feeders are extremely susceptible to physical disturbances, such as those already caused by bottom- trawling fisheries (Kaiser et al. 2006; Clark and Tittensor 2010; Williams et al. 2010), because they grow extremely slowly (a few mm to ~1 mm per year) and are long-lived (decades to thousands of years) (Roark et al. 2006; Clark et al. 2016). Most seamounts with high trawling impact have coral cover reduced to below 30–50 percent of the coral cover estimated as necessary to maintain habitat viability (Clark and Tittensor 2010). Impact by trawling fisheries is likely to differ from mining, where the entire substrate will be removed. For organisms dependent on cobalt-rich ferromanganese crusts on seamounts, recovery from substrate removal could require thousands to millions of years, given the rate of formation of crusts (Gollner et al. 2017). Sites identified as being the most favourable for crust mining are estimated to cover 1.7 million km^2 (Petersen et al. 2016); each contractor (there are presently five) may have contracts that cover up to 3000 km^2 consisting of 150 blocks, each no greater than 20 km^2. Polymetallic crusts on seamounts may be the most technically difficult resource to mine and the one most likely to support active fisheries.

At hydrothermal vents, distinct global faunal patterns, vent site distances and natural background disturbance regimes make it currently impossible to predict recovery rates using volcanic eruptions in other regions as an analogy for deep-seabed mining (Gollner et al. 2017). Recent observations of decadal stability and longevity at vents in the Pacific back-arc basins indicate recovery periods may be longer than initially thought (Du Preez and Fisher 2018). Active hydrothermal vents have been proposed by scientists to be set off limits to mining (Van Dover et al. 2018), but no regulations currently limit mining at active hydrothermal vents and many active sites inside exploration contract areas (both within and beyond national jurisdiction) are vulnerable to impacts from mining at nearby inactive vent sites. There is currently little baseline information and no data available for recovery times at inactive vent sites, making predictions there difficult (Gollner et al. 2017). Sites identified as being the most favourable for seafloor massive sulphide mining are estimated to cover 3.2 million km^2 (Petersen et al. 2016); individual contracts may cover up to 10,000 km^2, with up to 100 blocks of 100 km^2.

5.1.4 Deep-Seabed Mining Could Result in Loss of Species and Functions Before They Are Understood

The danger of biodiversity loss is of particular concern given the lack of baseline knowledge of the communities in habitats vulnerable to deep-seabed mining (Van Dover et al. 2017; Van Dover 2019; Niner et al. 2018). It is expected that there will be local extinctions, because many of the fauna inhabiting vents, nodule-rich abyssal plains and encrusted seamounts rely on the resources to be extracted as substrate (Vanreusel et al. 2016). For example, Amon et al. (2016) observed that half of the species over 1 cm in size in the eastern CCZ relied on the nodules as an attachment surface. Strong environmental control and prevalence of rare species makes the smallest invertebrates (meiofauna) in the CCZ vulnerable to the risk of extinction from nodule extraction (Macheriotou et al. 2020).

If mining was to go ahead with the current state of knowledge, species and functions could be lost before they are known and understood. A consideration of scale, placement and connectivity is key to prevention of biodiversity loss. In vast, contiguous systems such as the CCZ, cumulative impacts from more than one mining operation may threaten species persistence, depending on their location or timing. The same may be true for vents along a mid-ocean ridge or for seamounts in a chain. For this reason, the series of Regional Environmental Management Plans (REMPs), which the ISA has commenced developing as strategic environmental management tools (ISA 2019b), will need clear environmental objectives (Tunnicliffe et al. 2018). The purpose of REMPs, broadly, is to provide region-specific information, measures and procedures in order to ensure the effective protection of the marine environment in accordance with Article 145 of UNCLOS (UN 1982). To this end, REMPs should establish environmental management measures, including the designation of protected areas (in ISA nomenclature, Areas of Particular Environmental Interest or APEIs) prior to or independent of contract placement and periodic reassessment (Wedding et al. 2013; Mengerink et al. 2014; Dunn et al. 2018), and should be used as management tools which feed into regulatory decisions and actions. REMPs should take into account cumulative effects from multiple mine sites, or synergistic effects from different marine uses or stressors, and seek to manage potential conflicts occurring in the same region. Consideration of climate change in REMP development will help to inform spatial management and environmental impact assessment, and ensure that monitoring programmes can differentiate climate from mining impacts (Levin et al. 2020).

5.1.5 The Challenges of Mitigation and Restoration of Ecosystems

It is difficult to anticipate how best to mitigate the potential impacts of deep-seabed mining because there have been so few studies investigating mining impacts that resemble those actually caused by mining activity, as well as none on the scale on which deep-seabed mining would take place (Jones et al. 2017; Cuvelier et al. 2018). It is likely that the mitigation hierarchy (avoid, minimise, remediate and offset) used in terrestrial and shallow-water extractive activities is not applicable in the deep ocean (Van Dover et al. 2017). Challenges associated with restoration and recovery include the slow recruitment and growth of deep-sea species, the potentially vast scale of mining impacts, and the limited understanding of the requirements for proper ecosystem functions (Gollner et al. 2017). Additionally, the likely high cost of deploying assisted regeneration techniques, such as the use of artificial substrates, the transplantation or seeding of larvae and the artificial eutrophication of the ocean surface, may also be insurmountable (Van Dover 2014; Niner et al. 2018). Furthermore, no restoration strategies proposed have been tested, and even if benthic remediation were technically feasible, the financial commitment required may be extensive (Niner et al. 2018).

Offsetting is the last stage in the mitigation hierarchy and includes the protection of a similar type and equivalent amount of habitat under threat from other existing or planned activities (e.g. preventing trawling in cobalt- rich ferromanganese crust communities), and the creation or restoration of biodiversity of a similar type in a different location to that lost to ensure no net loss. It also includes compensatory mechanisms – for example, the creation of biodiversity of a different type and/or in a different location, such as in shallow or coastal environments – or additional actions that do not provide biodiversity gains ecologically linked to biodiversity losses, such as capacity-building. All of these options are currently unable to replicate biodiversity and ecosystem services lost through deep-seabed mining, so cannot be considered true offsets (Niner et al. 2018). This is, in part, due to gaps in current ecological knowledge and restoration abilities in the deep sea (Niner et al. 2018).

If deep-seabed mining moves forward, it must be approached in a precautionary and adaptive manner, so as to integrate new knowledge and avoid and minimise harm to habitats, communities and functioning (Jaeckel 2017; Niner et al. 2018). There are a number of ways in which this can be done, with each option informed by goals, standards, indicators and monitoring protocols. Avoiding harm altogether is unlikely to be achievable, given the destructive nature of deep-seabed mining, which will heavily impact the immediate mining sites. The size of mined sites would vary by deposit type, but a single operation might mine polymetallic nodules over about 8500 km^2 of seafloor over several decades (Ellis 2001; Van Dover 2014; Petersen et al. 2016; Jones et al. 2017; Van Dover et al. 2017; Niner et al. 2018). Some impacts may be avoided at a project level by reducing the footprint of mining within a contracted area and/or by leaving some minerals with associated fauna in place and undisturbed (protected areas or refugia). However, given that the effects of mining will be three-dimensional and diffuse, are poorly understood, and will involve impacts from sediment plumes as well as toxicity and noise, the identification of refugia that are free from impacts will not be straightforward, and biodiversity loss will likely still occur (Ellis 2001; Thiel et al. 2001; Van Dover 2014; Niner et al. 2018).

Minimising losses of biodiversity and other ecosystem damage to the greatest extent possible includes technologies and practices that may be developed and applied to reduce these risks. There is currently limited technological capacity to minimise harm but possible adaptations include instrument optimisation to limit sediment-plume dispersal, longevity and toxicity, to avoid seabed compaction, and to reduce light and noise pollution (Niner et al. 2018). The effectiveness of such measures at reducing biodiversity losses requires testing and will rely upon a strong regulatory framework, with monitoring and enforcement capabilities. Adaptive management has been identified as a useful regulatory approach that could be applied to deep-seabed mining operations once other challenges are addressed (Jaeckel 2016).

5.2 Economic, Societal and Cultural Costs and Benefits

5.2.1 Benefits of Ocean-Based Renewable Energy

Ocean-based renewable energy provides several benefits in comparison with other sources of energy. It has very low CO_2 emissions over the life cycle of deployment. Decarbonising the transport and construction in the sector will further reduce its CO_2 footprint. It also has negligible emissions of mercury, SO_2 and NO_2, and no waste generation. Estimating the total social cost of carbon emissions is a widely discussed topic in the literature, and is beyond the scope of the present paper. But it is clear that, if substituting ocean-based renewable energy for coal-fired power, the direct and indirect benefits for human health and well-being would be considerable.

In terms of employment opportunities, offshore wind provides more jobs than fossil fuel electricity. IRENA (2018b) estimates that a total of 2.1 million person- days is needed to develop an offshore wind farm of 500 MW capacity. The largest part of this effort is in manufacturing and procurement (59 percent), but even for countries that do not aim to stimulate production locally, operation and maintenance (24 percent) and installation and grid connection (11 percent) offer considerable local job opportunities. Gender balance is generally better in renewable energy jobs than in fossil fuel. Training and re-skilling of the oil and gas workforce is an attractive opportunity given the relevance of many skills. Much less information is available for other ocean- based renewable energy but a study of tidal stream and wave energy in the United Kingdom suggests that these can deliver similar employment opportunities to offshore wind when being scaled up (Offshore Renewable Energy Catapult 2018). Jobs will mostly be in coastal areas, some of which may currently suffer from a lack of employment opportunities.

Since, in contrast to thermal power plants, there is no water usage associated with ocean-based renewable energy, there will also be significant water savings. This can be important in many areas where water resources are scarce and costly. A brief overview of the impacts of accelerated deployment of ocean-based renewable energy on all the 17 SDGs was given in Hoegh-Guldberg et al. (2019), showing positive impacts on all. Only for the ocean goal SDG 14 was there a potential red flag, associated with negative impacts on marine life and biodiversity.

The deployment of power plants offshore can create conflicts about the use of ocean space for other human activities, such as maritime transport, offshore oil and gas, fisheries and potentially also offshore fish farming, as well as for marine protection (with Marine Protected Areas or MPAs). Baseline ecosystem mapping and marine spatial planning that takes the various interests into account will be required. In some cases, combinations could be fruitful; for example, wind farms with traffic and fisheries restrictions could usefully delineate MPAs. Such considerations will vary from place to place based on local conditions, and ultimately decisions will be based on what is socially and politically acceptable (the social/ political potential – see Fig. 3.5).

5.2.2 Benefits of Deep-Seabed Mining

Deep-seabed mining will bring increased metal supply to consumers globally and is likely to benefit the exploitation company, shareholders and members of the supply chain through financial profits (Kirchain and Roth 2019). Deep-seabed mining within a state's national jurisdiction or in the Area under a state's sponsorship has the potential to benefit that state by contributing to government revenues (through taxes and/or royalties).

The quantum may be significant. The UK Prime Minister's assessment of the UK sponsorship of an ISA contract as "a 40 billion £ opportunity" has been called "an overly cautious estimate" by one fellow Parliamentarian (House of Commons 2019). The Cook Islands government has valued their national seabed mineral resources at "hundreds of billions of dollars": a significant sum for any nation, let alone one with a population of fewer than 18,000 people (*Cook Islands News* 2018).

Further benefits may include creating jobs and training opportunities, strengthening the domestic private sector, encouraging foreign investment, funding public- service or infrastructure improvements, introducing a new supply of metals, and supporting other economic sectors (SPC 2012; World Bank 2017). Those benefits may not be large, but may nonetheless be significant, as, for example, in the case of small island developing states with limited land resources and economic options (Wakefield and Myers 2018).

Deep-seabed mining in the Area will bring revenue to humankind, collected and managed on humankind's behalf by the ISA. The quantum and form of that revenue will depend on the system of payments for contractors that is currently under negotiation in the ISA. An initial royalty of 2 percent (rising later to 6 percent) has been proposed for the ISA under an economic model based on contractor profits and contractor data. This could lead to the mining company receiving around 70 percent of the total project profits, and the ISA around 6 percent (with the remainder going to the sponsoring state or whichever state is receiving profit taxes from the mining company) (Africa Group 2018b). Some stakeholders have expressed concern with the principles used in that economic model, and the low royalty rate and return to the ISA. Opponents include all of the 47 African countries who are members of the ISA, and who calculated that the proposed payment regime would lead to a return to humankind of less than $100,000 per annum per country, which they did not deem to be fair compensation (African Group 2019). The international seabed regime established by UNCLOS (UN 1982) is predicated on the basis that mining be carried out (only) in such a manner as to "foster healthy development of the world economy and balanced growth of international trade, and to promote international co-operation for the overall development of all countries, especially developing States" (Article 150). So a regime that would see benefits from mining in the Area flow principally to developed states, or to wealthy shareholders of the companies that are conducting the mining should not be permitted (African Group 2018b).

Other benefits may involve technological innovation and the advancement of deep-sea science. Exploration and impact monitoring may expand scientific knowledge that is currently lacking (if levels of data quality and public-sharing are improved) (Pew Charitable Trusts 2017). Similarly, research associated with deep-seabed mining could also increase our understanding of genetic resources, with the potential for use in pharmaceuticals, industrial agents, biomedical products or bioinspired materials (Le et al. 2017).

Economic development is a key driver for most states, but many resource-rich developing states exhibit slow economic growth. The type of windfall income streams that may be generated if successful deep-seabed mining occurs in significant quantities, if not handled carefully, could have negative effects on a state's economic status (Taguchi and Khinsamone 2018). Commentators observe that the risk of this "resource curse" may be combated by sound revenue management, and an integrated resource management approach, grounded in transparent and non-discretionary policy and law, with funds that are generated by deep-seabed mining being used both for long-term investments in infrastructure or socio-economic projects, and also safeguarded for future generations ("intergenerational equity") (SPC 2016). Some Pacific Island countries (Cook Islands, Tonga, Kiribati, Tuvalu) have addressed this challenge by requiring by law the establishment of a ring-fenced sovereign wealth fund in which any proceeds from seabed mining within national waters must be invested.

The ISA has a different revenue management challenge: how to distribute the proceeds from mining in the Area equitably, and for the benefit of all of humankind (Feichtner 2019). This potentially complex aspect of the ISA's regime has received little attention to date, while the more immediately urgent operational rules for mining and the specific payment rate for contractors are under focus. Different models may include: direct distribution of a share of proceeds to individual member states, or some kind of ISA-managed fund to which states can apply for grants (ISA 2013). However, the proceeds available for distribution may not be large amounts, and may also be depleted by the need to cover operational costs of running the ISA (Thiele et al. 2019).

5.2.3 Costs

The economic costs of ocean-based renewable energy has been treated in Sect. 3 and costs to the environment in Sect. 5.1. It is clear that, provided that the environmental impact assessment is performed with an integrated ecosystem approach to avoid areas of particular value, ocean-based renewable energy, in particular offshore wind will increasingly become cost- competitive with other sources of electricity. This will be a driving force for expansion in more and more areas around the world, even if none of the indirect benefits to climate, human health and other aspects of sustainable development discussed in Sect. 5.2 are used as a rationale for policies or incentives for transitioning from fossil fuels to renewables. A cost–benefit analysis incorporating all of these aspects is beyond the scope of this paper but a preliminary assessment was included in the Annex to Hoegh-

Guldberg et al. (2019) and further analysis is available in Konar and Ding (n.d.).

Little cost–benefit analysis has been done for deep- seabed mining projects (SPC and Cardno 2016), although there have been recent calls for such analyses. For example, the UK government has recently committed to analyse the potential economic value to the United Kingdom of the two ISA contracts granted to UK Seabed Resources Ltd. under its sponsorship in the CCZ (House of Commons 2019). Pacific Island finance ministers and civil society organisations also agreed at a meeting in May 2019 that an independent regional study on deep- seabed mining and its implication for Pacific economies, the environment and ocean biodiversity, and people's livelihoods would provide a helpful evidence base to inform countries' policy decisions on seabed mining (Pacific Islands Forum Secretariat 2019).

The primary benefits of seabed mining are presumed to be economic, and the primary costs ecological. There may, however, also be economic costs to a state engaging in a deep-seabed mining operation (e.g., DSM Observer 2018), and in regulating it (SPC and Cardno 2016; World Bank 2017). In the Area, if third-party harm or unforeseen damages occur, then either the mining company or the sponsoring state will be liable to cover the costs of compensation or remediation (Craik et al. 2018). UNCLOS (UN 1982) specifically provides that mining in the Area must not adversely affect the economies of developing countries derived from terrestrial mining, or must compensate them (sections 1(5)I and 7(1) of the Annex to the 1994 Agreement). This may mean that proceeds flowing to the ISA from royalties for mining cobalt in the Area, for example, will be used to compensate countries such as the Democratic Republic of Congo (where most cobalt on land originates) for any losses caused by the ISA contract. This has the potential to limit financial benefits flowing to other parties (apart from the contractor and the compensated country). Alternatively, mining in the Area may occur in addition to terrestrial mining for the same metals (which obfuscates arguments about advantages of offshore mining relative to land mining, and adds to overall adverse impacts rather than replacing the existing ones). An increased supply of minerals could drive metal prices down, which again may require ISA proceeds to be used to compensate developing countries whose economies suffer as a result.

Although the mining activities will largely occur at sea, transporting and processing of minerals is likely to occur on land. There are concerns that associated land- based activities will adversely affect local communities' property, food sources and lifestyle (Aguon and Hunter 2018). Equally, local communities may seek to host industrial facilities or support services in the interests of attaining employment or building infrastructure and so on. There may also be concern that coastal communities in countries who permit deep-seabed mining within national waters, or whose national waters lie adjacent to deep-seabed mining sites under international or another state's jurisdiction, and who rely heavily on the sea for their food and income will be affected by deep-seabed mining through the disruption of fragile and diverse ecosystems, through displacement of fisheries, or through failure to respect the rights of indigenous peoples (SPC 2012; Aguon and Hunter 2018). In extreme cases, and particularly in the absence of strong governance systems, other extractive industry activity has been seen to worsen social tensions and even lead to political instability, such as the Bougainville Civil War in Papua New Guinea, which cost thousands of lives. It has also been noted that deep-seabed mining may cause a loss of cultural or spiritual value associated with a pristine ocean, or traditional sense of ownership of or identification with the ocean and its resources (World Bank 2017). Given strong ecological connectivity between waters in areas beyond national jurisdiction (ABNJ) and coastal zones (Popova et al. 2019), concerns have been expressed about transboundary impacts, whereby a mining operation within one jurisdiction causes deleterious effects to the marine environment or coastal communities of a neighbouring country (Singh and Pouponneau 2018). The international legal framework currently contains lacunae with regards to identifying and enforcing liability for compensation, clean-up or remediation (Craik et al. 2018; ITLOS 2011).

5.2.4 Environmental Costs, Ecosystem Services Valuation, Tradeoffs and Intergenerational Equity

When the value of the seafloor environment – for example, in terms of ecosystem services – is weighed against the value of the minerals residing on the seafloor, this comparison is almost always made in terms of monetary value. The value of minerals can be estimated based on past, current and predicted future market prices. The living environment can be valued for the services it provides to humans in the form of food, although other provisioning services (such as pharmaceuticals, industrial agents, biomaterials) may be discovered. Regulating services in the form of carbon sequestration or nutrient recycling are modelled rather than measured (e.g., Burdige 2007) and new elements such as dark carbon fixation are being uncovered. In 2015, the Nautilus Solwara 1 project at hydrothermal vents in Papua New Guinea – a very small pilot mine site – was estimated to have $245 million worth of gold and $397 million worth of copper which could be mined over 2.5 years. Earth Economics conducted a social benchmarking study to monetise the impacts of mining at

Solwara 1 on ecosystem services and determined that the dollar value of natural capital assets impacted was far lower for Solwara 1 than for a comparable terrestrial mine (Batker and Schmidt 2015). They used the UN Environment Program The Economics of Ecosystems and Biodiversity and Millennium Ecosystem Assessment in utilising a landscape and seascape approach to natural capital valuation based on the land cover type and area disrupted with conservative overestimates. It was determined that the value of ecosystem services of an acre of Solwara 1 hydrothermal vent (valued at $24,724) was either 80 or 1733 times less than two comparison terrestrial mines. The Earth Economics valuation method has been employed subsequently in social cost–benefit analyses of mining in Papua New Guinea, Cook Islands and the Republic of the Marshall Islands (Wakefield and Myers 2018), while also being criticised for its methodology, given the difficulty of quantifying impacts which have not been or are only just beginning to be studied (World Bank 2017).

The use of terrestrial metrics to quantify deep-sea services overlooks functions not found on land and fails to recognise that deep-sea vent ecosystems are small and among the rarest on the planet (active vents are estimated to cover a total area of less than 50 km^2 globally). Each hydrothermal vent is different from others, and the biodiversity and vent functions remain poorly known (Van Dover et al. 2018). For example, it was only recently found that skates lay their egg cases at vents (Salinas-de-León et al. 2018). In general, the ecosystem services of the deep sea are poorly known (Armstrong et al. 2012; Thurber et al. 2014), so are underconsidered in cost–benefit analyses and are rarely addressed in the development of mining regulations (Le et al. 2017). Particularly under-represented are the non- monetary social, cultural and livelihood values of seabed ecosystems or possible downsteam impacts where the minerals are landed. A greater focus is needed on how to value non-monetary assets linked to the existence and aesthetic and educational uses of biodiversity, as well as the functions and services not yet discovered.

Disruptions caused by deep-seabed mining at the seafloor, in the overlying water column and where ore is brought to land can cause conflict with other economic sectors and threaten loss of non-market ecosystem services (Thompson et al. 2018). Noise, light, sediment plumes with contaminants, and oil leakages can threaten both commercial and subsistence fisheries (Miller et al. 2018). In the case of phosphorites, there is often direct spatial overlap between fisheries and the mineral resource, as well as potential disruption in the overlying waters caused by extraction (Levin et al. 2016). It is also possible that mining activity could prevent future use of the mining site for other purposes. Seafloor substrates targeted for mining may hold genetic resources that could be lost (Le et al. 2017; Van Dover et al. 2018). These are subject to the Nagoya Protocol within national waters, and are the subject of negotiations in international waters (UN General Assembly 2018), but are not currently regulated in the Area (Vierros et al. 2016). Deep-seabed mining could disrupt carbon cycling linked to iron flux from hydrothermal vents, which plays a role in stimulating primary production and carbon drawdown from the atmosphere (German et al. 2015; Ardyna et al. 2019), and by removal of autotrophic microbes that fix carbon, and fauna that bury carbon in sediments (Sweetman et al. 2019). Loss of tourism from the threat of mining is feared in diverse settings such as Papua New Guinea, Fiji, Portugal and Spain (Thompson et al. 2018). Since no full-scale mining impacts have occurred, the nature and extent of these tradeoffs cannot be studied and thus remain speculative.

The value of lost ecosystem services due to mining impacts could appear in the financial code as a form of monetary compensation (e.g., to the common heritage of humankind) or be factored into the amount of the royalty payable by the miner. Built into the concept of the common heritage of humankind is the principle of intergenerational equity, in which, in addition to sharing the benefits of resources, the resources in the natural environment are preserved for generations to come (Jaeckel et al. 2017). The idea of partitioning resources among current and future generations is an important component of sustainability (and intergenerational equity) for non-renewable resources.

5.2.5 Decisions to Mine

Most discussions of deep-seabed mining address where, when and how to conduct deep- seabed mining, as well as what the impacts might be, but not.

whether to mine (Kim 2017). The distribution of metal resources and their production creates geopolitical uncertainties that were to be solved by designating minerals in the Area as the “Common Heritage of Mankind” (UN 1982). In 2012, most cobalt (68 percent) was mined in the Democratic Republic of the Congo, Chile produced 32 percent of copper, China 90 percent of REEs and almost 78 percent of terrestrial manganese resources were found in South Africa (Brown et al. 2014). Extraction of these minerals creates social and environmental problems on land (Kim 2017; IRP 2019), which proponents of deep-seabed mining have argued are mostly absent in the ocean (Lodge and Verlaan 2018).

Currently, opinions on whether deep-seabed mining should proceed span a broad spectrum (Box 3.1). At one end, there is the adamant opposition to any deep- seabed mining, with the claim that adverse effects on the environment will outweigh the benefit of additional metals (Kim 2017). This perspective argues that seabed minerals are not needed (Teske et al. 2016) and suggests that “we should do more with less" via a circular economy that advances recycling, reuse and extended product lifetimes.

Box 3.1 Scenarios for Deep- Seabed Mining

Scenario 1. Full steam ahead on current knowledge

Accept environmental and economic risks, social and equitability concerns and proceed with mining the seabed within and beyond national jurisdiction as soon as legally possible. Biodiversity and its ecological functions in the areas impacted could be lost, possibly irreparably. The scale and ramifications of those impacts – as well as the extent to which the mining will lead to overall benefit for humankind – are hard to predict on current knowledge.

Scenario 2. Slow the transition from exploration to exploitation – precautionary pause

Allow more time to fully assess and understand the environmental risks, including through additional scientific study prior to issuing exploitation contracts; design spatial protections carefully (including the identification of regions to set aside from mining) and develop additional methods to promote resilience; further clarify the need for deep-seabed metals; develop mining regulations in a careful, thorough and transparent manner, with independent expert input and engagement of all stakeholders. Stop issuing new exploration contracts, and do not grant any mining contracts, unless and until the above has been undertaken.

Scenario 3. Indefinite moratorium on deep- seabed mining

Deep-seabed mining does not move forward. Refocus on initiatives that enable transition to circular economies with emphasis on metal demand reduction through reuse, recycling, alternative materials, extended product lifetimes and behavioural change.

In the middle, there are calls for pilot testing and further scrutiny of the issue, as well as for a moratorium or precautionary pause to allow more scientific study and to see the highest environmental standards and the precautionary approach embodied in deep-seabed mining regulations and guidelines. A pause may in practice prevent the issue of additional mining contracts unless and until there is scientifically supported evidence – not currently available – that the impacts will be outweighed by the benefits. Concerns have been voiced that the process has gone too fast relative to the state of knowledge and the ISA's capacity for environmental management. Various bodies have proposed different forms of such a precautionary pause or moratorium on deep-seabed mining in international waters, namely the European Parliament, the UK House of Commons Environment Audit Committee, the Long Distance Fleet Advisory Council (LDAC) of the European Union (LDAC 2019), and the UN Secretary General's Special Envoy for the Ocean. A major aim of such a pause is to allow scientific research to advance, possibly in conjunction with the Decade of Ocean Science for Sustainable Development (Johnson 2019). Additionally, Fiji has proposed, and Papua New Guinea and Vanuatu may be considering, a similar moratorium within their national jurisdictions.

At the other end, there is the stance that deep-seabed mineral projects should be facilitated and incentivised (essentially the current position of the ISA). To date, no requests for exploration contracts have been denied by the ISA and there is a current push to develop the Mining Code (regulations, guidelines and procedures) by 2020 so that exploitation may commence (ISA 2017, n.d.).

The complexity of the stakeholder input to decisions about deep-seabed mining cannot be underestimated (Box 3.2). The most vocal are states with exploitation contracts (Fig. 3.3), and the mining companies that partner with them. Those states with mines on land, and those with a history of ocean conservation have also weighed in, while civil society and the public in general have had a limited voice to date (Fleming et al. 2019).

Box 3.2 Stakeholders for Deep-Seabed Mining

At this time, those expressing the greatest interest in deep-seabed mining, both actively and passively (and not necessarily always to propel the industry forward) include the following groups:

- Nations that have ISA exploration contracts (e.g., China, India, Japan, Russia, South Korea and various EU countries).
- Countries that have deep-sea mineral deposits of commercial interest within national jurisdictions (e.g., Papua New Guinea, Tonga, Cook Islands, Namibia, Japan, Kiribati).
- Countries that actively mine the same minerals on land (e.g., Democratic Republic of Congo, Chile, South Africa).
- Mining companies that have claims within EEZs or have partnered with states on international exploration claims (e.g. Nautilus Minerals, UK Seabed Resources Ltd, Global Sea Mineral Resources, Deep Green).

- Research institutions and scientific networks (e.g. JPI Oceans, the Deep-Ocean Stewardship Initiative, InterRidge, and the Deep Ocean Observing Strategy) interested in bringing science to decision-making and the development of regulations, and in providing sustained observations that can help to address outstanding scientific questions.
- States, environmental advocacy groups, intergovernmental organisations (IGOs) and non-governmental organisations (NGOs) focused on conservation and biodiversity maintenance (e.g. International Union for Conservation of Nature, Deep-Sea Conservation Coalition, Greenpeace, WWF, The Pew Charitable Trusts).
- Other components of the blue economy, such as the deep-sea fishing industry and underwater cabling companies, with potential conflict or spatial overlap.
- Civil society and religious groups that are largely active within EEZs and wary of exploitation of local and indigenous peoples and threats to their local environment and culture (e.g. the Holy See, Deep Sea Mining Campaign, the Pacific Conference of Churches, Alliance of Solwara Warriors, Fair Ocean, Misereor, Brot für die Welt).

It is possible, as has been shown with other habitats, that with time and education, civil society may be willing to pay to forgo blue industrial growth for conservation of the deep sea in order to preserve ecosystem services (Aanesen and Armstrong 2019). Deep-sea scientists are a growing constituency that is increasingly engaged as part of baseline surveys for contractors or discussions with the ISA via organisations such as the Deep-Ocean Stewardship Initiative and InterRidge.

Regulatory sectors overlap in areas targeted for or potentially impacted by deep-seabed mining. Water-column impacts in international waters falling under ISA jurisdiction will intersect with management by regional fisheries management organisations under the Food and Agriculture Organization of the United Nations or the regime overseen by the International Maritime Organization which regulates contaminants and dumping (and which is implemented via individual “flag states” to whom vessels are registered). Current negotiations on the conservation and sustainable use of marine biological diversity of areas beyond national jurisdiction (BBNJ), with its focus on spatial protections, environmental impact assessment, marine genetic resources and technology transfer and capacity-building, has large potential overlap with the ISA for the Area (which includes the entire seafloor). The designation and nature of spatial protections, applications of ecosystem- based management, the disposition and accessibility of data, and the development of shared goals and objectives to achieve sustainability are all areas where the ISA will need to work across sectors both within the United Nations, and with industry, academia and civil society.

6 Governance and Regulatory Framework for Deep-Seabed Mining

6.1 State Level

A state should adopt appropriate measures to exercise control over any seabed mineral activities under its jurisdiction and to secure compliance with international standards. State laws relating to the management of seabed mineral activities must be “no less effective than international rules, regulations and procedures” (UNCLOS; UN 1982)—such as the Mining Code of the ISA, currently under negotiation (ISA n.d., 2019d).

Direct obligations under international law in respect of seabed mining include: applying the precautionary approach, employing best environmental practice, and conducting prior environmental impact assessment (ITLOS 2011). These obligations apply to states regardless of their individual wealth or capacity (ITLOS 2011). A number of states, particularly in the Pacific region, have implemented national legislation to govern seabed mineral activities (both within national and international jurisdiction) (e.g. Fiji, Tonga, Tuvalu, Kiribati, Cook Islands, Federated States of Micronesia, Nauru, United Kingdom, Belgium, United States, Japan, Germany, China) (Lily 2018; World Bank 2017). It is notable, however, that several states actively engaged in exploration activities as yet have no detailed legal regime in place (e.g. India, France, South Korea, Brazil, Russia, Poland) (Lily 2018; ISA 2019a).

The creation of adequate legislative frameworks by states, while essential, is not sufficient in itself: implementation and enforcement of the rules created are also crucial (ITLOS 2011). This point is supported by international law (e.g., UNCLOS, Articles 214 and 215; UN 1982), which requires appropriate environmental standards not only to be governed by domestic legislation, but also to be implemented through monitoring and enforcement. Strong institutions are particularly important to the oversight of seabed mining; legal, fiscal and environmental matters will all require dedicated public administration capacity. This may be particularly challenging for small developing states with limited administrative and technical capabilities. Provision should also be made for independent oversight and public notification of, and participation in, decision-making (SPC 2012; United Nations Conference on Environment and Development 1992).

To date, little scrutiny has been applied to the states who sponsor ISA activities, including the extent to which relevant measures are in place to ensure ISA contractor compliance (and compensation for third- party damages) via domestic regulation (Lily 2018), and the nature of the arrangements between the state and the ISA contract-holder (Rojas and Phillips 2019). There is little information in the public domain as to the extent to which the sponsoring state, or another state, stands to benefit financially from the contract – which may be deemed of particular importance where the sponsoring state is a developing state.

6.2 International Level

The ISA is tasked to "organise and control" contractors to "secure compliance" with ISA rules, including those rules designed to deliver on the ISA's mandate to "protect and preserve the marine environment" (UNCLOS; UN 1982). Much of the oversight authority within the ISA rests with the Council and the Legal and Technical Commission (LTC) which provides initial recommendations regarding rules, regulations and procedures, as well as recommendations on applications for mining contracts (Box 3.3). In some instances, it is difficult for the Council to take a decision contrary to an LTC recommendation. For example, in order to decide not to approve an application for a mining contract where the LTC recommends approval, a two-thirds majority of the 36 Council member states would be required. Even then, any one of four chambers within the Council could veto that disapproval decision (UN 1994, Annex, section 3, para. 11(a)). For this reason, the potential for a mining "approval bias" at the ISA has been noted (Greenpeace 2019; Pew Charitable Trusts 2019), and the composition, election, expertise and capacity of the LTC are often under scrutiny. The fact that only 3 of the 30 commissioners currently in post appear to have ecological science backgrounds has been remarked upon as a particular challenge, given the ISA's environmental protection mandate, and the LTC's immediate task to review environmental impact assessment reports, to develop environmental management plans, and to draft regulations, standards and guidelines pertaining to environmental management and thresholds. Criticisms of the LTC have also extended to a lack of transparency and potential conflict of interests (Greenpeace 2019; Ardron et al. 2018; Seascape 2016).

Box 3.3 The International Seabed Authority (ISA)

The ISA is an intergovernmental agency created by the UN Convention on the Law of the Sea (UNCLOS; UN 1982), with a structure that includes the following organs: the Assembly, the Council, the Legal and Technical Commission, the Finance Committee, the Economic Planning Commission, The Enterprise and the Secretariat (Fig. 3.7).

The executive body of the ISA is its "Council", comprising 36 member states. These states are elected in a number of different groups, designed to ensure a diversity of nations, representing different interests. These groups include major consumers or importers of the relevant metals, the largest investors in deep-seabed mining in the Area, major exporters of the relevant metals from land-based sources, developing countries with special interests (e.g. land-locked, geographically disadvantaged, islands), and five regional geographic groupings (Africa, Asia-Pacific, Eastern Europe, Latin America and Caribbean, and Western Europe and Others). The groups are then organised into four chambers, for decision-making purposes (UN 1994, Annex, section 3, para. 15).

The Council reports to the Assembly, which comprises all 168 ISA member states. Both organs meet at least annually at the ISA's headquarters in Kingston, Jamaica.

The ISA is supported by a Secretariat, also based in Jamaica, headed by a Secretary-General who is the chief administrative officer of the ISA, and required to support all ISA meetings and to perform such other administrative functions as may be instructed (UNCLOS, Article 166).

Another key organ within the ISA is the Legal and Technical Commission (LTC). This is a group of, currently, 30 experts, serving in their individual capacities, who meet bi-annually with responsibility to prepare recommendations and advisory inputs to the Council. The LTC's mandate includes the provision of recommendations on applications for ISA contracts, and preparing drafts of rules, regulations and procedures of the ISA, for Council consideration or adoption (UNCLOS, Article 165).

The Finance Committee oversees the ISA's administrative budget. The Economic Planning Commission is tasked with examining the impacts of mining in the Area on land-based mining economies; its function is currently being covered by the LTC. The Enterprise is envisaged to be an in-house mining arm of the ISA, who will commence operations via joint ventures with other contractors. The Enterprise has not yet been operationalised.

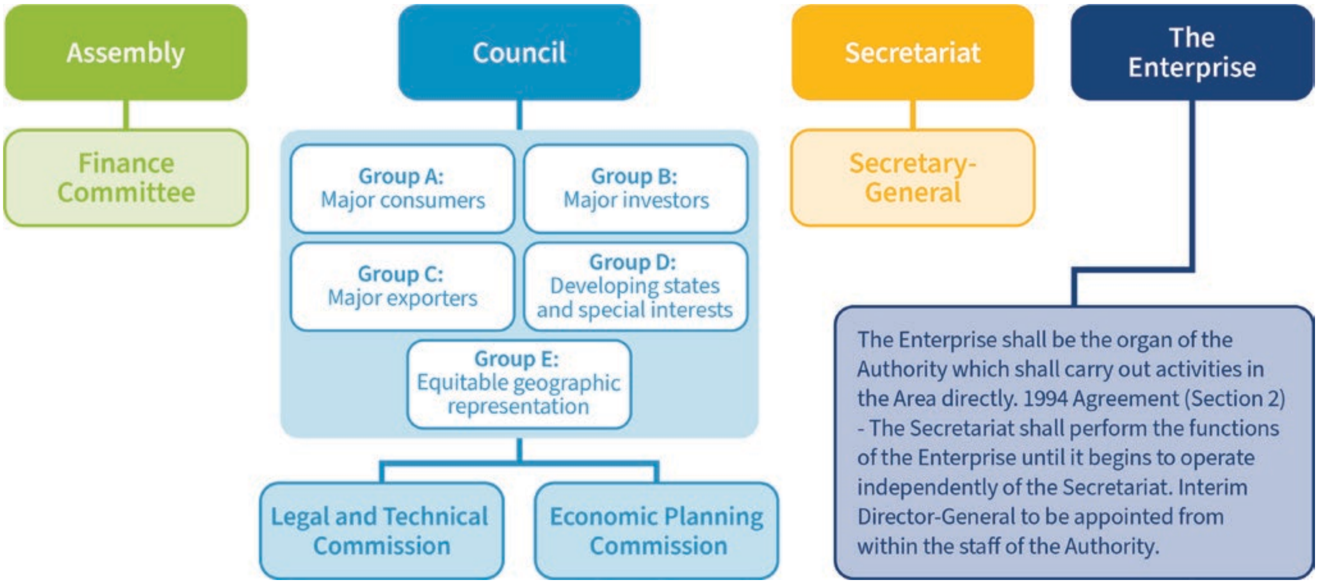

Fig. 3.7 The International Seabed Authority Governance Structure. Source: Adapted from Grid Arendal (https://www.grida.no/resources/6311)

There is no other precedent of an international intergovernmental treaty body (with 168 members, each with their own political priorities and interests) attempting to act as a minerals licensing, monitoring and enforcement, and revenue collection agency – as is required of the ISA (French and Collins 2019). UNCLOS even envisages an in-house mining wing of the ISA called "The Enterprise" (Article 170). When The Enterprise comes into existence, the ISA will be required to issue exploration or mining contracts to, and regulate, itself. These are functions that within national jurisdictions are usually performed by a raft of different government agencies operating under separate mandates. The ISA also faces constraints from the infrequency of meeting, a lack of funding and the fact that the same governments may be represented simultaneously in the ISA's advisory body, decision-making organ and as mining contractors. The challenges of conflict management and capacity constraint will be exacerbated if and when the ISA operates as a mining company itself ("The Enterprise"), as envisioned by UNCLOS (African Group 2018a). Different stakeholders have previously raised concerns with regards to the ISA due process and governance practice (Seascape 2016; Ardron et al. 2018; Belgium Government 2018; German Government 2018). Noting the capacity limitations and other constraints of the existing ISA structures, several parties have called for better incorporation of science and external, independent expertise in the ISA's development of regulations, rules and procedures, and in its regulatory oversight of contracts (Pew Charitable Trusts 2019).

The regulations for mining within the Area are under negotiation at the ISA currently. While there is a political push for these to be finalised by 2020 (ISA 2017), there appears to be a large amount of work still required to reach agreement on all necessary elements of the regime (ISA 2019c; Pew Charitable Trusts 2019), and at the ISA Annual Sessions in July 2019 and February 2020, several member states called for "quality over haste".

6.3 Mining in the Context of the UN Sustainable Development Goals

Several SDGs that affect materials use and natural resources (presumably designed for land use) are relevant to the ocean, including SDG 8.4, which addresses decoupling of materials use and environmental degradation, and SDG 12.2, which considers efficient use and sustainable management of natural resources (OECD 2018). Deep-seabed mining could contribute positively to several SDGs. Financial and economic benefits could help to relieve poverty (SDG 1), in the least developed countries such as Kiribati as an ISA-sponsoring state, or Solomon Islands as a state with sovereign rights over minerals within national jurisdiction, for example. But the benefit- sharing mechanisms have yet to be determined and are likely to be modest for non-mining countries (Kim 2017). Benefits from a greater availability of metals will almost certainly accrue to the most industrialised (or industrialising) nations, but could contribute to clean energy (SDG 7), which would counter climate change (SDG 13). These benefits all come with tradeoffs for the ocean environment under SDG 14, "Conserve and sustainably use the oceans, seas and marine resources for sustainable development", along with questions over the extent to which seabed mining can meet SDG 12.2, the target to "achieve the sustainable management and efficient use of natural resources" by 2030.

A recent report on mining governance on land introduces the concept of a Sustainable Development Licence to Operate

(SDLO). The SDLO adopts principles, standards of behaviour and best practices compatible with SDGs and their targets (IRP 2019). However, many struggle to understand what sustainability looks like in the context of deep-seabed mining. Obtaining maximum economic benefit in return for the extraction of minerals, and applying this to the long-term development goals of the poorest populations would seem to be a prerequisite.

Within SDG 14 targets, sustainability seems to encompass protecting ecosystems, conservation, economic benefits, scientific knowledge, and governance. When defined in relation to the extraction of living resources, sustainability often involves eco- certification, harvesting low on the food chain, avoiding government subsidies, technology innovation to avoid bycatch, and management to achieve maximum sustainable yield (Carr 2019). Could there be parallels for deep-seabed minerals? Could mining practices undergo review for a certification of limited damage to the environment? This is already effectively the mandate of the ISA. Could metal-containing end-products, such as mobile phones, come with source information about the metals in order to enable consumers to base their purchase choices on informed and ethical grounds? Could miners select mineral substrates of lesser value to biota or leave a significant fraction of the hard substrate on the seabed? What technologies can minimise the intensity, area or duration of impact on the environment? Given that most of the targeted minerals precipitate very slowly (e.g., 1–10 mm/million years for polymetallic crusts and nodules (Hein et al. 2013)), would there be an equivalent of maximum sustainable yield?

The drafters of UNCLOS appeared to pre-empt some of these issues, by stipulating that the ISA's production policy should be based on the principle that "there shall be no discrimination between minerals derived from the Area and from other sources. There shall be no preferential access to markets for such minerals or for imports of commodities produced from such minerals", while also requiring that state subsidies be avoided (UN 1994, Annex, section 6). These principles may be difficult to implement and police in practice.

Just as vulnerable marine ecosystems (VMEs) (e.g., dense corals and sponges) are protected from bottom fishing in international waters (UN General Assembly 2006), it has been proposed that active hydrothermal vents, which function as VMEs, should be protected from deep-seabed mining (Van Dover et al. 2018). There is a wholesale ban on bottom trawling in deep water (>800 m) in the European Union and elsewhere to prevent major habitat destruction. Although there are mineral resources of value in the EEZs of many countries, especially island nations in the West Pacific, none have permanently banned seabed mining. Notably, a precautionary pause/moratorium has recently been proposed by Fiji (Fiji Sun 2019) and mining licences for phosphorites have been denied in Mexico and New Zealand (Miller et al. 2018).

7 Opportunities for Action

Considering the above analyses, some high-level opportunities for action regarding ocean-based renewable energy (Sect. 7.1) and deep-seabed mining (Sect. 7.2) are presented here. The development of the global energy system referred to in Sect. 7.1 is intimately linked to both renewable energy and the use of minerals, Section 7.2. The Appendix provides further elaboration of challenges, detailed opportunities for action and associated benefits and some alternative or additional options. These are designed to ensure that ocean-based renewable energy is harvested in a manner that exploits its potential to contribute to sustainable development, and to ensure that the ocean, particularly in the context of deep-seabed mining, remains healthy and resilient for future generations.

7.1 Ocean-Based Renewable Energy and the Global Energy System

As discussed in Sect. 2.1, ocean-based renewable energy plays a significant role in cost-optimised models for transitioning the global energy system to a global temperature increase of 1.5 °C, in line with the Paris Agreement. In particular, offshore wind has the potential for further cost reductions and for the upscaling of implementation over the coming decade (see Sect. 3.1). The actual development path will depend upon several factors, including access to areas, grid connections, financing models, ownership and, in some cases, regulation of cross-border electric cables and legal conditions. While the expansion of offshore wind is well under way, the speed of development and implementation of further cost-reducing technologies, such as floating large turbines in deeper waters with bigger wind resources, depends on government incentives.

WindEurope has listed several challenges to be addressed to scale up offshore wind (WindEurope 2019). They also state six policy recommendations for Europe (WindEurope 2019, 66–67):

- Governments should set ambitious maritime spatial planning policies to deliver 450 GW by 2050.
- Governments should ensure that permitting and other relevant authorities have the necessary expertise and resources to consent enough sites.

- Governments should accelerate the expansion of the necessary on- and offshore grid infrastructure.
- The EU should elaborate a regulatory framework for offshore hybrid projects (e.g., hydrogen).
- Governments should accelerate the electrification of transport, heating and industrial processes.
- Governments should ensure visibility and confidence in volumes and revenue schemes.

ETIP Ocean (2019) describes a set of challenges and actions that would help lift ocean-based renewable energy in Europe towards delivering 100 GW by 2050.

Offshore wind and other ocean-based renewable energy does use metals, including some REEs, but it is not a major driver for deep-seabed mining exploration and exploitation. New technological solutions for components of offshore wind installations change the specific demands from one resource to another, showing the adaptability of the industry. The environmental impact of ocean-based renewable energy can slow down or limit its expansion. Baseline surveys and marine spatial planning exercises involving all stakeholders are required. Noise remains a concern but floating structures are expected to be more environmentally benign.

Other ocean-based renewable energy technologies should be developed to provide a wider range of energy sources in the future, particularly in areas with more limited wind resources. The low-carbon future energy system, as well as human activities in general, have to be developed and operated within given resource limitations. Minerals must be used in a way that is compatible with sustainable development in all its dimensions. In particular, the use of deep- seabed mining implies many potentially negative side effects and uncertainties and should be avoided at least until more knowledge has been gathered.

Opportunities for action are:

- **Strengthen research, development and demonstration programmes** to scale up offshore wind, in particular to make floating offshore wind cost-competitive more quickly.
- **Strengthen research and development and economic incentives to favour a less mineral-intensive global energy system**, including ocean-based renewable energy.
- **Support marine spatial planning and sustainable ocean economy plans** with taxation schemes and regulations that stimulate investments in variable renewable energy supply from the ocean to the shore.
- **Strengthen research and development for other ocean-based renewable energy technologies** to make them more mature and available to contribute significantly in later decades.

7.2 Deep-Seabed Mining

Deep-seabed mining represents a sustainability conundrum. The significant environmental and social impacts of mining on land (IRP 2019; Church and Crawford 2018) could be improved with focused effort, yet presently provide incentives to look to the ocean as a source of minerals (Batker and Schmidt 2015; IRP 2019). But extreme knowledge gaps remain, particularly in understanding how deep-ocean ecosystems will respond to industrial-scale mining disturbance. There is an inherent conflict between a duty to protect the marine environment, and a call to mine the deep sea for metals. The remote nature of the deep ocean and its unfamiliarity to most people raise the challenge of ensuring the participation of all relevant stakeholders to inform decisions taken at the international and state level that relate to areas out of sight. How society moves past these crossroads, and the decisions taken on behalf of humankind by governments at the ISA, will likely have a lasting impact on our ocean.

Because no deep-seabed mining has occurred yet, but substantial policy-making is in progress, four opportunities for additional action are proposed:

- **Develop and execute a road map to build the regulatory capacity of the ISA to ensure effective protection for the marine environment** from harmful effects of mining in a transparent and inclusive manner. This would include the creation of environmental consents, evidence, inspectorate and enforcement functions, and would involve a slower process of transitioning from exploration to exploitation.
- **Establish an international research agenda and timeline, in conjunction with the UN Decade of Ocean Science for sustainable development**, to collect and synthesise high- quality deep-sea scientific data to fill identified gaps in knowledge required for decision-making and environmental management, before any deep-seabed mining takes place.
- **Promote the identification, declaration and enforcement of spatial protections** (including large, biologically representative, fully protected no-mining zones established in perpetuity prior to any award of exploitation contracts), **Across all ocean regions under ISA jurisdiction**.

  This would enable states to demonstrate efforts towards their international duties to ensure effective protection for the marine environment from mining's harmful effects (UNCLOS; UN 1982), to achieve in-situ conservation (Convention on Biological Diversity; UN 1992) and to conserve a percentage of marine areas (SDG 14.5 and Aichi Biodiversity Target 11). More time could also allow new opportunities to emerge for industry and scientists to partner on testing technological and conceptual innovations for mineral recovery that minimise harm to the marine environment.

- **Create incentives and remove barriers to implement a circular economy**, which acts through improved product design, reduced demand, reuse, recycling, reclassification of materials and use of renewable energy for production (Ghisellini et al. 2016). For metals targeted by deep-seabed mining, this would require independent research and long-term planning with attention focused on Life Cycle Sustainability Analysis (Van der Voet et al. 2019). Alternative energy technologies are already under investigation which reduce the use of lithium, silver, neodymium and dysprosium. New solid-state battery designs avoid the use of cobalt and nickel and have great durability and longevity. Redesign of existing batteries is required to avoid additives that improve product quality and durability but make metal recovery from electronic products even more difficult (Tansel 2017). More government policy focus, consumer awareness and behaviour change to favour a less mineral-intensive renewable energy system will also be crucial.

Acknowledgements The authors thank the paper's technical reviewers, Saleem Ali, Matthias Haeckel, Siegfried Husak and Andrew Thaler, its arbiters, Mari Elka Pangestu and Kristian Teleki, and Jane Lubchenco, who all provided helpful technical comments.

The authors also thank World Resources Institute for providing support as the Ocean Panel Secretariat.

Support for authors contributing to the seabed mining discussion was provided by The PEW Charitable Trusts (HL), World Resources Institute (LL), JM Kaplan Fund (HL), Marc and Lynne Benioff (DA), and the European Union's Horizon 2020 research and innovation program under a Marie Sklodowska-Curie grant (DA).

While our colleagues were very generous with their time and input, this report reflects the views of the authors alone.

The authors thank Sarah Chatwin for copyediting and Shannon Collins for design.

Appendix: Detailed Opportunities for Action

The *Opportunities for Action* in the main document are expanded upon below.

- To ensure that ocean-based renewable energy is harvested in a manner that exploits its potential to contribute to sustainable development.
- To ensure that the ocean, particularly in the way it is considered for deep-seabed mining, remains healthy and resilient for future generations.

Each recommendation is prefaced by a specific challenge to be addressed, the recommendation itself, what following the recommendation would imply and the benefits to be achieved. In some cases, alternative or additional options are also described.

Detailed Opportunities for Action for Ocean-Based Renewable Energy

Detailed Opportunity for Action 1

Challenge 1: *Ocean-based renewable energy could contribute significantly to sustainable global energy supply, but the development is too slow for timely phase- out of fossil fuel.*

Detailed opportunity for action 1: Strengthen research, development and demonstration programmes and financing, taxation and legal regimes to scale up ocean-based renewable energy, in particular market incentives to make floating offshore wind cost- competitive faster, but also research and development to make other ocean-based renewable energy technologies more mature.

By doing this: The harmful effects of CO_2 emissions on the climate and on the ocean will be reduced. The urgent transformation of the global energy system will accelerate.

Associated Benefits: A new sector of the ocean economy will develop including new jobs. Less mineral- intensive options will reduce pressure on mining.

Alternative (or Additional) Option: Create regional national or international programmes focusing on different energy technologies, recognising that the various ocean-based renewable energy sources are unequally distributed because of varying wind resources, wave climate, tidal range and so on. Create floating or remote plants converting renewable electricity to hydrogen to supply fuel for shipping and transport to shore.

Detailed Opportunity for Action 2

Challenge 2: *Rapid transformation of the energy system helps to save the climate, but contributes to the demand for rare minerals and the pressure to accelerate deep-seabed mining during the decarbonisation phase, before re-use and the circular economy can be deployed.*

Detailed opportunity for action 2: Strengthen research and development and economic incentives to favour a less mineral-intensive renewable energy system.

By Doing This: The transformation of the global energy system can take place without risking harmful effects on the deep-sea environment, its ecosystem services or other potential resources.

Associated Benefits: The global energy system will develop in a more sustainable way with less material use overall. Note that the recommendation has system-wide implications beyond the choice of renewable energy source. For example, the need for batteries as well as the curtailment of electricity from renewable energy can be reduced in an energy system with well-developed demand management and other types of energy storage than batteries.

Detailed Opportunities for Action Specifically for Deep- Seabed Mining

A rapidly growing literature on deep-seabed mining has generated many ideas for the development of protection and management schemes for the marine environment, on governance options, ways to approach initial mining operations, and on alternatives to deep-seabed mining. The series of recommendations below emerge from the synthesis presented here, informed in part by the information gaps and scientific uncertainties associated with deep-seabed mining.

Detailed Opportunity for Action 3A and 3B

Challenge 3: *Unclos was written in a time of limited knowledge about deep- sea ecosystems, their vulnerabilities and the services they provide (e.g., hydrothermal vents had not yet been discovered). extreme knowledge gaps remain, particularly in understanding how deep-ocean ecosystems will respond to industrial-scale mining disturbance.*

Detailed opportunity for action 3A: Slow the process of transitioning from exploration to exploitation, and take the time necessary to fully develop – in a transparent and inclusive manner – the ISA rules, regulations and procedures for mining (possibly extending the ISA-imposed deadline from 2020 to 2030), and institute a precautionary pause in the issuance of new contracts by the ISA during this period.

By Doing This: The (legally required) precautionary approach is applied. More time is allowed for scientific study, and appropriate scientific input into regulations and decision-making, including the development of environmental goals and objectives, and identification of science-based indicators and thresholds.

Associated Benefits: More time would also allow for broader stakeholder input, and building of ISA capacity, to include data access and management mechanisms, access to relevant independent expertise, and regulatory capacity.

Alternative (Or Additional) option: Develop rules, regulations and procedures at the ISA that set highly stringent and prescriptive environmental standards, and give ISA decision-makers appropriate agility and powers to reject applications to mine, and to amend required conduct from contractors where there is a threat of serious, irreversible or otherwise unacceptable harm to the marine environment, including through cumulative impact. This should include the adoption by the ISA of a conscious policy of a controlled, staged development approach to exploitation: initially cautious about the number and size of sites licensed for mining activities – with new projects not authorised until existing ones are completed and the impacts measured.

Detailed opportunity for Action 3B: Create as soon as possible an international research agenda to collect and synthesise high-quality scientific data (during the Decade of Ocean Science for Sustainable Development, 2021–2030), which answers strategic questions about deep-sea ecosystems required for decision-making and environmental management related to deep-seabed mining.

By doing this: The deep-sea environment can be better understood before taking decisions that could irreparably affect it. Current knowledge of species distributions, connectivity, habitat requirements, ecological functions and ecosystem services, vulnerability to mining impacts (including cumulative impacts, sediment plumes, noise and light), resilience, recovery and mitigation potential, and the influence of cumulative impacts from climate stressors can be expanded. The agenda should also support and engage existing sustained observing programmes to enhance relevant deep-sea data acquisition, improve understanding of natural variability, and develop standards around the acceptable level of statistical power for monitoring impacts of seabed mineral activities. New opportunities can emerge for industry and scientists to partner on testing technological and conceptual innovations for mineral extraction techniques that minimise harm to the marine environment.

The agenda should promote FAIR data principles (findable, accessible, interoperable, reusable) and facilitate data portals that create compatibility across networks and agencies (e.g., the ISA, Intergovernmental Oceanographic Commission clearinghouse, regional fisheries management organisations).

Associated benefits: Greater understanding of deep-sea environments, and improved data quality and sharing will also assist with governance decisions beyond those relevant to seabed mining, including the negotiations at the Intergovernmental Conference on Marine Biodiversity of Areas Beyond National.

Jurisdiction (BBNJ), climate change talks at the United Nations Framework Convention on Climate Change (UNFCCC) and conservation initiatives, and will constitute important work towards SDG 14, including Target 14.A (“increase scientific knowledge, develop research capacity and transfer marine technology”).

Alternative (or Additional) option: ISA marine scientific research, data management and strategic environmental assessment functions should be strengthened, and additional requirements or incentives be exerted by the ISA upon contractors and member states, encouraging multilateral cooperation, so that more science across wider biogeographic areas is collected, analysed, published and used to inform ISA policy and regulation.

Detailed Opportunities for Action 4A and 4B

Challenge 4: *There is an inherent conflict between a duty to protect the marine environment, and a call to mine the deep seabed for metals.*

Detailed opportunity for action 4A: Enable as soon as possible an expert and independent environmental and scientific committee to handle ISA environmental regulations and decision-making, to assess monitoring and impact assessment and to identify triggers for regulatory action or cessation of mining.

By doing this: The ISA can bolster its capacity and expertise to manage its mandated environmental stewardship function. This should be run separately from other ISA functions (such as contract award and management, revenue collection and distribution, and direct engagement in mining, through The Enterprise).

Associated benefits: A science-driven, expert-led, transparent, independent, consistent and consultative regulatory agency will garner greater public and investor trust and confidence, which should enhance the ISA's ability to meet its bifurcated duty both to develop the mineral resources of the Area and to protect and preserve the marine environment. Any steps taken to strengthen the ISA's regulatory capacity will contribute towards the goal of preventing serious harm to the marine environment, and minimising other harmful effects from mining.

Detailed opportunity for action 4B: Ensure the declaration (by 2022) and enforcement of a network of large, biologically representative, fully protected no- mining zones established in perpetuity prior to any award of exploitation contracts, across all ocean regions under ISA jurisdiction. These should be designed according to scientific principles, and placed on the basis of physical, geochemical, ecological and social analyses. Ideally, they should cover at least 30 percent of the Area, ensure connectivity, be representative of habitats that will be lost to mining and protect particularly vulnerable habitats.

By doing this: The precautionary approach to environmental management of deep-seabed mining is enacted by ensuring that representative benthic habitats and associated ecosystems are protected from harm on regional scales. This is particularly important given uncertainties regarding the severity, frequency and spatial extent of mining impacts.

Associated benefits: Protected areas can serve as refugia for marine species, offer climate resilience and preserve ecosystem functions. Their declaration would enable states to demonstrate efforts towards their international duties to ensure that the marine environment is effectively protected from mining's harmful effects (UNCLOS; UN 1982), to achieve in-situ conservation (Convention on Biological Diversity; UN 1992) and to conserve a percentage of marine areas (SDG 14.5 and Aichi Biodiversity Target 11).

Detailed Opportunity for Action 5

Challenge 5: *The remote nature of the deep ocean and its unfamiliarity to most people raise the challenge of ensuring the participation of all relevant stakeholders to inform decisions taken at the international and state level that relate to areas out of sight.*

Detailed opportunity for action 5: *The ISA, member governments and non-governmental bodies should cooperate immediately to enhance societal awareness of the choices associated with deep-seabed mining (through social media, traditional media, formal educational programmes and other forms of outreach) and diverse and inclusive opportunities for interested parties to have their views heard and considered in deep-seabed mining decision-making processes.*

The ISA regime, and states with mining interests, should maximise opportunities for public and expert consultation, including during the contract application, approval and review process. Non-governmental observers should be facilitated to attend ISA and state meetings. Such meetings should be supported by technical advisory inputs that are comprehensive and fully explained (with dissenting views noted) and produced in a timely fashion. Meeting documents, contracts, financial information, compliance information and environmental data should all be made publicly available immediately.

By doing this: Better and more durable decisions will be taken. It will enable the collection of comprehensive relevant information by decision-makers and will enhance public understanding, consent and commitment to implementation. Trust and confidence in the ISA's decisions will be improved.

Associated benefits: Consultation with as wide a group of experts and stakeholders as possible will assist national and international policy-makers to take the complex and momentous judgement calls that are inherent in deciding what degree of environmental harm is deemed acceptable in order to facilitate access to metals. It will also be a means for governments to operationalise commitments made at the international level (various regional environmental treaties, the Rio Declaration (UN Conference on Environment and Development 1992) and Rio + 20), as well as the ISA's duty to act on behalf of all of humankind (UNCLOS; UN 1982).

Alternative (or additional) option: Member governments should:

- attend ISA meetings at which crucial decisions are taken (for example, approval of the ISA's Exploitation Regulations currently under negotiation, or a decision whether or not (and on what terms) to approve or disapprove the first mining application made tothe ISA);
- hold meaningful prior national consultations on the relevant issues, before attending; and
- reflect the results of those national consultations in their positions at the ISA.

Detailed Opportunity for Action 6

Challenge 6: *The growing global demand for metals is threatening to push extractive practices beyond planetary boundaries.*

Detailed opportunity for action 6: Engage urgently in independent research and long-term planning to facilitate a circular economy for targeted rare metals and rare earth elements, initially with a five-year programme (2020–25). Focus attention on Life Cycle Sustainability Analysis (Van der Voet et al. 2019) and developing alternative methods to address the metal demand. Create incentives and reduce barriers to promote the following:

- Recycle, reduce, re-use opportunities
- Product redesign that enables improved metal recycling or extended product lifetime
- Demand reduction via use of alternatives and consumer behaviour change
- Improved sustainability of on-land mining practices
- More sustainable metal waste disposal practices and less resulting pollution

By doing this: The negative environmental impacts of land-based mining can be minimised and the need for deep-seabed mining is reduced, while human development is supported, in line with the SDGs. Social, economic, behavioural and technical issues can be addressed together.

Associated benefits: More government policy focus, and consumer awareness and demand about metal sourcing and use, should stimulate innovation and lead to better environmental and human rights practices by extractive industries. The circular economy and enhanced secondary production of metals will reduce energy use and carbon emissions. It should also enhance competitiveness and economic growth, and new employment opportunities. This can also identify possible less harmful alternatives to deep- seabed mining.

About the Authors

Lead Authors

Peter M. Haugan is programme director at the Institute of Marine Research, Norway, and professor at the Geophysical Institute, University of Bergen, Norway.

Lisa A. Levin is a Distinguished Professor at the Scripps Institution of Oceanography, University of California, San Diego, USA

Contributing Authors

Diva Amon is a scientific associate at the Natural History Museum, London, UK.

Mark Hemer is a principal research scientist at CSIRO, Australia.

Hannah Lily is an independent consultant and lawyer based in the UK.

Finn Gunnar Nielsen is a professor and head of Bergen Offshore Wind Centre at the University of Bergen, Norway.

Highlights

- A sustainable ocean economy prioritises the conservation and sustainable use of the 'ocean genome' and leads to equitable outcomes for all.
- Marine life is incredibly diverse—having existed in the ocean for three times as long as life has existed on land—and comprises a minimum of 2.2 million existing eukaryotic marine species, of which some 91% remain undescribed.
- The ocean genome is the genetic material present in all marine biodiversity, including both the physical genes and the information they encode. It determines the abundance and resilience of biological resources, including fisheries and aquaculture, which collectively form a pillar of global food security and human well-being. It is the foundation upon which all marine ecosystems, including their functionality and resilience, rest.

J. Lubchenco, P. M. Haugan (eds.), *The Blue Compendium*, https://doi.org/10.1007/978-3-031-16277-0_4

- The ocean genome is threatened by overexploitation, habitat loss and degradation, pollution, impacts from a changing climate, invasive species and other pressures, as well as their cumulative and interacting effects.
- Fully and highly protected marine protected areas (MPAs) are proven tools for safeguarding genetic diversity at the ecosystem level, along with other effective area-based conservation measures (OECMs)—if they are effectively designed and managed. Yet, only 2.5% of the ocean is in MPAs considered fully or highly protected. Urgent action is required to apply measures based on scientific evidence and meet internationally agreed targets along with growing calls to fully or highly protect at least 30% of the ocean to support ocean health, productivity and resilience.
- In parallel, significant efforts are needed to ensure that genetic diversity in areas outside of MPAs and OECMs is conserved. These include effectively managing the sustainable use of resources; preventing habitat degradation; cautiously using previously unexploited places; enforcing and complying with regulations; and protecting rare, threatened and endangered species and populations.
- Rapid advances in sequencing technologies and bioinformatics have enabled exploration of the ocean genome. These new findings are informing innovative approaches to conservation and a growing number of commercial biotechnology applications, from anticancer treatments to cosmetics and industrial enzymes.
- At the same time, the environmental, social and ethical risks arising from using existing and new biotechnologies such as CRISPR (Clustered Regularly Interspaced Short Palindromic Repeats) remain under-investigated and poorly known, especially in marine environments.
- The capacity to undertake genomic research and to access, download and analyse massive amounts of sequence data relating to marine genetic resources is inequitably distributed among countries. There is an urgent need to build capacity; increase access to affordable innovation and technologies; and ensure that research and innovation is ethically and socially acceptable, environmentally sustainable, and delivering solutions to the problems of the poorest and most marginalised communities and income groups.
- Scientific and commercial benefits arising from using the ocean genome must be fairly and equitably shared. Reforms to intellectual property rights should support this shift.
- International legal measures governing aspects of the conservation and use of the ocean genome must comprehensively, actively and persistently engage with scientists and other actors from both commercial and noncommercial sectors. This will ensure that regulations reflect up-to-date scientific knowledge and understanding, are needs based and enable a shared sense of responsibility to conserve and protect the ocean genome.
- This paper takes a holistic approach to evaluating the prospects for conservation and sustainable use of the ocean genome. It does this by analysing our understanding of the genetic diversity of life within the ocean, the threats posed to such diversity, the benefits provided by genetic diversity and the ecosystems it supports in the context of a changing world, as well as tools and approaches for ensuring fair and equitable sharing of these benefits.
- The paper concludes with opportunities for action that, if followed, would improve our understanding of the ocean genome and support its conservation as well as its sustainable and equitable use.

1 Introduction

1.1 Overview

The 'ocean genome' is the foundation upon which all marine ecosystems rest and is defined here as the ensemble of genetic material present in all marine biodiversity, including both the physical genes and the information they encode. The dynamics of the ocean genome enable organisms to adapt to diverse ecological niches and changing environmental conditions. The ocean genome also determines the productivity and resilience of biological resources, including fisheries and aquaculture, which collectively support global food security, human well-being and a sustainable ocean economy.

A deeper understanding of the ocean genome has contributed to an increased awareness of the pressures facing marine biodiversity, including those from habitat loss and degradation; overfishing and other extractive activities such as mining; climate change and the spread of invasive species. Rapid advances in sequencing technologies and bioinformatics have enabled exploration of the ocean genome, which is informing the designation of marine protected areas as well as innovative approaches to conservation such as the establishment and incorporation of temporal genetic monitoring datasets into conservation planning and management as well as the sustainable use of resources. Exploring the ocean genome has also enabled a growing number of commercial biotechnology applications, extending from multiple anticancer treatments to cosmetics and industrial enzymes. At the same time, the environmental, social and ethical risks arising from the use of existing and new biotechnologies such as CRISPR (Clustered Regularly Interspaced Short Palindromic Repeats) remain under-investigated and poorly known, especially in marine environments.

As awareness of the unique nature and consequent value of the ocean genome grows and the importance of ensuring its conservation and sustainable use becomes more pressing, so too has the complexity of the national and transnational legal, institutional and ethical contexts that govern it. Within national jurisdictions, the Convention on Biological Diversity (CBD) and its Nagoya Protocol comprise key governance mechanisms for the conservation and sustainable use of marine biodiversity. For biodiversity in areas beyond national jurisdiction (BBNJ), a new United Nations (UN) agreement is under negotiation focusing on issues of crucial importance to the ocean genome, including area-based management tools, access to and intellectual property protection of marine genetic resources and their commercial exploitation, as well as capacity building.

Sharing benefits arising from the use of the ocean genome is a central issue. There is an urgent need to promote inclusive and responsible research and innovation that addresses equity differentials and fosters enhanced capacity and access to technology while facilitating the realisation of commitments to conserve and sustainably use the ocean's genetic diversity.

1.2 Scope and Ambition

This Blue Paper takes a holistic approach to the issue of the ocean genome and addresses

- our understanding of the genetic diversity of life within the ocean;
- the threats posed to these building blocks of life;
- the many benefits this diversity provides for functional ocean ecosystems, humanity and the biosphere in the context of a changing world;
- the tools and approaches that have been demonstrated to protect and restore genetic, species and ecosystem diversity; and
- stumbling blocks and opportunities for achieving sustainable and equitable use.

After introducing the ocean genome and the ecological benefits it provides, we present an overview of the expanding range of commercial activities it enables. This is followed by a description of the challenges facing the conservation and sustainable use of the ocean genome, including the primary anthropogenic threats to marine biodiversity. We then discuss the pathways to solutions, spanning novel conservation approaches, efforts to promote inclusive and responsible research and innovation and equitable access and benefit sharing from the use of marine genetic resources.

Ultimately, individuals, communities, companies and states have all contributed to different degrees to the degraded state of marine ecosystems. Their reliance on and stewardship of these resources varies, as do the benefits they derive from the ocean genome. Equity and sustainability are therefore crosscutting themes, and attention is given not only to evidence of inequitable and unsustainable practices, but also to the institutional and informal approaches and tools available to address these challenges.

The paper concludes with a number of opportunities for action that, if adopted, would improve our understanding of the ocean genome, and contribute to ensuring its conservation as well as its sustainable and equitable use.

1.3 What Is the Ocean Genome and Why Is It Uniquely Important?

The ocean covers 70% of the Earth's surface and represents 99% of the habitable space on the planet by volume (Costanza 1999). Life has existed in the ocean for at least 3.7 billion years, over three times as long as on land (Pearce et al. 2018; Strother et al. 2011). This long evolutionary history has resulted in some 2.2 million existing eukaryotic marine species (estimates range from 0.3 to 10 million species), of which 230,000 are confirmed (Mora et al. 2011; Louca et al. 2019). Marine species have been discovered at a higher rate than terrestrial species since the 1950s (Costello et al. 2012); indeed, the ocean harbours unique biodiversity that dwarfs the biodiversity found on land. For example, of the 34 major known animal phyla, 33 are found in the ocean while only 12 are found on land (Jaume and Duarte 2006). On land, a single phylum accounts for 90% of all terrestrial animal species (Arthropoda—including insects and arachnids), but in the ocean 90% of the animal species are distributed across 8 phyla (Mollusca, Arthropoda, Chordata, Annelida, Nematoda, Cnidaria, Bryozoa and Porifera), showing a remarkable range of biodiversity at higher taxonomic levels (Jaume and Duarte 2006). Depending on the taxon group, some 24–98% of eukaryotic marine species remain undescribed. Even less is known about prokaryotic marine life (bacteria and archaea) and viruses, which form the majority of life in the ocean by weight—some 1.2×10^{29} prokaryote cells (Bar-On et al. 2018) and 1.3×10^{30} virus particles (Cobián Güemes et al. 2016). The estimated number of microbial species (operational taxonomic units of bacteria, archaea and microscopic fungi) in the ocean ranges widely, due to extrapolation based on scaling laws, from 1.0×10^6 to 3.0×10^{27} (Locey and Lennon 2016; Louca et al. 2019; Mora et al. 2011).

Genetic diversity—the total number of genetic characters in the genetic makeup of a species—is a foundational component of biodiversity, strongly determining the biogeography of species distribution and allowing us to indirectly retrace the history of life and its evolution on Earth. Its conservation is necessary for evolution and, through genetic variability, for greater population fitness and potential to adapt and recover (Reed and Frankham 2003). Such attributes are especially critical in the context of rapid environmental change (Hilborn et al. 2003; Ellegren and Galtier 2016). Genetically diverse fish stocks, for instance, may be able to exploit a range of environments and have a better ability to withstand anomalous conditions, and are therefore of key interest to fishery managers (Schindler et al. 2010; Ruzzante et al. 2006). Genetic diversity is also important for understanding long-term climate resilience, such as the ability of some corals to be heat resistant in the face of mass bleaching events (Norström et al. 2016; Cornwall 2019; Morikawa and Palumbi 2019).

The 'ocean genome' is defined here as the ensemble of genetic material present in all marine biodiversity, including both the physical genes and the information they encode. While discussions of genetic resources typically centre on physical resources, the informational component of genes has become increasingly important. This is due to the possibility of storing the nucleotide sequences of DNA (deoxyribonucleic acid) and RNA (ribonucleic acid) as digital information and using this information to create proteins, molecular processes, innovation and even organisms (Gibson et al. 2010; Hutchison et al. 2016). Patent and ownership claims now often centre on using genetic sequence data in addition to the physical genetic material from which they were extracted. Patent applications require sequences to be disclosed, depending on what is being patented, and many scientific journals also require sequences to be deposited and an accession number to be supplied prior to publishing associated research (Giles 2011; Blasiak et al. 2019). Limiting genetic resources to their material representation does not encompass the diverse ways in which these resources are used and commercially exploited; therefore, for the purposes of this paper, we conceptualise genetic material, and by extension the ocean genome, to include both physical molecules and their genetic sequence information (Elkin-Koren and Netanel 2002). Figure 4.1, developed by Broggiato et al. (2014), provides an illustration of the pathways that can lead to using marine genetic resources (MGR) after sampling and identifying interesting applications.

Box 4.1 A Note on Scientific Terminology and Legal Scope

Following the negotiations and signing of the Convention on Biological Diversity (CBD), one observer claimed that 'biodiversity is dead' on the basis that its definition was simply too inclusive and non-specific.[a] Over two decades later, the term 'genetic resources' is causing similar disquiet due to its scope,[b] and an expanding library of sometimes overlapping terminology is complicating the global task of governing the access, use and circulation of genetic resources. The following is a brief guide to the current or emerging legal terminology relevant to this paper:

Biodiversity (from CBD): The variability among living organisms from all sources including, among others, terrestrial, marine and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, between species and of ecosystems.

Genetic resources (from CBD): Genetic material of actual or potential value.

Genetic material (from CBD): Any material of plant, animal, microbial or other origin containing functional units of heredity, such as individual genes or genetic sequences.

Digital sequence information (or data): Used in association with research and development, and the use of genetic resources, this is a placeholder term in international discussions under the CBD. As used, it includes various types of information including nucleic acid sequences; information on sequence assembly that may describe whole genomes, individual genes or fragments; single nucleotide polymorphisms; information on gene expression structures including morphological data and phenotype; data on macromolecules and cellular metabolites; information on ecological relationships and abiotic factors of the environment; behavioural data; information related to taxonomy; and modalities of use. The term is typically used in negotiating processes linked to international agreements such as the CBD, United Nations Convention on the Law of the Sea (UNCLOS) and the International Treaty on Plant Genetic Resources for Food and Agriculture.

Genetic sequence data: The order of nucleotides found in nucleic acid molecules—DNA (deoxyribonucleic acid) or RNA (ribonucleic acid)—which contain the genetic information that determines the biological characteristics of an organism or a virus. The term is widely used in the scientific community, and is preferred by some parties to the CBD.

Nucleotide sequence data: The arrangement of nucleotides on strands of naturally occurring DNA or RNA. Information about the genetic resources arises through analysis of these data.

Marine genetic resources: The genetic material of marine plant, marine animal, microbial or other origin containing functional units of heredity, which have an actual or potential value. The scope of this term is subject to negotiations related to biodiversity in areas beyond national jurisdiction, but, as such, it is not defined or used in UNCLOS.

In many ways, the battle over terminology is central to the effective and equitable governance of genetic resources. The terms above straddle environmental and biotechnological norms, and are therefore defined both by tangible parameters such as location and place, as well as intangible parameters such as information and function.

1.4 How Do We Benefit from the Ocean Genome?

The ocean genome is the foundation upon which all marine ecosystems rest and is therefore integrally linked to the existence of all life on Earth, including humanity. Throughout human history, diverse cultures, societies and knowledges have evolved that are integrally linked to marine and coastal biodiversity, leading over time to the emergence of a rich diversity of social-ecological systems and worldviews in coastal regions around the world. As the custodians of many coastal areas, and the repositories of associated traditional knowledge, local and traditional communities have played a critical role in contributing such knowledge toward our food, medicines, cosmetics and emotional connections to the ocean.

Maintaining the health of ocean ecosystems is critical; these ecosystems provide over 50% of the oxygen on the planet, sustain vast fisheries generating 17% of the animal protein we consume and shape and regulate global climate patterns (FAO 2018; IPBES 2019). The genetic diversity within the ocean genome contributes to the capacity of species and populations to adapt to a changing ocean and helps mitigate the impacts associated with realised and projected climate change (Reed and Frankham 2003).

Marine plants, animals, fungi and microorganisms have evolved to occupy a variety of niches, being able to thrive in the extremes of heat, cold, water chemistry and darkness found in the ocean. The resulting adaptations are recorded in their genetic codes, enabling them to produce a wide variety of primary and secondary metabolites with significant biological activities that have attracted growing commercial interest from a range of industries (Blasiak et al. 2018; Arnaud-Haond et al. 2011; Arrieta et al. 2010). Applications include the development of industrial enzymes, pharmaceuticals, cosmeceuticals, nutraceuticals, antifoulants, adhesives and tools for research and conservation purposes (Leary et al. 2009). Over 34,000 marine natural products—naturally occurring molecules produced by marine organisms—have been discovered (MarinLit 2020), many with remarkable levels of bioactivity, resulting in rates of drug discovery from marine organisms that are up to 2.5 times the industry average (Carroll et al. 2019; Gerwick and Moore 2012; Arrieta et al. 2010).

In addition to these commercial uses, a range of noncommercial applications based on the ocean genome has also emerged. Through the use of genetic sequence data, a substantial and growing body of work has been done in the fields of evolution and ecology to inform our knowledge on taxonomy, connectivity, demography and evolution, while new techniques, such as the sampling of environmental DNA (eDNA), are enhancing our understanding of marine taxonomy and enabling noninvasive study methods (Hansen et al. 2018). DNA barcodes have also been used to help identify mislabeled seafood and fight wildlife trafficking (Di Muri et al. 2018). Finally, the potential of gene editing tools like CRISPR (Clustered Regularly Interspaced Short Palindromic Repeats) as novel conservation techniques is now being explored (Phelps et al. 2019), although its application remains theoretical. Moreover, environmental, social and ethical risks remain under-investigated and poorly known, especially for the marine environment (CSS et al. 2019; Jasanoff et al. 2015).

1.5 How Is the Ocean Genome at Risk?

Multiple threats face the ocean genome, largely through overexploitation, habitat destruction, pollution, invasive species and, increasingly, the degradation of marine ecosystems, all of which are additionally impacted by a changing climate (Aburto-Oropeza et al. 2020). Land-based activities such as high-input industrialised agriculture are leading to pollution and eutrophication from excessive nutrient runoff and expanding low-oxygen dead zones around river deltas. Coastal aquaculture (mariculture) can also have significant environmental impacts due to high nutrient inputs, chemical pollution, the removal of large amounts of fry from the wild and the large-scale destruction of coastal habitats such as mangroves, among other issues (Hamilton 2013; Ahmed and Glaser 2016). Mariculture has also created an immediate threat to the genetic diversity of native fish populations, most prominently perhaps in the southern hemisphere where salmonids, absent from the native fauna (Arismendi et al. 2009), have been introduced as aquaculture escapees and in areas supporting wild capture salmon fisheries (McGinnity et al. 2003, 2009). Shipping activities and the flow of ballast water and waste into the ocean have contributed to the spread of invasive species and pathogens, and to the creation of anoxic, no-oxygen zones and toxic red tide algal blooms (Pitcher and Probyn 2016).

Ocean-based activities like trawl fisheries, mining, dredging and the construction of artificial islands are drastically reducing biodiversity and completely reshaping some marine environments (Halpern et al. 2008; Du Preez et al. 2020). Overfishing has led to the collapse of major fisheries like the Newfoundland cod fishery, where a regime shift has subsequently resulted in a restructuring of regional food webs (Pedersen et al. 2017). Overfishing is also damaging the genetic diversity of fish and bycatch species, with one study suggesting that overfished species carry about 18% fewer unique genetic variations than their lightly fished relatives (Pinsky and Palumbi 2014). In some cases, multiple threats combine synergistically; for instance, aquaculture salmon broodstock escapes and fishing of wild populations have led to the loss of genetic diversity (Waples et al. 2012).

At a global scale, the burning of fossil fuels has generated greenhouse gas emissions and led to climate change—and the ocean absorbs 93% of the increased heat associated with these greenhouse gas emissions (Resplandy et al. 2018). The majority of marine species have narrower windows of thermal tolerance compared with those of terrestrial species, and local extinctions of marine species have been twice as common as those of species on land based on a global dataset of the range-edge positions of species on land and in the sea (Pinsky et al. 2019). Increased heating of the ocean remains the biggest climate impact to date, with the absorption of excess carbon also resulting in ocean acidification, which has negatively impacted marine ecosystems as it interacts synergistically with other drivers of loss such as direct exploitation and pollution (IPBES 2019).

About 20 marine species are known to have gone extinct over the past 500 years (McCauley et al. 2015), yet this is likely an underestimate given that little is known about how many species inhabit the marine environment. Some marine species have not been observed for decades and could already be extinct, while others, including 25% of marine mammals, sharks and rays, are at risk of extinction or are globally threatened (IUCN 2019; Dulvy et al. 2014). Although advances in working with ancient DNA may still allow species' genomes to be recovered from remains held in museums (McCormack et al. 2017), these would be devoid of the variability present in viable existing populations.

In the face of these threats to marine biodiversity and the ocean genome, adequate protection lags significantly. For most of human history the ocean was largely a de facto fully protected area that was too remote, too distant and too deep to exploit based on technological, economic and social limitations to access (Lubchenco and Gaines 2019). The creation of marine protected areas (MPAs) is in recognition of the need to reestablish places that are protected from exploitation. International targets including the Convention on Biological Diversity's Aichi Target 11 and the United Nations' Sustainable Development Goal 14 call for protecting 10% of the ocean by 2020 in MPAs and other effective area-based conservation measures (OECMs). Yet only 8% of the ocean is in any kind of designated MPA, including 5% in implemented MPAs, and only 2.5% is in fully or highly protected, implemented MPAs (Sala et al. 2018, updated via Marine Conservation Institute 2020). Further, there are growing calls from the scientific community for at least 30% of the ocean to be fully to highly protected to maintain a healthy, productive and resilient ocean (O'Leary et al. 2016; Gaines et al. 2010). In parallel, significant efforts are also needed to ensure that genetic diversity in areas outside MPAs and OECMs is conserved. This would include ensuring the sustainable use of resources; preventing habitat degradation; cautiously using previously unexploited places; and protecting rare, threatened and endangered species and populations.

Marine science has contributed significantly to revolutionary scientific and technological transformations in the life sciences and microbiology over the past two decades. Advances in genomic technologies, with sequencing costs declining 4000-fold over the past decade (Green et al. 2017), mean that millions of DNA fragments can be sequenced simultaneously and inexpensively, creating an intensely data-rich field (see Fig. 4.2) (Pevsner 2015). While such innovations have rapidly expanded the boundaries of our knowledge, vast knowledge gaps remain (Wetterstrand 2019). For instance, a large fraction of predicted genes from marine prokaryotes cannot be assigned functions (Sunagawa et al. 2015), and the functions of some 90% of genetic sequences collected from viruses remain unknown (Hurwitz and Sullivan 2013).

The rapidly growing field of synthetic biology now allows genes from different organisms, from different parts of the world, and from the ocean, soil and rivers to be combined into new patented organisms, including some synthesised components. Although the full contribution of MGR remains unknown, the Synthetic Biology Project reports at least 116 synthetic biology products and applications to be near to or on the market. The pace has rapidly increased over the past 5 years due to the introduction of fast, reliable and low-cost genome-editing techniques such as CRISPR, gene drives, TALENs (transcription activator-like effector nucleases) and oligonucleotide-directed mutagenesis techniques (Doudna and Charpentier 2014).

While such developments could yield important benefits, they also carry significant and often unknown risks. It is especially hard to predict the ecological consequences of introducing transformed organisms into marine environments. Containing introduced organisms is likely impossible and escaped transgenic fish or bacteria may establish viable populations in the wild, leading to altered natural ecosystems (Li et al. 2015). For instance, simple, commercially available kits (GeneArt® *Synechococcus* Engineering Kits) allow the photosynthetic cyanobacteria *Synechoccocus*—responsible for up to 80% of the photosynthetic production in the oligotrophic ocean (Campbell et al. 1994)—to be genetically manipulated. Accidental release of genetically modified strains in the ocean could, if viable, generate significant risks to the entire biosphere. The introduction of genome-editing techniques heightens such concerns, raising a suite of important questions about the governance and regulation of such technologies, about how problems are framed and solved, about how decisions get made about the release of modified organisms, and about the ethical considerations of international, intergenerational and interspecies justice (CSS et al. 2019).

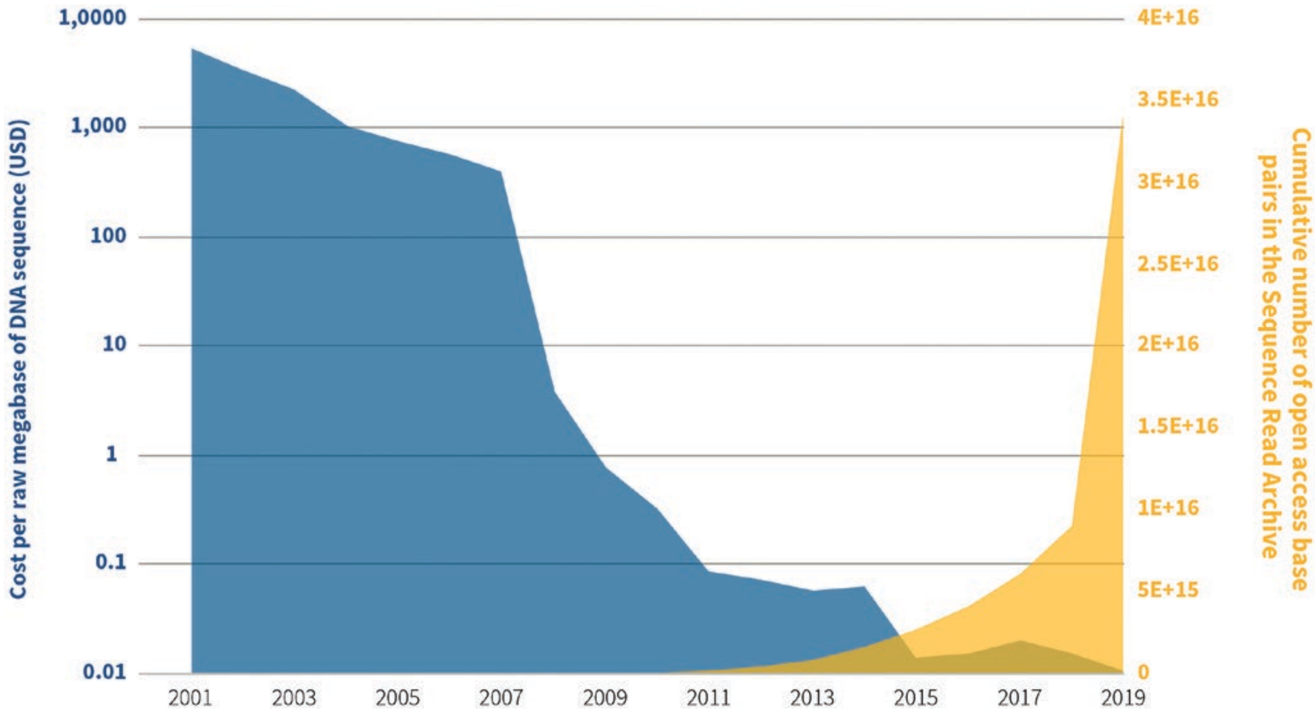

Fig. 4.2 Growth in GenBank Sequence Read Archive Records, and Trend in Average Cost of Sequencing. *Notes: GenBank is the genetic sequence database of the United States National Institutes of Health. It maintains the Sequence Read Archive, a bioinformatics database of sequencing data, particularly the short reads of fewer than 1000 base pairs typical of high-throughput sequencing methods. Also note that a logarithmic scale is used on the left axis. DNA stands for deoxyribonucleic acid.* (*Source: Data from National Center for Biotechnology Information. 2018. "Sequence Read Archive." 1.6 How Is the Ocean Genome Governed and Regulated?

Governance of the ocean genome is complex. This is due, not least, to its conceptual broadness, the lack of boundaries for the spread of species in the ocean, the diversity of threats it faces and the mix of its commercial and noncommercial dimensions. The United Nations Convention on the Law of the Sea (UNCLOS), concluded in 1982, acts as a sort of 'constitution' for the ocean, specifying provisions for the protection of the marine environment. The convention itself does not refer to either biodiversity or genetic resources, but it does refer to the 'conservation and utilization of living resources' (Articles 61 and 62), including on the high seas (Articles 116 and 117). UNCLOS combines elements of different conceptions of property, with a governance approach to achieving social objectives (Allott 1992).

UNCLOS also defined a series of maritime zones and jurisdictional claims (Fig. 4.3). Of particular relevance is the distinction between exclusive economic zones (EEZs) and areas beyond national jurisdiction (ABNJ), which comprise roughly 36% and 64% of the ocean's area, respectively (Smith and Jabour 2018). According to UNCLOS, each coastal state has 'sovereign rights [within its EEZ] for the purpose of exploring and exploiting, conserving and managing the natural resources'. In the case of straddling and highly migratory fish stocks, many of which are found across multiple EEZs as well as ABNJ, the UN Fish Stocks Agreement applies (UN 1995). According to that agreement, states 'shall apply the precautionary approach widely to conservation, management and exploitation [. . .] to protect the living marine resources and preserve the marine environment'.

Two international agreements under the CBD are of particular relevance: the Cartagena Protocol on Biosafety (2000), which aims to protect biological diversity from risks associated with biotechnology innovations, including genetically modified organisms; and the Nagoya Protocol on Access and Benefit-Sharing (2010), which aims to operationalise the CBD's third objective. The 196 parties to the CBD have agreed to a wide range of obligations and relevant global targets, including safeguarding genetic diversity, operationalising the Nagoya Protocol and ensuring the integrity of ecosystems. Meeting these targets entails committing to protect 10% of coastal and marine areas by 2020 (Aichi Target 11) and maintaining the genetic diversity of wild ani-

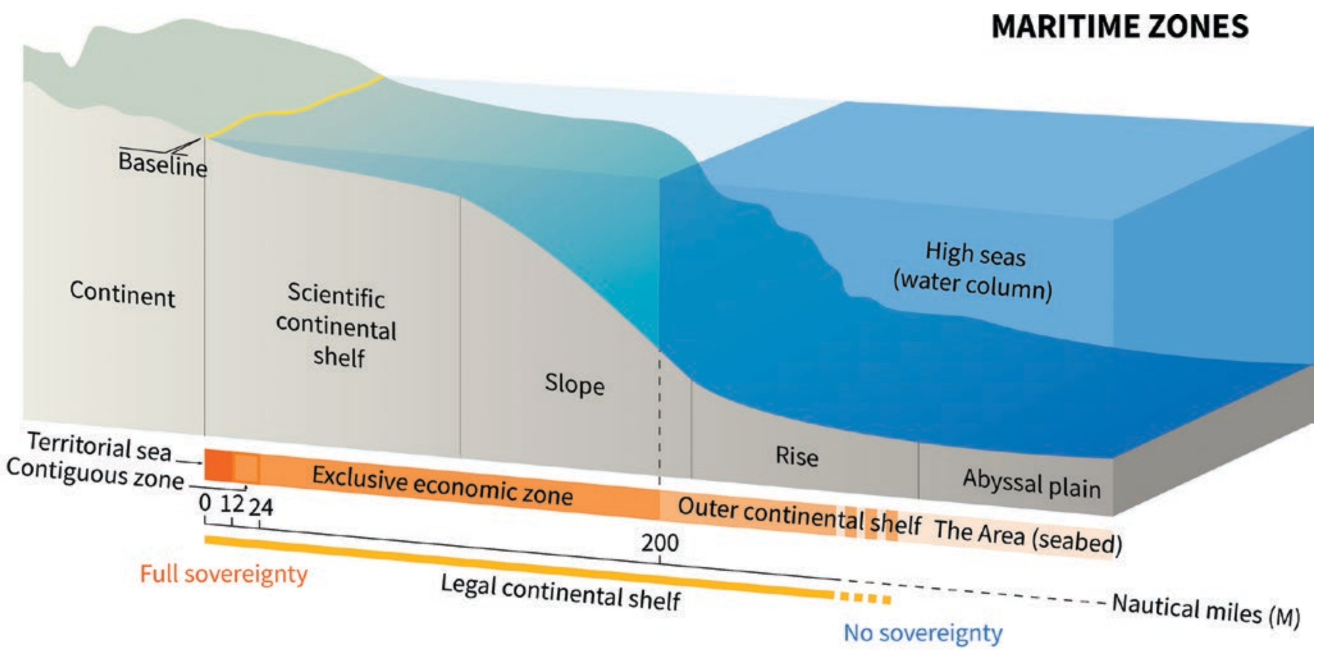

Fig. 4.3 Maritime zones and levels of sovereignty. (*Source: Courtesy of Riccardo Pravettoni, cartographer. Pravettoni, R. 2010. "Maritime Zones." UN Environment Programme.* http://www.grida.no/resources/7923)

mals, in addition to domesticated species, by using strategies to minimise genetic erosion (Aichi Target 13).

As mandated by UN General Assembly Resolution 72/249, an intergovernmental conference began in 2018 with the aim of negotiating a new legally binding international treaty on biodiversity in ABNJ (BBNJ). The negotiations cover four elements of a package: marine genetic resources including issues related to access and benefit sharing; measures such as area-based management tools, including MPAs; environmental impact assessments (EIAs); and capacity building and technology transfer.

These negotiations have been complicated by a focus on marine scientific research and the noncommercial aspects of research and development of MGR as well as the intersection with intellectual property issues. These controversies arise from the potential commercial exploitation of these resources, along with the desire to 'not undermine' mandates of the World Intellectual Property Organization (WIPO) and the World Trade Organization's Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) (see Sect. 4.2). Additionally, definitions from the CBD and Nagoya Protocol have not been embraced by state parties in the negotiations. Strong views on the scopes and definitions of terms such as 'genetic resources', 'access', 'digital sequence information', 'derivatives' and even the need for, and scope of, a definition of 'utilisation' of genetic resources threaten the possibility of multilateral consensus positions (see Box 4.1).

2 Existing and Potential Benefits

2.1 Ecological Benefits Associated with Marine Genetic Diversity

The genomes of organisms encode the biological, morphological, behavioural and physiological attributes that define their structures and roles within ecosystems. In the ocean, functioning ecosystems supported by this genetic diversity contribute essential services, including producing and recycling organic matter, channelling energy across food webs, providing food, maintaining water quality, regulating climate, establishing cultural values and providing recreational opportunities and other ecosystem services that benefit humanity (Worm et al. 2006). The ecological benefits of the ocean genome are vast (see Sect. 1.2), with their scope broadly organised into two equally important and interrelated themes.

First, genetic diversity in the ocean is critical because it stabilises ecosystems, as well as the species and ecological processes they encompass and the ecosystem services they provide. Genetic variability, including single nucleotide base pair substitution, insertion-deletion and structural variability, can result in the presence of species with redundant functions (Li et al. 2015) as well as genotypes within species that encode variable responses to environmental pressures. These support ecosystem stability and ensure that ecosystems remain functional even if unpredictable changes lead to the loss of some species, or the loss of within-species genetic diversity at the population level (Webster et al. 2017). For example, genetic variability across more than 100 discrete populations of Bristol Bay salmon in Alaska entails greater heterogeneity and resilience to anomalous conditions, resulting in lower variability in fisheries production and greater stability than that of a homogeneous population. This has also led to fewer fisheries closures for the fishing community (Schindler et al. 2010). At the ecosystem level, nutrients from the salmon spread throughout the system as predators feed on the population during spawning season.

Genetic diversity can also stabilise populations during restoration efforts. Seagrass restoration experiments in North America and Indonesia showed plots with higher genetic diversity had increased survival, density and/or growth (Reynolds et al. 2014). In the Chesapeake Bay, restoration efforts were linked to ecosystem services, including increased primary production and nutrient retention (Reynolds et al. 2012).

Second, genetic diversity enables biological variability and drives genetic potential, which allow species to persist in changing environmental conditions and to evolve as environments change over time. Overexploitation of and declines in marine populations can lead to dwindling population sizes and greater potential for lost genes compared with the greater standing genetic variation in larger populations. This variation helps species persist and adapt to perturbations (Thornburg et al. 2018), including those associated with anthropogenic changes. For example, an experiment on marine phytoplankton showed that cultures with higher genetic diversity were better able to withstand low salinities. High diversity in the simulated populations corresponded to the highest primary production and greatest nitrogen uptake under salinity stress (Sjöqvist and Kremp 2016). This is particularly important alongside increasing evidence that adaptation in some species can take place faster than previously thought; adaptation has been shown to occur in only 200 generations of short-lived species such as tropical diatoms (Jin and Agustí 2018). Corals also provide context for this adaptive capacity with their ability to respond relatively quickly via symbiont and microbiome shuffling, phenotypic plasticity, acclimatisation and adaptation. Some corals may have already adapted to ocean warming since the Industrial Revolution (Webster et al. 2017).

The ecosystem stability and adaptive potential afforded by genetic diversity are already vital to species, populations and communities as we know them. Yet their future values may go beyond these, as systems change at rates that are unprecedented and in ways that are unexpected, involving additive and synergistic effects. This underscores the benefits of conserving the ocean genome (see Sect. 4.1), particularly in areas that are minimally explored but may harbour high genetic diversity and isolated populations, including the fragile communities on seamounts and in the deep sea (Taylor and Roterman 2017; Zeng et al. 2017).

2.2 Commercial Benefits of Marine Genetic Resources

An intact and healthy ocean genome provides not only ecological benefits but also the foundation that has enabled and supported a growing range of commercial applications. Although the monetary benefits associated with these innovations are notoriously difficult to quantify (see, for example, Fig. 4.4), it is important to emphasise how these innovations contribute to human well-being. For instance, bioactive compounds from marine microorganisms associated with sea sponges are considered promising candidates for the development of novel antibiotics, which are relevant in the context of increasing antimicrobial resistance (El Samak et al. 2018). Likewise, the venoms of species such as cone snails are of interest for the development of new drugs (see, for example, Table 4.1) that could replace opioids and consequently lower instances of misuse (Zachos 2017).

2.2.1 Marine Drug Discovery

The targeted search for compounds with biological activity against human diseases began in the late 1960s, but structures of compounds with high potency and selectivity were not defined until the 1980s. Extensive funding by the United States' National Cancer Institute along with its commitment to collect MGR globally meant that the focus was on the treatment of cancer, using compounds mostly collected from shallow tropical reefs and derived from marine invertebrates (Thornburg et al. 2018). As a result, five out of the eight clinically approved drugs derived from MGR are treatments for cancer; the remaining three are treatments for neuropathic pain, *Herpes simplex* virus and hypertriglyceridemia (Table 4.1). Out of these, seven are derived from marine invertebrates and one is derived from an oily fish. Development of and approval for all of these took many years.

As is the case for most drugs derived from MGR, the issue of a sustainable supply of the raw material/compound needs to be addressed. Attempts to solve this have involved

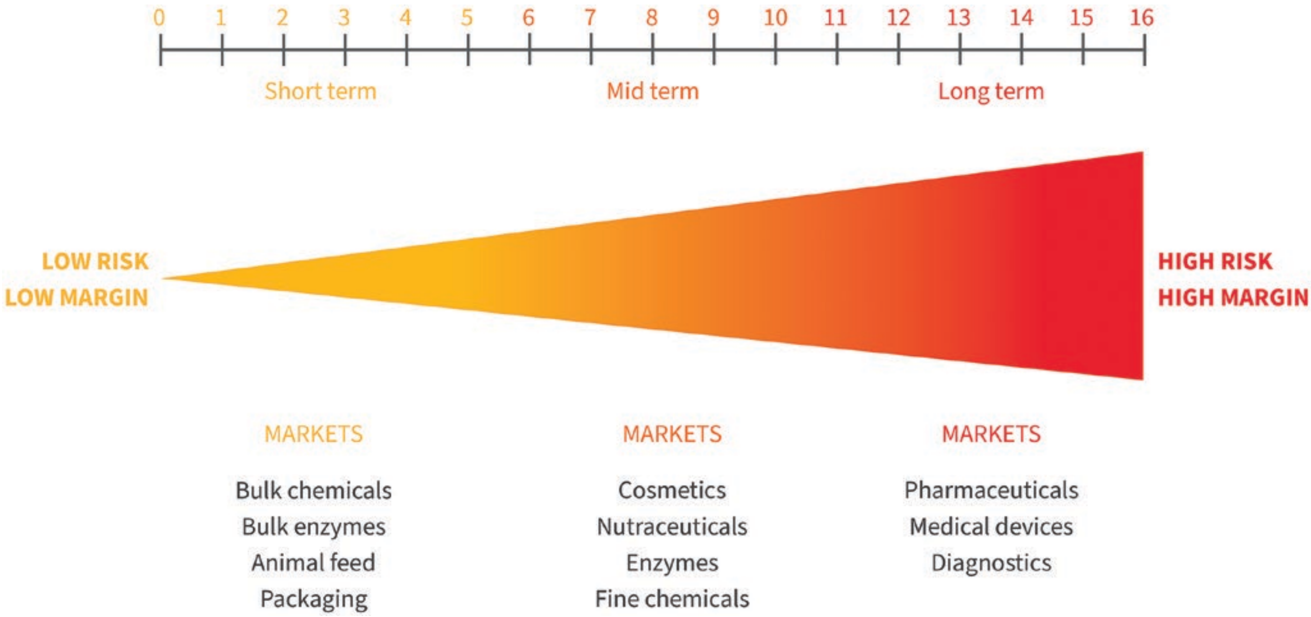

Fig. 4.4 Risk, profit margins and timelines for commercial activities associated with marine genetic resources. (*Source: Authors*)

several approaches, the most common being total chemical synthesis. Biotechnological approaches have also been employed, including hybrid synthetic/biotechnological approaches (Table 4.1). As an example, the case of Yondelis is described in Box 4.2. Two of the compounds in Table 4.1, Vidarabine and Cytarabine, now have second-generation analogues, Fludarabine (Fludara) and Nelarabine (Arranon), respectively (Alves et al. 2018). The European Medicines Agency has approved some over-the-counter medications based on MGR, such as Carragelose, a broadly effective antiviral drug that can be used to treat respiratory viruses such as the common cold (Alves et al. 2018). Currently, 28 marine-derived products are in clinical trials with a further 250 in preclinical investigation, all from around 33,000 reported marine natural products (MarinLit 2020). This is an astounding success rate when compared with terrestrial natural products. This success may be due in part to the vast taxonomic diversity in marine environments. For sessile marine invertebrates, the lack of an evolved immune system, combined with the pressures of preventing predation and competing for space and resources, may have led to the evolution of a chemical arsenal for survival.

Because of the supply issue associated with marine invertebrate-derived pharmaceutical candidates, the marine natural product research community has also focused on investigating marine microorganisms as sources of bioactive compounds. The long time lag between discovery and development (see Fig. 4.4) means that most of these are still under preclinical investigation, with a smattering of microbial compounds in human clinical trials (Mayer et al. 2017) and many more at preclinical stages of development. The ability to sequence genomes quickly and cheaply coupled with bioinformatics tools—such as antiSMASH, which enables the rapid identification of secondary metabolite gene clusters in bacteria and fungi—often renders the inherent capacity for microorganisms to produce chemicals predictable even before testing begins (Medema et al. 2011). Challenges remain when genes are of completely unknown function, as is the case for many marine viruses. Advances in chemoinformatics, such as Global Natural Products Social Molecular Networking, allow scientists to verify this latent talent, massively speeding up the biodiscovery process. Finally, advances in assay technology mean we use less material in bioassays while obtaining better quality data with higher information content (e.g. Caicedo et al. 2017). Compound isolation and structure determination, the final stages of the biodiscovery process that were previously a bottleneck, have also improved over the last decade (Chhetri et al. 2018). Much development is also focused on finding secure methods other than chemical synthesis to reliably and sustainably generate and modify bioactive compounds, using, for instance, synthetic biology (e.g. for the plant-derived natural product artemisinin, see Paddon and Keasling 2014) and enzymes in synthesis (e.g. for chemoenzymatic synthesis of cyanobactins, see Houssen et al. 2014).

Table 4.1 Marine-derived compounds currently in clinical use

Plitidepsin	TRADEMARK YEAR	Aplidin® (2018)
	MARINE ORGANISM	Tunicate
	SOURCE	Mediterranean
	CHEMICAL CLASS	Depsipeptide
	MOLECULAR TARGET	eEF1A2
	DISEASE AREA	Cancer: multiple myeloma, leukaemia, lymphoma
	COMPANY	Pharmamar
	ROUTE OF MANUFACTURE	Synthesis
Trabectedin (ET-743)	TRADEMARK YEAR	Yondelis® (2015)
	MARINE ORGANISM	Tunicate
	SOURCE	Caribbean
	CHEMICAL CLASS	Alkaloid
	MOLECULAR TARGET	Minor groove of DNA
	DISEASE AREA	Cancer: soft tissue sarcoma, ovarian
	COMPANY	Pharmamar
	ROUTE OF MANUFACTURE	Semi-synthesis
Brentuximab vedotin (SGN-35)	TRADEMARK YEAR	Adcetris® (2011)
	MARINE ORGANISM	Mollusk/cyanobacterium
	SOURCE	Mauritius
	CHEMICAL CLASS	ADC (MMAE)
	MOLECULAR TARGET	CD30 and microtubules
	DISEASE AREA	Cancer: anaplastic large T-cell systemic malignant lymphoma, Hodgkin's disease
	COMPANY	Seattle Genetics
	ROUTE OF MANUFACTURE	Synthesis/biotechnology
Eribulin Mesylate (E7389)	TRADEMARK YEAR	Halaven® (2010)
	MARINE ORGANISM	Sponge
	SOURCE	Japan
	CHEMICAL CLASS	Macrolide
	MOLECULAR TARGET	Microtubules
	DISEASE AREA	Cancer: metastatic breast cancer
	COMPANY	Eisai Inc.
	ROUTE OF MANUFACTURE	Synthesis
Omega-3-acid ethyl esters	TRADEMARK YEAR	Lovaza® (2004)
	MARINE ORGANISM	Fish
	SOURCE	Undisclosed but manufactured in the United States
	CHEMICAL CLASS	Omega-3 fatty acids
	MOLECULAR TARGET	Triglyceride-synthesising enzymes
	DISEASE AREA	Hypertriglyceridemia
	COMPANY	GlaxoSmithKline
	ROUTE OF MANUFACTURE	Refined from fish oils
Ziconotide	TRADEMARK YEAR	Prialt® (2004)
	MARINE ORGANISM	Cone snail
	SOURCE	Philippines
	CHEMICAL CLASS	Peptide
	MOLECULAR TARGET	N-Type calcium channel
Ziconotide	DISEASE AREA	Pain: severe chronic pain
	COMPANY	Jazz Pharmaceuticals
	ROUTE OF MANUFACTURE	Biotechnology
Vidarabine (Ara-A)	TRADEMARK YEAR	Vira-A® (1976)
	MARINE ORGANISM	Sponge
	SOURCE	United States
	CHEMICAL CLASS	Nucleoside
	MOLECULAR TARGET	Viral DNA polymerase
	DISEASE AREA	Antiviral: herpes simplex virus
	COMPANY	Mochida Pharmaceutical Co.
	ROUTE OF MANUFACTURE	Synthesis

Table 4.1 (continued)

Cytarabine (Ara-C)	TRADEMARK YEAR	Cytosar-U® (1969)
	MARINE ORGANISM	Sponge
	SOURCE	United States
	CHEMICAL CLASS	Nucleoside
	MOLECULAR TARGET	DNA polymerase
	DISEASE AREA	Cancer: leukaemia
	COMPANY	Pfizer
	ROUTE OF MANUFACTURE	Synthesis

Despite these developments, there is a lagging interest from major pharmaceutical companies to explore marine and terrestrial natural products as potential sources of new leads. Most large pharmaceutical companies have closed their natural product discovery sections, while small and medium-sized companies are filling this gap and leading the way in the development of innovative new treatments using MGR. Large pharmaceutical companies will often buy small companies that have developed potential treatments to a certain stage of development, thus reducing their own risk while gaining access to the most recent innovations. The redefinition of the industrial landscape and the development of new tools and processes to investigate and develop MGR-derived bioactive compounds is thus critical for realising the overall potential of MGR for pharmaceutical discovery.

However, the benefits of marine biodiscovery extend far beyond the successful development of a product. Acknowledging the potential commercial value of biodiversity may lead to better funding for biodiversity surveys that access a broad range of marine life and assess these for bioactivity, which may lead to improved biodiversity conservation measures (Van Soest et al. 2012, see Sect. 4.1.3). A study carried out by the UN on the collaboration between Griffith University in Queensland, Australia, and the large pharmaceutical company AstraZeneca clearly articulates the regional benefits of engaging in biodiscovery research (Laird et al. 2008). These benefits include the availability of biorepositories of local species for further investigation; access to sophisticated bioassay and analytical equipment; the availability of highly skilled researchers and expertise; an improved publication profile and an enhanced research reputation. All of these together can boost the capacity of a region to thrive via multiple medical and biotechnological industries while contributing to the protection and sustainable use of biodiversity itself.

Box 4.2 Development of the Anticancer Agent Yondelis (Trabectedin)

The discovery of the active pharmaceutical ingredient in Yondelis, Ecteinascidin-743, from the Caribbean ascidian (seasquirt) *Ecteinascidia turbinata*, was first reported by two research groups in 1990. It was shown to have antineoplastic activity in cell-based and animal models, being particularly effective against soft tissue sarcoma, for which no good treatment options existed at that time. It was shown to have a unique mechanism of action, interfering with DNA (deoxyribonucleic acid) transcription by binding to the minor groove of DNA, which together with the new structure offered a strong commercial outlook. It was licensed to the Spanish company PharmaMar, which started the development process in the early 1990s. Initially, material was produced by aquaculture (Fig. 4.5, photo a), but this avenue was abandoned due to variability in production coupled with low yields, contamination issues and the high cost of infrastructure, among other reasons. Nevertheless, much of the clinical data were obtained using this aquaculture-derived material. To ensure a continuity of supply as well as quality of material, a semi-synthetic process was developed, modifying the fermentation product cyanosafracin-B to produce Yondelis economically. In 2007, the European Medicines Agency approved the use of Yondelis for advanced soft tissue sarcoma, but it took a further 8 years for the U.S. Food and Drug Administration to follow suit (Fig. 4.5, photo b). A combination treatment of Yondelis/Doxil is also being investigated as a second- and third-line treatment for ovarian cancer.

2.2.2 Nutraceuticals

The original definition of nutraceuticals, or functional foods, was given as 'food, or parts of a food, that provide medical or health benefits, including the prevention and treatment of disease' (Mannion 1998). Regulation for nutraceuticals is currently changing, with stricter rules being developed in many jurisdictions to prevent unrealistic claims of possible benefits. Marine resources have a huge nutraceutical potential (Bonfanti et al. 2018; Hill and Fenical 2010; Suleria et al. 2015). Indeed, due to their genomic diversity, they comprise a very wide range of enzymes and, as a consequence, of metabolic pathways. These in turn yield an extreme diversity of bioactive compounds with possible positive effects on health and well-being. These compounds encompass specific oligo- and polysaccharides; fatty acids and more complex lipids; proteins (including enzymes); and peptides, vitamins, minerals, phenolic substances, carotenoids, halogenated compounds and many others (Suleria et al. 2015).

Omega-3 fatty acids—EPA (eicosapentaenoic acid) and DHA (docosahexaenoic acid)—are of particular importance to the overlapping areas of nutrition and highly bioactive substances. Microalgae (as well as fish and some crustaceans, due to their consumption of microalgae) are a rich source of these polyunsaturated fatty acids (Rincón-Cervera et al. 2019; Ryckebosch et al. 2012), which are known for their positive health effects on inflammatory conditions (more importantly, EPA), cardiovascular disease (see Table 4.1 for examples of highly purified fish oils approved for clinical use, though the health benefits need confirmation; Manson et al. 2019) and neurocognitive development and health (DHA) (Echeverría et al. 2017). As a result, fish, crustacean and algal oils are deemed the best sources of EPA and DHA. Algal oils are a more recent development and a response to the overexploitation of fish resources. Microalgae may be produced under controlled conditions and in large quantities, and are rich in lipids (Rodolfi et al. 2009). Thraustochytrids, large-celled marine heterokonts classified as oleaginous microorganisms, are an important example of algal sources for their lipid productivity and particular richness in EPA and DHA (Gupta et al. 2012). The technological advantages of phototrophic microalgae have fostered research that has led to a growing number of applications. While the global supply of fish oil has stabilised at around one million metric tonnes every year and is constrained by overexploitation, phototrophic microalgae can be cultivated using renewable resources such as sunlight, carbon dioxide and cheap and plentiful nutrient sources (Chauton et al. 2015).

The potential for lipid production and the ability to produce EPA and DHA differ across microalgal species (Chauton et al. 2015). Strains with a desirable fatty acid profile can be obtained by selection (Rodolfi et al. 2009). For more ambitious targets, microalgae strains can be modified by inserting genes that enhance EPA and DHA synthesis or, alternatively, by silencing gene expression in competing metabolic routes (Mühlroth et al. 2013). Provided that environmental and social risks as well as ethical and safety concerns are fully addressed, such transgenic approaches may become solutions for the production of these invaluable marine nutrients, especially if new genes and corresponding enzymes from not yet prospected resources are drawn into a rigorous research and development effort.

2.2.3 Cosmetics

Cosmetics are big business—worth US $532 billion worldwide in 2017, growing at around 7.14% annually and expected to reach above $800 billion by 2023 (Orbis 2018). There is growing interest in naturally sourced products, including those derived from marine biodiversity. Additionally, products that show verifiable effects such as reducing wrinkles and protecting skin from the damaging effects of ultraviolet or infrared radiation attract a price premium and are placed at the high end of the market; these are often referred to as cosmeceuticals. The first true marine cosmeceutical, formulated in Estée Lauder's Resilience line, is a mixture of pseudopterosins derived from the Caribbean gorgonian (seawhip) *Pseudopterogorgia elisabethae*. These compounds were originally discovered as potent anti-inflammatory agents, but their physical properties meant they were unsuitable for systemic administration and they were therefore used topically. The material for the Resilience products is derived from environmentally managed seawhip farms, with population-level effects of the harvest studied in detail (Lasker 2013).

Two cosmeceuticals derived from vent bacteria have been commercialised, Abyssine 657 (Meyer/L'Oreal) and Venuceane (Sederma/Croda). The active product in Abyssine, Deepsane, is an anti-inflammatory polysaccharide obtained from a deep-sea bacterium *Alteromonas macleodi*, which is isolated from an annelid worm collected from a hydrothermal vent in the East Pacific Rise at 2625 metres (m) depth (in ABNJ) (Rogers et al. 2015). Venuceane, a product marketed as anti-ageing, detoxifying and moisturising, screens damaging infrared radiation and is derived from another hyperthermophile bacterium, *Thermus thermophilus*, obtained at 2000 m depth in the Guaymas Basin in the Gulf of California (Marteinsson et al. 1999). It has also been shown to screen ultraviolet radiation to prevent radical damage of DNA, thus protecting skin.

2.2.4 Aquaculture and New Food Products

Whereas marine aquaculture, developed originally in Egypt, spans 4000 years (Duarte et al. 2007), industrial aquaculture was initiated 40 years ago with the development of mussel raft aquaculture and fish aquaculture, along with the closing of the life cycle of salmon in captivity. Controlled food production from land organisms predates aquaculture by about 10,000 years, yet the number of marine species that have already been domesticated (about 270) matches that on land (about 294) (Duarte et al. 2007). Moreover, the domestication of new land species for food has remained nearly stagnant for the past two centuries, while about one-third of new marine species were domesticated in the past decade. The number of domesticated marine species continues to grow at a pace of about ten new species introduced to marine aquaculture every year (Duarte et al. 2007). The spider crab (*Maja brachydactyla*) (Pazos et al. 2018) and the common octopus (*Octopus vulgaris*) (Cerezo Valverde et al. 2019) are examples of two species domesticated in the past 2 years. Indeed, there is significant potential to domesticate all 3000 species harvested from the ocean as human food (Duarte et al. 2007).

Land species typically require a long selection process to achieve suitability for farming. On the other hand, the existing genetic diversity of marine species means that many mariculture-suitable species already exist (though selection often occurs when those growing these marine species select for specific traits—e.g. faster growth or better color). While natural and cultured populations of South African abalone (*Haliotis midae)* register similar levels of genetic diversity, cultured populations are genetically distinct from wild abalone, potentially as a result of selective pressures particular to each mariculture facility (Rhode et al. 2012). These findings highlight the need to maintain genetically diverse natural populations to support the mariculture industry, and to make provisions to ensure that commercially grown abalone are not released, accidentally or otherwise, into natural systems, as the latter poses a serious risk to the genetic integrity of an already vulnerable stock (Rhode et al. 2012; Bester-van der Merwe et al. 2011). Moreover, ongoing genetic monitoring is required for these species to maintain the genetic integrity of wild populations and to prevent genetic erosion, especially with the ongoing and largely uncontrolled release of cultivated organisms to the wild (da Silva and van Vuuren 2019). Thus far, only one aquaculture species, salmon, has been genetically modified for production (Waltz 2017), while on land genetically modified crops that are commercialised include maize, soya, cotton and canola, among others (Abberton et al. 2016).

Aquaculture now supplies almost half of the fish consumed worldwide (Troell et al. 2014), releasing some pressure on wild stocks. Yet sustainability within the sector and issues of genetic diversity within the industry will need to be addressed more comprehensively given projected expansions, linked to increased demand (Oyinlola et al. 2018).

The advantages of MGR also extend to new food products. Indeed, poorly known resources may yet be evaluated for their nutritional value and become subject to exploitation, which may then lead to cultivation. Some MGR may also provide novel functional food ingredients (Shahidi and Ambigaipalan 2015). These may encompass chitosans, specific carbohydrates, enzymes and protein hydrolysates given their ability to confer new properties to foods (e.g. altering their texture) or extend their shelf life (e.g. protein hydrolysates) (Shahidi and Ambigaipalan 2015). Recent developments in nanotechnology also bring new possible applications, such as the preparation of biogenic nanoparticles of marine algae for antioxidant and stabilisation effects on food matrices through active packaging (Gu et al. 2018; He et al. 2019). In addition, marine microbial enzymes encompassing agarases, cellulases, collagenases, lipases and proteases display valuable properties and offer various applications. The biochemical diversity of marine microorganisms makes these enzymes possible tools for food processing (Beygmoradi and Homaei 2017).

Considerable research is still needed to explore the use of MGR for engineering new foods. Indeed, only a little more than 40 fish species and even fewer in other marine taxonomic groups have had their genomes fully sequenced (Zhu and Ge 2018). These sequenced genomes and all genetic engineering tools, including recently available gene editing techniques such as CRISPR, may pave the way for a new generation of cultured seafood products (Zhu and Ge 2018), although questions of consumer acceptability, environmental risk and social desirability remain paramount. At present, genetic transformation of fish is mainly directed toward individual growth enhancement to increase the economic advantages of aquaculture. Atlantic salmon (*Salmo salar*) is the species that has been most targeted by genetic engineering efforts (Hafsa et al. 2016). For example, a transgenic Atlantic salmon (AquAdvantage)—recently approved by the U.S. Food and Drug Administration (Ledford 2015) after a 20-year review process—has a gene construct consisting of growth hormone cDNA (complementary DNA) from Chinook salmon (*Oncorhynchus tshawytscha*) that is regulated with anti-freeze protein gene sequences obtained from an ocean pout (*Zoarces americanus*), leading to growth rates that are much higher than those of non-transgenic salmon, with fish reaching market size in 16–18 months instead of 3 years (Smith et al. 2010; Waltz 2016). Questions remain, however, about the overall impacts of such enterprises, given that carnivorous fish such as salmonids and Asian bass still require significant quantities of fishmeal and fish oil in their pelleted diets. Limited attention has been given in aquaculture to seaweeds and lower-trophic-level organisms such as bivalves, which might offer more sustainable targets for aquaculture and might also bring additional benefits such as removing nutrients that cause eutrophication or particulates in seawater (Aburto-Oropeza et al. 2020).

2.2.5 Bulk Chemicals

MGR-derived products and processes could make a big impact in the bulk market, which includes bulk chemicals, enzymes for industrial processes and laundry detergents, probiotics in animal feed and packaging and further applications being researched to replace plasticisers in plastics with renewable resources. One of the largest markets is in alginates obtained from brown algae by wild harvest and aquaculture, which are used extensively as stabilisers and emulsifiers in food production as well as in specialty bandages for burns. Alginates are now being used to generate biodegradable drinks and food packaging, such as the Oohos produced by the Skipping Rocks Lab (Ooho Water n.d.). Its model is based around the product (e.g. ketchup) being put in the packaging at the retail outlet and being produced for that day's needs, as the material degrades in less than 6 weeks. Seaweed polymers are gaining attention as a source of sustainable bioplastics (Guedes et al. 2019) across a range of commercial applications, ranging from seaweed-based straws (Beygmoradi and Homaei 2017) to flip-flops (Algenesis Materials n.d.). The use of seaweed products as probiotics extends beyond human consumption, and with the 2006 banning of in-feed antibiotics given to animals in the European Union, using probiotics to prevent bacterial infections in livestock has been proposed as a sustainable solution. Sulfated polysaccharides prevent bacterial infections in pigs and other animals, thus reducing animal suffering and economic damage. Recent evidence also shows that the addition of ~1% red seaweed to the feed of ruminants reduces methane emissions by over 50% (Roque et al. 2019), thereby offering an opportunity to mitigate this significant component of global greenhouse gas emissions. However, concerns exist about the ozone-depleting properties of bromoform, a secondary metabolite produced by these seaweeds, if industrial-scale production for animal feed is pursued (Carpenter and Liss 2000).

The marine environment offers important opportunities for cold- and heat-adapted enzymes. The former is of utility in low temperature laundry detergents to reduce electrical costs during washing. One example of using heat-adapted enzymes in the bulk market is a thermostable enzyme from a hydrothermal vent organism that can be used in the production of bioethanol. Dubbed 'Fuelzyme' and licensed to the German chemical company BASF by Verenium, it is a genetically modified version of the original enzyme that is able to function over a wide temperature and pH range, thus improving the efficiency and economics of bioethanol production (Synthetic Biology Project n.d.).

2.2.6 Other Applications

Additional commercial applications of MGR relate to the capacity of certain marine microorganisms to produce extracellular polymeric substances (EPSs), which are naturally occurring polymers. EPSs can be used as vehicles of bioremediation due to their capacity to detoxify heavy metals and other pollutants (Pal and Paul 2008). ArcticZymes, a developer and marketer of enzymes for highly specialised research applications, has developed a family of isothermal polymerases—enzymes of marine origin that can be used to synthesise DNA and RNA molecules under high salinity conditions and across a flexible temperature range (Ward 2018).

Fouling of ship hulls by marine plants and animals slows vessels and increases costs, while fouling of nuclear power plant cooling water intake by mussels and other species can compromise operations (Rittschof 2017). Antifoulants such as organotin have been banned by the International Maritime

Organization due to their broad toxicity and environmental impacts. There is therefore considerable interest in understanding the complexity of active and passive biological fouling processes and developing nontoxic, environmentally benign marine antifoulants. Research has focused on marine bacteria and antifoulant biomolecules, including at least 198 marine invertebrates such as gorgonians and soft corals, and over a dozen synthetic analogues with the capacity to adhere to a variety of substrates (Wang et al. 2017; Leary et al. 2009; Qi and Ma 2017).

The bioluminescence in a jellyfish discovered in the North Atlantic (*Aequorea victoria*) was found to be due to interactions between two proteins, namely aequorin and green fluorescent protein (GFP). A broad range of applications of GFP have emerged over the years, including as a reporter of gene expression, in the tagging (and subsequent photomicrography) of proteins and as a biosensor indicating levels of environmental toxicity. The scientists responsible for discovering GFP and developing its initial applications were recognised with the 2008 Nobel Prize in Chemistry, 1 of more than 20 Nobel Prizes linked to the ocean and ocean biology (Rogers 2019).

3 Challenges

3.1 Threats to Conserving the Ocean Genome

Human activities have been intensifying globally, threatening marine species' survival, contributing to the rapid loss of genetic diversity and weakening species' adaptive capacities (Laikre and Ryman 1996; Law 2007; Allendorf et al. 2008; Palkovacs et al. 2011; Jouffray et al. 2020). Fishing has significant negative impacts on marine ecosystems and biodiversity, which has implications for species extinction (Dulvy et al. 2014; de Mitcheson et al. 2013) and the reduction of genetic diversity or selection at specific *loci* (Pinsky and Palumbi 2014; Czorlich et al. 2018; Madduppa et al. 2018). Unsustainable coastal development, land- and sea-based pollution and growing interest in deep-sea exploration and mining constitute additional significant threats to biodiversity that often compound those from overharvesting (Devine et al. 2006; Prouty et al. 2011; Nielsen et al. 2016).

Climate change is leading to a warmer, more acidic and less oxygenated ocean, directly affecting all stages of marine life (Pörtner and Peck 2010) across all latitudes (Doney et al. 2012; Barton et al. 2016; Scheffers et al. 2016; Pratchett et al. 2018). Specific responses have included geographic distribution shifts to higher latitudes and deeper water, advances in spring phenology and increases in the abundance of warm-water species (Poloczanska et al. 2016). Climate change affects biodiversity through changes in the distribution of genetic variants in space and time, changes to the degree of phenotypic plasticity (the individual characteristics of organisms that result from interacting with the environment) as well as changes in the ability of organisms to adapt over time to changing environmental conditions (Hoffmann and Sgrò 2011). Realised climate change has already had substantial deleterious impacts across a range of biological processes and taxa, including critical habitat-forming species such as corals (Carpenter et al. 2008; Davidson et al. 2012; Spalding and Brown 2015; Ainsworth et al. 2016). Arguably, one of the most documented impacts of climate change has been a redistribution of species as they track their preferred environmental niches (Perry et al. 2005; Pinsky et al. 2013; Pecl et al. 2017; Morley et al. 2018). Such shifts are likely to be associated with differences in genetic variability between the historical and range extension zones as well as within the extended ranges themselves (Ramos et al. 2018). Critically, patterns in genetic diversity, connectivity and population size associated with species shifts are important determinants of whether species will be able to continue shifting, adapting, establishing and persisting in their new ranges (Ramos et al. 2018). Knowledge of how genetic variation is distributed across a species' range is of particular significance, as historic refuges often harbour a large proportion of total diversity (Hampe and Petit 2005), yet are also often threatened by climate change (Provan and Maggs 2012).

While the loss of certain marine species due to human impacts has been documented (see below), this is likely an underestimate as humans have been responsible for ecological, commercial and local extinctions (McCauley et al. 2015), and the substantial decline of genetic diversity within species and across populations (Chapin et al. 2000; Pinsky and Palumbi 2014). Loss of both types of variation in genetic diversity has pervasive impacts on ecosystem processes as well as on species' capacities to respond and adapt to change (McNaughton 1977; Allendorf et al. 2008; Grorud-Colvert et al. 2014). Continued loss of genetic diversity contributes to reduced population viability and ultimately can lead to extinction (Dawson et al. 2011).

Our activities have altered life in the ocean substantially, impacting the ability of ocean systems to provide ecological, socioeconomic and cultural benefits (Worm et al. 2006; Halpern et al. 2008). Such impacts have eroded the genetic base of biological diversity, and may make it more difficult to sustainably harvest and manage marine species (Walsh et al. 2006).

3.1.1 Species Extinctions

While extinction rates in the ocean currently appear far lower than species loss in the terrestrial realm (McCauley et al. 2015), species extirpations due to climate change are likely to be twice as common in the ocean as on land due to the narrow thermal range tolerated by marine species (Pinsky et al. 2019). Estimates of marine extinctions are likely to be conservative—little is known about how many species inhabit the marine environment and there is a lack of monitoring or specific assessments of extinction risk under the IUCN Red List. Heavy use of the maritime space by humans has led to dramatic declines in the abundance of the baiji river dolphin (*Lipotes vexillifer*) and the vaquita (*Phocoena sinus*), leading the former to be declared functionally extinct (Smith and Jabour 2018) and the latter to become the most endangered cetacean in the world as declared by the International Union for Conservation of Nature (IUCN) (Roche et al. 2016). IUCN has recorded 15 marine species extinctions, including the Caribbean monk seal (*Monachus tropicalis*), the Japanese sea lion (*Zalophus japonicus*) and the sea mink (*Neovison macrodon*) (IUCN 2019). Some species have not been observed for several decades and may be extinct. Based on available data, IUCN considers 25% of marine mammals at risk of extinction (Davidson et al. 2012). Eight percent of marine bony fishes from the Arabian/Persian Gulf are also considered regionally threatened due to fishing and loss of habitat—an estimate twice that of other regions where such assessments have been undertaken (Buchanan et al. 2019). In addition, 25% of sharks, rays and chimaeras are globally threatened (Dulvy et al. 2014). Smaller-size organisms may have a similar risk of extinction due to habitat destruction, introduction of invasive species, exploitation and the effects of climate change (Cowie et al. 2017). Yet census and extinction inventories are largely lacking for smaller marine species.

Many parts of the ocean remain unexplored (Van Dover 2014). For instance, scientific expeditions to the deep sea regularly encounter new species—a 3-week expedition off the coast of Costa Rica in early 2019 led to the discovery of at least 4 new species of deep-sea corals and 6 other animals (Schmidt Ocean Institute 2019). Commercial deep-sea mining activities may result in the loss of habitat, leading to potentially irreversible negative impacts on the biodiversity of vulnerable deep-sea communities (Van Dover et al. 2017). In June 2019, the scaly-foot snail (*Chrysomallon squamiferum*) became the first species at risk of extinction in the event of future deep-sea mining (two of the three hydrothermal vent systems where it is found are within areas under exploratory mining licenses), and it is expected to soon be joined by at least a dozen more hydrothermal vent species on the IUCN Red List (Sigwart et al. 2019).

3.1.2 Loss of Populations

Population extirpations and declines in abundance due to unsustainable fishing practices, habitat destruction and pollution have led to contractions in the ranges of many fish species—including large pelagics—and invertebrates (Musick et al. 2000; Hutchings and Reynolds 2004; Worm and Tittensor 2011). Salmon have suffered significant declines in numbers and now occur over a much smaller range than historically documented (Levin and Schiewe 2001). Several sockeye salmon (*Oncorhynchus nerka*) subpopulations are classified as extinct as a result of the construction of impassible dams throughout the Columbia River basin. Columbia River chinook salmon (*Oncorhynchus tshawytscha*) have been documented to have lost up to two-thirds of their genetic diversity (Johnson et al. 2018). Declines in population diversity have been shown to increase the variability in salmon returns (Hilborn et al. 2003; Schindler et al. 2010). Declines in the size or density of individual populations also result in greater fluctuations in the frequency of certain genotypes due to the loss of certain genes over time. This process, known as genetic drift, is magnified in smaller populations (Palstra and Ruzzante 2008)—or in larger populations with a reduced number of adults who can reproduce (Hauser et al. 2002; Hare et al. 2011).

In addition, as ecosystem connectivity decreases among marine populations due to habitat fragmentation as well as lower dispersal via ocean currents, which are projected to shift with climate change, a potential loss of populations is predicted, which could result in decreased genetic connectivity (i.e. through genetic drift leading to increased isolation by distance) (Hastings and Botsford 2006; Hellberg 2009; Gerber et al. 2014; Carr et al. 2017). Genetic drift and subpopulation losses both lead to declines in genetic diversity, in turn undermining a species' ability to recover, adapt and survive in changing conditions (Walsh et al. 2006; Hare et al. 2011). This is particularly critical as species face increasingly variable environmental conditions as a result of climate change; climate change itself is projected to have impacts on populations' and species' genetic diversities, further lowering their stress resistance and adaptive potentials (Frankham 2005).

3.1.3 Invasive Species

Aquaculture and shipping are two important means by which species are being translocated around the world, leading to a rise in invasive species. While the introduced species often do not survive, when they do, they may outcompete native species or prey on them, leading to cascading changes in native communities (Sorte et al. 2010; Green et al. 2012). While aquaculture is rapidly becoming a critical component to ensuring food security (Béné et al. 2016; Thilsted et al. 2016), the sector presents important concerns with regard to genetic diversity (Weir and Grant 2005). Aquaculture often breeds species (which are often introduced) by favouring certain traits that give them an advantage over native species in the wild (Fleming et al. 2002). While the environment in which cultured species are grown tends to be carefully contained and monitored, escape events do happen. Such events can lead to farmed species interbreeding with native species (genetic introgression) and rapid genetic homogenisation (Fleming et al. 2000), resulting in the irreversible reduction in genetic diversity and fitness of wild fish (McGinnity et al. 2003; Weir and Grant 2005; Waples et al. 2012; Glover et al. 2017)—and hence lowering their capacities to adapt to environmental change. Farming can also facilitate the spread of pathogens (Naylor et al. 2005), placing further pressure on stocks and posing a serious challenge to the management of farmed and wild populations (Karlsson et al. 2016).

3.1.4 Cumulative Effects

It is important to recognise that many marine species and communities are now under pressure from more than one direct or indirect human impact (Jouffray et al. 2020; Halpern et al. 2019). While species can be resilient to a single impact or even several, the additive or synergistic effects of multiple pressures or interactions between them can drive decreases in populations; affect spatial genetic structures and gene flow, including impacts on connectivity; and drive large-scale regime changes at the community level. Fishing, for instance, has led to rapid changes in growth and reproduction schedules (e.g. earlier maturation at a smaller size, smaller adult body size). And climate change—particularly changes in temperature and dissolved oxygen—is expected to have evolutionary consequences that are qualitatively similar to those observed from exploitation (Hutchings and Fraser 2008; Waples and Audzijonyte 2016; Czorlich et al. 2018; Duncan et al. 2019). One example of synergistic effects is the interactions between eutrophication, overfishing and invasive species in the Black Sea (Oguz and Velikova 2010). Another is between aquaculture—through the release of fingerlings and escapes of broodstock—and fishing of salmon, where both activities have reduced genetic variability of wild populations (Waples et al. 2012). Such effects can prove difficult to reverse (an ecological state called hysteresis) and can lead to the occurrence of new/alternative stable states in marine ecosystems (Fauchald 2010; Fung et al. 2011).

3.2 Impediments to the Equitable Use of the Ocean Genome

3.2.1 Impediments to Innovation, Equity and Benefit Sharing

Investments in marine biodiscovery are typically costly and risky due in part to the extreme expense of sampling in areas like the deep sea, the low chances of success and the significant regulatory hurdles for product approval (Broggiato et al. 2014; Morgera 2018). Moreover, each stage of the research, development and commercialisation process requires high levels of technical, financial and scientific investment, with costs depending on the form and ease of access, the type of technology required to collect the material and undertake the research, and the sector or envisaged product involved (Laird and Wynberg 2012). Equipment costs remain high, although the costs of molecular technologies have decreased considerably in recent decades, alongside an increase in speed, efficiency and capacity. Marine biotechnology remains a rapidly developing and fast-moving sector (Leary et al. 2009; Broggiato et al. 2014). The nature of the research enterprise is also changing, as research shifts toward bioinformatics—the collection, classification, storage and analysis of complex biological data—and the mining and exploration of these vast and growing datasets of genetic information, which requires advanced computational resources that are not broadly available (Muir et al. 2016).

The considerable costs involved in marine bioprospecting research, alongside the advanced technologies and expertise required, have meant that most exploration has been undertaken by high-income countries. Notably, these are the United States, United Kingdom, Australia, Canada, Japan, Germany and Russia—but, as Fig. 4.6 indicates, with the sampling often conducted in low- or middle-income tropical countries, and Australasia in particular (Greiber 2012; Leal et al. 2012; Oldham et al. 2013).

As an indicator, Fig. 4.7 illustrates the global distribution of research efforts focused on marine genetic resources, using scientific publications as a proxy. Similarly, studies of patents associated with marine genes demonstrate disparities in capacity to engage in commercial activities associated with these resources, although such studies do not distinguish whether the genes are for reference or are claimed in the filings. Arnaud-Haond et al. (2011) found that patents citing marine genes originated from only 31 of the 194 countries in the world, with 10 countries responsible for 90% of them. By 2017, this imbalance had grown, with the share of the top 10 countries increasing to 98%, and 70% filed by researchers or companies in the United States, Germany and Japan (Blasiak et al. 2018). Approximately 1600 patent sequences were derived from species associated with the deep sea and hydrothermal vent systems, commonly found in ABNJ, and are of particular relevance in the context of the ongoing BBNJ negotiations. Greater specification is hampered by the lack of a legal obligation to disclose sample origin or source in patent filings, and the tendency for applicants to not volunteer such information (Blasiak et al. 2019).

Other researchers emphasise that studies of patent filings actually highlight how limited commercial interest in MGR has been (Leary 2018). Blasiak et al. (2018), for instance, analysed 7.3 million sequences and identified only 12,998 of marine origin from 862 species. A text-mining analysis employing more liberal definitions of what constitutes a ‘marine’ species identified only 1464 marine species in the patent system (Oldham et al. 2013). However, while patents are an indication, they should not be taken as a proxy for the

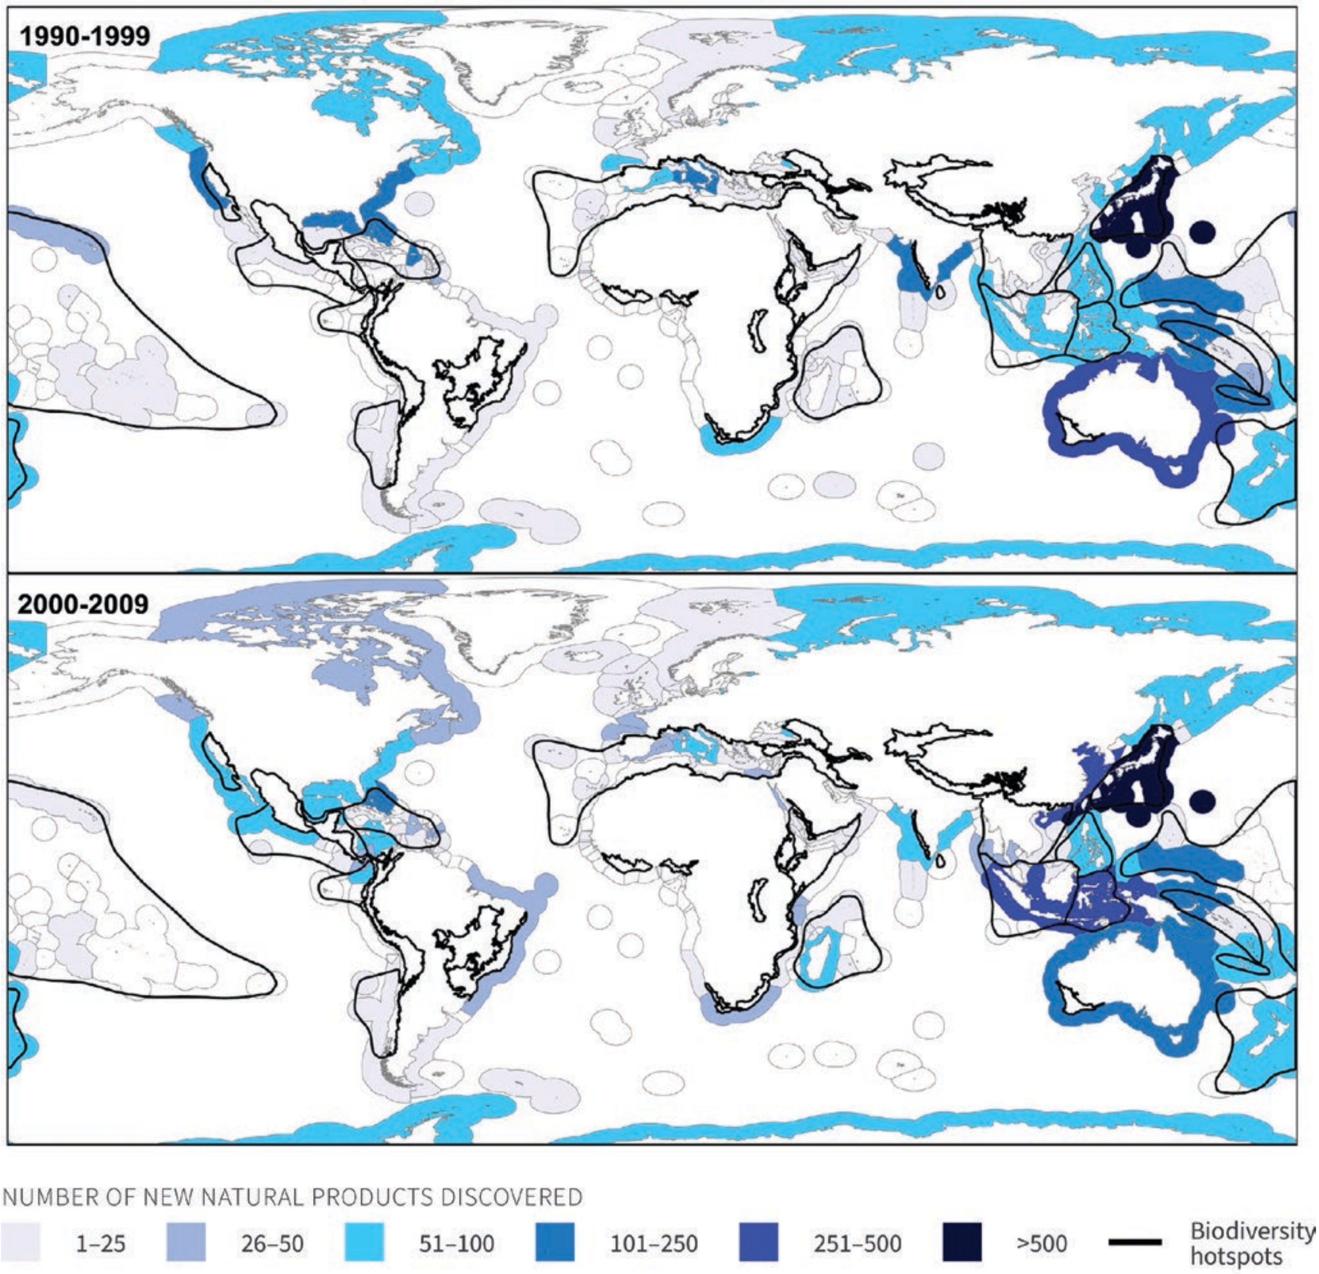

Fig. 4.6 Sources of natural products from marine invertebrates. *Note: This figure shows the number of new natural products from marine invertebrates found in exclusive economic zones during the 1990s and 2000s, as well as boundaries of biodiversity hotspots.* (*Source:* Leal et al. 2012)

full scale of mature commercial interest, or research and innovation that might be pre-competitive. Not all inventions are patentable, many that are patented will never be commercialised and there are strategies other than intellectual property to protect competitive or commercial advantages, including publication (Merges 2004; Thambisetty 2007; Herrera and Schroth 2000; Quah 2002).

Disparities in research capacity, technology and finances represent major constraints that prevent the inclusion of low- and middle-income countries in marine biotechnology efforts. Biodiversity and molecular expertise is unevenly spread (Hendriks and Duarte 2008); research vessels or submersibles are typically owned by only a few high-income nations and entail substantial operational costs (Stokstad 2018); and while there are growing numbers of collaborations between high-income and lower-income countries (Kyeremeh et al. 2020), the model of international collaboration is still characterised by a pharmaceutical or biotech company working with established centres of excellence located in high-income countries. As an example, despite active marine biodiscovery programmes in the Western Indian Ocean, with the exception of South Africa and, to a

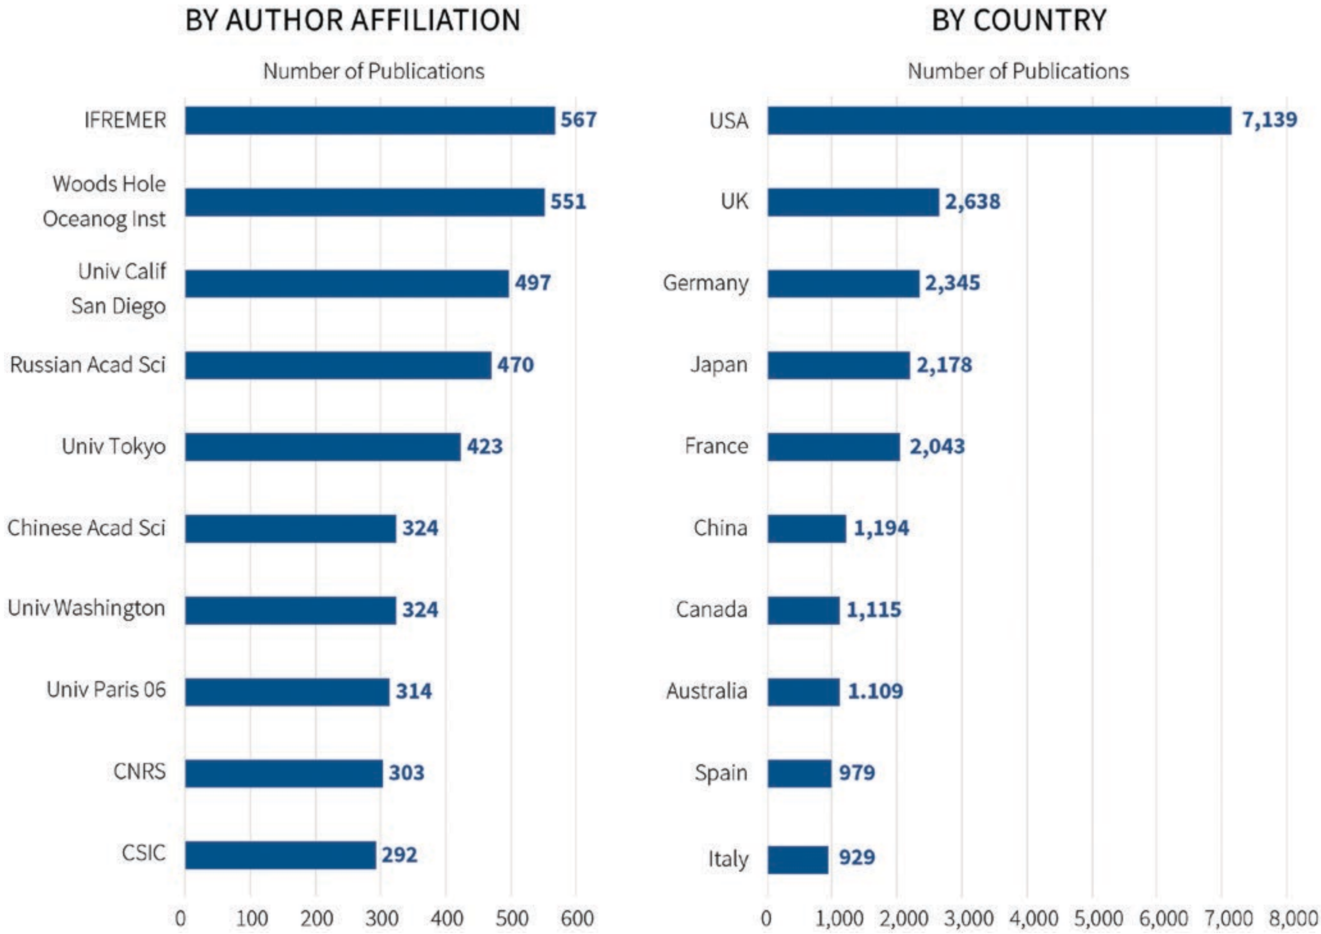

Fig. 4.7 Author and country affiliations for scientific literature focused on marine genetic resources. *Notes: The full names and locations of the authors' affiliate institutions include, from top to bottom, French Research Institute for Exploitation of the Sea, France; Woods Hole Oceanographic Institution, United States; University of California, San Diego, United States; Russian Academy of Sciences, Russia; University of Tokyo, Japan; Chinese Academy of Sciences, China; University of Washington, United States; University of Paris 06, France; French National Center for Scientific Research, France; Spanish National Research Council, Spain.* (*Source:* Oldham et al. 2014)

lesser extent, Kenya, few African countries have engaged actively as research collaborators in international endeavours (Wynberg 2016). A particular concern across countries is the gender imbalance in marine biotechnology (and science in general) and the attrition of women in this male-dominated field (Ceci and Williams 2011; Kitada et al. 2015).

3.2.2 Regulating Fair and Equitable Access and Benefit Sharing

The CBD, Nagoya Protocol and International Treaty on Plant Genetic Resources for Food and Agriculture together provide an important platform around which new models of equitable research partnerships can evolve, on the basis of the presence or absence of national sovereign rights over biological resources. As described earlier, marine biodiscovery depends in part upon access to marine organisms, which in turn is governed by multiple legal regimes and national and international laws (Fig. 4.3). Under UNCLOS, coastal states have the exclusive right to regulate, authorise and conduct marine scientific research in their territorial sea (Article 245). MGR found within the EEZ are subject to domestic measures implemented under the Nagoya Protocol or directly under the CBD. This means that coastal states that choose to regulate marine bioprospecting in their EEZ can specify conditions of access to this material, including mutually agreed terms on access and benefit sharing (ABS). As noted by Oldham et al. (2013), natural product research has historically concentrated on marine invertebrates *inside* national jurisdictions, with most marketed products derived from organisms found there—with limited exceptions for enzymes from extremophiles and Antarctic krill (*Euphausia superba*) as a source of nutraceuticals.

In practice, the CBD has spawned a number of approaches to regulating genetic resources, but a common element across these approaches is the requirement that researchers abide by local conditions of access to and use of genetic resources. The evolving nature of ABS governance—and negotiated compliance in different contexts and gaps in workable policies in many countries—makes this difficult terrain to navigate (Morgera 2018). From a legal perspective, perhaps the greatest current challenge is determining the full scope of the term 'genetic resources' and discussing whether this includes digital sequence information/genetic sequence data. For some countries, not incorporating genetic sequence data within the scope of ABS approaches undermines sovereign control over genetic resources. Other countries insist that the publication of sequence information in open-access databases can be seen as a globalised and important form of benefit sharing (Laird and Wynberg 2018).

Monitoring is an important concern given that informational resources are highly mobile and malleable and are more difficult to track than physical genetic resources, with most data held in databases typically lacking identification and origin information (Garrity et al. 2009). Several groups are working to improve monitoring by attaching information on origin to sequences, and by including stronger links between physical samples and sequences. But monitoring has grown increasingly difficult over time as sequences pass through multiple hands, are modified or have their identities eroded (Garrity et al. 2009; Slobodian et al. 2015). The technological gap described above is exacerbated by a failure to capture traceability in legal frameworks to support appropriate law and policy.

Specialised ABS rules for MGR from ABNJ have not yet been developed and it is one of the four main issues within the BBNJ negotiations, which are ongoing under the parent treaty, UNCLOS (Leary 2018; Thambisetty 2019, 2020). The negotiations should clarify the status of MGR found beyond national jurisdiction, including whether they are to be regarded as the common heritage of humankind and what implications that would have for the private appropriation of the ocean genome in tangible and informational forms.

Such discussions also extend to the scope of regulation of marine scientific research in ABNJ. Due to the open nature of the ocean, biogeographical ranges of marine species are typically large (including those of prokaryotes, which contribute the bulk of marine genes) with connectivity driven by very large population sizes and ocean transport systems resulting in large distributions (Villarino et al. 2018). Therefore, MGR are often shared among the EEZs of multiple nations and ABNJ, which renders delineation over different ownership and governance regimes cumbersome. Central questions include whether the benefits arising from the commercial use of these resources should be shared by the entire international community; the scope of the obligation on states and corporations with the technological capacities to exploit these resources to share benefits; and whether those who first locate and describe MGR should be given certain rights of priority.

A central issue—and one that is not confined to MGR—is the blurring between noncommercial and commercial research as the academic community and governments increasingly partner with industry, and patent laws change patterns of appropriability. Most sequences move fluidly between commercial and noncommercial institutions, and if uploaded to public databases might be available for all to use without the original providers aware of or involved in this process. Most benefit sharing under the Nagoya Protocol occurs through bilateral arrangements between users and providers who are obligated by local and international laws to enter into mutually agreed terms on benefit sharing, often when research moves from an academic to a commercial phase. The performance of contracts cannot easily be monitored by provider countries (Young and Tvedt 2017). Additionally, if scientific data and information were treated solely in a bilateral, benefit-sharing manner, countries would not benefit from information generated from non-endemic species, or from *ex situ* collections. Environmental management in particular benefits from increasing the quantity of available data.

Bilateralism presents other problems in the marine context given the challenges of delineating ownership. A multilateral mechanism such as that found in Article 10 of the Nagoya Protocol may become salient in the context of the BBNJ negotiations. The complexity of the regulatory environment demands fresh approaches that can help shape and negotiate ethical and responsible conduct on the part of marine scientists. Initiatives such as voluntary codes of conduct, good practices, training for younger scientists, funding incentives by research councils and grantmaking bodies, mentoring and other initiatives can speed up the process to internalise new behaviours and norms of research.

An important concern stems from the overregulation or poorly implemented application of ABS laws, especially given the blur between commercial and noncommercial use. Although the CBD and Nagoya Protocol explicitly support research for biodiversity conservation and enhanced scientific knowledge, national ABS legislation has often had unintended negative impacts on basic biodiversity research (Bockmann et al. 2018; Prathapan et al. 2018). It is important that new laws to regulate the use of MGR learn from these experiences to ensure that basic biodiversity research to support conservation efforts, the advancement of knowledge and equitable benefit sharing is promoted, rather than hindered.

4 Pursuing Solutions

4.1 Conservation

4.1.1 Managing Competing Interests in the Ocean to Conserve Biodiversity

Despite recognition by the CBD, genetic diversity is still largely neglected in policies and management and conservation plans (Laikre 2010). Much greater attention is needed to embed genetic diversity in policies, plans and programmes and to ensure that holistic strategies are developed to use the ocean sustainably and maintain the genetic diversity that underpins biodiversity and the benefits it provides (Karlsson et al. 2016). The distribution of those uses and benefits is of particular importance when considering how to manage the many interests and stakeholders at the table. In marine systems, there are opportunities for change via key tools, among them ecosystem-based approaches to fisheries management, spatial planning, effective quotas, MPAs, protecting and managing key marine biodiversity areas, reducing runoff pollution into the ocean and working closely with producers and consumers (IPBES 2019). The conservation of genetic diversity is embedded in all of the above.

The goal of 'conserving' genetic diversity can differ depending on the perspective of each stakeholder. What is more, what constitutes high biodiversity in an area may mean different things to different people, especially as baselines shift and successive generations consider increasingly degraded systems to be the norm. Different stakeholders will also have inherently different interests, yet may benefit from using the same approach to conservation. A representative from a biotech firm may be primarily interested in protecting the highest diversity of marine genes possible to discover and develop new products. An ocean manager may desire the same outcome, with an interest in conserving a diversity of species in the ecosystem to provide resilience and adaptive capacity to environmental change. Many conservation goals exist, encompassing different species with distinct distributions of genetic diversity and patterns of connectivity, yet there are also multiple management strategies that balance trade-offs with positive outcomes (Ingeman et al. 2019). If these strategies move forward from an agreed upon set of minimum conservation imperatives, multiple interests can be supported as long as incentives are in place to support participation (Lubchenco et al. 2016).

For example, North Atlantic right whales (*Eubalaena glacialis*) were historically decimated by whaling and have consistently declined after a brief increase in population size that peaked in 2010 (Corkeron et al. 2018). Anthropogenic impacts including historical whaling have reduced their abundance and the genetic variability within the small breeding population (Kraus et al. 2005). The current primary causes of mortality are ship strikes and entanglement in fishing gear—every individual North Atlantic right whale shows evidence of entanglement in fishing gear at some point in their life (Corkeron et al. 2018). If the minimum conservation imperative is to recover this species to a viable population level that prevents a further genetic bottleneck, emerging management strategies—such as real-time whale position data to prevent ship strikes and ropeless fishing gear that remains free of vertical lines until the time of retrieval—can still support multiple activities (Ingeman et al. 2019). Using real-time data also allows flexibility as management needs evolve.

This management flexibility can be critical as ecosystems change, due to both natural cycles and increasing anthropogenic impacts. At its core, adaptive management assumes that activities and regulations need to be recalibrated as changes in the system occur. Yet tighter feedback loops will be required to keep pace with the changing ocean and to acknowledge the impacts if genetic diversity is diminished (Ingeman et al. 2019). As opposed to predict-and-prescribe approaches—which require a thorough scientific understanding of the dynamics within a system to predict how that system will change—scenario planning can help identify a number of alternative strategies that could potentially arise within a system (Schindler and Hilborn 2015). Management appropriate to one scenario may shift to another, making it necessary to combine the range of conditions encompassed by these alternate scenarios with decision-making structures that are streamlined for faster responses (Ingeman et al. 2019). Governance structures must match the flexibility required for this approach with the use of impact assessments that account for biodiversity and at the appropriate scales needed to conserve genetic diversity, whether at the scale of ecosystems, species, populations or individual genes. As technologies such as eDNA evolve, and the understanding of genomics increases, it will become increasingly feasible to implement such requirements for genetic diversity.

Prioritising interventions to conserve biodiversity, and the underlying genetic diversity, requires taking a robust approach based on sound science and available data. Yet ocean genome data over space and time are largely lacking, even though this scientific information is critical for evaluating the status and future outlook for genetic diversity, such as for fisheries encompassing multiple populations or when protecting areas of particularly high biodiversity. In the absence of data, reasonable surrogates may serve as a proxy for genetic diversity (e.g. guild-level diversity or representation of species within given taxonomic families), yet these should be coupled with the incorporation of genetic monitoring into preexisting programmes, and the creation of targeted genetic monitoring programmes for species and areas of particular interest. Such activities must go beyond simply documenting what genetic material is where, and how it is being extracted and used, to also encompass the changes in this genetic diversity and the trends in those changes over time. This requires having a baseline understanding of the genetic variability of each species. Coupled modelling and empirical approaches will also be increasingly important.

However, waiting until comprehensive datasets are available before making interventions also runs the risk of losing rapidly deteriorating storehouses of genetic information due to the overharvesting of species and habitat degradation. Interventions are already proceeding and a precautionary approach is needed to stem the loss of marine genetic resources, including those that are not well protected by area-based management, such as pelagic species with large home ranges. Ecosystem-based fisheries management; reduction of gear impacts and bycatch; and consideration of species' life histories, population genetics and historical exploitation are all important aspects of sustainable fisheries management. As technological advancements enable the exploration and exploitation of new areas in the ocean, including the deep sea, permitting and extraction limits will need to ensure both sustainability of the resource as well as conservation of its ecosystem. Caution is needed when approving new or expanded uses of managed areas for extractive activities such as mining, particularly in areas where biodiversity is not well characterised or is potentially vulnerable. The potential loss of rare, threatened and endangered species and populations poses a serious risk of contributing to an overall loss in genetic diversity, and such populations require continual monitoring and conservation efforts to ensure their persistence. In addition, safeguarding areas of high biodiversity or those of particular importance to exploited species in fully or highly protected areas is a key strategy for protecting genetic diversity, both in the short and long terms, while scientific monitoring and evaluation keep pace with the rapidly changing ocean.

To meet the needs and uses of multiple actors, protected areas should be balanced with those set aside to support sustainable use for key services such as harvesting genes for product development by industry, or wilderness areas to protect pristine habitat that provides key ecosystem services for those actors (Schleicher et al. 2019; see also Österblom et al. 2020). Although conflicting uses can be balanced across ocean spaces in particular contexts, this is not always possible. Commercial activities are being carried out across the majority of the ocean, yet only 8% is set aside for biodiversity conservation, of which only 2.5% is fully or highly protected and implemented (Sala et al. 2018, updated via Marine Conservation Institute 2020). This falls significantly short of the targets to effectively protect 10% of the ocean by 2020 (see Box 4.3) while also leaving open the conversation around sustainability and conservation of marine genetic resources in the other 90% of the ocean, of which two-thirds is in ABNJ. This points to the urgent need to prioritise decisions toward biodiversity conservation, given the foundational role this plays both for ecosystem health and for the well-being of human and nonhuman species.

Many countries fail to explicitly address the genetic level of biodiversity in fisheries policy and legislation (Dulvy and Reynolds 2009). Therefore, in enacting strategies for conservation and sustainable use, genetic biodiversity should be integrated or mainstreamed into the planning and decision-making of multiple sectors that may impact and benefit from the ocean genome, including from species that are new to science (Manuel et al. 2016). This includes fisheries, mariculture, mining, shipping and marine biodiscovery. New approaches should help integrate genetic biodiversity into ocean use planning; environmental authorisations such as licenses, permits and registrations; and environmental management. Maintenance of genetic diversity needs more explicit consideration and planning in food systems policies and management, including for wild capture fisheries and mariculture. In addition to legal and policy instruments, industry collaboration is also needed to prevent genetic erosion, prevent and manage marine invasive species and increase the benefits from genetic diversity through inclusive and responsible research and innovation. Mainstreaming may also include strategies through which activities in production sectors may actually benefit biodiversity. For example, mariculture could relieve pressure on commonly harvested wild species if undertaken in a sustainable and responsible manner (FAO 2016).

4.1.2 Protecting Storehouses of Genetic Diversity

Genetic diversity in the ocean is important and needs to be conserved and managed to protect the resources it provides and the people it sustains. Many have embraced this imperative at the local, national, regional and international levels, as reflected in various commitments, goals and targets for biodiversity conservation (Grorud-Colvert et al. 2019). For example, the CBD's Aichi Target 11 and the United Nations' Sustainable Development Goal 14 call to conserve ocean areas 'through effectively and equitably managed, ecologically representative and well-connected systems of protected areas and other effective area-based conservation measures.' These protected areas—MPAs and OECMs—are central tools for protecting marine genetic diversity (Fig. 4.8). They have been rapidly growing in number and extent over the last few decades (Lubchenco and Grorud-Colvert 2015; Sala et al. 2018), but many are poorly enforced and the total area remains below global targets, far below what scientists have recommended, and is not representative of the full range of habitats and ecosystems.

Decades of data from scientific research conducted in hundreds of fully and highly protected MPAs around the globe show clear ecological trends (Sala and Giakoumi 2018). MPAs tend to lead to positive ecological outcomes and often result in social and cultural benefits if they are properly designed, managed and sustained to ensure that full protection is real and lasting (Gill et al. 2017; Giakoumi et al. 2018). Key to achieving these benefits is an open and transparent planning process that engages stakeholders representing diverse perspectives and that integrates science-based solutions (Ruiz-Frau et al. 2015; Twichell et al. 2018).

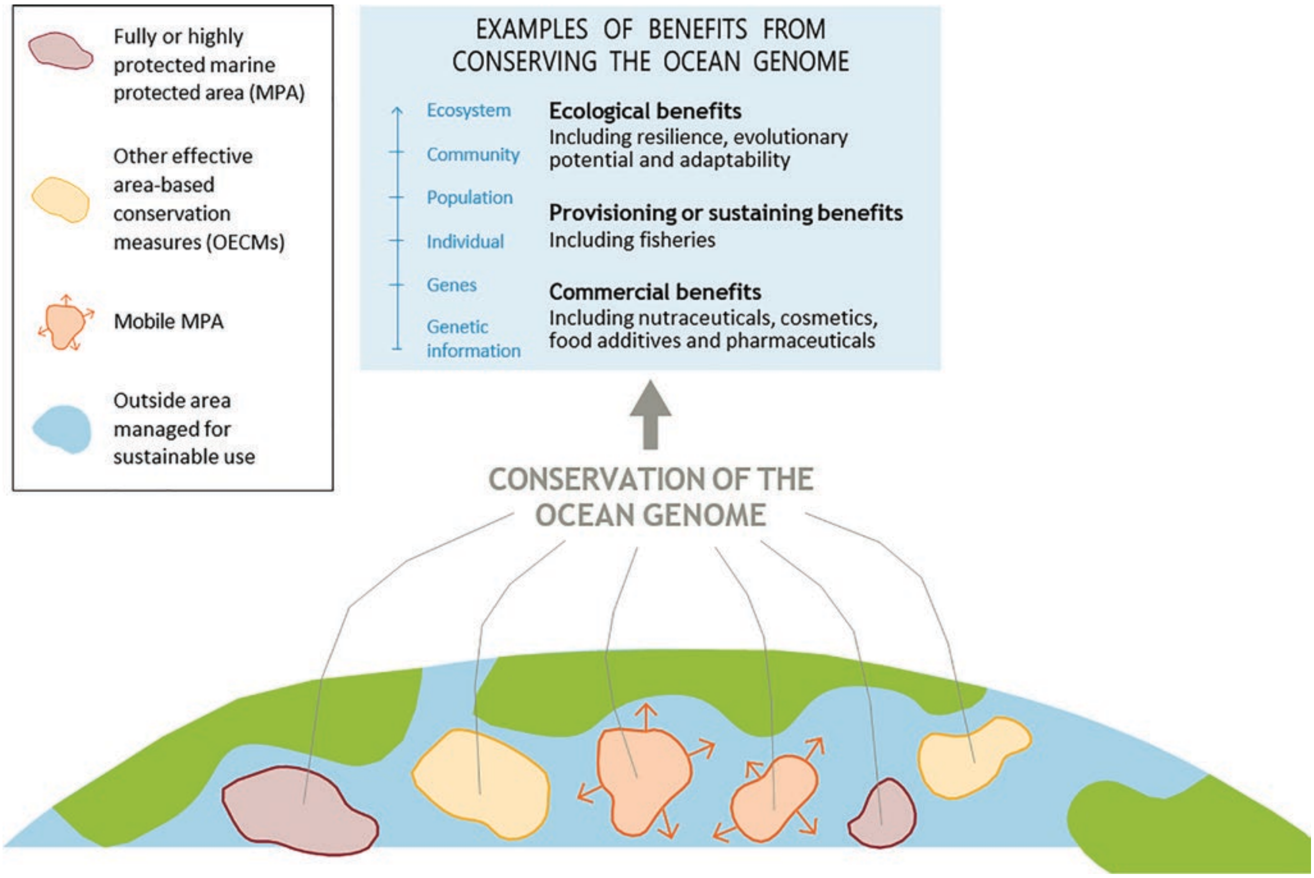

Fig. 4.8 How area-based conservation measures and sustainable use help conserve the ocean genome and its associated benefits. *Note: This figure depicts a portfolio approach for conserving the ocean genome and its associated benefits. Effective conservation hinges on using multiple tools, including area-based conservation measures such as fully and highly protected MPAs, that provide the greatest protection from the impacts of extractive and destructive activities. Coupling these with effective management of sustainable use can ensure wide-ranging benefits that are ecological, sustaining, provisioning and commercial.* (*Source: Developed by the authors. Designed by J. Lokrantz/Azote*)

When users are involved in MPA planning, compliance with regulations tends to be higher, boosting the ecological and social benefits (e.g. Viteri and Chávez 2007; Weeks and Jupiter 2013; Giakoumi et al. 2018).

When ecosystems, habitats and species are fully protected from all extractive and destructive activities within their borders, ecological communities tend to be more diverse, and formerly targeted individual species tend to be more numerous and larger in size, and have greater reproductive capacities and higher potential to move outside the MPA borders into areas beyond (Claudet et al. 2008; Halpern et al. 2009; Lester et al. 2009; PISCO and UNS 2016). When well-designed and managed, fully and highly protected MPAs result in greater abundance and size of previously exploited species, restoration of ecological interactions, habitat recovery, enhanced reproductive output due to larger body size of previously exploited species, greater resilience inside the MPA and higher potential for adaptation to climate and other environmental changes (e.g. Roberts et al. 2017; Hastings et al. 2017; Magris et al. 2018; Sala and Giakoumi 2018; Cheng et al. 2019). These ecological outcomes are also integrally tied to outcomes for human well-being. These can include income generated from tourism to fully and highly protected areas that preserve higher biodiversity and spectacular seascapes (e.g. Sala et al. 2013) as well as spillover from the MPA to augment catches in fished areas outside (e.g. Vandeperre et al. 2011). Fully protected areas tend to have more positive human well-being outcomes than MPAs with lower protection levels (Ban et al. 2019), provided key enabling conditions are met to ensure good governance, sound ecological and social design, and ongoing management. Fully and highly protected areas also provide reference areas for evaluating the impacts of extraction outside them, a buffer against accidental mismanagement or environmental changes, and often some enhancement of fisheries outside the MPA (e.g. Allison et al. 2003; McCook et al. 2009; De Leo and Micheli 2015; Di Lorenzo et al. 2016). Although the impacts of MPA networks on genetic diversity are implied and theoretically supported (e.g. Costello 2014; National Academies of Sciences, Engineering, and Medicine

2019; see also McInerney et al. 2012), there is an urgent need for research to test the potential outcomes of protecting genetic diversity in multiple, connected MPAs.

To effectively protect the ocean genome, fully and highly protected MPAs must be sufficiently large to encompass the relevant ecosystem and the full distribution of genetic diversity within it. Yet, in many contexts this is not possible, such as in the Mediterranean Sea, where use is high, coastal populations are dense and many countries share the sea's waters (Giakoumi et al. 2017). To support effective conservation while working within these realities, networks of MPAs are frequently used to protect multiple sites that are connected through the movement of adult or young marine organisms (Allison et al. 2003; Roberts et al. 2003). MPAs in a network can collectively encompass a large area and protect genetic diversity represented by different species while still allowing for sustainable use outside. A network also provides redundancy in the event that one MPA is impacted by a disturbance that reduces its ability to sufficiently protect the genetic diversity of the species inside. Networks of MPAs can have synergistic effects that lead to even greater ecological benefits than separate, unconnected MPAs that are not networked (Grorud-Colvert et al. 2014). When fully and highly protected, MPA networks provide a unique opportunity to protect storehouses of genetic diversity in a changing ocean. As organisms adapt to these changing conditions (see Sect. 2.1), adaptation networks can be established to identify and protect areas where genetic diversity and/or the potential for adaptation is high (Webster et al. 2017). For example, in coral reef systems, adaptation networks may be particularly useful as corals are increasingly threatened by rising temperatures, ocean acidification, pollution and overfishing (Hughes et al. 2018) while simultaneously showing quantifiably high rates of adaptation (Munday et al. 2013). A single species of coral can have a wide geographic range and inhabit different reef environments where genetic diversity is high across scales as small as less than 100 m (Barshis et al. 2013; Webster et al. 2017). These species may benefit from networks of protected areas that span different depths and allow for redistribution across latitudes. Future research should test the rate and limit of different adaptive responses for coral species across latitudes to better understand the ranges these adaptation networks need to encompass (Logan et al. 2014).

Box 4.3 Marine Protected Areas

One of the most effective tools to protect marine genetic diversity at an ecosystem scale is through implemented and fully or highly protected marine protected areas (MPAs). Because MPAs provide place-based protection, they can conserve not only target species and genetic material, but also all associated biodiversity within that habitat. International targets such as the Convention on Biological Diversity's Aichi Target 11 and the United Nations' Sustainable Development Goal 14.5 recognise the importance of using MPAs and other effective area-based conservation measures (OECMs) to protect biodiversity in 10% of the ocean by 2020. However, there are growing calls from the scientific community to fully or highly protect at least 30% of the ocean to achieve conservation goals, and for a corresponding post-2020 target to be formulated (see Sect. 1.3). But what exactly is an MPA or OECM? And which types are most effective for protection?

An MPA is a clearly defined geographical space, recognised, dedicated and managed through legal or other effective means to achieve the long-term conservation of nature with associated ecosystem services and cultural values.[a]

OECMs also provide conservation benefits, but biodiversity conservation is not their primary goal.[b] They are sites that are not by definition protected areas but are governed and managed in ways that achieve positive and sustained long-term outcomes for the in situ conservation of biodiversity, with associated ecosystem functions and services and, where applicable, cultural, spiritual, socioeconomic and other locally relevant values.[c]

MPA and OECM are broad terms that encompass many types of areas. MPAs are a focal tool for protecting genetic diversity because by definition these areas have biodiversity conservation as their primary goal. Yet MPAs can have different levels of protection and may be at different stages of establishment. *The MPA Guide*[d] provides a common language for describing the types of MPAs and the outcomes arising from areas with different protection levels.

Based on these definitions, 'fully and highly protected areas' are the only protection levels that are expected to deliver sufficient biodiversity conservation to protect genetic diversity.

In fully protected areas, no extractive or destructive activities are allowed, and all impacts are minimised.[e] In highly protected areas, only light extractive activities are allowed, and other impacts are minimised to the extent possible.[f] These may be stand-alone MPAs or fully and/or highly protected zones within multi-use MPAs.

Lightly or minimally protected areas allow for multiple uses and activities that have moderate to high impacts on species and habitats. Thus, these are not recommended for the goal of preserving genetic diversity within a system.

Further, for biodiversity conservation to occur, an MPA cannot be merely proposed or committed through an informal announcement; an MPA must be more than designated by law or other authoritative rule on paper. An MPA must be implemented—with regulations in force on the water such that users know to comply.[g] It is critical for public consultations and appropriate notification and transparency measures, as well as up-to-date scientific information, to become part of the designation and management of MPAs. Ideally, such areas should be actively managed with monitoring, enforcement and frequent review of management goals and outcomes.

By networking fully and highly protected areas of high diversity and ensuring connectivity among sites as well as sufficient spatial scale and ecosystem representation, it is possible to mitigate the risk of species moving outside the protected areas as their ranges shift in response to changing environmental conditions. Adaptation networks can also provide an insurance policy against ecosystem and species loss if they are sufficiently replicated within the system (Allison et al. 2003). MPAs in any effective network, including an adaptation network, should encompass a range of environmental conditions and habitat types—including both disturbed and pristine areas—that are sufficiently replicated. Networking can also accommodate different species distributions, as well as their underlying genetic diversity, by supporting species ranges and patterns of connectivity with multiple MPAs of varying sizes and distances from each other (Pujolar et al. 2013; Jonsson et al. 2016). Connectivity is particularly vital for ensuring adaptation pathways in a network (Almany et al. 2009; Blowes and Connolly 2012). Sites should be at appropriate sizes and distances from each other to promote the exchange of genes as young organisms disperse in the plankton or adults migrate out of the protected areas. Connected areas also provide sources of population replenishment within the network if one or more sites are compromised by local disturbances or become insufficient for protection due to shifting species ranges.

The existing coverage of MPAs should be continuously evaluated, especially in the case of MPAs functioning as a network, to identify areas where urgent protection of genetic diversity is needed. MPA planning processes should identify gaps, including areas of high genetic diversity that are currently unprotected and areas where highly variable systems have led to higher adaptation rates and possibly greater capacity for adaptation in the future.

The BBNJ process is now debating the declaration and functioning of MPAs in ABNJ as a tool for area-based management. There are divergent views on whether MPAs could be used to achieve long-term biodiversity conservation and sustainable use, and whether decision-making related to MPAs should be informed by strategic environmental assessments (SEAs) (High Seas Alliance 2019). This would include broader factors relating to social and economic considerations, traditional knowledge and cultural values. The management of ABNJ is not currently designed to protect genetic diversity, and MPAs could provide a mechanism to do so (Protected Planet 2020). These should be coupled with other facets of ecosystem-based management such as sustainable fisheries, habitat restoration efforts, pollution reduction and climate mitigation. Agreements on area-based management tools would in turn need to align with EIA and SEA processes under existing national, regional and international regimes.

4.1.3 Leveraging Biotechnology for Conservation and Biodiversity Management

Starting in the late 1970s, Sanger sequencing became the primary genetic technology employed to generate organisms' genetic information. Though it produces only a single DNA sequence for a given gene region (Sanger et al. 1977), it is still considered a highly valuable tool and is often used in wildlife biology, conservation and management. For example, it remains the gold standard in seafood surveillance and for identifying biological invasion pathways and sources of introductions (e.g. Roman and Darling 2007; Dlugosch and Parker 2008; Barbuto et al. 2010; Cawthorn et al. 2012; Di Pinto et al. 2013; Xiong et al. 2016; Tinacci et al. 2018). However, over the past two decades, key advances in molecular markers, new sequencing technologies and new statistical methods have enabled researchers to tackle a wider range of questions and issues to better inform species conservation and management.

Next-generation sequencing (NGS) offers improved resolution relative to early molecular markers and Sanger sequencing, provides high throughput and better enables large-scale spatial and temporal syntheses for single species as well as entire community assemblages through DNA metabarcoding (e.g. Taberlet et al. 2012; Lindeque et al. 2013; Aylagas et al. 2016; Pitz et al. 2017; Djurhuus et al. 2018). Moreover, because multiple regions across the genome can be sequenced using NGS, fewer samples are needed to acquire a wide breadth of the genetic diversity available within populations or species—a key benefit for studying marine taxa, which often occur in small numbers or are difficult to access (Xiong et al. 2016; Arulandhu et al. 2017).

With respect to seafood surveillance, NGS has proven effective at identifying multispecies seafood products (Giusti et al. 2017), and may even prove instrumental in identifying whether certified stocks have been swapped with uncertified stocks of the same species (Barendse et al. 2019). For marine invasions, using NGS with transcriptomic and epigenetic markers provides an unprecedented opportunity for identifying adaptive variation within and among native and nonindigenous populations, uncovering candidate genes responsible for certain adaptive traits and understanding the mechanism of epigenetic variation in plastic responses to novel environments (Sherman et al. 2016; Chan et al. 2017). Moreover, NGS coupled with environmental DNA can be used for early detection and monitoring of marine invasive species (e.g. Ardura et al. 2015; Carugati et al. 2015; Simmons et al. 2015; Zaiko et al. 2018), as well as the monitoring of rare, threatened and difficult-to-study or detect species (e.g. Bakker et al. 2017; Weltz et al. 2017; Boussarie et al. 2018; Pikitch 2018; Parsons et al. 2019).

Environmental DNA is a molecular approach that uses a passive sampling technique to acquire DNA from specific species or entire community assemblages. As species interact with their environments, their DNA is continuously being shed into their surroundings—be it soil, sediment or water—via their faeces, saliva, urine and skin cells (Baird and Hajibabaei 2012; Rees et al. 2014; Thomsen and Willerslev 2015; Deiner et al. 2016). As such, it is not necessary to have visual signs of the species under investigation, a requirement of more traditional sampling methods. The primary focus of eDNA has been to acquire species' presence and absence data to quantify their distributions, extents and connectivities (e.g. Weltz et al. 2017; Jeunen et al. 2019). Furthermore, given that several tens of species (from microbes to vertebrates) can be identified in a single sample, this technique can help identify areas of high species richness, which could prove instrumental in informing MPA design and ecosystem-level monitoring (e.g. Andruszkiewicz et al. 2017; Deiner et al. 2017; Pitz et al. 2017; Djurhuus et al. 2018; Stefanni et al. 2018). Moreover, eDNA has a very short life-span of hours or days in seawater, so analysis provides near real-time insight into the presence of species. The ability of eDNA to detect multiple species also holds great promise for rapid biodiscovery (Heidelberg et al. 2010; Chang and Brady 2012). However, the effectiveness of eDNA is fundamentally dependent on the availability of reference collections (e.g. in museums and aquaria) and a genetic reference library, which may not exist and may be difficult to create for elusive marine species. Recently, the focus of eDNA studies has evolved beyond simple presence/absence to studies quantifying the abundance of species (Stewart 2019), which holds great value for threatened and invasive species monitoring and response planning. Moreover, there is a growing body of research focused on quantifying population genetic structures from eDNA in marine species (e.g. Jeunen et al. 2019; Parsons et al. 2019).

The latest molecular technology with a potential conservation application is CRISPR. Considering the discovery of CRISPR as a genome-editing technology was only first reported in 2012 (Jinek et al. 2012), it is still very much in its infancy and its application in threatened species conservation has yet to be tested (Johnson et al. 2016; Piaggio et al. 2017; Phelps et al. 2019). Moreover, beyond unease about the manipulation of human germline cells, significant ethical and governance concerns remain about the use of the technology. Gaps in knowledge with regard to the environmental, social and economic impacts heighten such concerns, alongside fears about the stability of modified genomes (Caplan et al. 2015; Jasanoff et al. 2015; CSS et al. 2019). The interconnectivity of marine environments in particular underpins the importance of having full and adequate knowledge before moving forward with any applications.

Despite coral reefs being among the oldest ecosystems on Earth (Roark et al. 2009), many have suffered unprecedented losses. Although their decline is partly attributed to human-mediated disturbances such as land-based pollution, introductions of invasive species and overexploitation of coral reef ecosystems (e.g. Johannes 1975; Grigg and Dollar 1990; Wilkinson and Buddemeier 1994; Roberts 1995), the rapid decline is also likely linked to the rapid changes in the Earth's climate over the past century (National Academies of Sciences, Engineering, and Medicine 2019). Many coral populations may not have the capacity to adapt to these altered conditions. The plethora of benefits that coral populations provide (see Moberg and Folke 1999)—including as sources of medicine to treat various infections and diseases (e.g. Bruckner 2002)—underscores the importance of supporting their persistence and resilience. Gene editing could theoretically provide an opportunity to increase genetic diversity within populations to allow them to adapt to a changing environment, or permit selection of traits that may improve the resilience of coral populations and species (van Oppen et al. 2015; National Academies of Sciences, Engineering, and Medicine 2019).

The jury is still out as to the costs and benefits of CRISPR, and discussions of its usage are highly controversial. For instance, one proposition by Phelps et al. (2019) is to apply genome-editing in a manner that mirrors the threat level classifications of the IUCN, whereby CRISPR is used primarily as a means of slowing the rate of decline without altering the underlying genetic diversity of species with 'near threatened' or 'vulnerable' statuses (e.g. via genetic barcoding for enhanced monitoring of populations). For more threatened species where genetic erosion is evident (e.g. those that are categorised as 'critically endangered'), this would imply a focus on enhancing the adaptive capabilities of the species within its environment. In such cases, Phelps et al. (2019) propose making genetic modifications in the form of targeted beneficial mutations and gene replacements as potential tools for species survival. However, understanding the genetic underpinnings of these adaptations (e.g. via transcriptomics and epigenetics) is critical before any such steps are explored. For example, while CRISPR may be technically feasible to apply to corals, little knowledge exists regarding candidate genes on which it could operate to increase resilience, and whether it may translate to phenotypic changes (National Academies of Sciences, Engineering, and Medicine 2019). For corals, such work has already begun with differences in genome expression found between corals that were sensitive or resilient to thermal stress (Barshis et al. 2013; Palumbi 2014). From a broader perspective, arguments have also been made about addressing the root cause of the problem rather than relying on technological 'fixes' that might well go awry (CSS et al. 2019) (Box 4.4).

Box 4.4 South Africa Case Study: A Lack of Knowledge and Techniques Limits Our Ability to Assess the Risks to the Genetic Component of Marine Biodiversity

South Africa has an established community of biodiversity assessment and planning practitioners whose collective experience led them to establish spatial plans for ecological sustainability. A series of spatial biodiversity layers have been used to support the Marine Protected Area Expansion program, and the National Biodiversity Assessment (NBA), which is used to inform policies and management decisions. This allowed for systematic assessments of the state of biodiversity in 2004 and 2011. In addition to the statuses and trends of ecosystems and species, the 2018 NBA reports on the state of genetic diversity.[a]

From a genetics perspective, the general outcome was a clear lack of temporal genetic diversity datasets and indicators—a finding mirrored throughout the globe.

Although genetic studies have been conducted on several species, these data typically represent a snapshot of a species' genetic diversity and are applicable to only a limited portion of the species' range. Although still highly informative, the lack of a temporal component prevents the tracking of genetic changes and limits the assessment of genetic risks to marine biodiversity; however, efforts are underway to rectify this.

Within the past two decades, a strong baseline understanding of the spatial genetic patterns in various coastal species and offshore commercially exploited fish stocks has been established.[b] This work is primarily based on mitochondrial DNA and, to a lesser extent, microsatellite markers.[c] More recently, with the advent of NGS, research is being directed toward epigenetics[d] and genome-wide scanning of various coastal species to identify intraspecific variability and structure. Given the heterogeneous marine environment of South Africa, which spans a variety of ecological gradients (e.g. temperature, primary productivity, oxygen, salinity), such work is likely to provide insights into signals of local adaptation and population connectivity. In doing so, areas of evolutionary importance, persistence and resilience may be identified, which could inform marine spatial planning. Moreover, environmental DNA coupled with metabarcoding is assisting with large-scale foundational surveys to quantify the vast and mostly unexplored portions of the marine environment. These data can act as a baseline for more targeted monitoring and assist in amassing phylogenies on specific taxonomic groups for national-level monitoring.

Although single species are typically the focus of genetic monitoring studies, the ability to track genetic diversity across species for a given taxonomic group at a seascape or ecosystem level could greatly inform biodiversity planning at a national scale. South Africa is developing a Critical Biodiversity Area (CBA) map as a spatial plan for ecological sustainability, including identification of CBAs and Ecological Support Areas (ESAs), which together with protected areas are important for landscape and seascape functioning. To bring in the genetic diversity component to this planning process, work has already begun on intertidal chitons using phylogenetic diversity to help prioritise areas of high genetic diversity for marine spatial planning.[e] However, additional metrics should also be considered, such as phylogenetic endemism, evolutionary distinctiveness, and evolutionarily distinct and globally endangered. Each of these metrics can be useful for evaluating biodiversity under different scenarios, and the choice of metric depends on the conservation objectives.

A recent study used all four metrics to examine patterns of genetic diversity across South Africa for terrestrial reptiles.[f] Similar studies focusing on marine taxa would be of great value.

To help guide genetic monitoring research, South Africa is developing a National Genetic Diversity Monitoring Framework to ensure that comparable long-term datasets can be established and used to better inform biodiversity management. This framework will outline how to strategically prioritise taxa; identify the most appropriate genetic markers and metrics to use for national-, ecosystem- and species-level monitoring; and provide advice on the frequency of monitoring. It will also inform the spatial plan currently in revision to refine the boundaries of existing CBAs, ESAs and MPAs.

4.2 Toward Responsible and Inclusive Research and Innovation

Important conceptual approaches to take forward these ideas are responsible research and innovation (RRI) and inclusive innovation. RRI envisages a transparent, interactive process by which societal actors and innovators become mutually responsive to each other with a view to the ethical acceptability, sustainability and societal desirability of the innovation process and its marketable products (Von Schomberg 2013). As observed by Laird and Wynberg (2018), the CBD and ABS provisions of the Nagoya Protocol already encapsulate the principled basis of RRI, although by default rather than by design. Inclusive innovation is an alternative, and perhaps a more contextually appropriate, framing of RRI. It explicitly includes those who have been excluded from the development mainstream (Foster and Heeks 2013), and refers to the production and delivery of innovative solutions to the problems of the poorest and most marginalised communities (Heeks et al. 2013).

For example, the extent to which MGR are used to treat neglected diseases has not been as prominent as the search for treatments for cancer where the direction of research has been influenced by major funders such as the U.S. National Cancer Institute (Mayer et al. 2017). However, the funding landscape seems to be changing due to, among other things, the growing prominence of philanthropic organisations. The potential for philanthropy to help fill gaps left by a lack of focus from national science programmes or demand from the market is one of several positive contributions to ocean science: A growing fleet of research vessels are operated with philanthropic support, and some are offering access to scientists from developing countries. Yet a lack of coordination as well as a tendency for philanthropies to have narrow missions suggests the potential for more added value if efforts were aligned with global agendas such as the UN Decade of Ocean Science or the Sustainable Development Goals (SDGs). Where appropriate, these efforts could also be aligned with national initiatives such as the United Kingdom's Global Challenges Research Fund, which aims at a more inclusive approach to meeting the needs of developing countries in a range of areas, including through efforts to discover novel pharmaceuticals for neglected diseases. There is a clear need to forge more equitable research partnerships between industrialised and developing countries—and between users and providers of MGR—centred on scientific capacity, technology transfer and adequate finance. But it is also important to look at new models of partnerships driven by scientific advances that are changing the way researchers work. These are enabling the creation of dynamic knowledge hubs, and diffuse scientific collaborations, with increasing reliance on data and information (Broggiato et al. 2014). As marine genomics increasingly enters the big data realm, the challenges in equitable access are increasingly loaded toward computational and bioinformatics capacity, a trend that will continue in the future. This trend also underscores the need to resolve what some have termed the 'definitional mistake' of the CBD and Nagoya Protocol, which is the challenge of moving beyond the physical dimension of genetic resources (Ruiz Muller 2015).

The use of genetic sequence data presents both opportunities and challenges for benefit sharing, and is an increasingly central issue within several multilateral fora and organisations, including UNCLOS, the CBD, the World Health Organization and the Food and Agriculture Organization of the United Nations (Blasiak 2019; Laird et al. 2020). Dramatic changes in science and technology have also shifted the nature of benefits (Wynberg and Laird 2018). An important benefit has emerged in the form of publicly available databases, but it has also raised questions about the monetary and nonmonetary benefits that accrue to hosting countries (typically those that can provide funds, expertise and technological capacity) and the lack of access to such databases by countries that lack sufficient molecular research capacity or biotechnology infrastructure (Rabone et al. 2019). Concerns have also been expressed about the loss of control and benefits over national patrimony when DNA is sent overseas for more affordable sequencing and loaded onto public or open-access databases (Elbe and Buckland-Merrett 2017). Progress toward creating standards for the publication of genomic data and making scientific data open access, which is now mandatory for projects funded by public funds in many places (e.g. European Union, United States, Australia), has led to massive growth in publicly available data on the ocean genome. This has become big data (Stephens et al. 2015), with several petabytes of sequence data available, including hundreds of millions of predicted genes (e.g. Sunagawa et al. 2015; Carradec et al. 2018; Gregory et al. 2019). This development is leading toward the consideration of the global ocean genome sequence catalogue as a universal resource, although this risks exacerbating inequity due to widely differing technological capacities to benefit from such shared access. At the same time, it may well be that enabling virtual access to data and the ability to use it might prove an easier task than equalising physical access to marine genetic resources.

Industry sequencing efforts are generally excluded from benefit-sharing obligations unless supported with public funds and/or published in peer-reviewed scientific literature. This provides industry with the advantage of accessing publicly funded sequence data for the global ocean genome without any corresponding obligations to share the data they generate. This raises serious questions about equitable use and distributional justice. In addition, this development is also redefining the challenge of access—from advanced ocean sampling and sequencing technologies, to advanced computational resources and enhanced predictive modelling capacities. These modelling capacities require bandwidth to access and download massive amounts of sequence data, which in turn requires high-speed broadband connections, supercomputers to mine and analyse the sequence data and scientists with advanced bioinformatics skills to query the datasets (Quince et al. 2017).

4.3 Equitable Governance and Benefit Sharing

Capacity building, access to and the transfer of marine technology, and information exchange are critical components of responsible and inclusive research and innovation and benefit sharing (Broggiato et al. 2018; Morgera 2018; Collins et al. 2019). The low chance of commercial success from biodiscovery, combined with the long time frame for potential financial returns, means that some of the most significant benefits are nonmonetary, emerging from the research process itself rather than from commercial products. These might include scientific training; access to research infrastructure; and increased collaboration and cooperation in marine science through data collection, technical exchange and the development of joint scientific research projects and programmes. The complexities of MGR governance mean that in addition to the scientific, institutional and legal capacities necessary to develop and administer international and national regulatory frameworks, capacity is also needed to negotiate equitable agreements, resolve disputes and untangle the knotty problems of ownership and access. A deepened social and ethical understanding (Morgera 2018), focused on the role of marine scientists, is also required to manage the use of commonly shared MGR in a sustainable and equitable manner.

Independent of the legal status of MGR, a more principled approach toward benefit sharing should be adopted, in turn fostering ‘deeper and cosmopolitan cooperation’ via existing UNCLOS obligations on scientific research, capacity building, technology transfer and environmental protection. Such a principled approach would see equitable benefit sharing as an emerging principle of international law of which the human right to science is a part (Morgera 2018).

Current frameworks, including the intersection between environment and intellectual property norms, are extrapolated from constructs that apply on land, where boundaries are more tangible and organisms tend to have restricted ranges. These frameworks neglect the open nature of the ocean, where flows transport organisms across vast distances, including microbes aerosolised from the sea surface to be deposited back in the ocean thousands of kilometres away (Mayol et al. 2017; Ramesh et al. 2019). The 200-nautical-mile legal boundary that separates most national exclusive economic zones from areas beyond national jurisdiction lacks a biological rationale or scientific basis, and a successful mechanism regulating access and benefit sharing with regard to marine genetic resources will need to address this, possibly through collaborative mechanisms between the CBD and UNCLOS.

It is important that the BBNJ process does not replicate the implementation challenges that follow from the wide disparities in domestic measures under the Nagoya Protocol. One way to avoid the pitfalls of disparate implementation would be to agree on what equitable benefit sharing means as a principle of international law, rather than as a mere modality that has polarised the ABS debate. With benefit sharing as a freestanding principle of international law, the links between other global mandates would become clearer, including as an aspect of the human right to science (Article 15 of the International Covenant on Economic, Social and Cultural Rights), contribution to other human rights such as those to food and health, and therefore significant for the realisation of SDGs 2 (hunger) and 3 (health and well-being). It could also be linked to UNCLOS's preambular language—'just and equitable international economic order which takes into account the interests and needs of [hu]mankind as a whole'—as this was the basis for UNCLOS benefit-sharing provisions in relation to outer continental shelf resources and deep-seabed mineral resources. These are issues that require international political will (Morgera 2018), and are subject to negotiations in the upcoming intergovernmental conference.

A key question that threatens swift progress in these negotiations is the issue of intellectual property rights over marine genetic resources and their commercialisation, as well as in relation to capacity building and technology transfer. It is important to note that given existing disparities in technical capabilities to engage in marine scientific research in ABNJ, leaving intellectual property regimes unchanged would likely lead to an exacerbation of technology gaps and inequity due to differential access to MGR and technologies arising from marine scientific research. It is in this context that negotiations related to intellectual property rights and marine genetic resources in the BBNJ process are particularly significant (Thambisetty 2020) for progress toward conservation and sustainable use goals.

One of the main pillars of disagreement and a significant challenge for research on MGR is the inability of the CBD and other international processes to agree on the use of disclosure requirements in the international patent system. The patent specification is a technical and legal document that contains clear and specific information about the invention seeking to be patented. Often these specifications will include information about the source or origin of biological material. As a mandatory measure, such disclosure could facilitate bilateral, global and multilateral benefit sharing. It could also help resolve the artificial distinction between physical and informational genetic resources, inhibit the possibility of public domain or open-access information ending up in private patents, improve trust and ease the global compliance burden of marine scientists.

In the context of the BBNJ negotiations, a global multilateral benefit-sharing mechanism would go some way toward ensuring that the commercial exploitation and use of MGR from ABNJ, whether in physical or intangible form, are subject to benefit-sharing obligations. A multilateral mechanism is particularly important as some countries are advocating for MGR of unknown provenance to be deemed to be from ABNJ. Unless benefit-sharing obligations in the new instrument match or go beyond those in the CBD, this assumption is likely to lead to a race to the bottom of lax benefit-sharing regimes. Some scientists are also urging a rethink of existing rules on disclosing the origin of genetic resources (Blasiak et al. 2019; Chiarolla 2019) while ensuring that intellectual property rights including patents, copyright trade secrets and database rights do not impede capacity building around valuable information.

One of the lessons of the CBD and Nagoya Protocol is the inadequacy of international legal measures to actively engage with scientists and researchers. This in turn negatively impacts confidence in domestic regulatory authorities and the ability to develop laws based on up-to-date scientific understanding. Such concerns highlight the need for scientists to take a more active role in self-regulation, and to instigate training, particularly for younger researchers. Global engagement by scientists and other researchers across jurisdictional boundaries is potentially a powerful dynamic that can, with the right kinds of support and incentives, catalyse effective and equitable governance, and strengthen a shared sense of responsibility to conserve and protect the ocean genome.

5 Conclusion and Opportunities for Action

The ocean genome is the genetic material present in all marine biodiversity, determining the abundance and resilience of biological resources—such as fisheries and aquaculture—that collectively form a pillar of global food security and human well-being. It is the foundation upon which all marine ecosystems, including their functionality and their resilience, rest. Thus, protecting and conserving the ocean genome is crucially important not only for the functioning, stability and integrity of ocean ecosystems and the life within these systems, but for the biosphere and humanity. Yet the ocean genome is also being degraded and eroded through overexploitation, habitat loss and degradation, pollution, impacts from a changing climate such as ocean acidification, invasive species and other pressures, as well as their cumulative and interacting effects.

Simultaneously, exploration of the ocean at a genetic level has resulted in new insights into taxonomy and adaptive capacity that can help optimise conservation efforts, while also spawning a growing number of marine biotechnology applications of commercial importance, from anticancer treatments to cosmetics and industrial enzymes. Initiatives to commercialise the ocean genome should be coupled with considerations regarding conservation, with attention given to both monetary and nonmonetary benefits, and associated environmental, social and ethical risks.

Ensuring that the ocean genome is both conserved and used in a sustainable, fair and equitable manner is urgently important, particularly through the implementation of fully and highly protected areas in the ocean. The sustainable ocean economy is underpinned by the conservation and sustainable use of the ocean genome and a focus on equitable outcomes for all. Yet effective conservation, sustainable use and economic benefits from the ocean genome are challenged by a fragmented ocean governance landscape, gaps in scientific understanding and a world in which the capacity to access and share in the benefits of utilisation of marine genetic resources and associated information varies widely across states. Addressing these issues requires the adoption of effective national and transnational legal measures that ensure both incentives for research and development as well as equitable technology diffusion. Better coordination is needed to ensure that the resources available for promoting conservation, capacity development and other activities associated with the ocean genome are effectively used and equitably shared.

Following from these conclusions, we have identified the following eight opportunities for action to address these issues:

5.1 Opportunities for Action

5.1.1 Protect Marine Genetic Diversity as Part of Conservation Measures and Monitor Outcomes

- **Protect at least 30% of the ocean in implemented, fully or highly protected MPAs** to effectively conserve genetic diversity and ensure ocean health, productivity and resilience. Support this progress by connecting with existing international commitments in the post-2020 framework such as those in the CBD and UN SDGs, and through new voluntary commitments, as well as with support from philanthropies.
- **Ensure the conservation of genetic diversity beyond the boundaries of MPAs and other area-based management** by supporting the sustainable use of resources; avoiding habitat and ecosystem degradation; affording special protections for rare, vulnerable, threatened or endangered genotypes and species; and using precautionary approaches when initiating exploitation of species or places.
- **Incorporate considerations for marine genetic diversity directly into the management plans of industry/production sectors and conservation,** and support monitoring under existing and new international mechanisms. **Form a joint working group of scientists, legal experts and practitioners** with expertise spanning geography, ecoregions and sectoral international institutions (CBD, UNCLOS, World Trade Organization, WIPO) to advise on best practices in genetic monitoring, planning and management.
- **Use strategic environmental assessments** to manage conflicting uses, address the cumulative effects of multiple human activities and guide marine spatial planning and EIAs.
- **Report on the conservation and use of marine genetic diversity in national and local biodiversity strategies and action plans (NBSAPs/LBSAPs).**

5.1.2 Support Greater Equity in Genomics Research and Commercialisation

- **Ensure that marine science capacity building, information exchange, collaboration and appropriate technology transfer are given adequate attention**, including through their integration into access and benefit sharing (ABS) approaches, research agreements and funder policies. Ensure that new and additional funding streams are employed beyond repackaging existing funds.
- **Facilitate the implementation of domestic legal measures** to ensure that intellectual property norms support an equitable ocean economy. Mechanisms include limitations to the exercise of intellectual property rights through fair, nonexclusive licensing terms, and in ways that do not hinder capacity building, technology transfer or affordable access to technologies.
- **Build the above components into national research policies, plans and programmes and innovation strategies**. **Increase efforts to ensure that biodiscovery programmes are aware of capacity-building priorities**, and that users and providers of marine genetic resources and associated information are brought into discussions about how best to implement these actions. Make analytical platforms freely available to anyone able to access an internet connection.

5.1.3 Promote Inclusive and Responsible Research and Innovation in Marine Genomics Research

- **Support a transparent, interactive process by which societal actors, innovators and scientists become mutually responsive** to each other with a view to the ethical acceptability, environmental sustainability and societal desirability of the innovation process and its marketable products.
- **Provide incentives for research that are targeted toward important, underfunded objectives,** for example, diseases afflicting the global South. Ensure a focus on lower-income countries, the most marginalised and vulnerable communities, women and environmental concerns.
- **Support scientists to enable their engagement in socially responsive processes, including through the development of new communication tools,** to determine key needs and priorities and feed these into national research agendas.

5.1.4 Embed Conservation of the Ocean Genome Within Research and Commercialisation, Including Benefit-Sharing Approaches and Agreements

- **Develop a global, multilateral benefit-sharing mechanism** for the fair and equitable use of marine genetic resources beyond national jurisdiction. This could include a review of international voluntary codes of conduct, and the cataloguing of examples where conservation outcomes have been achieved through such efforts.
- **Enhance the legal capacity of developing countries** to domestically address issues emerging from multilateral processes, including those related to intellectual property, benefit sharing, capacity building and technology transfer.
- Parties to the Convention on Biological Diversity should **develop benefit-sharing agreements with mutually agreed terms** focused on conservation and sustainable and equitable use outcomes when granting access to marine genetic resources within national jurisdictions, and support countries in monitoring the performance of such contracts.
- **Funders of research related to the ocean genome should require applicants to explain the potential conservation, sustainability and equity applications and benefits of their research**.

5.1.5 Disclose the Biological and Geographical Origins of Genetic Material as a Norm Across All Associated Commercial and Noncommercial Activities

- **Modify procedural aspects of international patent law to require disclosure of the origin of genetic material in patent filings.**
- **Encourage and incentivise the disclosure of the origin of genetic material among marine scientists and private institutions as an aspect of responsible research and innovation.**
- Regardless of legal obligations, funding bodies, genetic sequence database administrators and journal editors should **require disclosure of the origin of genetic material.**

5.1.6 Increase Financial and Political Support to Improve Knowledge of the Ocean Genome

- **Build support for integrative taxonomic research** aimed at understanding the ocean genome by making this a key element of the UN Decade of Ocean Science for Sustainable Development.
- **Support the research needed for genetic monitoring as part of existing environmental assessments.** Research and share results on the links between genetic diversity and adaptive capacity in the context of global change.
- **Support research on the functional biology of the ocean**, including the systematic unveiling of gene function, gene networks and species interactions.
- **Prioritise the allocation of resources to build scientific capacity** using approaches such as environmental DNA, DNA metabarcoding and other emerging genetic monitoring techniques, as well as to develop more cost-efficient methods.

5.1.7 Comprehensively Assess the Risks and Benefits of Transgenic Marine Organisms as well as the Use of New Molecular Engineering Technologies: Such as CRISPR-Cas (Gene Editing) and Gene Drives—In the Marine Environment

- **Initiate a deliberative process, beginning with a working group,** to gather scientists, ethicists, environmentalists, policymakers and other actors to develop principles and debate approaches for whether and how genetic technologies should be used in the marine environment. Address the limits and directions of current research and development activities, assess risks and wider impacts and engage in dialogue about associated ethical considerations.

5.1.8 Strengthen the Role of Philanthropy in Providing Infrastructure and Funding for Marine Science

- **Establish a network to better coordinate privately funded initiatives, align their priorities with those of states** that are acquiring knowledge for societal needs and improve the transparency of philanthropic funding.
- **Encourage financial supporters of ocean science, including philanthropies, to publish and comply with an ethical code of conduct, and sign a 'Declaration for Coordinated Ocean Action'** based on the principles set forth in the Paris Declaration on Aid Effectiveness and the Accra Agenda for Action to ensure that support is aligned and coordinated with the objectives of the UN Decade of Ocean Science for Sustainable Development, the SDGs and priorities identified by developing countries.

Acknowledgements The authors thank the paper's technical reviewers, Sophie Arnaud-Haond, Elisa Morgera and Jorge Torre, its arbiter, Kristian Teleki, and Ocean Panel Expert Group co-chairs Jane Lubchenco and Peter Haugan, who all provided helpful technical comments.

The authors also thank World Resources Institute for providing support as the Ocean Panel Secretariat, and particularly Katie Flanagan for guiding the paper through to its publication. A. Rogers wishes to thank REV Ocean for its financial support. R. Wynberg's contribution is supported by the South African Research Chairs Initiative of the Department of Science and Innovation and National Research Foundation of South Africa.

While our colleagues were very generous with their time and input, this report reflects the views of the authors alone.

The authors thank Sarah DeLucia for copyediting and Billie Kanfer for design.

About the Authors

Lead Authors

Robert Blasiak is a researcher at the Stockholm Resilience Centre at Stockholm University in Sweden and a visiting researcher at the Graduate School of Agricultural and Life Sciences at the University of Tokyo in Japan.

Rachel Wynberg is a professor and bio-economy SARChI research chair in the Department of Environmental & Geographical Science at the University of Cape Town in South Africa.

Kirsten Grorud-Colvert is an associate professor in the Department of Integrative Biology at Oregon State University in the United States.

Siva Thambisetty is an associate professor in the Department of Law at the London School of Economics and Political Science in the United Kingdom.

Contributing Authors

Narcisa M. Bandarra is a researcher at and the head of the Aquaculture, Upgrading and Bioprospecting Division of the Portuguese Institute for Sea and Atmosphere in Portugal.

Adelino V.M. Canário is professor at and president of CCMAR, the Centre for Marine Sciences, at the University of Algarve in Portugal.

Jessica da Silva is a researcher at the South African National Biodiversity Institute and the Centre for Ecological Genomics and Wildlife Conservation at the University of Johannesburg in South Africa.

Carlos M. Duarte is a professor at the Red Sea Research Center and Computational Bioscience Research Center at King Abdullah University of Science and Technology in Saudi Arabia, and a member of the Expert Group for the High Level Panel for a Sustainable Ocean Economy.

Marcel Jaspars is a professor at and founder of the Marine Biodiscovery Centre in the Department of Chemistry at the University of Aberdeen in the United Kingdom.

Alex D. Rogers is science director of REV Ocean and a senior research fellow at Somerville College, University of Oxford in the United Kingdom.

Kerry Sink is a scientist at the South African National Biodiversity Institute and a professor at the Institute for Coastal and Marine Research at Nelson Mandela University in South Africa.

Colette C.C. Wabnitz is a senior research scientist at the Institute for the Oceans and Fisheries at the University of British Columbia in Canada and at the Stockholm Resilience Centre at Stockholm University in Sweden.

Appendix

To support success, we include in this table potential barriers to implementation and strategies to overcome them (Table 4.2).

Table 4.2 Opportunities for action to conserve and use marine genetic resources fairly, equitably and sustainably

	Theme	Opportunities for action	Barriers to implementation	Overcoming barriers
1.	Protect marine genetic diversity as part of conservation measures and monitor their outcomes.	International level	Securing funding to establishing a joint working group.	Connect with existing commitments (e.g. under UNCLOS and within the Sustainable Development Goals [SDGs]), voluntary commitments (e.g. from UN Ocean Conference) and philanthropy (see Opportunity for Action 8).
		Post-2020 Convention on Biological Diversity (CBD) targets on marine protected areas (MPAs) should follow the scientific evidence showing that protecting at least 30% of the ocean in fully to highly protected, implemented MPAs is needed to conserve biodiversity and genetic diversity and to sustain ocean health, productivity and resilience.	Lack of capacity at national, regional and local levels to engage in genetic monitoring activities.	On lack of capacity, see Opportunity for Action 4; on gaps in taxonomic knowledge, see Opportunity for Action 1.
		Form a joint working group of scientists, legal experts and practitioners with expertise spanning geography, ecoregions, and sectoral international institutions (CBD, United Nations Convention on the Law of the Sea [UNCLOS], World Trade Organization, World Intellectual Property Organization) to mainstream genetic monitoring into existing international mechanisms (e.g. International Seabed Authority [ISA] mining code for prospecting and exploration) and new international mechanisms (e.g. Biodiversity in Areas Beyond National Jurisdiction treaty, ISA mining code for exploitation).	Gaps in taxonomic knowledge and datasets to enable genetic monitoring activities.	
		With respect to identifying priorities for conservation in areas beyond national jurisdiction, strategic environmental assessments, comprehensively understood, can help avoid conflicting uses, address cumulative effects of multiple human activities, and guide environmental impact assessments for specific current and proposed activities.		
		The CBD should issue guidance on how to incorporate aspects of genetic diversity into National Biodiversity Strategies and Action Plans.		
		National, regional and local levels		
		Marine genetic diversity should be explicitly incorporated into the design and management of conservation measures, including by establishing fully and highly protected MPAs, as well as subsequently monitoring their outcomes.		

Table 4.2 (continued)

	Theme	Opportunities for action	Barriers to implementation	Overcoming barriers
2.	Support greater equity in genomics research and commercialisation.	International level	Ensure that prioritisation of allocating resources for researching the ocean genome results in new funding streams rather than a simple repackaging of existing funds.	See Opportunity for Action 8 on developing a 'Declaration for Coordinated Ocean Action'.
		Ensure that marine science capacity building, information exchange, collaboration and appropriate technology transfer are given adequate attention in international research programmes, and that priorities are well articulated in CBD and UNCLOS decisions.		
		Articulate and facilitate internationally the implementation of hard-edged domestic legal measures such as limitations to the exercise of intellectual property rights through fair, nonexclusive licensing terms; market authorisations that take note of compliance with benefit-sharing mechanisms; and the application of international legal norms that facilitate technology transfer and affordable access to technologies.		
		National level		
		Build these components into national research policies, plans and programmes and innovation strategies. **Ensure that biodiscovery programmes are aware of capacity-building priorities**, and that users and providers of marine genetic resources and associated information are brought into discussions about how best to implement these actions. Make analytical platforms available to anyone able to access an internet connection.		
		Explore the full range of limitations and exceptions to intellectual property rights so that capacity building and technology transfer are not precluded by exclusive intellectual property rights.		
3.	Promote inclusive innovation in marine genomics research.	International level	Funding for research and development programmes is often driven by commercial entities, with products geared toward affluent markets rather than to either broader societal needs or diseases afflicting the global South.	See Opportunity for Action 8 on developing a 'Declaration for Coordinated Ocean Action'.
		Support a transparent, interactive process by which societal actors and innovators become mutually responsive to each other with a view to the ethical acceptability, sustainability and societal desirability of the innovation process and its marketable products.		
		Provide incentives for research that are targeted toward societally important yet underfunded objectives. Ensure a focus on lower-income countries, the most marginalised and vulnerable communities, women and environmental concerns.		
		National level		
		Support scientists to enable their engagement in socially responsive processes that determine key needs and priorities and feed these into national research agendas. Ensure a focus on the most marginalised and vulnerable communities, women and on key environmental concerns. **Develop communication tools to improve linkages between societal actors.**		

(continued)

Table 4.2 (continued)

	Theme	Opportunities for action	Barriers to implementation	Overcoming barriers
4.	Embed conservation of the ocean genome within research and commercialisation, including through benefit-sharing approaches and agreements.	International level	No legal obligation exists to undertake such actions, so states and funding bodies would be acting in a voluntary manner. Resistance to depart from the status quo.	Develop international voluntary codes of conduct, and catalogue case studies and best practices when conservation outcomes are achieved through such efforts.
		Facilitate a fair, equitable, global, multilateral benefit-sharing mechanism for the use and exploitation of marine genetic resources beyond national jurisdiction.		Develop opportunities for legal pluralism for specific problems through training and the exchange of legal expertise.
		Enhance the legal capacity of developing countries to address domestically issues emerging from multilateral processes including those related to intellectual property, benefit sharing, capacity building and technology transfer.		
		National level		
		Parties to the Convention on Biological Diversity should **include benefit-sharing agreements with mutually agreed terms focused on conservation and sustainable and equitable use outcomes** when granting access to marine genetic resources.		
		When allocating funding for **research associated with marine genetic resources**, grant-making bodies and research councils **should require applicants to explain the potential conservation, sustainability and equity applications and benefits of their research**.		
5.	Disclose the origins (species and geographical area where organisms were extracted) of genetic material as a norm across all associated commercial and noncommercial activities.	International level	Slow pace of consensus building within relevant international forums.	Reputational benefits accrued by voluntary disclosure of origin by scientists, with potential to shape norms of best practice.
		Modify procedural aspects of international patent law to require the disclosure of the origins (species and geographical area where organisms were extracted) of genetic material in patent filings. This could be achieved through either in-application disclosure or the development of new categories in the international patent classification system. Such measures could help identify cases of noncompliance with the Nagoya Protocol and ensure compliance with existing and emerging access and benefit-sharing obligations.		
		National, regional and local levels		
		Regardless of legal obligations, funding bodies, genetic sequence database administrators and journal editors should **require disclosure of origin**.		

Table 4.2 (continued)

	Theme	Opportunities for action	Barriers to implementation	Overcoming barriers
6.	Increase financial and political support to improve knowledge of the ocean genome.	International level	Convincing policymakers and funding bodies to prioritise taxonomic research and genetic monitoring approaches.	Communicate the range of benefits associated with improved knowledge of the ocean genome (for both conservation and commercial purposes).
		Build support for taxonomic research aimed at understanding the ocean genome by making this a key element of the UN Decade of Ocean Science.		See Opportunity for Action 8.
		National, regional and local levels		
		Responsible ministries, departments, research councils and other relevant actors should **support research needed for basic taxonomic knowledge**, **genetic monitoring** as part of existing environmental assessments, and **research** on the links between genetic diversity and adaptive capacity in the context of global change.		
		All levels		
		Funding agencies should **prioritise the allocation of resources to support the building of scientific capacity** to enhance understanding using the range of available resources, including environmental DNA, DNA metabarcoding and other emerging techniques to enable genetic monitoring.		
7.	Comprehensively assess the risks and benefits of transgenic marine organisms as well as the use of new technologies— such as CRISPR-Cas (gene editing) and gene drives—in the marine environment.	International level	Different worldviews and knowledge systems are difficult to bring together.	Ensure that scientific information is effectively translated into accessible language; improve interdisciplinary understandings; build awareness among policymakers.
		Initiate a deliberative process or 'observatory' think tank to bring together scientists, ethicists, environmentalists, policymakers and other actors to develop principles and debate approaches to using genetic technologies in the marine environment, and to engender robust conversations about the limits and directions of research and development, risk assessments, and wider impacts as well as ethical considerations.	Rigid positions may be adopted by different actors.	
			Communication between actors remains a major challenge.	

(continued)

Table 4.2 (continued)

	Theme	Opportunities for action	Barriers to implementation	Overcoming barriers
8.	Increase the role of philanthropy in providing infrastructure and funding for marine science.	International level	Hesitance by national research councils, philanthropies or others to commit to a coordinated and aligned approach in their financial support.	Take a stepwise approach, first asking signatories to recommit to existing development frameworks, and then seeking more ambitious commitments to align and coordinate support over time.
		Establish a network to better coordinate privately funded initiatives with those of states that are acquiring knowledge for societal needs, as outlined by global agendas such as the SDGs and the UN Decade of Ocean Science.		
		Financial supporters of ocean science, including philanthropies, sign a 'Declaration for Coordinated Ocean Action' that is based on the principles set forth in the Paris Declaration on Aid Effectiveness and the Accra Agenda for Action to ensure that support is aligned and coordinated with the objectives of the UN Decade of Ocean Science and the SDGs.		
		Communicate with the Organisation for Economic Co-operation and Development's Development Assistance Committee for data illustrating the impact of the Paris Declaration on Aid Effectiveness and Accra Agenda for Action, and use these experiences to communicate the added value of a coordinated approach.

5 Leveraging Multi-target Strategies to Address Plastic Pollution in the Context of an Already Stressed Ocean

Jenna Jambeck, Ellie Moss, Brajesh Dubey, Zainal Arifin, Linda Godfrey, Britta Denise Hardesty, I. Gede Hendrawan, To Thi Hien, Liu Junguo, Marty Matlock, Sabine Pahl, Karen Raubenheimer, Martin Thiel, Richard Thompson, and Lucy Woodall

Highlights

- Plastic is the newest pollutant to be entering the ocean in significant quantities. It joins nonplastic solid waste; nutrients; antibiotics, parasiticides and other pharmaceuticals; heavy metals; industrial chemicals including persistent organic pollutants; pesticides; and oil and gas, each of which has a longer history of scholarship and greater body of existing research as an ocean pollutant than does plastic.
- There are four major sources that discharge pollutants into the ocean: municipal, agricultural (including aquaculture), industrial and maritime. These pollutants have damaging impacts on ecosystems and marine life, human health and the economy.
- The presence of plastic in the ocean in growing quantities is symptomatic of many societal challenges that are relevant to the other pollutants and pollution pathways: the lack of access to sanitation and wastewater and stormwater processing for millions of people around the world, the need for safe use and disposal of chemicals, the development and degradation of coastal zones, the need for an efficient use of natural resources, and the need for improved access to safe food and water.
- This paper proposes seven holistic approaches for the reduction of pollutants in the ocean: improve wastewater management; improve stormwater management; adopt green chemistry practices and new materials; implement coastal zone improvements; practice radical resource efficiency; recover and recycle the materials we use; and build local systems for safe food and water.
- These seven approaches address the major sources of pollution entering the ocean and contribute to multiple United Nations Sustainable Development Goals.
- Each of the approaches identified are cross-sectoral and system-level in nature, making them perfect candidates for delivery through public-private partnerships, innovative financing arrangements and leveraging capital from a range of sources.
- To solve the pollution challenge we need to start with the premise that there is no such thing as waste. The Earth is a closed system and there is nowhere for damaging pollution to go that won't harm ecosystems, plant and animal life and, ultimately, human life.
- Once we adopt a no-waste approach, our economy will be very effective at finding the most efficient ways to stop the problem of pollution

1 Introduction

1.1 Overview

The ocean is the ultimate sink for anthropogenic pollution. According to the HydroSHED model, over 80% of the land mass on Earth is in a watershed that drains directly to the ocean (Lehner and Grill 2013). Until recently, the ocean seemed to be endlessly able to absorb all the waste that human activity has discharged into it. The Ocean Health Index (OHI) scores the health of the ocean on a range of criteria, from how clean the water is to the ability of the ocean to continue providing services such as food provision,

carbon storage, tourism and recreation, and biodiversity (Halpern et al. 2012). The 2019 combined global ocean score was 71 out of 100 (as it has been for the last five years), showing that significant impairment has occurred, but that many of the functions and services of the ocean remain and must be better managed (OHI 2019). The Clean Water section of the OHI includes details on the statuses and pressures of chemical, nutrient, pathogen and trash pollution. It also includes social pressure as a further pressure. Indicators of resilience were based upon the Convention on Biological Diversity (in particular for marine ecosystems) and quality of governance (using Worldwide Governance Indicators). The score for Clean Water has tracked closely to the overall score, remaining at 70 for the past five years (OHI 2019). With an estimated 91% of all temperate and tropical coasts predicted to be heavily developed by 2050 (Nellemann et al. 2008), this is a critical time to significantly reduce and prevent anthropogenic pollution to the ocean.

Pollutants enter the ocean in four ways: They may be discharged directly into the ocean, discharged into rivers which flow to the ocean, washed from land by stormwater into rivers or directly into the ocean or deposited from the air onto land to be washed into waterways or directly into the ocean.

There are many anthropogenic sources of pollution, and this paper focuses on pollution inputs to the ocean from four sectors: municipal, agricultural, industrial and maritime. This paper focuses first on plastic, as the newest and least well understood pollutant, and puts plastic pollution in the context of an ocean already receiving significant pollution from nutrients, heavy metals, persistent organic pollutants (POPs), pesticides and oil.

While successful implementation of all the United Nations (UN) Sustainable Development Goals (SDGs) would help protect the ocean, SDG 14: Life Below Water is the primary SDG directly related to the ocean. But there are several other SDGs that are very relevant to pollution reaching the ocean: SDG 2: Zero Hunger, SDG 3: Good Health and Well-Being, SDG 6: Clean Water and Sanitation, SDG 8: Decent Work and Economic Growth, SDG 9: Industrial Innovation and Infrastructure, SDG 11: Sustainable Cities and Communities and SDG 12: Responsible Consumption and Production.

1.2 Context

Plastic is the newest pollutant to be entering the ocean in significant quantities. It joins nonplastic solid waste; nutrients (nitrogen, phosphorous); antibiotics, parasiticides and other pharmaceuticals; heavy metals; industrial chemicals including persistent organic pollutants; pesticides; and oil and gas, each of which has a longer history of scholarship and greater body of existing research as an ocean pollutant than does plastic. This paper seeks to put ocean pollution from plastic into the context of total pollutant inputs to the ocean and identify the interventions that can have the greatest total impact on all pollution to the ocean, capitalising on the current global attention on plastic pollution.

In this Blue Paper, four major sectors that create pollutants are explored—municipal, agricultural (including aquaculture), industrial and maritime—and three types of impacts are characterised—ecosystems and marine life, human health and economic. The impacts on ecosystems include harm to marine life from ingestion of and entanglement from plastic, eutrophication and hypoxia, and biomagnification of chemicals. The human health impacts from direct or indirect exposure to these pollutants include reproductive, developmental, behavioural, neurologic, endocrine and immunologic adverse health effects; acute or chronic toxicity; cancer; increased exposure to pathogens and mosquito-borne diseases; and risk of entanglement or entrapment. The economic impacts come from impaired productivity of fisheries, loss of seafood supply resulting from toxicity and reduced tourism and recreation in coastal areas.

The presence of plastic in the ocean in growing quantities is one symptom of a set of societal challenges that are also relevant to the other pollutants and pollution pathways: the lack of access to sanitation and wastewater and stormwater processing for millions of people around the world; the need for safe use and disposal of chemicals; the development and degradation of coastal zones; the need for an efficient use of natural resources; and the need for improved access to safe food and water.

At the heart of these challenges is recognising that the notion that things can be thrown away is a myth—there is no ‘away’ where pollutants can safely go.

This paper proposes seven intervention approaches that lead with reducing plastic inputs to the ocean but also seek to maximise the reduction of other pollutants as co-benefits. Four types of actions were considered: innovation, infrastructure, policy and mindset. Specific actions of each type were identified across the sectors and pollutants described in the report. These actions were then bundled into the following seven holistic opportunities for action (not in ranked order):

1. Improve wastewater management
2. Improve stormwater management
3. Adopt green chemistry practices and new materials
4. Implement coastal zone improvements
5. Practice radical resource efficiency
6. Recover and recycle the materials we use
7. Build local systems for safe food and water

These seven opportunities for action address the major sources of pollution entering the ocean, and contribute to achieving the United Nations Sustainable Development Goals (SDGs). They would directly influence SDG targets 2.1, 2.3, 3.9, 6.1, 6.2, 6.3, 6.B, 8.3, 11.6, 12.2, 12.4, 12.5 and 14.1 and indirectly influence a number of others, such as through expanded economic opportunities, benefits to people's livelihoods and increased well-being. The cross-sector, system-level nature of these challenges makes them perfect candidates for public-private partnerships, innovative financing arrangements and leveraging capital from a range of sources.

Finally, while the body of research on plastic is growing rapidly, there remain significant data gaps both on inputs and impacts. More research is needed to better understand and document the scope and scale of plastic pollution, as well as its impacts on ecosystem and human health. Given the global nature of the problem, open data protocols that can facilitate the aggregation and sharing of compatible data are critical.

2 Sources of Ocean Pollution

This paper includes pollution inputs from land and sea, grouped into four sectors: municipal, agricultural, industrial and maritime.

Municipal sources are residential and commercial solid waste and wastewater as well as runoff from roads and landscaping activities. Additionally, debris entering the ocean as a result of natural disasters is included here.

Land-based agricultural activities impacting the ocean include plastic, pesticide and nutrient use as well as waste management for animal agriculture. **Ocean-based aquaculture**'s pollution impacts include the use of antibiotics and parasiticides, antifoulants containing heavy metals, loss of equipment and management of fish waste.

The **industrial** sector includes manufacturing, mining and energy production. Pollutants coming from this sector include plastic pellets and waste, other solid waste, dredge spoils, industrial chemicals including POPs, heavy metals, pharmaceuticals and pharmaceutical waste products, and oil and gas.

Maritime pollution comes from the shipping, cruise and fishing industries and from recreational boating. Pollution from these sources includes litter, food waste, sewage and accident debris.

Figure 5.1 shows the primary sources of pollution in the marine environment from these sectors. Table 5.1 summarises the types of pollution entering the ocean and the ways that each sector contributes to ocean pollution.

Other than specific pollutants regulated by international treaties in certain situations—e.g. International Convention for the Prevention of Pollution from Ships (MARPOL) for plastic discharges; Stockholm Convention for specific chemicals; Basel Convention for waste exportation; London Convention and Protocol for ocean dumping—and acts that have regulated discharge nationally and locally—e.g. total maximum daily loads under the Clean Water Act in the United States—pollutants continue to enter the ocean without consistent and global limits or regulation.

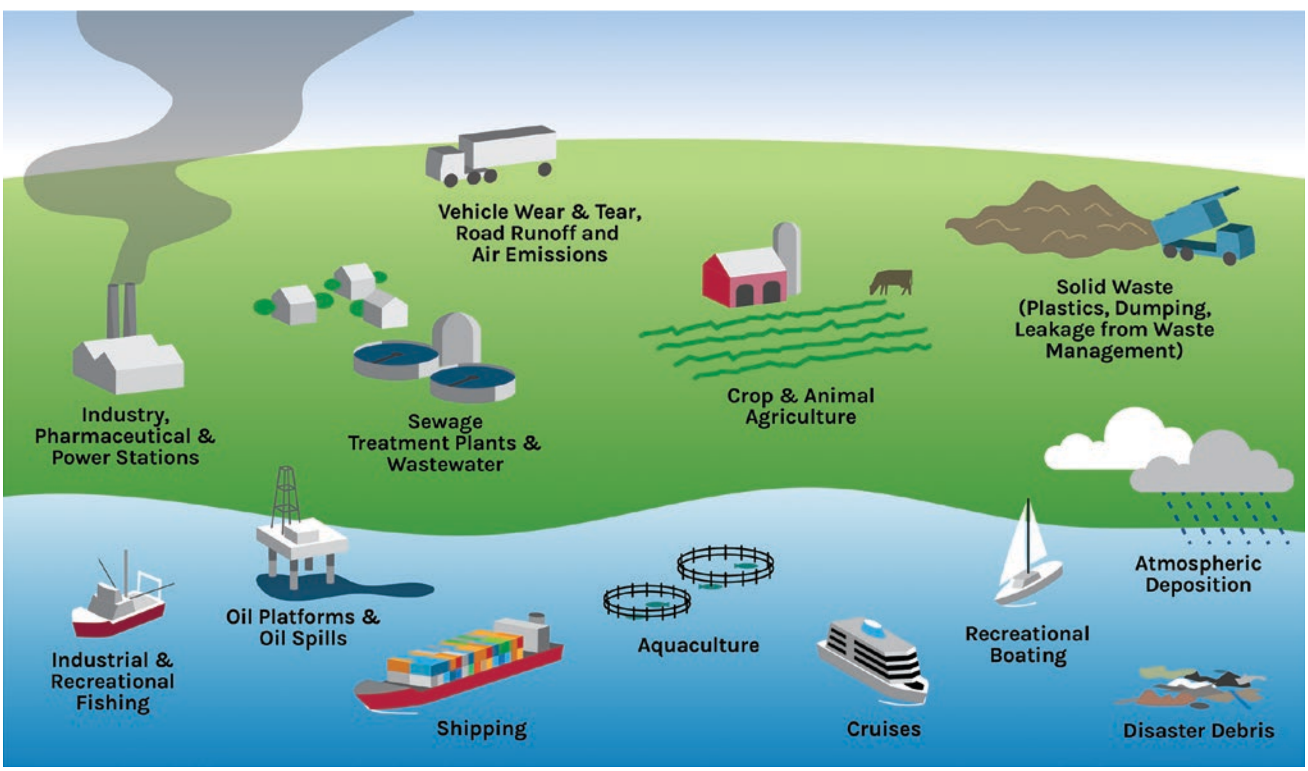

Fig. 5.1 Sources of ocean pollution. (Source: Graphic developed by K. Youngblood)

Table 5.1 Sources of pollutant discharges into the ocean

Subcategories	Municipal (coastal or near rivers)	Agricultural and aquacultural	Industrial	Maritime
	Residential, commercial	Crops, animal land, aquaculture	Manufacturing, energy	Fishing, cruise, shipping, recreation
Microplastics (<5 millimetres [mm])[a]	Microbeads, microfibres, tire dust, fragments in runoff from land	Slow release fertiliser pellets, plastic mulch fragments	Industrial pellets	Pellets lost at sea in shipping accidents, dredged materials and breakdown of other wastes dumped at sea[b]
Macroplastics (>5 mm)[a]	Unmanaged plastic waste within 50 kilometres (km) of river or ocean[1]	Aquaculture infrastructure and equipment, greenhouses, plastic sheeting and associated equipment	Unknown	Fishing gear, lines and lures; litter from ships and boats; debris from shipping accidents
Other solid waste	Unmanaged solid waste within 50 km of river or ocean, disaster debris, wood, food waste dumping[c]	Lost/unmanaged aquaculture infrastructure and equipment, manure and biosolids land application	Dredge spoils	Fishing gear, litter from ships and boats, debris from shipping accidents, food waste discharge from ships
Pesticides[2]	Residential and commercial landscaping and gardening	Crop-based agriculture	Minimal	Minimal
Nutrients (N, P)	Untreated municipal wastewater, residential and commercial landscaping and gardening, airborne nitrogen from vehicle exhaust deposition into ocean	Crop-based agriculture, lagoon leakage, aquaculture fish waste	Airborne nitrogen from energy production deposition into ocean	Sewage discharges into ocean
Antibiotics, parasiticides, other pharmaceuticals	Treated and untreated wastewater	Aquaculture/mariculture, land-based animal agricultural runoff	Pharmaceutical production waste-water	Treated and untreated wastewater from ships
Heavy metals	Urban runoff: copper, chromium, nickel; mismanaged electronic waste	Aquaculture/mariculture: arsenic, mercury, cadmium, lead	Mining manufacturing: copper, zinc, lead, cadmium, chromium, nickel, arsenic, mercury	Paints and pigments: zinc, tributyltin, lead, cadmium
Industrial chemicals and persistent organic pollutants[c]	Treated and untreated wastewater, urban runoff	Use of organochlorine pesticides	Regulated and unregulated discharge from manufacturing	Treated and untreated wastewater from ships
Oil and gas	Urban runoff	Accidental discharge from agricultural equipment use and maintenance	Spills, water contamination, and improper disposal from oil refineries and logistics (pipelines, rail, trucks)	Drilling rigs, bilge water and fuel release, tanker spills, shipping

Table includes both point source (e.g. specific discharge points) and nonpoint source (e.g. stormwater runoff) forms of pollution

[a]*Macroplastics are any plastics larger than 5 mm. Microplastics are small pieces or fragments of plastic smaller than 5 mm (*Galgani et al. 2010*;* SAPEA 2019*)*

[b]*Wastes allowed to be dumped at sea according to the London Convention and Protocol include dredged materials; sewage sludge; fish waste, or material resulting from industrial fish processing operations; vessels and platforms or other man-made structures at sea; inert or inorganic geological material; organic matter of natural origin; bulky items comprising primarily iron, steel, concrete or non-harmful materials; and carbon dioxide streams from carbon dioxide capture processes for sequestration*

[c]*Jambeck et al. (*2015*)*

[d]*Persistent organic pollutants are organic compounds that are resistant to environmental degradation through chemical, biological and photolytic processes. They include polybrominated diphenyl ethers (PBDEs), per- and polyfluoroalkyl substances (PFASs), polychlorinated biphenyls (PCBs) and organochlorine (OC) pesticides.*

2. Weibel et al. 1966

Past emissions of ocean pollution remain relevant today, especially in the case of persistent pollutants such as plastics, heavy metals and POPs, as they remain in the ocean interacting with each other and the marine environment. For example, while 28 POPs are banned or restricted and have been for a number of years (12 since 2004, 16 since 2010), they are readily absorbed by plastic in the ocean, which creates a new mechanism for them to interact with the marine ecosystem (Rochman et al. 2013, 2014b; Rochman 2015). Heavy metals have also been found to adhere to plastic in the ocean as biofilms accumulate on its surface (Rochman et al. 2014a; Richard et al. 2019).

It should be noted that the ocean is also subject to other forms of pollution, including acidification (see Blue Paper 2, Gaines et al. 2019) and other nonphysical forms like thermal, noise and biological pollution. Thermal pollution is a change in temperature in the ocean water from discharges, often warmer water from powerplant cooling, that can change both physical and chemical properties of the ocean, impacting, for example, bivalves since they are stationary (Dong et al. 2018). Noise pollution in the ocean from shipping, oil and gas exploration and military activities can also impact marine life (Francis and Barber 2013). The International Whaling Commission and Convention on Biological Diversity have groups working on noise pollution. Biological pollution is the transfer of, for example, invasive species, which has been exacerbated by evolving habitats due to climate change and ocean acidification (Miranda et al. 2019), topics covered in Blue Paper 2 (Gaines et al. 2019). The transport of invasive species by plastic is covered in this paper. While these other pollution sources are out of scope for this paper, it is worth noting them here as they underscore the high number of stressors that ocean ecosystems are facing.

2.1 Plastic Pollution

Plastic is a material that has permanently changed our world since its introduction into mainstream society (in some countries) after World War II; global annual plastic production has increased from 1.7 million metric tonnes per year (mmt/yr) in 1950 to 422 mmt/yr. in 2018 (Geyer et al. 2017; PlasticsEurope 2019). Along with a steep increase in production, we have seen a resulting increase in plastic in the waste stream from 0.4% in 1960 to 13.2% in 2017 (by mass) in the United States (EPA 2014, 2019). In 1966, two U.S. Fish and Wildlife Service employees, Karl W. Kenyon and Eugene Kridler, were among the first scientists to document plastic and wildlife interactions when they discovered plastic had been consumed by seabird (albatross) chicks that died in the Hawaiian Islands National Wildlife Refuge (Kenyon and Kridler 1969). Since then, analysing plastic material flows (especially the waste streams), contamination in our environment and the economics of the material has become a recognised scientific discipline, with rapid increases in the science, especially in the last five years (Beaumont et al. 2019). But as a relevantly young scientific discipline, there are still many gaps in knowledge and a lack of information for solutions to plastic pollution (Bucci et al. 2019; Forrest et al. 2019). Even with knowledge gaps, plastic pollution has quickly become one of the most salient topics of late—people around the world passionately care about and want to address this issue.

2.1.1 Municipal Plastic Pollution

Plastic pollution is often subdivided into macroplastics and microplastics (e.g. the U.S. National Oceanic and Atmospheric Administration uses this division), and although there is much discussion internationally about terminology (GESAMP 2015), these size categories are currently used extensively around the world. Macroplastics are any plastics larger than 5 millimetres (mm) and can include both short-use items (e.g. food packaging and foodservice disposables) and longer-use items (e.g. flip flops, printer cartridges, synthetic textiles). Microplastics are small pieces or fragments of plastic less than 5 mm (Galgani et al. 2010; SAPEA 2019) that enter the environment as a consequence of either the direct release of small particles such as microbeads from cosmetic products; the fragmentation of larger items of litter in the environment; or the wear or abrasion of products during use, such as the release of fibres from textiles or particles from car tires (Law and Thompson 2014). The term microplastic was first used in this context in 2004 (Thompson et al. 2004) and the identification of microplastics is a relatively new field (Shim et al. 2017), with nanoscale plastics (not even yet formally defined) especially challenging to identify because of limits to the capabilities of the current instrumentation used for environmental samples. As a consequence, quantifying inputs has been challenging (Koelmans et al. 2015; Rist and Hartmann 2017; SAPEA 2019).

As of 2017, 8 billion metric tonnes of plastic had been produced for human use. Because a large quantity was used for packaging (about 40%) and single-use items, 6.4 billion metric tonnes had already become waste by 2015 (Geyer et al. 2017). Many packaging and single-use materials are composed of polyethylene (high and low density, HDPE and LDPE), polypropylene and polyethylene terephthalate (PET). These polymers are often the materials used in the most common items found littering the environment, especially on coastlines: cigarette butts, plastic bottles, plastic food wrappers, straws, plastic bags and bottle caps (Ocean Conservancy 2018).

The total quantity of plastic entering the ocean every year is still unknown. While there have been estimates of some sources (e.g. municipal waste), there are more sources that do not have current estimates. While many scientists would agree that a large portion of mismanaged plastic comes from land, even the 80% from land is a questionable statistic since the true total from all sources remains unknown. Some of the sources have been quantified. Jambeck et al. (2015) found that the annual input from mismanaged solid waste on land (one of the major sources) in 2010 was between 4.8 and 12.7 mmt/yr. Other estimates have come from riverine input and other geographic information system (GIS) analyses, which have found that from 0.41 to 4 mmt of plastic is entering the ocean every year from rivers (a subset of the total quantity entering the ocean) (Lebreton et al. 2017; Schmidt et al. 2017). Up to 99 mmt of mismanaged plastic waste has been estimated to be available to enter waterways around the world (Lebreton and Andrady 2019). The estimate of 8 mmt as a middle estimate for input to the ocean (Jambeck et al. 2015) remains the most widely used value for land-based input of plastic waste into the ocean, although this is likely conservative. Forrest et al. (2019) built on the existing research by incorporating additional estimates of plastic waste flows to the ocean arising from imported waste by developing countries from wealthier consumer economies. This export/import imbalance was initially outlined in (Brooks et al. 2018), which describes the plastic import ban, more commonly known as the National Sword policy, imposed by China and its impacts on global plastic scrap trade. Forrest et al. (2019) estimated current plastic flows to the ocean from all sources to be at least 15 mmt/yr.

There are at least two more global baseline estimates in the process of being calculated for plastic, one by a working group through the National Socio-Environmental Synthesis Center funded by the U.S. National Science Foundation and one through The Pew Charitable Trusts and SYSTEMIQ, which, while not available before publishing this document, will make it possible to measure the impacts of interventions at the global and country levels, similar to the wedges approach developed for climate change (Pacala and Socolow 2004). Clearly topography and proximity to the ocean are relevant for land-based or riverine plastic, but some of the biggest data gaps in modelling and measuring quantities entering the ocean exist for these pathways. The most credible current estimates nonetheless indicate that the quantities of plastic entering the ocean are significant. The only regulatory limits on plastic concentrations in the ocean are the total maximum daily load limits in aquatic systems in the United States (Smith 2000; MDOE and DCDOE 2010), the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter 1972 (the 'London Convention' for short, and then later the 'London Protocol' upon its revision in 1996) (International Maritime Organization n.d.), and MARPOL Annex V, all of which have zero tolerance for plastic pollution.

2.1.2 Agricultural Plastic Pollution

Land-based agricultural plastic use typically includes greenhouse or hoop house sheeting, netting, plastic mulch (film), irrigation tape and piping, agrochemical containers, silage, fertiliser bags and slow release fertiliser pellets. The best current estimate of agricultural plastic usage extrapolates from the European Union's (EU's) demand for agricultural plastics of 1.6 million tonnes annually to place world demand at approximately eight to ten million tonnes in 2015 (Cassou et al. 2018). A separate calculation projected that the global agricultural film market would reach 7.4 million tonnes in 2019 (Sintim and Flury 2017). At the end of the growing season, plastic mulch should be recovered from fields but this is difficult because it shreds easily, so it is common practice to till plastic mulch into the soil (Steinmetz et al. 2016). Depending on the proximity to the ocean or ocean-bound waterways, this improper end-of-life management of the mulch could contribute to inputs of plastic, especially microplastic, into the ocean.

Aquaculture also contributes significantly to marine plastic pollution. Several studies have reported abandoned, lost and discarded aquaculture gear in coastal waters or on shores (Heo et al. 2013; Liu et al. 2013; Hong et al. 2014). Near aquaculture centres, beaches often contain large amounts of lost or discarded plastic materials (Fujieda and Sasaki 2005; Hinojosa and Thiel 2009; Andréfouët et al. 2014; Jang et al. 2014b; Bendell 2015). Lost aquaculture gear that is floating at the sea surface can also be transported over long distances, potentially bringing non-native species to other ecoregions (Astudillo et al. 2009). One of the few studies that has estimated the losses from aquaculture activities and their contribution to marine plastic debris has been conducted in South Korea (Jang et al. 2014b). The authors showed that lost aquaculture gear contributes a significant amount of plastic litter (mostly expanded polystyrene, or EPS) in the coastal waters of South Korea.

2.1.3 Industrial Plastic Pollution

Plastic resin pellets, the raw material from which plastic items are made, continue to leak into the ocean despite voluntary industry campaigns like Operation Clean Sweep that encourage secure handling of the pellets. Pellet pollution in the ocean has been further documented because they are used to study POPs and bacteria as well (Heskett et al. 2012; Rodrigues et al. 2019). While quantities of inputs have not been published on a global scale, one case study quantified inputs from a facility along the west coast of Sweden (Karlsson et al. 2018). While most of the pellet pollution was reported to be localised, 3 to 36 million pellets (above 300 μm) were estimated to enter the waterways surrounding the production facility annually. Karlsson et al. (2018) also stated that while there are regulatory frameworks that can be applied to reduce this pollution, they are not being effectively applied or enforced. Lechner and Ramler (2015) found that the regulations in Austria still allowed a production facility to legally discharge 200 g of pellets per day and up to 200 kilograms (kg) during a high rainfall event. An important legal precedent was just set in the United States with Formosa Plastics agreeing to pay a US $50 million settlement for a lawsuit against them for discharging resin pellets into Lavaca Bay and other nearby waterways (Collier 2019). Besides paying the settlement, it has to adhere to a 'zero discharge' policy moving forward with fines that increase over time for any future discharges (Collier 2019).

2.1.4 Maritime Plastic Pollution

Fisheries activities contribute to pollution through the accidental or intentional discarding of nets, ropes, buoys, lines and other equipment, also known as 'abandoned, lost or otherwise discarded fishing gear' (ALDFG) (see Box 5.3 for a discussion of aquaculture). Historic fishing nets were made from biodegradable, locally sourced natural materials like cotton, flax or hemp, but as materials like nylon and other polymers were introduced, fishing practices (and efficiencies) were increased, as early as 1951 in the United States and Canada (Pycha 1962). United Nations General Assembly and United Nations Environment Assembly resolutions have addressed ALDFG (UNEP, 2017), encouraging the reduction of impacts from this marine debris that is designed to capture and kill marine animals (Gilman 2015; Gilman et al. 2016). The Food and Agriculture Organization of the United Nations' (FAO's) Committee on Fisheries, the FAO Code of Conduct for Responsible Fisheries and the FAO's Voluntary Guidelines for the Marking of Fishing Gear have also presented on marking fishing gear and ALDFG reporting and recovery (Gilman et al. 2016). Richardson et al. (2019) reviewed 68 publications from 1975 to 2017 that contain quantitative information about fishing gear losses and found that at an annual rate, all net studies reported gear loss rates from 0% to 79.8%, all trap studies reported loss rates from 0% to 88%, and all line studies reported loss rates from 0.1% to 79.2%. Based upon this review, Richardson et al. (2019) performed a meta-analysis estimating global fishing gear losses for major gear types, finding that 5.7% of all fishing nets, 8.6% of all traps, and 29% of all lines are lost around the world each year. Abandoned, lost or discarded fishing gear can ensnare or entangle marine wildlife, have economic consequences due to losses of commercially important food fish and can smother sensitive coral reef ecosystems (Macfadyen et al. 2009; Gunn et al. 2010; Wilcox et al. 2013; Richardson et al. 2018). Commercial shipping and discharge from ocean-going vessels result in plastic inputs through accidental releases of cargo during ocean transit, which may occur during rough weather or when containers are insufficiently secured during transport (World Shipping Council 2017).

Box 5.1 Spotlight on Africa's Current and Future Rapid Growth

Africa's contribution to waste generation is currently low by global standards.[a] However, the continent is set to undergo a major social and economic transformation over the coming century as its population explodes, cities urbanise and consumer purchasing habits change.[b] These changes will lead to significant growth in waste and wastewater generation, including nutrient exports to coastal waters,[c] with sub-Saharan Africa forecast to become the dominant region globally in terms of municipal solid waste generation.[d] This will put significant strain on already constrained public and private sector services and infrastructure.[e]

As noted by Yasin et al. (2010) and UNEP (2018a), there are limited reliable, geographically comprehensive waste and water quality data for Africa. This makes it extremely difficult to assess the potential impacts of waste and wastewater systems locally and regionally. However, anthropogenic sources of nutrients in rivers, including agricultural sources and human sewage (often untreated) from urban centres, will become more important than natural sources in large parts of Africa.[f] Furthermore, with growing population comes increased waste generation and changing waste types.[g] As such, in the absence of reliable waste and water quality data, population growth and economic development can provide signals of potential 'geographic areas of concern' with regard to plastic, industrial, agricultural and municipal wastes. According to the United Nations' Department of Economic and Social Affairs, more than half of the world's projected population growth between 2017 and 2050 is expected to come from only 10 countries, with 6 of these in Africa—Nigeria, the Democratic Republic of the Congo, Ethiopia, Tanzania, Uganda and Egypt (ordered by their expected contribution to global growth).[h]

Where the impacts of plastic and nutrients on coastal systems in Africa have been modelled, the models have forecasted significant growth in waste generation and potential impact.[i] Tonnages of mismanaged plastic waste is expected to increase significantly between 2010 and 2025, particularly in coastal countries such as Nigeria, Egypt, Algeria, South Africa, Morocco and Senegal (ordered by their forecasted 2025 mismanaged plastic).[j] The nutrient risk for large marine ecosystems forecast for 2050 shows very high coastal eutrophication risk off the coast of West Africa around the Gulf of Guinea.[k]

While waste volumes produced in Africa are currently low, waste is impacting the environment due to a number of factors, including limited environmental regulation and often weak enforcement, inadequate waste and wastewater systems and the transport of waste into Africa, often from developed countries.[l] With an average municipal solid waste collection rate of only 55% for Africa,[m] the potential for plastic to leak into the environment is high. There is growing citizen and government concern around the leakage of plastic waste into the environment, resulting in many African countries moving to ban single-use plastics as a way of limiting their negative impacts. According to UNEP (2018b), 29 countries in Africa, predominantly coastal countries, have already implemented some sort of regulation against plastics. Currently, these regulations vary from a ban on single-use (thin) plastic bags, with associated requirements for bag thickness, to a complete ban on all plastic carrier bags. However, the growing concern around plastic waste is sparking discussions in many African countries on possible further bans on other single-use plastic products, such as PET beverage bottles and food service industry products such as straws, cups, containers and utensils.

There is, however, a growing response from a number of brand owners, retailers and convertors to address the current waste problems in Africa. South Africa, for example, has had voluntary industry initiatives in place for over a decade aimed at growing the local plastic recycling industry. Initiatives such as the South African PET Recycling Company, which has achieved a 65% post-consumer PET bottle recycling rate in South Africa,[n] are now being rolled out in Kenya, with plans to launch in Ethiopia and Uganda.[o] There are also a number of social innovations emerging in Africa to deal with the plastic waste problem. These often focus on innovative community-driven collection systems and associated financial rewards for recyclables, such as Wecyclers in Nigeria and Packa-ching in South Africa.

2.2 Other Pollutants Compounding Ocean Stress

Pollution in this category stems from anthropogenic development (including in rural and urban areas). Municipal sources of pollution can be especially high where population densities are high. Lack of infrastructure that can handle sanitation and waste management in rapidly growing cities, especially near the coasts, is a large source of ocean pollution. Sources in this sector include residential and commercial solid waste and wastewater as well as runoff from roads and landscaping activities. Additionally, debris entering the ocean as a result of natural disasters is included here.

2.2.1 Other Municipal Solid Waste Pollution

The World Bank estimates that 2 billion metric tonnes of municipal waste are generated globally with 33% (663.3 mmt) being managed by 'open dumping' (Kaza et al. 2018). Approximately 50% or more of this waste is organic waste (e.g. food waste) in many places except for Europe and North America, which generate around 30% organic waste. In high-income countries (as ranked by the World Bank), 51% of the waste stream is plastic, paper, cardboard, metal and glass, while in low-income countries, only 16% of the waste stream is estimated to be dry waste and able to be recycled (Kaza et al. 2018). These statistics do not even include special waste materials like medical and electronic waste (e-waste), which pose even further management challenges beyond municipal waste. While regulated by the Basel Convention in international trade, e-waste continues to be processed in areas without adequate infrastructure or protection for workers; to access the metal, the plastic housing and coatings on wires are often burned, releasing toxic emissions impacting ecosystems and human health (Asante et al. 2019).

Box 5.2 Waste Management in Indonesia

The Indonesian government, through President Act No. 83 in 2018 regarding marine debris management, has committed to reducing plastic waste up to 70% by 2025.[a] To support this effort, the Coordinating Ministry of Maritime and Investment Affairs plans to build a protocol to collect marine debris data from several big cities in Indonesia, including Banjarmasin, Balikpapan, Bogor and Denpasar, and has taken action through the Mayor Act (Peraturan Wali Kota) and Governor Act (Peraturan Gubernur) to regulate the reduction of single-use plastic. While some regulations regarding waste reduction, segregation, collection and transport already existed, the lack of enforcement has caused them to be poorly implemented. To amplify efforts to reduce plastic waste, the national government has also constructed a cross-government collaboration approach through a National Plan of Action (Rencana Aksi Nasional) on marine plastic debris for 2018–2025, which includes five main actions: change behaviour, reduce land-based leakage, reduce sea-based leakage, enhance law enforcement and financial support, and increase research and development.[b]

In addition to regulatory solutions, some villages are setting up their own waste management facilities. In 2018, Muncar, a small village in East Java, worked with a private organisation named SYSTEMIQ on a pilot project called Project STOP, which, if successful, can be implemented in other villages throughout Indonesia. For this project, they built a waste management system in the area that focuses on waste segregation in households and capacity building through a sorting centre. The plan has five strategies, including optimised waste collection, behaviour change, regulation setting, village waste management, institutional capacity building and optimised waste processing for both inorganic and organic waste. In December 2019, 47,500 people received waste collection, mostly for the first time, from two facilities established by the project. These facilities have collected 3000 tonnes of waste so far and employ 80 local people.[c]

Indonesia is also looking for alternatives to landfills for plastic waste that cannot be recycled. One option being investigated is a plastic road tar that uses plastic waste, mainly LDPE and HDPE. The plastics are shredded, melted and added into road-tar mix. In 2017, this method was piloted at Udayana University, Bali, where they laid a 700-metre-long plastic road. However, an evaluation hasn't yet been done assessing the potential for contamination into the environment.

[c] *National Geographic (2020)*

Another contribution beyond municipal waste is disaster debris. With climate change increasing both the intensity and frequency of storms around the globe, this pollution input may increase in the future. One quantified example of disaster debris originated from the 2011 Japanese tsunami that washed out 3.6 mmt of debris, with 0.91 mmt floating across the Pacific Ocean and portions of it reaching the western shores of North America (NOAA 2013).

2.2.2 Pesticide Pollution

Municipal pesticide pollution has been recognised in non-point source stormwater runoff since the 1960s (Weibel et al. 1966). It is sourced from use in commercial and residential landscaping and wastewater (Sutton et al. 2019). Pesticide use and pollution can be significant in densely populated areas where use is common, but it is often on a smaller scale compared with agriculture use. One study of the Marne River in France determined that urban uses of pesticides were considerably lower (47 tonnes/yr) than agricultural ones (4300 tonnes/yr) (Blanchoud et al. 2007), with similar trends observed in eight urban streams in the United States (Hoffman et al. 2000).

Agricultural pesticides represent a category of human-made or human-appropriated chemicals that are used to prevent, destroy, repel or mitigate any pest, or as a plant regulator, defoliant or desiccant (U.S. Code 1947). Pesticides are categorised based on the target class of organisms they are designed to impact. The most common categories include herbicides, insecticides, fungicides, rodenticides, algaecides and antimicrobials.

The ocean is exposed to pesticides through air, water, soil and biota. The air transports pesticides globally, documented as early as 1968 (Risebrough et al. 1968; Seba and Prospero 1971), and has resulted in detectable levels of pesticides in every part of the biosphere, including in arctic ice (Pućko et al. 2017; Rimondino et al. 2018). Pesticide transport through surface runoff occurs in both the liquid phase, where the pesticide is solubilised in the runoff water, and the solid phase, where the pesticide is bound with soil particles that erode with surface runoff. Both mechanisms transport pesticides from their application sites to the ocean. More areas are likely to face high pesticide pollution risk as global population grows and the climate warms, likely requiring even higher rates of pesticide use for increased agricultural activity and crop pests (Ippolito et al. 2015).

2.2.3 Nutrient Pollution

Untreated sewage carries a large volume of pollutants to the ocean (Islam and Tanaka 2004) and wastewater itself contains a number of pollutants: nutrients, pathogens, plastics, chemicals, pharmaceuticals and other suspended solids. On a volume basis, raw sewage discharge is of most concern where sanitation infrastructure is still developing. For example, in Southeast Asia, more than 600,000 tonnes of nitrogen are discharged annually from the major rivers. These numbers may become further exacerbated as coastal population densities are projected to increase from 77 people per square kilometre (people/km^2) to 115 people/km^2 in 2025 (Nellemann et al. 2008). The global anthropogenic nitrogen (N) load to fresh water systems from both diffuse and point sources in the period 2002–2010 was 32.6 mmt/yr (Mekonnen and Hoekstra 2015), though only a portion of this might reach the ocean.

The accumulated anthropogenic N loads related to gray water footprints in the period 2002–2010 was 13×10^{12} cubic metres per year, with China contributing about 45% to the global total. Twenty-three percent came from domestic point sources and 2% from industrial point sources (Nellemann et al. 2008). From 2002 to 2010, the global total phosphorous (P) load to freshwater systems from the sum of anthropogenic diffuse and point sources was estimated to be 1.47 mmt/yr, though only a portion of this might reach the ocean. About 62% of this total load was from point sources (domestic, industrial) while diffuse sources (agriculture) contributed the remainder. China contributed most to the total global anthropogenic P load, about 30%, followed by India (8%), the United States (7%), and Spain and Brazil (6% each) (Bouwman et al. 2011).

A global indicator of wastewater treatment to inform the SDGs has been recently created: Wastewater treatment was normalised by connections to wastewater systems around the world. The regions with the greatest average scores (i.e. the most comprehensive wastewater treatment) are Europe (66.14 ± 4.97) and North America (50.32 ± 17.42). The Middle East and North Africa (36.45 ± 6.33), East Asia and the Pacific (27.06 ± 6.91), Eastern Europe and Central Asia (18.34 ± 5.40), and Latin America and the Caribbean (11.37 ± 2.51) had scores falling in the middle, with some infrastructure lacking. Sub-Saharan Africa (3.96 ± 1.50) and South Asia (2.33 ± 1.34) have the lowest scores with extensive needs for wastewater treatment improvements (Malik et al. 2015). Even where treatment facilities exist, they may sometimes discharge untreated sewage into waterways and the ocean due to decayed infrastructure, facility malfunctions or heavy rainfall events that overwhelm systems using combined sewers and stormwater drains (known as combined sewer overflows).

Nutrient pollution from agricultural sources comes from using synthetic nitrogen and phosphorus fertilisers and from discharging animal waste into the ocean, either via direct runoff, rivers or disaster events (e.g. hurricanes). Globally, humans increased the application of synthetic nitrogen fertilisers by ninefold and phosphorous fertilisers by threefold between the 1960s and the 2000s (Sutton et al. 2013). The global agricultural system fixed 50–70 Teragrams (Tg) of N biologically, while nearly double that, 120 Tg per year of N, was added as synthetic fertilisers to support the production of crops and grasses as well as feedstock for industrial animal agriculture (Galloway et al. 2008; Herridge et al. 2008). A large share of the human-applied N is lost, including some 40–66 Tg N/yr exported from rivers to the ocean from 2000 to 2010 (Seitzinger et al. 2005, 2010; Voss et al. 2011, 2013). Estimates show an increase in the total N and P exports to coastal waters by almost 20% and over 10%, respectively, from 1970 to 2000 (Seitzinger et al. 2010). Diffuse sources, including agriculture, contributed about 28% of the global total P load to freshwater systems, which eventually lead to the ocean.

Global crop production is often seen as the primary accelerator of N and P cycles. However, the demand for animal feed produced from different crops and by-products of the food industry has rapidly increased in the past century. At present, about 30% of global arable land is used for producing animal feed, probably also involving a similar fraction of fertiliser use to produce crops for human consumption (Steinfeld et al. 2006). In addition, total N and P in animal manure generated by livestock production exceed the global N and P fertiliser use (Mekonnen and Hoekstra 2018). Livestock production has increased rapidly in the past century, with a gradual intensification that has influenced the composition of livestock diets. In general, intensification is accompanied by decreasing dependence on open range feeding in ruminant systems and increasing use of concentrate feeds, mainly feed grains grown with fertiliser and fed to animals at feedlots with concentrated manure to manage.

2.2.4 Antibiotics and Other Pharmaceuticals

Antibiotics and other pharmaceuticals are present in most wastewater both from improper disposal (flushing down sinks or toilets) and from human waste. Where wastewater treatment facilities exist, treatment primarily removes solids and pathogens, but is not typically able to remove pharmaceuticals without advanced treatment (Keen et al. 2014). A rapid increase (up 65% in defined daily doses) of antibiotic use between 2000 and 2015 was seen globally, with the largest increases in lower-middle-income countries where wastewater treatment may be less available (Klein et al. 2018).

Box 5.3 The Impacts of Aquaculture

The four primary discharges to the ocean from ocean-based aquaculture, as identified and quantified by the Global Aquaculture Performance Index, are antibiotics, antifoulants (primarily copper), parasiticides and uneaten feed and faeces, the last of which impacts the biochemical oxygen demand of the water.[a] There are two additional biological impacts—escaped fish and pathogens—that are considered out of scope for this paper. Plastics discharged by aquaculture are presented at the beginning of this section. The relative volume and impacts of these four discharges vary by species, geography and type of aquaculture, with impacts ranging from relatively benign to quite damaging for the marine environment and marine life. The index identified the worst-performing sector as marine finfish in tropical and subtropical water, such as groupers, red drum and cobia, and the worst geography as Asia, with Asian countries holding the lowest 15 spots in the species-country ranking. These countries tended to score particularly poorly on biochemical oxygen demand and use of antibiotics and parasiticides.[b]

2.2.5 Heavy Metals, Persistent Organic Pollutants and Oil and Gas

Urban runoff, especially roadway runoff, is the primary source of heavy metals, POPs and oil and other chemicals from municipal sources, although some of these can also be contained in wastewater. One recent example from China shows road runoff contains significant cadmium, chromium, copper, manganese, nickel, lead and zinc when classifying with a pollution load index, and that roadways have two to six times greater metal concentrations than rooftop runoff (Shajib et al. 2019).

Pollution from industry refers to any discharges of hazardous substances, which may be a result of effluent discharges from manufacturing operations and cleaning equipment and any accidental spills. Industrial activities may generate waste that contains heavy metals, carcinogenic hydrocarbons, dioxins, pesticides, and noxious organic and inorganic substances. Hazardous substances are used to produce electrical equipment, oil and petrochemicals, organic and inorganic chemicals, pesticides and heavy metals (mercury, arsenic, lead, cadmium), and are used by the wood/pulp processing and electroplating industries. Additionally, by-products of industrial processes include toxic dioxins (e.g. $C_4H_4O_2$) produced in the manufacture of certain herbicides and chlorine from paper pulp bleaching. Hazardous materials can be explosive, toxic or carcinogenic, and must be treated and managed appropriately. Like other pollutant pathways already discussed, industrial pollutants can enter the ocean directly through point discharges or by flowing in rivers (water or sediment transport) to the ocean, but may also come from atmospheric deposition as illustrated in a river and estuary source and transport case study of organochlorine compounds by Wu et al. (2016).

Industrial water consumption comprises 22% of global water use (UN-Water 2018). In 2009, industrial water use in Europe and North America was 50% of total water use compared with 4–12% in developing countries, but it is expected to increase by a factor of five in the next 10–20 years in rapidly industrialising countries (UN-Water 2018). As far back as 2002, 160,000 factories were estimated to discharge between 41,000 and 57,000 tonnes of toxic organic chemicals and 68,000 tonnes of toxic metals into coastal waters (UNDP 2002). Globally, 80% of wastewater, including some industrial wastewater, is discharged into the environment without treatment (UN-Water 2018). In the United States, around 60% of coastal rivers and bays had already been degraded by 2006 (UNEP/GPA 2006). The Mediterranean coastline has faced major environmental pressures from industrial development, with wastewater flows from the mineral, chemical and energy sectors (GRID Arendal 2013). Meanwhile, China has discharged approximately 20–25 billion tonnes per year of industrial wastewater since 2000 (Jiang et al. 2014). The real number may be even higher, due to underreporting and a mismatch in both water quality standards and wastewater standards. In 2018, only about 71% of the industrial wastewater was treated in Vietnam—craft villages near Hanoi, for example, were discharging 156,000 cubic metres of water a day into the Red River Delta near the coast (World Bank 2019). The World Bank (2019) also states that treating 22 million cubic metres of wastewater from industrial clusters along the Nhue-Day River could considerably improve coastal water quality. The Ganga River, despite being a sacred river, is heavily polluted by untreated industrial activities. Seven hundred sixty-four units of industry generate 501 million litres of wastewater from tanneries, textile mills, paper, pulp and other sources (India Ministry of Water Resources 2017). The Tiram River in Malaysia had high levels of toxics due to the improper treatment of industrial effluent in 2015 (Asri 2015). Only one-third of Philippine river systems are considered suitable for public water supply due to untreated domestic and industrial wastewater (Asian Development Bank 2009). These polluted rivers stream to the ocean and threaten the coastal resources in the Philippines. Monitoring of fish and macroinvertebrates in Manila Bay, Philippines, showed the content of cadmium, lead and chromium were considerable (Sia Su et al. 2009). Heavy metal pollution for lead and hexavalent chromium had accounted for 99.2% of disease burden from toxic exposure among those in India, Indonesia and the Philippines (Chatham-Stephens et al. 2013). Seawater along the coast of the Korean Peninsula was analysed for heavy metal concentrations three times from 2009 to 2013 and copper and zinc concentrations were found to exceed acceptable standards all three times (Lee et al. 2017). Untreated industrial discharges threaten not only ecosystem services, but potentially billions of people.

Box 5.4 Jakarta Bay Struggles with Industrial Pollution

Jakarta Bay is on the northern coast of Jakarta Metropolitan City, Indonesia. Three large rivers, the Citarum, Ciliwung and Cisadane, flow into Jakarta Bay. These rivers are used by inhabitants as well as industry in the Jakarta, West Java and Banten Provinces. There has been significant anthropogenic impact on the Citarum River dating back to the increase in use of the area for industrial activities in the early 1980s.[a] Septiono et al. (2016) discovered heavy metals—namely cadmium, chromium hexavalent, zinc, mercury, lead and copper—exceeding the national concentration standards in the river. The concentrations of lead and copper in the sediment of Jakarta Bay increased five and nine times, respectively, between 1982 and 2002 (Arifin 2004). In 2006–2007, sampling found that sediment distribution in the estuary of Jakarta Bay consisted mostly of black clay, which is indicative of anthropogenic influences from the Jakarta River Basin.[b] Sampling done from June 2015 to June 2016 showed that around 97,000 debris items entered the bay daily through nine rivers, and about 59% of it was macroplastic,[c] a further stressor on Jakarta Bay.

Thousands of people, such as fishers in North Jakarta and those along the Thousand Islands, depend on the ecosystem goods and services provided by the river. However, the extreme pollution of toxic chemicals, eutrophication and sediment load in the area, as well as overexploitation of marine resources, are threatening coastal communities. Production of the capture fishery sector decreased in the last five years. Fish production continuously declined from about 35,000 tonnes in 1999 to almost 18,000 tonnes in 2002.[d] Jakarta Bay is under stress from both intensive fishing and degraded water quality due to pollution from both land and marine sources. Mercury content in green mussels and arsenic concentrations in green mussels and tuna samples in Jakarta Bay are above the national standard concentrations (1.0 milligram per kilogram),[e] yet the polluted green mussels can be found in local markets. Despite being highly used for food and to support livelihoods, Jakarta Bay is a sea of wastewater and solid waste.

2.2.6 Maritime Pollution

Pollution into the ocean does not arise only from land; the ocean is also impacted by ocean-sourced pollution. Pollution other than plastic (see Sect. 2.1.4 for a discussion of plastic pollution), results from fishing, shipping and transportation, cruises, recreational boating, ocean exploration and other maritime activities. Similar to land-based sources, wastewater and grey water contribute to nutrient and chemical loading in the ocean, and unique to ocean-going vessels, improper management of bilge water can also cause pollution. Sewage and grey water are regulated under MARPOL Annex IV and bilge water under Annex I. Beyond that, oil spills are one of the most evident forms of ocean pollution due to large areas that may be impacted and the visible consequences for seabirds and other marine wildlife (Palinkas et al. 1993). Most maritime oil spills occur due to transportation mishaps or accidents on oil rigs. Less frequently, a sunken vessel or discharge of oil-containing bilge or ballast water may be released. Because of policies by the International Maritime Organization (IMO) and goals to improve safety and reduce environmental risk, the overall trend of oil spills from tankers (not including rigs and platforms) has decreased over time (Kontovas et al. 2010). However, in 2010 BP's Deepwater Horizon oil spill resulted in 4.9 million barrels of oil entering the ocean, the largest oil spill in the history of the petroleum industry; thousands of scientific papers have assessed the impacts of this oil spill since it occurred.

2.3 Compounding Effects of Multiple Pollutants

More than one source and pollutant can cause a complex mix of stressors on the ecosystem and marine life, with sometimes synergistic effects (the impact of the two together is greater than the sum of their individual impacts).

Distinct pollutants may also enter the ocean through similar pathways. The municipal sector, for example, is a source of both plastic waste and wastewater. In general, wastewater also carries all the contaminants of urban stormwater runoff in addition to pollutants in sewage. When municipal infrastructure for handling solid and liquid wastes is lacking, rapid economic development exacerbates pollution. In some cases, open sewage canals are sometimes used to 'manage' wastewater in urban systems, yet solid waste on land washes into these canals and drains into waterways that can lead to the ocean. In other cases, aging infrastructure incapable of handling stormwater leaks both sewage and plastic into waterways from combined sewer overflow events. Just as negative synergies exist, so do positive ones: Waste management of the residual solids from wastewater treatment are often managed within the solid waste management sector, and development of infrastructure to manage biosolids can help properly manage other solid waste, including plastic waste.

The agriculture sector has the highest input of nutrients to the ocean. In one of the largest river basins, the Mississippi River, fertiliser use delivered 64% and 41% of the N and P, respectively, to the Gulf of Mexico. Pasture use delivered another 5% and 38% of the contribution, for a total N and P from agriculture of 70 to 80% of the total (by comparison, urban use is 9 to 11%) (Alexander et al. 2008). The research also found that source reductions on land near large rivers (nearly 1:1) or quickly flowing streams (2:1) had the greatest reduction of overall nutrient loading to the Gulf (Alexander et al. 2008). This means that in large river basins, it is possible to get a nearly kg per kg reduction to the ocean by decreasing fertiliser use and adjusting management of grazelands. Figure 5.2 shows use of N and P on land, as well as all the major watersheds that drain to the ocean.

Box 5.5 Spotlight on Vietnam

Vietnam has a coastline of 3260 km with over 3000 islands and 114 river mouths and estuaries. Due to the rapid rate of population increase, urbanisation and industrialisation, a large amount of pollution has been introduced into the coastal zone in recent decades. The major sources of pollution discharges into the ocean include untreated or incompletely treated effluents from the municipal and industrial sectors, as well as waste from agriculture activities and seaport and tourism activities.

The total amount of domestic wastewater in both urban and rural areas in Vietnam is estimated to be 8.7 million cubic metres per day (million m^3/day).[a] Major pollutants are nutrients, organic matter, suspended solids and nitrogen-containing organic substances. According to the Vietnam Ministry of Construction, the total designed capacity of 39 domestic wastewater treatment plants over the country is approximately 907,950 m^3/day, which covers only 11% of domestic wastewater.[b] In Ha Noi capital and Ho Chi Minh City, the two largest cities in the country, the percentage of all domestic wastewater processed by centralised wastewater treatment plants is 20.6% and 13% of the total wastewater, respectively.[c] By the end of 2016, 344 industrial zones had been established with the amount of industrial wastewater varying in the regions, and 220 industrial zones were in operation of which 86% had a centralised wastewater treatment plant. Only 98 of 620 industrial clusters, or 16%, were designed with a wastewater treatment system—and those treatment systems have been shown to have a number of limitations. In addition, wastewater from handicraft villages also contributes to marine pollution.[d]

Waste from agricultural activities also contributes to marine pollution, especially from the livestock, aquaculture and crop sectors. The estimated livestock solid waste— including nutrients, suspended solids, organic matter, pathogens and pharmaceuticals—was reported to be 47 million tonnes in 2016, of which 40–70% was treated and the rest discharged into lakes, streams and rivers.[e] For instance, 70–90% of the wastewater from one pig farm, comprised of nutrients (nitrogen), minerals, heavy metals and pharmaceuticals, was reported to be excreted into the environment. Aquaculture activities also release a large amount of untreated waste directly into the ocean with high levels of nitrogen and phosphorus. In 2014, more than 10 billion cubic metres of wastewater containing 51,336 metric tonnes of nitrogen and 16,070 metric tonnes of phosphorus in a pangasius fish farm were estimated to be discharged to local canals to eventually end up in the Mekong Delta River.[f]

The use of pesticides and chemical fertilisers in agricultural production is another major source of surface water pollution. Fertilizer use is increasing in Vietnam. From 1983 to 2013, fertiliser consumption increased nearly sevenfold to 26 mmt in 2013, and about 80,000–100,000 tonnes of pesticides, herbicides and fungicides were used from 2012 to 2014.[g] On average, 20–30% of pesticides and chemical fertilisers applied will not be retained by plants and will be washed by rainwater and irrigation water into surface water resources as well as accumulate in the soil and groundwater in the form of residues. In summary, the pollutants released by these activities include, among others, nutrients, organic chemicals, sediments and pesticides, which ultimately end up in the sea of Vietnam. In addition, wastewater is also discharged from ocean-going ships, other maritime facilities, ship building and repair plants, seaports and freight yards and stores.

The two major river basins in Vietnam, the Mekong and the Red River, annually discharge approximately 500 million and 137 billion cubic metres of water into the ocean, respectively.[h] Sediment is discharged from the Mekong alone at a rate of 36 mmt/yr, although this is a decrease from previous estimates since dams are now reducing that transport.[i] However, both of these water and sediment flows can transport pollutants from the anthropogenic activities in the river catchment and coastal areas to the ocean.[j] About 13 mmt of solid waste is mismanaged in Vietnam each year, with 1.8 mmt of that plastic, and an estimated 0.28–0.73 mmt entering the ocean from Vietnam each year.[k]

In Vietnam, not many studies on plastics, including microplastics, have been conducted, although Vietnam is one of the top countries in the world in terms of plastic waste.[k] The plastic industry during 2010–2015 was the third-largest industry in terms of growth, with an annual increase of 16–18% (following the telecommunications and textile industries). The amount of plastic used per capita increased from 3.8 kg/year in 1990 to over 41 kg/year in 2015.[l] Although there are no official statistics on the amount and varieties of plastic in the Vietnamese sea, plastic waste, originating from wastewater and solid waste from the mainland, can enter the ocean through 114 river mouths and estuaries.

Fishing, aquaculture and on-sea activities are also major sources of plastic in the Vietnamese sea. Every day, about 80 tonnes of plastic waste and bags are thrown away in Ho Chi Minh and Ha Noi combined.[m] In Ho Chi Minh, microplastics were found in urban canals with 172,000 to 519,000 items/m^3,n and in the surface water in Can Gio Sea at a rate of 0.176 ± 0.0 items/m^3.[o]

Vietnam is addressing the plastic issue on both the national and regional scales. The government has released a national action plan for marine litter (Government of Vietnam 2020). Regionally, the Lower Mekong Initiative, a multinational partnership among Cambodia, Laos, Myanmar, Thailand, Vietnam and the United States to create integrated subregional cooperation among the five Lower Mekong countries, launched in 2009, is now also working to address plastic contamination upstream before it gets to the ocean.

To more effectively address plastic waste, more research is needed. In particular, research that provides a more complete characterisation of macro and microplastics at sea is needed, as well as further study on effective strategies for managing plastic waste—particularly microplastics (including microbeads).

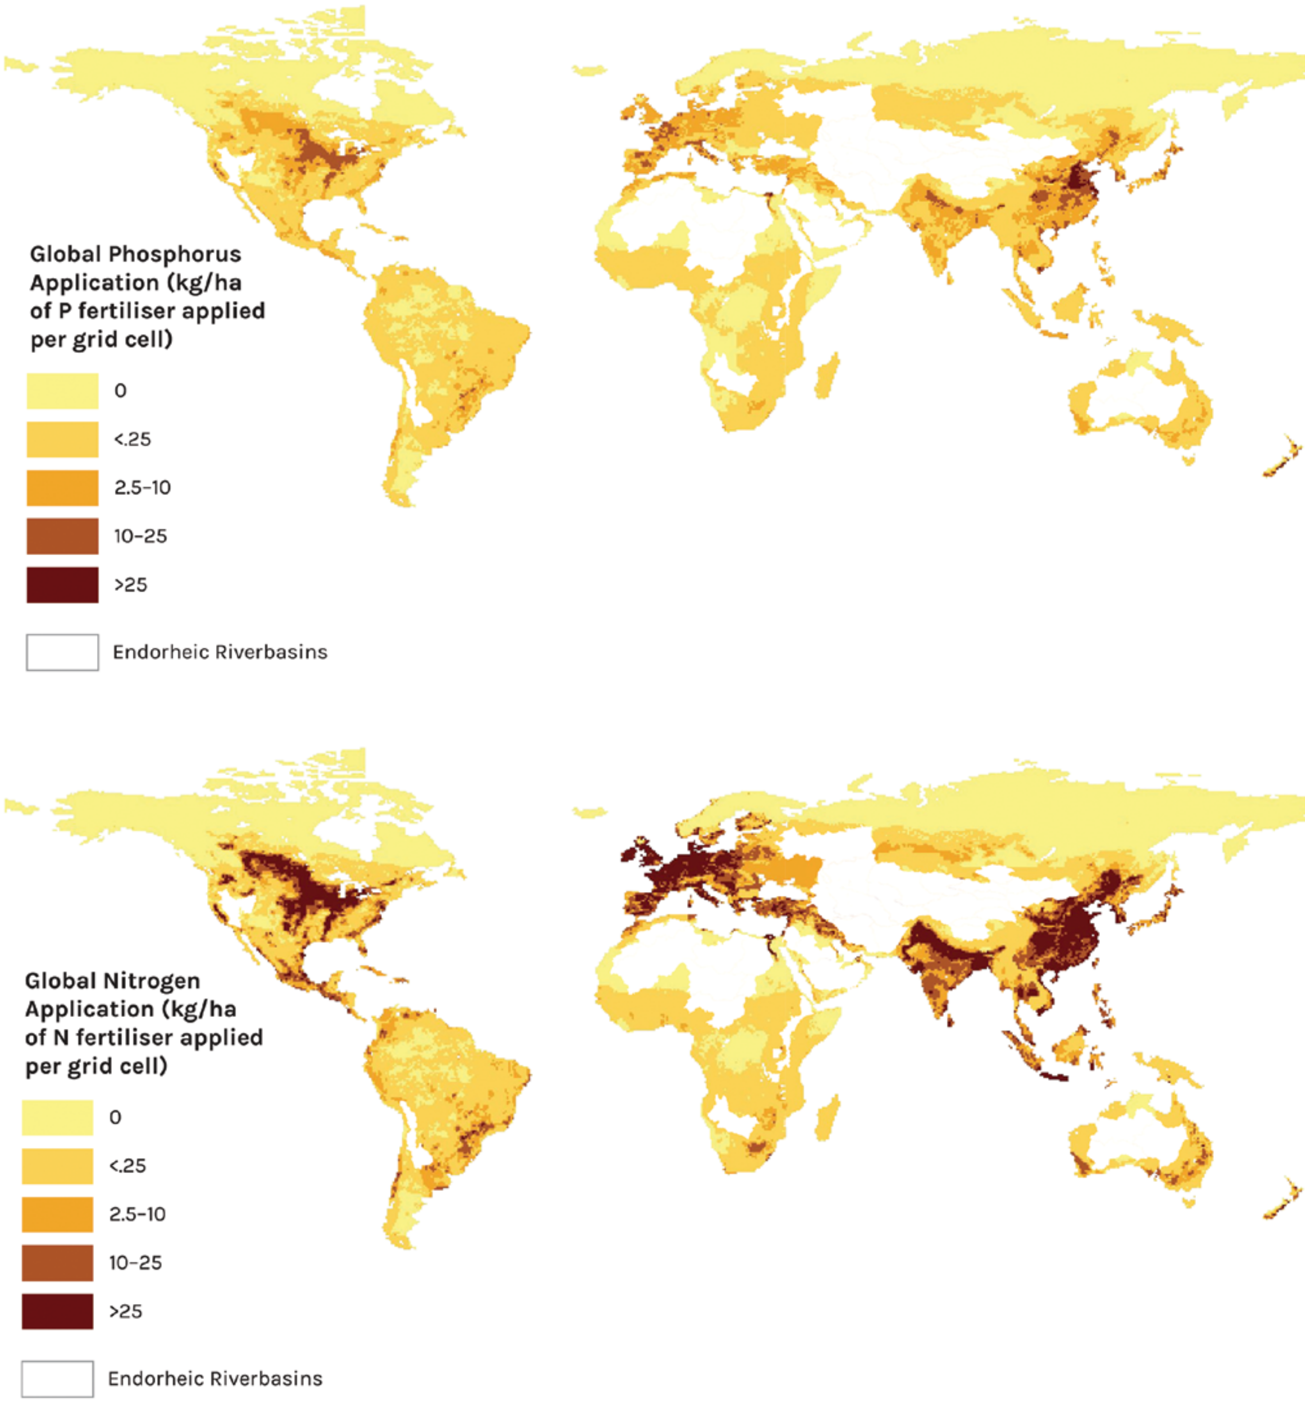

Fig. 5.2 Global Nitrogen and Phosphorous Applications (minus endorheic basins). Notes: These applications could impact the ocean based upon runoff and drainage. Kg/ha stands for kilogram per hectare. N stands for nitrogen, and P for phosphorous. As used here, an endorheic basin is a body of water that has no outflow to other bodies of water, such as rivers or the ocean. [Sources: Potter et al. (2010), Potter et al. (2011a), and Potter et al. (2011b). Map created by A. Brooks]

3 Impacts of Ocean Pollution on Ecosystems, Marine Life, Human Health and Economies

There are a multitude of potential impacts pollutants can have on the ocean, which we have categorised into four types: ecosystem, marine life, human health and economic. See Table 5.2 for a brief outline of these impacts.

3.1 Impacts of Plastic

3.1.1 Impacts on Ecosystems and Marine Life

Microplastics

Microplastics have accumulated across a wide range of environmental compartments including marine, terrestrial and freshwater habitats as well as in the air (SAPEA 2019; Eerkes-Medrano et al. 2015). These areas also include remote

Table 5.2 Potential ecosystem, marine life, human health and economic impacts from ocean pollution

Pollutant	Ecosystem impacts	Marine life impacts	Human health impacts	Economic impacts
Microplastics	• Potential to alter the distribution of sediment dwelling organisms in assemblages • Can provide surface vectors that facilitate the transport of potentially harmful microorganisms	• Negative effects on food consumption, growth, reproduction and survival across a wide range of organisms at the individual level • Starvation (due to ingestion) • Potential of exposure to toxic substances (in or absorbed by plastics) • Trophic transfer	• Unknown impact of ingestion through consumption of marine animals with microplastics in their tissues • Unknown exposure to toxic chemicals due to ingestion • Unknown exposure to pathogens	• Reduction in global marine ecosystem services has been estimated at US $0.5–2.5 trillion[1]
Macroplastics	• Smothering and impact on coral reefs • Transport of invasive species	At the individual level: • Starvation (due to ingestion) • Entanglement • Chemical exposure	• Increase in mosquito-borne diseases • Potential for exposure to pathogens	• Estimated $40 billion in negative externalities annually[2] • Global damage to marine environments from plastic pollution estimated at a minimum $13 billion per year[3] • Aggregated estimates across the plastics life cycle concluded that annual damages from plastic production and the current stock of plastic waste in the ocean amount to $2.2 trillion[4] • Fishermen lose time and efficiency from catching trash in nets • Damage to maritime industries in the APECa region was estimated at $1.26 billion per year[5] • Loss of revenue from tourism, e.g. reducing marine debris by 100% was estimated to improve the savings and welfare of local residents by $148 million over the three-month summer period[6]
Other solid waste	• Additive nutrients to the ocean as source of hypoxia (from organic waste) • Source of heavy metals (e-waste)	• Ingestion, entrapment or entanglement causing impairment or death • Transport of invasive species	• 15 million people worldwide work informally in waste management in poor, unhealthy conditions[7] • Risk of entrapment/ bodily injury • Heavy metal contamination and exposure (e-waste) • Pathogen exposure (medical waste)	• Fishermen lose time and efficiency from catching trash in nets • Debris in water can damage fishing gear and nets • Loss of revenue from tourism

Table 5.2 (continued)

Pollutant	Ecosystem impacts	Marine life impacts	Human health impacts	Economic impacts
Pesticides	• Reduced photosynthetic efficiency of sea grass, corals and algae (herbicides), resulting in chronic stress • Measurable impacts on seagrass productivity, especially when combined with light attenuation from high sediment loads from agricultural runoff • Can restrict or fully inhibit coral settlement and metamorphosis at concentrations as low as one part per billion, and at higher concentrations can cause coral branch death	• Death, cancers tumours and lesions on fish and animals, reproductive inhibition or failure, suppression of immune system, disruption of endocrine system, cellular and molecular damage, teratogenic effects, poor fish health marked by low red to white blood cell ratio, excessive slime on fish scales and gills, intergenerational effects, and other physiological effects such as egg shell thinning[b]	• Toxicity via consumption of marine sumption of marine bioaccumulated or biomagnified pesticides in their tissue. Most at risk are vulnerable populations (children, elderly) in communities with high levels of seafood consumption	• Loss of productivity and resiliency of seagrass beds and coral reefs due to pesticide pollution impacts global economic security by reducing provision of ecosystem services that are essential for human society. While exact level of damage is not known, if we assume a reduction in productivity of these ecosystems by 25%, the annual economic impact of those pesticides in the ocean would be $200 billion per year[8]
Nutrients (N, P)	• Eutrophication and hypoxia • Biodiversity losses • Ecosystem losses	• Fish kills, red tides • Decreases in population and species diversity with benthic and fish communities • Release of ammonia and hydrogen sulfide, which can be toxic to marine life	• Respiratory irritation from harmful algal blooms (HABs), e.g. red tides • Illness from consuming seafood exposed to HABs	• Black Sea fishery value was reduced by 90% (from roughly $2 billion). Other economic impacts included an estimated loss of $500 million in tourism revenue[9] • A major and extensive red tide outbreak occurred along the coast of Hong Kong and south China, covering an area of more than 100 km^2. Over 80% (3400 tonnes) of mariculture fish were killed, and the total loss was over $40 million[10] • Major economic impacts on fisheries, aquaculture and tourism
Antibiotics, parasiticides, other pharmaceuticals	• The occurrence of subtherapeutic doses of antibiotics on bacteria over a prolonged period leads to resistance, which is a threat to the environment	• The occurrence of subtherapeutic doses of antibiotics on bacteria over a prolonged period leads to resistance, which is a threat to the environment	• Carcinogenic, mutagenic and re-productive toxicity potential • Endocrine system	• Unknown

(continued)

Table 5.2 (continued)

Pollutant	Ecosystem impacts	Marine life impacts	Human health impacts	Economic impacts
Heavy metals	• Toxicity to some micro-organisms and animals, cancer in animals, uptake by plants	• Increase in the permeability of the cell membrane in phytoplankton and other marine algae, leading to the loss of intracellular constituents and, therefore, cellular integrity • These include lymphocytic infiltration, lesions and fatty degeneration • In addition, cadmium, lead and mercury are potential immunosuppressants; of concern is the buildup of mercury, which marine mammals tend to accumulate in the liver	• Acute toxicity at high doses, chronic toxicity, cancer, impacts to the nervous system and behaviour (especially lead)	• Unknown
Industrial chemicals and persistent organic pollutants[c]	• Food chain interactions, birth defects, cancer, accumulation and transformations in the environment	• Abnormal behaviour, birth defects in fish, birds, mammals • Biomagnification in the food chain	• Reproductive, developmental, behavioural, neurologic, endocrine, and immunologic adverse health effects	• Unknown
Oil and gas	• Coat and smother benthic areas	• Death • Negative impacts on reproductive health • Carcinomas and papillomas on the lips of bottom-feeding fish, as well as changes in the cell membrane • Severe eye irritation with subsequent blindness in seals • Individual birds become unable to swim or fly and nervous system abnormalities can occur • Population-level effects of oil toxicity on aquatic birds occur through the loss of egg viability	• Localised health impacts from immediate exposure, potential for longer-term impacts from exposure, e.g. cancer, mental health issues if fisheries and livelihoods are impacted	• BP's Deepwater Horizon spill in the Gulf of Mexico is estimated to have cost the company $61.6 billion in penalties and fines; cleanup and remediation; and payments to affected companies, communities and individuals[11] • The 'true' cost of the 2010 Deepwater Horizon oil spill including loss of tourism, cost of cleanup, and loss of fisheries is estimated to be $144.89 billion[12]

Notes: Pathogens present in human and animal waste discharged to the ocean can infect marine animals, but this is considered out of scope for this analysis

[a]*APEC stands for Asia-Pacific Economic Cooperation.*

[b]*These effects are not necessarily caused solely by exposure to pesticides or other organic contaminants, but may be associated with a combination of environmental stresses such as eutrophication and pathogens.*

locations far from population centres such as in the deep sea (Woodall et al. 2015) and the Arctic (Obbard et al. 2014). There is clear evidence that microplastics are ingested by a wide range of species including marine mammals, birds, fish and small invertebrates at the base of the food chain (Law and Thompson 2014; Lusher 2015). While it has been shown that particles can pass through the digestive system and be excreted, it has also been established that some particles can be retained in the body for several weeks (Browne et al. 2008; Ory et al. 2018). Microplastics can also transfer between prey and predator species within food webs (Watts et al. 2015; Chagnon et al. 2018). Many of the species that have been shown to be contaminated with microplastics are commercially important for human consumption (Lusher et al. 2013).

Laboratory experiments indicate that at high doses ingesting microplastics can induce physical and chemical toxicity (SAPEA 2019). The physical presence of microplastic particles has been shown to have negative effects on food consumption, growth, reproduction and survival across a wide range of organisms, and there is evidence that zooplankton, non-mollusc invertebrates and juvenile fish are particularly sensitive (Cole et al. 2015). For example, a reduction in feeding efficiency has been demonstrated for zooplankton, lugworms and fish. In addition, when ingested, microplastics can transfer potentially harmful chemicals to biota; this can occur as a consequence of the transfer of hydrophobic chemicals from the surrounding water or the release of additive chemicals incorporated at the time of manufacture (Teuten et al. 2007; Tanaka et al. 2013). While the transfer of chemicals by plastics to biota has been demonstrated, it is the dose that determines the poison. In a recent bird feeding experiment, Roman et al. (2019) found that plastic ingestion caused higher frequencies of male reproductive cysts and minor delays in chick growth and sexual maturity, but did not affect ultimate survival or reproductive output. With regard to the transfer of chemicals by plastics from seawater, recent work has shown that other pathways including direct uptake from water and natural foods are likely to be more important pathways than microplastics (Bakir et al. 2016; Koelmans et al. 2016). Less is known about the risks associated with the release of additive chemicals from plastic. Determining the release of additives is particularly challenging since chemical formulations are not typically in the public domain (SAPEA 2019).

Most experimental work on effects has focused on those on individuals, but there is some evidence of wider ecological effects including the potential to alter the distribution of sediment-dwelling organisms in assemblages (Green 2016) and to influence the sinking rates of faecal material to the seabed (Cole et al. 2013). Microplastics also provide a surface that can readily become colonised by microorganisms including pathogens and there are concerns that microplastic particles may therefore provide vectors facilitating the transport of potentially harmful microorganisms (Zettler et al. 2013; Kirstein et al. 2016).

Plastic is rapidly colonised by microorganisms in a marine environment (Harrison et al. 2014). Plastic surface habitat has even been defined as the 'plastisphere' in recognition of the unique communities it harbours (Zettler et al. 2013). In fact, litter items made with many materials appear to have unique biofilm communities (Woodall et al. 2018). These communities include potentially harmful pathogens such as *Vibrio* spp. (Kirstein et al. 2016) and *E. coli* (Rodrigues et al. 2019) and are known to colonise the surfaces of submerged plastic surfaces, similar to how they colonise other hard submerged surfaces (Shikuma and Hadfield 2010). A submerged plastic cup laid on a seagrass meadow can serve as a home for more than 500 individual meiofauna, which potentially affects meiofauna community structure (Susetiono 2019). These communities might also impact biogeochemical cycles (Cornejo-D'Ottone et al. 2020).

It is important to recognise that most studies of physical and particle toxicity have been conducted using concentrations and/or particle sizes that are not typical of those currently recorded in the environment (Lenz et al. 2016). There are challenges since environmental concentrations are not known with confidence, especially for particles smaller than 300 μm, which are less likely to be collected from water using conventional net sampling. Plastics can fragment because of environmental exposure and so the abundance of very small particles in the nano-size range could be considerable. These particles are currently too small to detect in environmental samples, but laboratory studies show the potential for these particles to transfer from the gut to the circulatory system with the potential to rapidly become widely distributed in organisms (Brandelli 2020). More work is needed to understand the potential toxicological impacts of this. Despite the uncertainties about environmental concentrations in relation to evidence of harm, there is some consensus based on risk assessment approaches that if microplastic emissions to the environment remain the same or increase the ecological risk may become widespread within a century (SAPEA 2019).

Macroplastics

To date, around 700 species of marine life have been demonstrated to interact with plastic (Gall and Thompson 2015), with the main impacts occurring through entanglement, ingestion and chemical contamination (Wilcox et al. 2015). Far more is known about harm to individuals through interaction with plastic than is known about harm to populations, species and ecosystems within the marine environment (Rochman 2015).

Entanglement in Plastic Debris

Impacts on marine systems from entanglement are most commonly associated with abandoned, lost, or derelict fishing gear. Called 'ghost fishing', derelict fishing nets can continue to indiscriminately catch fish (and other marine organisms) for weeks, months or decades, which, in addition to impacting ecosystems and marine life, results in food security issues through lost resources to feed the world's population (and the associated economic consequences of lost revenue). With an estimated 640,000 tonnes of gear lost to the ocean each year per a census taken a decade ago (Macfadyen et al. 2009), some areas have reported up to three tonnes of derelict nets per kilometre of coastline in a given year (Wilcox et al. 2013). Derelict nets have been reported to ensnare or entangle invertebrates, crabs, fish, sharks, rays, sawfish, turtles, seabirds, crocodiles, dugongs, whales, dolphins and numerous other marine taxa. Ghost nets can also damage fragile habitats (such as by smothering or breaking coral reefs (Sheavly and Register 2007), entangle propellers, cause navigation hazards to other vessels (Gunn et al. 2010; Hong et al. 2017) and transport invasive species (Macfadyen et al. 2009). Impacts can be substantial—it has been estimated that in the Gulf of Carpentaria in northern Australia alone, derelict nets have likely entangled more than 10,000 sea turtles (Wilcox et al. 2013).

Ingestion of Plastic Debris

There are numerous demonstrated effects of plastic ingestion by marine fauna. These may include not only death (van Franeker 1985; Schuyler et al. 2012; Wilcox et al. 2015) but also reduction in body mass (Schuyler et al. 2012), starvation that may result from the physical blockage of the gut (van Franeker 1985; Laist 1987; Acampora et al. 2014; Hardesty et al. 2015), ulceration or perforation of the digestive tract (van Franeker 1985; Laist 1987; Schuyler et al. 2012) and potential toxicity due to sorption of chemicals contained within and sorbed to the plastic (Teuten et al. 2009). In some studies, incidence of plastic ingestion was as high as 60–80% or more of individuals sampled [crustaceans as reported by Murray and Cowie (2011); green turtles in Brazil as reported by Bugoni et al. (2001) and deep sea species as reported by Jamieson et al. (2019)].

Chemical Contamination from Plastic Debris

At present, far less is known and understood about the effects of chemical contamination (which takes place through ingesting plastic) than impacts from entanglement. In laboratory experiments, it has been demonstrated that ingested plastic can induce hepatic stress in fish (Rochman et al. 2013). Plasticisers (softening and other chemical agents such as dibutyl phthalate and diethylhexyl phthalate that are often added to plastics) have been detected in the preen gland oil of wild-caught seabirds, with higher levels of plasticisers found in birds that had eaten more plastic pieces (Hardesty et al. 2015). Polystyrene, heavily used in fisheries and aquaculture, is also of particular concern, as styrenes have been shown to leach into marine systems (Kwon et al. 2015). Jamieson et al. (2019) found plastics in animals in some of the deepest parts of the ocean. Endocrine-disrupting compounds leaching into tissues from plastics are of increasing concern, not only for wildlife (Olivares-Rubio et al. 2015), but also for humans (Meeker et al. 2009; Halden 2010).

3.1.2 Human Health Impacts

The risk of marine plastic debris to human health can be measured by the likely exposure of humans to marine plastic multiplied by the potential for harm by the plastic. This is not a simple equation, as plastics comprise many and diverse chemical additives in addition to their primary polymer component. The limitless combinations of polymers and additives mean that each plastic product has a different combination of chemicals, uses and disposal pathways with varying levels of risk to humans. As a result, plastics should not be treated as a single product, and need to be addressed separately (Lithner et al. 2011). To understand the risk, potential exposure should be identified and quantified, and the potential for harm, including from factors such as the concentration of chemical additives, size fraction (Smith et al. 2018) and ageing (Kedzierski et al. 2018), should also be determined. Because there are so many confounding variables and ethical issues, and a lack of a control group, studying human exposure to various plastic materials and forms is challenging. This section outlines exposure pathways, but without reliable measures for all exposure pathways (pre and post waste) it is not possible to calculate the relative risk of plastic waste on human health.

Humans have been exposed to plastics and their constituent components since they were first mass produced in the 1940s and 1950s. The growing use of plastics in primary food packaging has resulted in increased exposure to them over recent years, and the increased waste has resulted in more plastic entering the environment (Jambeck et al. 2015). Consequently, a host of recent studies have reported microplastics found in nonmarine foodstuffs—e.g. honey (Liebezeit and Liebezeit 2013), beer (Liebezeit and Liebezeit 2014) and seafood (Rochman et al. 2015)—and the air (Dris et al. 2016). However, realistic measures of humans' exposure to plastics have neither been taken nor modelled (Koelmans et al. 2017).

Potential Pathways of Harm

Ingestion

A recent review (Wright and Kelly 2017) concluded that toxicity from chemical constituents could occur via leaching from plastics ingested by eating seafood, and this also could result in the chronic exposure of some chemicals due to the bioaccumulation of toxins in tissues. It is known that additives such as plasticisers (e.g. phthalates) and bisphenol (BPA) can cause harm directly or from their breakdown products. For example, BPA, which has received the most interest to date, can migrate out of polycarbonate to contaminate food and drink products (Guart et al. 2013). Once internalised, this chemical interacts with hormone receptors, resulting in a complex bodily response (Koch and Calafat 2009). Plastics are also known to adsorb persistent organic pollutants and heavy metals once they have become waste in the natural environment. With a larger surface area–to–volume ratio, microplastics can act as a conduit and/or sink for these chemicals, and hence can transport them into humans through ingestion. Physical interactions between internal tissues and microplastics may also be problematic. Smaller particles have been flagged as the most concerning (reviewed in Galloway 2015), but, again, knowledge gaps mean the potential for harm is unknown.

Inhalation

Inhaling fibrous material is known to be hazardous to human health at high concentrations; consequently, this type of exposure has been monitored by industry for many years. These studies have shown that fibres (natural and synthetic), once inhaled, can cause chronic irritation and inflammation (reviewed by Prata 2018). The harm caused at the exposure level generally found in the environment is unknown.

Littering and Human Health

The connection between human well-being and ocean proximity has only recently been investigated, and studies have revealed that coastal proximity and blue spaces positively affect well-being (Wheeler et al. 2012; White et al. 2010). However, beach litter and microplastics are considered a risk to well-being (Gollan et al. 2019), and are one of the biggest threats to the benefits local communities receive from the marine estate. Litter can undermine the positive effects of a coastal estate and inhibit beach use (Wyles et al. 2016; Rangel-Buitrago et al. 2018), potentially reducing enjoyment outdoors and exercise, both of which are known to positively affect mental and physical health (Gladwell et al. 2013). As society begins to better recognise mental health challenges, this is an area that requires more research as it could be the most important influence marine plastic has on human health.

3.1.3 Economic Impacts

Plastic pollution in the ocean also has broad economic consequences. All sectors of the economy use plastic, and, across sectors, plastic waste is generated in near proportion to the level of use (Lin and Nakamura 2019). The full life cycle cost of plastics is not reflected in the pricing of plastic products (Oosterhuis et al. 2014). Plastic production is therefore not a fully costed system. Instead, the economic costs of plastic pollution are predominantly borne by the environment and by society (United Nations Environment Assembly of the United Nations Environment Programme 2017; Forrest et al. 2019).

The costs of plastic pollution can be broadly divided into two categories: direct and indirect. The direct costs of plastic pollution include prevention (e.g. environmentally sound waste management, awareness-raising, behaviour change campaigns), remediation (e.g. beach grading, fishing-for-litter programmes) and direct damage (e.g. lost productivity from fish mortality or reduced ecosystem services, repairs to equipment). The indirect costs of plastic pollution have proven difficult to quantify, partly due to differences in the values held by individuals (such as the importance of a clean beach), but also due to the challenges in placing an economic value on a healthy environment. Irrespective of the categorisation and estimation methodologies, the above direct and indirect costs are 'avoidable costs' (McIlgorm et al. 2008).

Direct and Indirect Costs of Plastic Pollution

The impact of plastic not being a fully costed system is highlighted by the particularly problematic plastic packaging sector. It produces a conservatively estimated \$40 billion annually in negative externalities, such as degradation of natural systems and greenhouse gas emissions, outstripping the profits of the sector (Ellen MacArthur Foundation et al. 2016). Including plastic products, the total environmental cost in 2015 to society from plastics was estimated to be over \$139 billion, which equated to nearly 20% of revenues in the plastic manufacturing sector (Lord et al. 2016).

The UN Environment Programme has estimated the global damage to marine environments from plastic pollution to be a minimum of \$13 billion per year (UNEP 2014). Moving beyond damage costs to the environment, the reduction in global marine ecosystem services has been estimated at \$0.5–2.5 trillion, based on 2011 stocks of marine plastic pollution (Beaumont et al. 2019). Forrest et al. (2019) aggregated estimates across the plastics life cycle to conclude that annual damages from plastic production and the current stock of plastic waste in the ocean amount to \$2.2 trillion. The European Parliament's new measures to regulate single-use plastics cite benefits including avoiding the emission of 3.4 million tonnes of carbon dioxide equivalent and environmental damages equivalent to €22 billion by 2030, as well as an estimated savings to consumers of €6.5 billion (European Commission 2019).

Marine litter and plastics in particular both originate mainly from sea-based and coastal activities (fishing, aquaculture, tourism, shipping) and can, in turn, significantly impact these economic sectors (Newman et al. 2015; Krelling et al. 2017). For example, fishermen report nets fouled with plastic litter (Wiber et al. 2012; Brennan and Portman 2017) sometimes even reaching levels that cause them to move to areas less polluted with plastic litter (Nash 1992). Litter accumulating in the net may also affect the efficiency of the nets (Eryaşar et al. 2014). Fishermen lose time cleaning litter out of nets but surprisingly then dump the same litter overboard (Neves et al. 2015). Similar to cultured species, commercially caught fish may have ingested microplastics (see, for example, Rochman et al. 2015), which could affect the

health of the fisheries and, eventually, the economic value of the catches.
Aquaculture may suffer from marine litter through fouled holding cages and health risks to the cultured species, which may ingest small microplastics. There is special concern regarding cultured bivalves, which have been shown to contain microplastics in their tissues in several independent studies (De Witte et al. 2014; Van Cauwenberghe and Janssen 2014; Davidson and Dudas 2016; Li et al. 2016, 2018a,b; Naji et al. 2018; Phuong et al. 2018; Cho et al. 2019; Teng et al. 2019). While this is of concern for consumers, there are other sources of microplastic ingestion (e.g. from air on food) that might far exceed those taken up by bivalves (Catarino et al. 2018). Interestingly, ingesting small microplastics (between 1 and 10 μm) by oyster larvae had no effect on the survival or growth of those larvae (Cole et al. 2015), but a similar study on mussel larvae showed detrimental effects of microplastic ingestion (Rist et al. 2018).

There is also concern of trophic transfer of microplastics (Nelms et al. 2018), but a recent study suggested that large predators rapidly egest microplastics taken up with their small prey organisms (Chagnon et al. 2018). Commercially important crustaceans can contain large numbers of microplastics, but it is suggested that they significantly reduce their accumulated microplastic load during moulting (Welden and Cowie 2016). In addition, the risk of ingesting microplastics is reduced when the gut is removed (such as those of fish, crustaceans and most other species) prior to consumption by humans (Lusher et al. 2017).

Shipping can be severely impacted as vessels can get entangled with marine litter, causing high risk of damage to the ships and injury to mariners and travellers (Newman et al. 2015; Hong et al. 2017). These risks might be exacerbated in harbour waters where the same structures that protect the harbour from wave exposure accumulate large quantities of marine litter (Aguilera et al. 2016), including fishing lines (Farias et al. 2018), which ships can become entangled in.

McIlgorm et al. (2008) estimated damage to maritime industries in the Asia-Pacific Economic Cooperation (APEC) region to be $1.26 billion per year in 2008 terms. For comparison, the gross domestic product for this same region of 21 member countries was $29 billion in 2008 (McIlgorm et al. 2008). McIlgorm et al. (2020) have updated these numbers, now estimating $10.8 billion in damage per year to industries in the marine economy attributable to marine debris. This is eight times greater than the previous estimate due to improved data, growth in the marine economy and an increase in the amount of plastic in the ocean over that time. By 2050, this damage is projected to be $216 billion (McIlgorm et al. 2020).

Beach litter may cause annoyance among beach visitors (Schuhmann et al. 2016; Brouwer et al. 2017; Shen et al. 2019) or even induce people to abandon a heavily littered beach (Krelling et al. 2017) and travel to more distant, cleaner beaches (Leggett et al. 2014). A study in South Korea showed that following a litter event (rains flushing inland litter onto coastal beaches) visitor numbers decreased dramatically; the authors estimated income losses of millions of dollars (Jang et al. 2014a). On tourist beaches, large amounts of litter are removed daily (Williams et al. 2016), incurring substantial costs for local municipalities (de Araújo and Costa 2006). Interestingly, several studies show that people would be willing to pay to visit beaches if they were cleaned (Brouwer et al. 2017; Shen et al. 2019). Besides the impact on the aesthetic value of beaches (Rangel-Buitrago et al. 2018), litter can also pose a health risk to visitors (Campbell et al. 2016), especially to young children (Campbell et al. 2019).

In California, modelling indicated that a 25% reduction in marine debris on all 31 of its beaches would improve the welfare of local residents by $32 million over three summer months by improving the welfare value of beach visits by residents and increasing the number of visits made. Improving marine debris reduction to 100% raised the savings to $148 million for the same period (Leggett et al. 2014). The chemical burden and disease cost of endocrine-disrupting chemicals within the European Union has been estimated at €119 billion (Trasande et al. 2015), of which some daily contact is likely via plastics (Feldman 1997; Magliano and Lyons 2013). The environmental costs of marine plastic pollution are not fully understood. The concern, however, is of such gravity that the issue is now being considered within the realm of a planetary boundary threat (Villarrubia-Gómez et al. 2018).

3.2 Impacts of Other Solid Waste

Inadequate waste collection and uncontrolled dumping or burning of solid waste still occurs around the world, but primarily where waste infrastructure is lacking, often in low- and middle-income countries (Kaza et al. 2018). This other waste includes all other municipal waste, medical waste, e-waste and disaster debris, and mismanagement of it has a range of impacts. Inadequate sanitation and mismanagement of organic waste and medical waste can cause exposure to pathogens and disease, and e-waste mismanagement results in the release of heavy metals into the environment. For example, the plastic used to house wires and cases is often open burned where informal processing takes place, releasing dioxin, particulate matter and heavy metals into the air (Asante et al. 2019).

3.2.1 Impacts on Ecosystems and Marine Life

Leachate (liquid that accumulates from waste containing organic compounds as well as heavy metals and POPs) can drain directly into the ocean (depending on the proximity of the waste) or into rivers, groundwater and the soil (Yadav et al. 2019), further contributing to ocean pollution. Organic waste from garbage can also contribute to nutrient loading in waterways and the ocean, and the open burning of solid waste gives off particulate matter and emissions (Wiedinmyer et al. 2014) that can contribute to atmospheric deposition into the marine ecosystem. According to the International Solid Waste Association, greenhouse gas emissions across the economy—which indirectly impact the ocean through climate change effects—can be reduced by 15–20% with improved global waste management (UNEP 2015).

3.2.2 Human Health Impacts

Inadequate waste management, especially open burning and dumping, around the world produces pollution (Vasanthi et al. 2008; Wiedinmyer et al. 2014) that can impact people living near management facilities and those working directly with solid waste. About 15 million people globally, often called waste pickers (who include men, women, children, migrants and the underemployed), work informally in the waste sector (Medina 2008). In China alone, it is estimated that 3.3 to 5.6 million people work informally in the recycling of solid waste (Linzner and Salhofer 2014), and Forrest et al. (2019) acknowledge the millions of people working in poor conditions for little money in jobs that would not qualify as decent work by the International Labour Organization. While these issues must be addressed, it is also important to recognise that waste and plastic management constitute the livelihoods of millions of people. Any interventions used to address plastic and other waste must incorporate the views and participation of informal workers, and especially waste pickers, so that millions of people aren't negatively impacted through the unintended consequences of 'traditional' infrastructure, such as eliminating a crucial source of income (Dias 2016). Women can be disproportionately harmed by the formalisation of waste management, as they are typically excluded from formal employment in the formalized sector. But they can be helped through inclusive improved recycling operations, capacity building, provision of equipment, formal training and awareness building, financial assistance and health insurance since they have high levels of participation in the informal sector but often have less access to these kinds of benefits (Krishnan and Backer 2019).

3.2.3 Economic Impacts

While there are global data on the cost of plastic pollution (see Sect. 3.1, Impacts of Plastic), there is not a global number for the cost of mismanaged waste. The World Bank estimates that proper waste management infrastructure would cost $50–100 per metric tonne (Kaza et al. 2018), which is in the same range as tipping fees charged for municipal solid waste disposal in the United States. In Palau, where the ocean is extremely important to the economy, the cost of waste-related pollution, or mismanaged waste (not the cost of waste management which is estimated at $87 per tonne), was estimated at be $1.9 million per year, which is 1.6% of the country's gross domestic product and equates to an annual cost of $510 per household (Hajkowicz et al. 2005).

3.3 Impacts of Pesticides

Pesticide mixtures include active and inert ingredients; both are important, as the active ingredient is the toxicant for the target organism, and the inert ingredient often amplifies the exposure mechanism. For example, an herbicide with an active ingredient might be mixed with an inert ingredient that is water soluble to more effectively penetrate soil, while the same active ingredient can be mixed with a non-water-soluble oil to more effectively penetrate the leaf. The same active ingredient can have different toxic effects on the target organisms, and potential environmental effects, based on the carrier or inert ingredient. In the United States, only the active ingredients must be disclosed in pesticide labelling, making impact assessments very difficult to conduct.

Pesticides are very effective at improving the efficiency of agricultural production by reducing crop and animal losses. However, there are risks associated with pesticide applications to nontarget organisms. Nontarget organisms include the people who apply the pesticides, process the products and consume the products. There are also risks to nontarget organisms in the fields and paddocks where these pesticides are applied. Broad spectrum insecticides kill desirable insects such as pollinators and the biological predators of undesirable insects. Some pesticides persist in the environment and move through the food chain, resulting in toxic impacts on nontarget organisms including song birds, raptors, rodents, reptiles and fish (UNEP 2019).

3.3.1 Impacts on Ecosystems and Marine Life

Pesticides that reach the ocean can impact nontarget organisms in several ways, depending on the active ingredient pesticide category, inert ingredient mediator, transport mechanism and depositional environment. The toxic impact of pesticides is generally proportional to the concentration, so very low concentrations often have very low impacts. However, pesticides can be bioconcentrated and biomagnified through the food chain to result in cumulatively higher impacts on predators and scavengers (including humans). Bioconcentration is the process of uptake of a chemical by an organism from the abiotic environment, resulting in higher concentrations in that organism than in the environment (LeBlanc 1995). Bioconcentration of pesticides occurs when the active ingredient persists in the environment long enough to be ingested by an organism such as krill, where it is either metabolised, excreted or stored in fatty tissues (Cincinelli et al. 2009). The pesticides that are stored in fatty tissues can persist through many cycles of ingestion, and thus accumulate in the organism. Biomagnification is the process whereby the amount of the pesticide is amplified up the food chain, and the active ingredient can be concentrated in the fatty tissues of top predators such as swordfish, sharks and tuna. These concentrations can be amplified over 1000-fold through this process. Most modern pesticides have been designed to not persist in the environment, and thus are less prone to bioconcentration. However, early twentieth-century pesticides, which are banned in Europe and the United States but are still manufactured and used in many countries, can last over 100 years in the environment and are very prone to bioconcentration and biomagnification (Dromard et al. 2018). In general, organochlorine pesticides (OCPs), which were developed in the early-to-mid twentieth century, are the world's most persistent legacy pollutants in the ocean. These include dichlorodiphenyltrichloroethanes (DDTs), hexachlorocyclohexanes, heptachlor, aldrin, alpha and beta-endosulfans, dieldrin, endrin, endrin aldehyde, endrin ketone, methoxychlor, endosulfan sulfate and heptachlor epoxide (Guo et al. 2007).

Pesticides have been documented to reduce the photosynthetic efficiency of sea grass, corals and algae (herbicides), resulting in chronic stress (Brodie et al. 2017). Certain herbicides in common use, including Diuron, Atrazine, Hexazinone and Tebuthiuron, have been shown to have measurable impacts on seagrass productivity, especially when combined with light attenuation from high sediment loads from agricultural runoff (Flores et al. 2013). Seagrass beds are critical habitats for many marine species and support global fisheries. Insecticides, including organophosphates, organochlorines, carbamates and pyrethroids, as well as fungicides, have been shown to restrict to fully inhibit coral settlement and metamorphosis at concentrations as low as one part per billion (Markey et al. 2007). Concentrations just ten times that amount have caused coral branch death. These concentrations are at or below detection levels for conventional laboratory analyses, rendering these pesticides virtually invisible to investigators.

3.3.2 Human Health Impacts

The primary exposure mechanism to humans from ocean-borne pesticides is through ingestion of species that biomagnify those pollutants. The most common pesticides found in seafood at concentrations above background levels are OCPs. Communities whose diets are seafood-based are most at risk given their higher rates of fish consumption. Consuming fatty piscivores such as hairtail, mackerel and tuna in South Korea was shown to increase exposure of vulnerable populations (children and elderly) to increased OCPs (Moon et al. 2009). In general, these pesticide concentrations are below chronic toxicity levels for most people (Smith and Gangolli 2002). Toxicants of concern in fish from biomagnification include heavy metals (mercury, cadmium and lead—see Sect. 3.7 on heavy metals), and legacy organochlorines from industry such as polychlorinated biphenyls (PCBs) (Storelli 2008).

3.3.3 Economic Impacts

The economic impacts of pesticides in the ocean are largely through decreased productivity rather than human toxicity. The loss of productivity and resiliency of seagrass beds and coral reefs is having a significant impact on global economic security. These critical ecosystems provide a portfolio of ecosystem services that are essential for human society, including the provision of food, water, energy and other resources, and tourism. The estimated net present value for 2050 of Earth's coral reefs was almost $800 billion (Cesar et al. 2003). If pesticides are reducing the productivity of these ecosystems by only 25%, the annual economic impact of those pesticides in the ocean would still be $200 billion per year. These critical ecosystems are also stressed by other pollutants, sediment and climate change. Some estimates suggest that under a high greenhouse gas emissions scenario, more than 90% of coral reef communities would be lost by 2100 (Speers et al. 2016). Cumulatively, these pose imminent threats to Earth's ocean ecosystems.

3.4 Impacts of Nutrient Pollution

3.4.1 Impacts on Ecosystems and Marine Life

Nutrient pollution, which occurs when anthropogenic sources of primarily N and P are discharged into marine systems, leads to eutrophication, algal blooms, dead zones and fish kills in freshwater and coastal waters. Scientists have estimated that about 80% of large marine ecosystems in the world already suffer from serious eutrophication, hypoxia and anoxia in coastal waters (Selman et al. 2008; Diaz et al. 2011; STAP 2011). In addition, related incidences of toxic algal blooms such as 'red tides' have become more frequent (Rabalais 2002). Eutrophication also leads to habitat changes and the loss of species of high value (Heisler et al. 2008).

Many species can be impacted directly or indirectly by nutrients in marine ecosystems as nutrient inputs have altered the abundances and distributions of marine species (e.g. through algal blooms). Eutrophication and oxygen depletion (often referred to as 'dead zones' when affecting a large area) have direct adverse effects on coral reefs, seagrass beds, fish and shellfish (Bouwman et al. 2011). Diaz et al. (2011) identified more than 770 eutrophic and hypoxic coastal systems worldwide, where 70% of the areas had documented hypoxia and almost 30% were developing hypoxia. The dead zone in the Gulf of Mexico resulting from agricultural runoff into the Mississippi River has been studied extensively, but there is less data on these zones in developing countries, so these estimates are likely conservative.

One example of the direct impact of increased nutrients in the ocean is the world's largest macroalgal bloom, which was recorded from 2011 to 2018 (the most recent data available). Using satellite images, (Wang et al. 2019) showed that since 2011, the free-floating mats of brown macroalgae called *Sargassum* spp. have increased both in density and size, generating a long belt of 8880 km extending from West Africa to the Caribbean Sea and Gulf of Mexico. *Sargassum* is a naturally occurring seaweed that provides a critical habitat to a diverse array of species in this ecosystem. However, when the *Sargassum* mats overcrowd the coasts, it can impact the movement of some marine species. When the excess *Sargassum* dies and sinks to the ocean bottom in large quantities, corals and seagrasses can be smothered. On the beach, rotten *Sargassum* releases a strong smell, potentially imposing health challenges for people who have asthma. *Sargassum* blooms and their adverse effects could reduce the number of tourists during a bloom. For example, in 2018, Barbados had to declare a national emergency because of a bloom.

The ocean is becoming more stratified, and while there is still some discussion over coastal marine ecosystems being N- or P-limited, (Elser et al. 2007) found that, for coastal systems, N and P limitations play a similar role, implying that reducing the discharges of both N and P is important for alleviating pollution in coastal areas. This is exactly what was shown by (Beman et al. 2005), who found that areas that are nitrogen deficient were especially vulnerable to nitrogen pollution. They also found that agricultural runoff had a strong and consistent influence on biological processes, stimulating algal blooms 80% of the time within days of fertilisation in the Gulf of California. They then projected that by 2050, 27–59% of all nitrogen fertiliser would be applied in developing regions upstream of nitrogen-deficient marine ecosystems. These ecosystems are especially vulnerable to agricultural runoff and nitrogen pollution impacts (Beman et al. 2005).

3.4.2 Human Health Impacts

Some important drinking water sources (e.g. Lake Erie) cannot be used during algal blooms, as the toxins either increase the cost of treatment or make it impossible to treat. Other human health impacts come from direct or indirect exposure to toxins resulting from algal blooms—for example, a red tide can cause ciguatera poisoning, paralytic shellfish poisoning, neurotoxic shellfish poisoning (NSP), amnesic shellfish poisoning and diarrhetic shellfish poisoning, which are the five most commonly recognised illnesses related to harmful algal blooms (HABs). Exposure to the toxins from HABs is mediated through the consumption of contaminated fish and shellfish, or through exposure to aerosolised NSP toxins near water bodies where a bloom is occurring (Grattan et al. 2016).

3.4.3 Economic Impacts

Attempts to evaluate the monetary impacts of eutrophication have been made over the last two decades. Studies indicate a variety of impacts and costs that are quantifiable fairly directly, for instance, when cities of hundreds of thousands of people are deprived of drinking water for several days. One example is the toxic algal bloom that occurred in the western Lake Erie basin in 2011, which led to a disruption of water supplies for 400,000 people (Watson et al. 2016). In another example, a major and extensive red tide outbreak occurred along the coast of Hong Kong and south China, covering an area of more than 100 km^2. Over 80% (3400 tonnes) of mariculture fish were killed, and the total loss was over $40 million (Yang and Hodgkiss 2004). On the other hand, integrating all the environmental, health and socioeconomic impacts in the calculations of indirect effects poses more of a challenge.

3.5 Impacts of Antibiotics, Parasiticides and Other Pharmaceuticals

3.5.1 Impacts on Ecosystems and Marine Life

Our understanding of the impacts of emerging contaminants is limited to what has been learned by studying specific instances where they have been found and identified; impacts on the overall marine environment are not well-understood. Pharmaceutical substances have been examined worldwide in surface water, groundwater, tap/drinking water, manure, soil and other environmental matrices. (aus der Beek et al. 2016) reviewed 1016 articles and found that pharmaceuticals or their transformation products have been detected in the environment of 71 countries covering all continents. Six hundred thirty-one pharmaceutical substances were found at levels above the detection limit of the respective analytical methods employed. Residues of 16 pharmaceutical substances were detected in each of the five UN regions, and the antibiotic tetracycline was detected in wastewater treatment plant effluents in all UN regions. Regional patterns of pharmaceutical leakage to the environment emerged as well: Antibiotics were most prevalent in Asia, analgesics edged out other pharmaceuticals as most prevalent in Eastern Europe, lipid-lowering drugs were highest in Europe and Latin America, oestrogens were found most in Africa, and the ‘other pharmaceutical’ category was predominant in Western Europe (aus der Beek et al. 2016).

Research presented at the 2019 annual meeting of the Society of Environmental Toxicology and Chemistry found that of the sites monitored, 65% of them contained at least one of the 14 most commonly used antibiotics. These sites were located in rivers in 72 countries across six continents. The concentration of one antibiotic, metronidazole, found by the researchers at a site in Bangladesh was 300 times the ‘safe’ level. (The AMR Industry Alliance recently established ‘safe’ levels of antibiotics in the environment, ranging from 20 to 32,000 nanograms per litre depending on the antibiotic.) Ciprofloxacin, a general antibiotic used to treat various bacterial infections, most frequently exceeded safe levels, surpassing the safety threshold in 51 places.

Geographically, 'safe' limits were most frequently exceeded in Asia and Africa (to the greatest degree in Bangladesh, Kenya, Ghana, Pakistan and Nigeria), but sites in Europe, North America and South America also had levels of concern, showing that antibiotic contamination is a global problem. Sites with the highest risk of contamination were typically adjacent to wastewater treatment systems and waste or sewage dumps and in areas of political turmoil, including the Israeli and Palestinian border (University of York 2019).

Benzophenone-2 (BP-2) is an additive to personal-care products and commercial solutions that protects against the damaging effects of ultraviolet (UV) light. BP-2 is an 'emerging contaminant of concern' that is also often released as a pollutant through municipal and boat/ ship wastewater discharges and landfill leachates, as well as through residential septic fields and unmanaged cesspits. Although BP-2 may be a contaminant on coral reefs, its environmental toxicity to reefs is unknown. This poses a potential management issue, since BP-2 is a known endocrine disruptor as well as a weak genotoxicant (Downs et al. 2014).

There is concern over the impacts of commonly used organic UV filters, including oxybenzone (benzophenone-3), 4-methylbenzylidene camphor, octocrylene and octinoxate (ethylhexyl methoxycinnamate), on the marine environment. Oxybenzone, octocrylene, octinoxate and ethylhexyl salicylate have been identified in water sources around the world, and are not easily removed by wastewater treatment plant techniques (Schneider and Lim 2019). Oxybenzone has been specifically linked to coral reef bleaching. In addition, 4-methylbenzylidene camphor, oxybenzone, octocrylene and octinoxate have been identified in various species of fish worldwide, which has possible consequences for the food chain (Schneider and Lim 2019). Danovaro et al. (2008) found that even low concentrations of sunscreens caused bleaching of corals. The organic UV filter induces the lytic viral cycle in symbiotic zooxanthellae with latent infections. Therefore, sunscreens may be playing an important role in coral bleaching by promoting viral infections in areas with high recreational use by humans (Danovaro et al. 2008).

3.5.2 Human Health Impacts

Wastewater treatment plants are a main source of antibiotics released into the environment. An overabundance of antibiotics in wastewater may generate antibiotic resistance genes and antibiotic resistant bacteria. Some scientists are concerned that wastewater treatment plants are becoming hot spots for resistant genes and bacteria, which has implications for human health should people get infections that are then resistant to typical antibiotics (Rizzo et al. 2013).

3.6 Impacts of Industrial Chemicals Including Persistent Organic Pollutants

3.6.1 Impacts on Ecosystems and Marine Life

Polybrominated diphenyl ethers (PBDEs) and POPs are toxic, are not easily degradable in the environment, bioaccumulate in the food chain and undergo long-range transport (European Environment Agency 2019). Many industrial chemicals and POPs are known to be poisonous and to damage the environment and the organisms living in the affected ecosystems. These pollutants have become distributed throughout the ocean and have been found in seemingly pristine environments. These pollutants also bioaccumulate in marine organisms such as fish and invertebrates such as corals, which can lead to various physiological impairments, varying from subcellular changes such as direct effects on DNA (deoxyribonucleic acid) to metabolic stress (Logan 2007; van Dam et al. 2011).

3.6.2 Human Health Impacts

POPs and PBDEs can cause cancer and toxicity in the liver, kidneys and reproductive system (Qing Li et al. 2006). The main impacts of industrial pollution to human health are derived from making direct contact with contaminated water. The direct contact with polluted water puts people at risk when the toxins are heavy metals. The chemical content in the water, whether carcinogenic or not, may nevertheless play a role in contributing to cancer mortality risk (Hendryx et al. 2012). Bathing in contaminated water increases the risk of respiratory disease and skin problems.

Human consumption of marine organisms that have been contaminated with polluted water is one major impact of industrial pollution on humans. Many of the fish that are a primary food source for the indigenous people in the Canadian Arctic are heavily contaminated by POPs (Dewailly 2006). While some persistent organic pollutants have started to decrease in humans and food in monitored Arctic locations because of international restrictions, levels of oxychlordane, hexachlorobenzene, polybrominated diphenyl ether and perfluorinated compounds are not decreasing (Abass et al. 2018).

Greenland has some of the highest concentrations of POPs in humans in the Arctic—with the exception of PBDEs, Greenland populations had the highest measured levels of POPs than any other Arctic country (Gibson et al. 2016).

3.6.3 Economic Impacts

Studies indicate a variety of economic impacts from industrial pollution. The tangible economic impacts include those that occur during pollution incidents as well as from activities undertaken to prevent, mitigate, manage, clean up or remedy pollution incidents. The global economic cost related to the pollution of coastal waters is $16 billion annually, largely due to human health impacts (UNEP 2006). An additional source of cost is the loss of earnings caused by damage to natural resources. The intangible costs are the loss of marine biodiversity and the provision of other environmental services caused by industrial pollution.

3.7 Impacts of Heavy Metals

3.7.1 Impacts on Ecosystems and Marine Life

Exposure to heavy metals can increase the permeability of the cell membrane in phytoplankton and other marine algae, leading to the loss of intracellular constituents and cellular integrity, and inhibiting metabolism (Sunda 1989; González-Dávila 1995; Hindarti and Larasati 2019). High trace element burdens in marine mammals have been associated with lymphocytic infiltration, lesions and fatty degeneration in bottlenose dolphins, and decreasing nutritional states and lung pathologies in other marine mammals (Siebert et al. 1999). In addition, cadmium, lead and mercury are potential immunosuppressants; of particular concern is the buildup of mercury, which marine mammals tend to accumulate in the liver.

3.7.2 Human Health Impacts

Mercury and Arsenic Methylmercury is a neurotoxic compound responsible for microtubule destruction, mitochondrial damage, lipid peroxidation and accumulation of neurotoxic molecules such as serotonin, aspartate and glutamate (Patrick 2002). Consumption of contaminated aquatic animals is the major route of human exposure to methylmercury (Trasande et al. 2015). Seafood contaminated by heavy metals or metalloids such as mercury and arsenic can contribute to human health risk (Harris et al. 2014; Gao et al. 2018). One unforgettable case was the mass poisoning of people in Minamata, Japan, in the 1950s, when 2252 people were impacted by the contamination and 1043 died (Harada 1995).

Cadmium and Lead Consuming fish containing to cadmium and lead can cause major diseases in humans such as renal failure, liver damage and symptoms of chronic toxicity in the kidney (Bosch et al. 2016; Gao et al. 2016).

Chromium Because of its mutagenic properties, hexavalent chromium is a carcinogen that humans can get exposed to through soils, sediment and surface waters, as well as some fish (Copat et al. 2018; Tseng et al. 2019).

3.7.3 Economic Impacts

Heavy metal pollution results in substantial economic impacts to the fishing sector. Bioaccumulation of metals in fish limits the species that can be safely eaten and the frequency that those fish can be eaten, and as a result can limit imports and exports. For example, in 2006, European Commission Regulation 1881/2006 established the maximum levels for cadmium, lead and mercury in food products. High quantities of heavy metals in fish are one of the principal reasons why fish are detained at EU borders and the main problem that importers from non-EU countries must address. The economic losses deriving from EU border detentions amount to hundreds of millions of euros each year (FAO n.d.).

3.8 Impacts of Oil and Gas

3.8.1 Impacts on Ecosystems and Marine Life

Oil spills tend to disproportionately impact sea birds, which can be harmed and killed by exposure to oil. Individual birds become unable to swim or fly and nervous system abnormalities can occur. Population-level effects of oil toxicity on aquatic birds occur through the loss of egg viability. Because it is inherently poisonous, oil in the marine environment has the potential to harm any creature that comes in contact with it. This includes larger animals such as sea turtles, which are sensitive to chemical exposure at all stages of life and lack an avoidance behaviour, and seals, which can become blind, as well as smaller organisms, such as zooplankton and larval fish. Oil spills, and their associated responses, can be particularly damaging to fragile but vital marine ecosystems such as coral reefs and mangroves, but are believed to damage life throughout the water column. Heavier oils settle and can coat and smother benthic areas. In areas impacted by oil spills, bottom-feeding fish have developed carcinomas and papillomas on their lips, as well as changes in their cell membranes. Spilled oil can persist in the environment, continuing to injure and kill marine life. More research is needed to fully understand the less obvious impacts of oil spills on the marine environment (NOAA OR&R 2019).

3.8.2 Human Health Impacts

A 2016 review article on the human health impacts of oil spills looked at mental health effects; physical and physiological effects; and genotoxicity, immunotoxicity and endocrine toxicity. While there exist a number of obstacles to calculating human health impacts—such as challenges to determining exposure levels and the level of effectiveness of personal protective gear as well as a reliance on self-reported health symptoms and variations in genetic sensitivities to chemical exposure— the authors concluded that there is sufficient evidence to establish a relationship between exposure to oil spills and the development of adverse health effects in exposed individuals (Laffon et al. 2016).

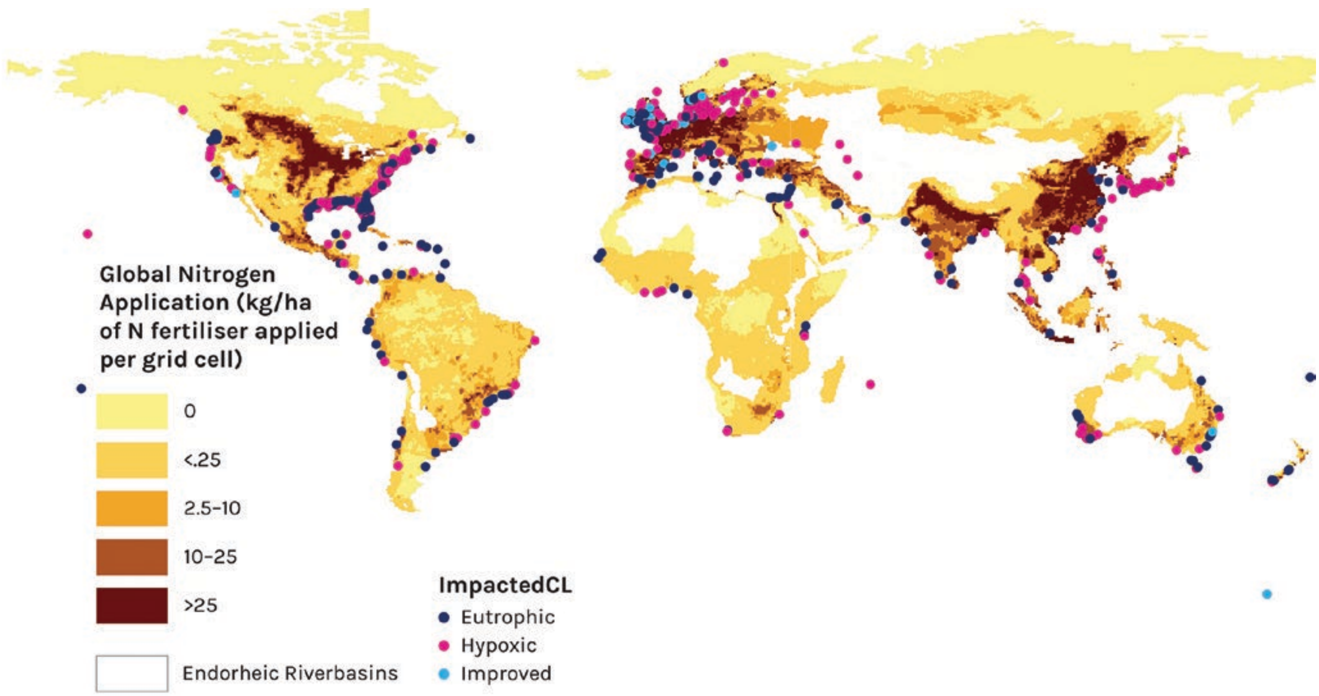

Fig. 5.3 Global nitrogen use and hypoxic areas in the ocean. Note: Mismanaged nitrogen use on land and incidences of eutrophication and hypoxia. [Sources: Data compiled from Potter et al. (2011a) and World Resources Institute (2013). Map created by A. Brooks]

3.8.3 Economic Impacts

Oil spills can be very costly to the responsible companies as well as to the fishing and tourism industries affected by the spill. For example, BP's Deepwater Horizon spill in the Gulf of Mexico is estimated to have cost the company $61.6 billion in penalties and fines; cleanup and remediation; and payments to affected companies, communities and individuals (Mufson 2016). The sinking of the Prestige oil tanker in November 2002 off the coast of Galicia, Spain, resulted in estimated losses to the Galician fishing sector of €76 million by December 2003 (Surís-Regueiro et al. 2007). Kontovas et al. (2010) calculated a per metric tonne cost for oil spills based upon a regression of 38 years of oil spill and cost data—the average value being $4118 per metric tonne in 2009.

3.9 Impacts Summary

3.9.1 Inputs Lead to Impacts

Based upon the literature reviewed for this Blue Paper, it is evident that all pollutants discussed in this report are concerning to our ocean, though some may be more urgent or easier to address than others. In addition, multiple pollutants can act synergistically, creating a greater effect on the ocean than the sum of their individual impacts. Exploring the present and future impacts, as was done in this section, is one way to start to prioritise which pollutants to tackle first. At this moment, the plastic pollution crisis is very salient—the issue is tangible and understandable, and countries around the world are working on solutions because of marine ecosystem and economic impacts. It is also evident from this work that nutrient pollution is of great concern to the ocean. Nutrients contribute to harmful algal blooms and create low-oxygen hypoxic zones and stratification, ultimately impacting the health of marine life and humans. Without changes to either of these two pollutant input systems in a business-as-usual trajectory, the impacts from them will get only worse as populations grow and economies continue to develop. Figure 5.3 provides a global map showing nitrogen use, along with the drainage basins and the impact of this drainage by showing hypoxic areas in the ocean. Urgent action is needed to protect the ocean from further impacts from pollution.

4 Human Dimensions

The issue of pollutants leaking into the ocean is entirely a consequence of human decisions and behaviours. It is determined by individuals, communities, companies and politicians, to name but a few of the actors within the social-environmental system (Pahl and Wyles 2017; SAPEA 2019). These actors have varying perceptions, goals and values that motivate existing practices (and can also be harnessed for change). For example, a farmer might decide to employ a pesticide to increase yield and be willing to accept adverse effects on wildlife. A cosmetics company might decide to replace natural ingredients with plastic microbeads to save money and reduce allergens in their products.

Within the social and behavioural sciences' research on environmental pollution, the focus has been on principles of risk perception and determinants of behaviour (Pahl and Wyles 2017). In other words, how does a person or community decide that a pollutant poses a risk, and what factors motivate behaviour change (including not just individual actions but also demand for legislation and policy change)?

Researchers have found that how experts assess risk is different from how non-experts assess risk (see (Böhm and Tanner 2013). Experts apply scientific methods of risk assessment that focus on specific thresholds or outcomes such as fatalities or concentrations, whereas non-experts judge risk levels using a wide range of factors such as moral evaluation of the issue, perceived fairness, perceived control and positive and negative emotions such as dread and pride. These discrepancies can contribute to conflict between stakeholders. Mental model approaches are useful in this context because they can illustrate different expectations about the sources, pathways and impacts of pollution, which can provide triggers for change. However, it has also been noted that perception of risk in itself is not strongly linked to action, and if too strong, could even undermine action (Peters et al. 2013). However, when the risk is associated with an emergency event such as a natural disaster, this may encourage people to take action, depending on personal agency, community capacity and resilience (Brown and Westaway 2011). It is important to understand risk perception differences among stakeholder groups because they can influence how media reporting is interpreted, and should be taken into consideration when policies and interventions are developed.

Behavioural practices can contribute to pollution but are rarely quantified. For example, the dosage of fertilisers and timing of applications might vary according to practices and knowledge available to farmers, and fine-tuning practices could greatly reduce environmental (and health) impacts. Behaviour is determined by a range of factors beyond mere knowledge. To illustrate, most people understand healthy lifestyles but few eat very healthily and regularly exercise. This is similar in the environmental domain, where knowledge is one factor that can motivate behaviour change, but other factors are more powerful, including perceived control, social approval and moral norms, among others. In addition, contextual factors, such as the accessibility and design of the waste disposal system and availability of materials, are important. For example, if there is no recycling bin nearby, a person needs to have a strong motivation to recycle to put in the extra effort to find one (Pahl and Wyles 2017; SAPEA 2019).

To change perceptions and behaviours, a multipronged approach can target actors individually. Laws, bans and restrictions are powerful tools that can signal a social norm of undesirable behaviour. While outlawing a particular substance can be the most powerful tool, some materials, such as plastics, are so widespread that a simple ban would fall short or could be applied only to certain products. Education and public outreach campaigns are necessary to accompany policy change and are powerful instruments in their own right. Good campaigns build on behavioural science insights and integrate key elements that have been shown to work, e.g. empowering individuals, making specific suggestions for behavioural solutions that are effective and socially acceptable. It is important not to crowd out intrinsic motivation but rather to build on personal norms and values and develop a pro-environmental identity as this could spill over into other domains and behaviours. Effective interventions link to the target group's understanding of the issue and to their motivations and concerns, and build on existing social networks and channels. Often, there is initial reluctance to change (e.g. introduction of seat belts, smoking bans), but early adopters may forge the path. Trusted members of a community can trigger wider change and could be empowered as change agents. Change can happen top down and bottom up; to target plastic pollution, for example, there are many examples of community-led actions, voluntary efforts in the retail sector (e.g. bans on plastic bags) and nonprofit initiatives.

5 Opportunities for Action

Over the last several years, marine plastic pollution has captured the world's attention and inspired hundreds of commitments from governments, businesses and nongovernmental organisations (NGOs); dozens of innovation challenges; hundreds of start-up companies seeking to create solutions; and millions of citizens taking action, whether as citizen scientists, as part of a beach clean-up or by changing their own consumption choices.

It is extremely challenging, at least with available data, to weigh the damage done by marine plastic pollution against the harmful impacts of nonplastic pollution from municipal, agricultural, industrial and maritime sources, though the latter group has been more exhaustively studied. A more helpful question to ask, however, might be this: How can action to address plastic pollution be leveraged to maximise the benefits across as many other ocean pollutants as possible? If plastic pollution is uniquely able to catalyse action on solutions, how can we prioritise and design solutions to also stop the flow of other pollutants into the ocean?

The seven approaches developed from this research and presented below begin to address these questions. Each approach includes recommendations for interventions and actions to address ocean pollution through four levers: infrastructure, policy, mindset and innovation. These levers consider actions that may be taken by companies large and small, by elected officials and policymaking staff, by citizens and by innovators. There is likely a role for some form of voluntary collective action from the biggest producers and users of plastics. In fact, hundreds of companies have signed on to frameworks such as the New Plastics Economy, facilitated by the Ellen MacArthur Foundation, and/or have set goals regarding how they will address the problem of plastic pollution. This paper does not speculate about the precise paths companies will take, but rather focuses on the specific actions most likely to move the needle on plastic and other types of pollution reaching our ocean. After the details of the approaches are introduced, they are then summarised and compared based on their breadth of mitigation across pollutants and sectors.

In this section, the list of key interventions and actions are mapped to the following:

- Sectors: Municipal (M), agricultural (A), industrial (I), maritime (Mar)
- Types: Infrastructure, Policy, Mindset and Innovation
- Pollutants: Sourced from Table 5.1. Given below each corresponding intervention table
- Relevant UN Sustainable Development Goals (SDGs)

Improve wastewater management			
Infrastructure	Policy	Mindset	Innovation
1. Create or expand wastewater treatment capacity (M) 2. Add tertiary treatment for nutrients and microplastics (M) 3. Install toilets (wet or dry) where needed to prevent open defecation (M) 4. Install septic tanks where access to municipal wastewater systems is limited (M) 5. Ensure industrial wastewater is appropriately treated, whether through municipal or other infrastructure (I)	1. Ensure supporting policies for wastewater improvements and sustainability of infrastructure over time are in place (M)	1. See wastewater as a natural resource, especially in water-constrained regions (M)	1. Develop washing machine filters for microplastic fibres (M) 2. Innovate ways to remove pharmaceuticals and antibiotics from wastewater effectively and affordably (M)

Sectors: *Municipal (M), industrial (I)*
Pollutants: *Macroplastics; microplastics; other solid waste; nutrients; antibiotics, parasiticides and other pharmaceuticals; heavy metals; and industrial chemicals and POPs*
SDGs: *6.2, 6.3*

Improve stormwater management			
Infrastructure	Policy	Mindset	Innovation
1. Use natural filters such as berms and clay to minimise runoff into the ocean (A, M) 2. Implement stormwater and storm drain filtration and river mouth trash collection (M)	1. Set total maximum daily loads (TMDLs) for trash (M) 2. Impose regulatory limits, TMDLs for discharge (I) 3. Employ stormwater permitting (M) 4. Regulate animal waste lagoons that have the potential to discharge into the ocean (A) 5. Regulate use of pesticides, herbicides and nutrients for residential and commercial use (M) 6. Require nutrient management plans and pesticide management plans (A) 7. Require reporting of and/or limit usage of nutrients and pesticides (A)	1. Change cultural norms around having manicured lawns to reduce the use of pesticides, herbicides and fertilisers used for residential and commercial landscaping (M) 2. Create a culture of responsibility regarding picking up dog feces (M) 3. Change habit of washing with excessive soap, shampoo and products that contain high levels of nitrogen and phosphorus (M)	1. Conduct research and development in stormwater and other treatment systems (M, A, I) 2. Change crops, seeds and farming practices to minimise nutrient application prone to leakage (A)

Sectors: *Municipal (M), agricultural (A), industrial (I)*
Pollutants: *Macroplastics; microplastics; other solid waste; pesticides; nutrients; antibiotics, parasiticides and other pharmaceuticals; heavy metals; industrial chemicals and POPs; oil and gas*
SDGs: *None*

Adopt green chemistry practices and new materials			
Infrastructure	Policy	Mindset	Innovation
1. Construct treatment facilities with 'green engineering' principles (M) 2. Develop infrastructure for the production of new or alternative materials	1. Ban or limit the use of chemicals of concern and hazardous materials (I) 2. Ban hard-to-manage materials (M) 3. Require tracking/ manifest of chemicals of concern (I)	1. Adopt green chemistry principles as a practice for companies (I) 2. Change cultural norms around having manicured lawns to reduce the use of pesticides, herbicides and fertilisers used for residential and commercial landscaping (M)	1. Develop new materials that maintain the desirable performance characteristics of plastics but not the problematic ones, e.g. true biodegradables (M, A) 2. Develop alternative cleaning products, e.g. phosphate-free soap and detergents (M) 3. Use fish waste or seaweed to make biopolymers for fishing gear (A) 4. Support research and development in green chemistry and alternative chemicals (I) 5. Reduce and prevent tire wear and tire dust by using new materials or other mechanisms 6. Use new materials for fishing gear, e.g. biodegradable components (Mar) 7. Support the development of products and services that do not use any chemicals of concern (I)

Sectors: *Municipal (M), agricultural (A), industrial (I), maritime (Mar)*
Pollutants: *Macroplastics; microplastics; other solid waste; pesticides; heavy metals; industrial chemicals and POPs*
SDGs: *3.9, 12.4*

Practice radical resource efficiency			
Infrastructure	Policy	Mindset	Innovation
1. Enable the development of circular business models through shared infrastructure, for example, reverse logistics or commercial washing services for reusable foodservice items (M)	1. Impose fees on single-use or other high leakage items (M) 2. Encourage industry voluntary contributions to reduce fossil-fuel-based plastics (M, A, I, Mar) 3. Support policies that allow personal container use in shopping and dining (M) 4. Enable treatment and use of food and human waste in appropriate applications (M, A)	1. Change cultural norms around waste generation/consumption and reuse, in particular to reduce the use of single-use plastic items (M)	1. Design zero-packaging grocery stores or include 'packaging free' or 'plastic free' aisles in regular grocery stores (M) 2. Develop new purchasing models that end reliance on single-use plastics (e.g. packaging as a service, reuse models) (M) 3. Pricing structure/business model for nutrients and pesticides to optimise outcomes and minimise waste (A) 4. Require fishing gear tracking (Mar)

Sectors: *Municipal (M), agricultural (A), industrial (I), maritime (Mar)*
Pollutants: *Macroplastics; microplastics; other solid waste; pesticides; nutrients*
SDGs: *8.4, 12.2, 12.5*

Recover and recycle the materials we use (formal and informal sectors)			
Infrastructure	Policy	Mindset	Innovation
1. Implement systems for compliance with bale contamination standards in exported/imported waste (M) 2. Deploy technology for advanced waste drop-off facilities (M) 3. Use materials that are recyclable and retain value (M) 4. Improve technology used at recycling facilities (M) 5. Use equipment and processes to recover and recycle chemicals and materials (I)	1. Implement extended producer responsibility laws (M) 2. Provide incentives for waste segregation and recycling (M) 3. Strengthen markets for recycled plastics (e.g. mandate use, secure demand, create price premiums) (M) 4. Implement Fishing for Litter programmes (Mar)	1. Change cultural norms around proper sorting and recycling (M) 2. Expand home composting (M) 3. Promote and expand commercial composting infrastructure (M)	1. Invest in tracking technology to combat illegal dumping (M) 2. Develop and scale on-demand waste collection (M)

Sectors: *Municipal (M), agricultural (A), industrial (I)*
Pollutants: *Macroplastics; microplastics; other solid waste; nutrients; industrial chemicals and POPs*
SDGs: *8.3, 8.8, 11.6, 12.2, 12.5*

Implement coastal zone improvements			
Infrastructure	Policy	Mindset	Innovation
1. Provide for sediment/dredge material removal and treatment (I, Mar) 2. Conduct sediment remediation with in situ mats (Mar) 3. Improve wastewater and solid waste management on ships (Mar) 4. Build ships and rigs to prevent and minimise oil spills (Mar) 5. Improve infrastructure at ports to manage waste generated from ships, including making waste management affordable (M, I, Mar) 6. Land solid waste where infrastructure is available (Mar)	1. Enforce international dumping agreements (M, Mar) 2. Strengthen oil spill prevention policies (M) 3. Restrict locations and types of coastal and open-ocean aquaculture (A)	1. Engage people to adhere to MARPOL to reduce illegal discharge (Mar) 2. Ensure that shipping/maritime developments prioritise marine protection (M, Mar) 3. Operate and manage oil rigs and ships to minimise oil spills (I) 4. Encourage participation in beach cleanups, Adopt-a-Beach programmes and clean beach certifications such as Blue Flag and Project Aware (M) 5. Use citizen science apps such as the Debris Tracker to engage citizens on pollution issues (M)	1. Innovate equipment and methods for managing wastewater and solid waste on ships (Mar) 2. Develop new oil spill prevention technology (Mar) 3. Conduct research and development in individual pollutant cleanup systems (I, Mar) 4. Shift to land-based aquaculture systems (A)

Sectors: *Municipal (M), agricultural (A), industrial (I), maritime (Mar)*
Pollutants: *Macroplastics; microplastics; other solid waste; pesticides; nutrients; antibiotics, parasiticides and other pharmaceuticals; heavy metals; industrial chemicals and POPs; oil and gas*
SDGs: *None*

Table 5.3 Summary of interventions and pollutants addressed across sectors and SDGs

	(1) Improve wastewater management	(2) Improve stormwater management	(3) Adopt green chemistry practices and new materials	(4) Practice radical resource efficiency	(5) Recover and recycle	(6) Improve coastal zones	(7) Build local systems for safe food and water

Build local systems for safe food and water			
Infrastructure	Policy	Mindset	Innovation
1. Expand drinking water infrastructure (M) 2. Develop municipal composting systems to support local food production (M, A)	1. Ensure adequate drinking water standards (M)	1. Use technology to raise awareness and provide practical solutions, e.g. Fill it Forward and apps to locate water fountains 2. Encourage local sourcing of food (e.g. people, restaurants, government) (M) 3. Encourage people to bring their own pack-aging to purchase local food (M) 4. Use sustainable methods of food production (both on land and aquaculture) and minimise pesticide and nutrient use (A)	1. Use multitrophic aquaculture production—'waste' from one aquatic species becomes food for another (A) 2. Farm mussels, sea grass or other nutrient-ab-sorbing species for nutrient equilibrium (A)

Sectors: *Municipal (M), agricultural (A)*
Pollutants: *Macroplastics; microplastics; other solid waste; pesticides; nutrients; antibiotics, parasiticides and other pharmaceuticals; heavy metals; industrial chemicals and POPs; oil and gas*
SDGs: *6.1, 6.B. 2.1, 2.3*

For comparison purposes, the scope of each intervention approach is presented in Table 5.3. As the data do not exist today to quantitatively compare the value of one approach versus another, this table focuses on showing the reach of each intervention by sector for each pollutant and those directly related SDGs.

Figure 5.4 presents spider graphs of each intervention to visually compare their effects on each class of pollutants across the sectors. These graphs do not illustrate a score for each intervention, but show the extent to which they impact pollutants across single or multiple sectors (depicted by how far the shape spreads outward). In general, the overall impact

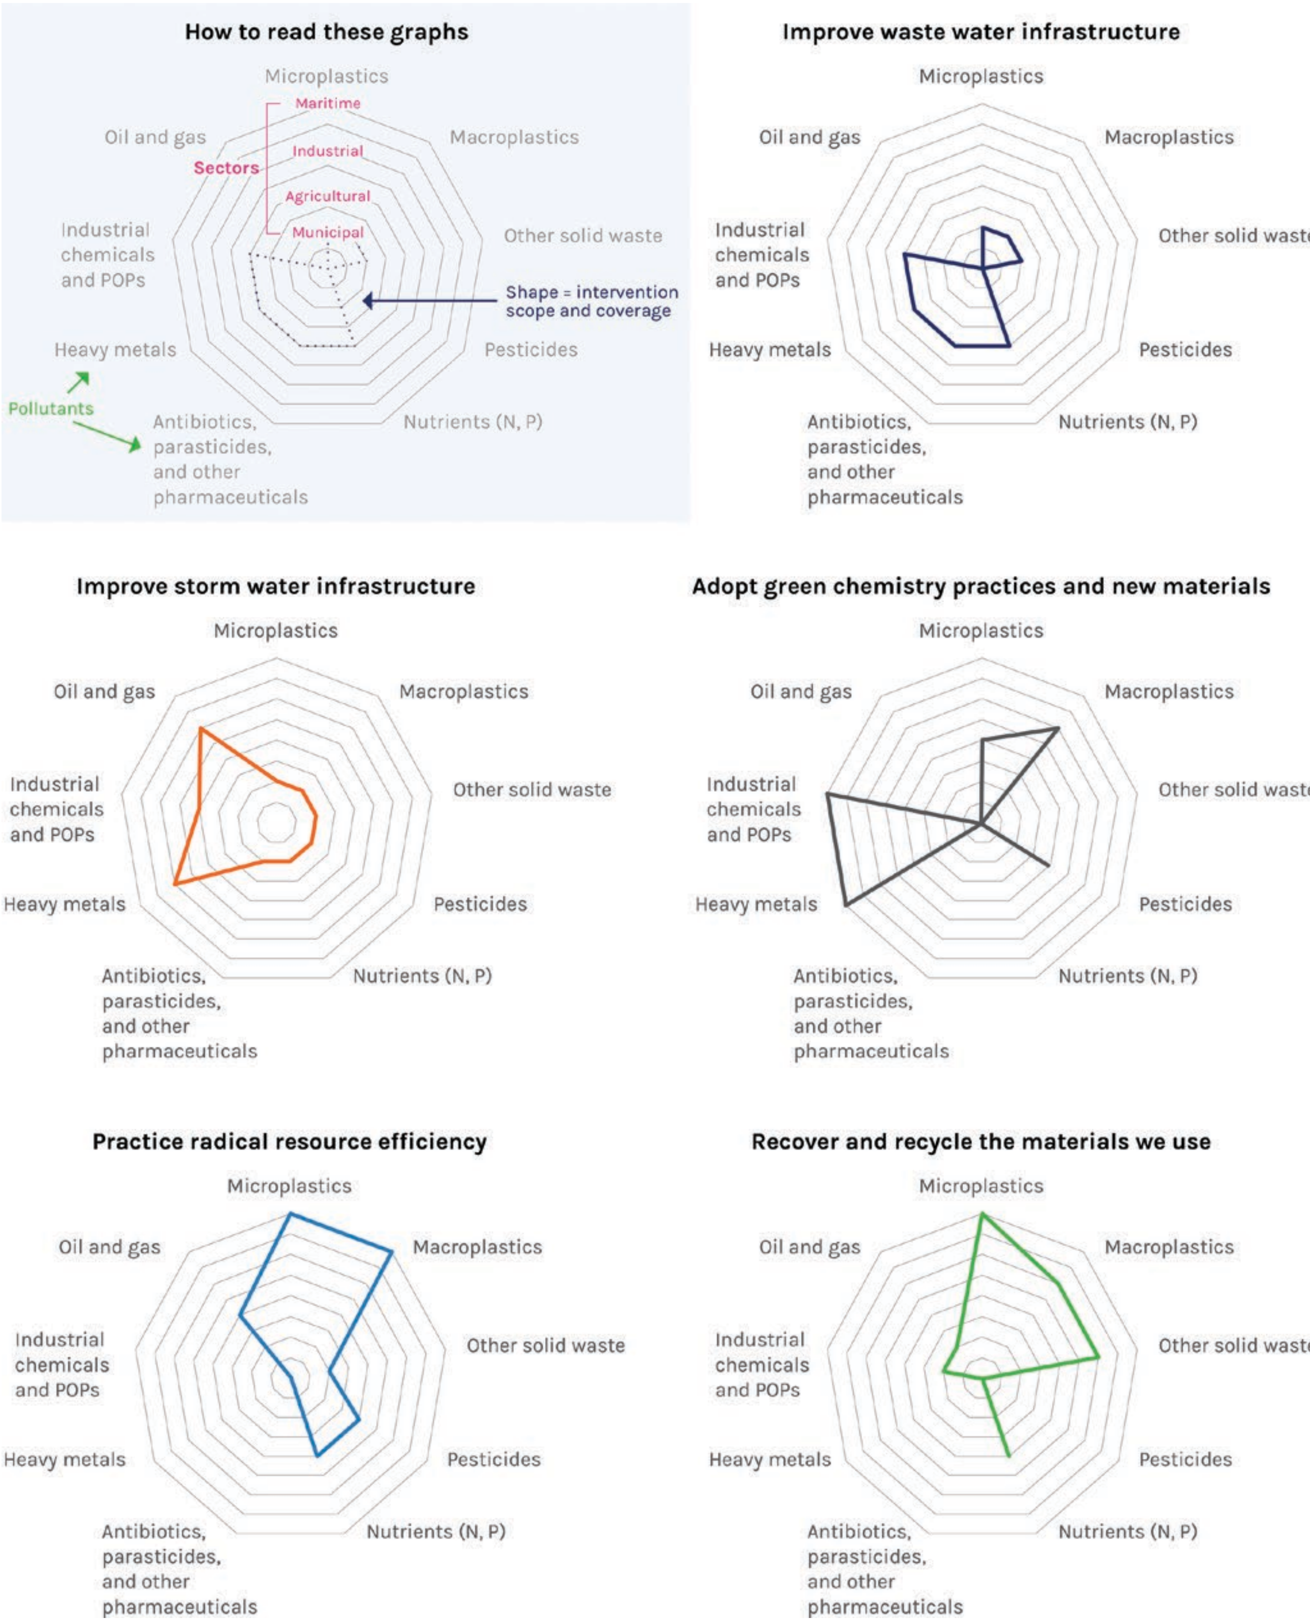

Fig. 5.4 Spider graph illustrations of approaches 1–7 by pollutant and sector. (Source: Authors)

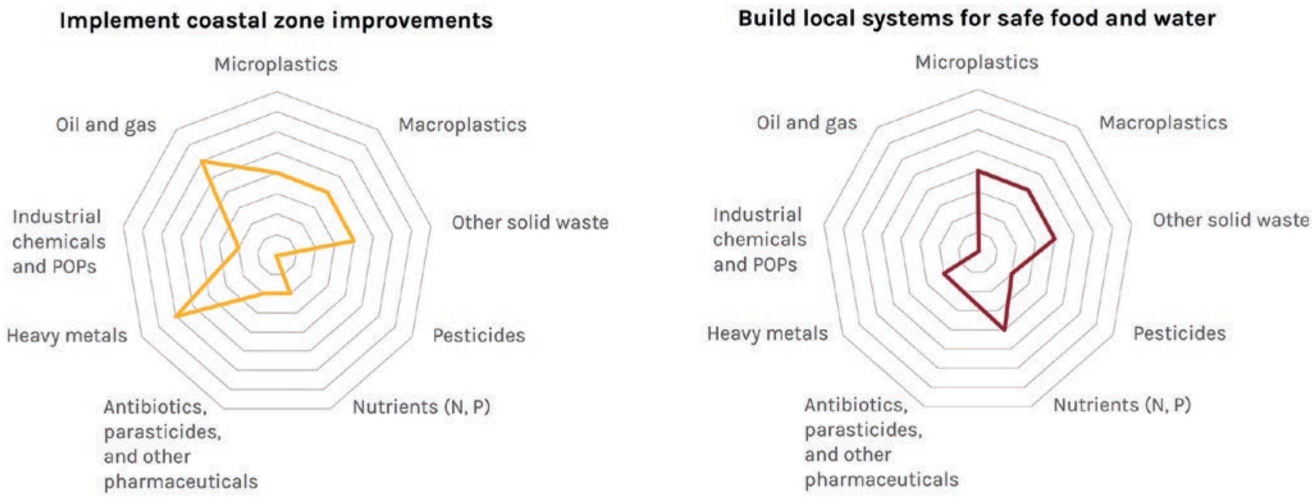

Fig. 5.4 (continued)

increases as more pollutants and sectors are impacted, but the metrics of mass quantities, discrete counts and values, as well as risk and impact, are not able to be taken into account in these illustrations. However, synergies in addressing other pollutants while addressing plastic pollution are illustrated.

Governments, together with businesses, investors, individuals, communities and NGOs, can have a major impact on changing the trajectory of pollution discharges into the ocean—with the opportunity to address other intersectional social and environmental challenges in the process. Solutions will come from innovative policies, support for research and innovation, investment in wastewater and solid waste infrastructure and shifting mindsets and behavioural practices. Many companies that are facing increased costs—or are taking responsibility for costs that they have historically imposed on others—will inevitably claim that these actions will only result in a loss of jobs, profits and economic prosperity.

It is important that we don't confuse the minimisation of harmful pollution with a reduction in quality of life, livelihood opportunities or economic success. In fact, the reality can be quite the opposite. Pollution in the ocean is already negatively impacting human health, economic prosperity for ocean-based businesses and marine ecosystems on which humans depend for essential ecosystem services. Solutions to ocean pollution can create jobs, reduce costs to many businesses and governments and improve the health and prosperity of millions of people.

Pollution is an externality of a linear economy. In creating an economic system where product costs nearly always exclude the environmental impacts for those products (whether during their creation, useful life or end of life), we have effectively designed our economies to maximise pollution, in service of maximising profits. We have invented the idea of 'throwing things away'—and the vastness of the ocean has enabled this fiction to persist for a very long time.

Alternative economic systems, such as the circular economy or regenerative economy, begin with the premise that there is no such thing as waste; that in a closed system like that of Earth, there is nowhere for damaging pollution to go that won't end up harming ecosystems, plant and animal life and, ultimately, human life. The branding of an economic model is less important than this fundamental premise: There is no 'away,' so we must design our economic system to recognise complete life cycle costs. Once the boundaries of the economic system are fixed, the machinery of the economy itself will be very effective at finding the most efficient ways to stop the problem of pollution.

How One Place Can Make a Difference

While no single community or country can solve the problem of ocean pollution alone, a single country can be a first mover in adopting innovative policies and solutions that show the way for others to follow. One barrier innovators face is helping to bridge the imagination gap between today's and tomorrow's realities. A community, country or region can bring the vision of a pollution-free future to life and make it easier for others to begin to adopt the same solutions.

Regional Strategies

Smaller communities and countries can consider adopting regional strategies to help achieve critical mass for certain types of innovations, investments and infrastructure. For example, regions that align their requirements for companies to innovate around packaging, end-of-life responsibility and other issues can make it more compelling and less complex for multinational companies to comply.

Global Collaboration
The ocean is a global resource impacted by all actions everywhere. Given this, it would be appropriate and effective to organise a global compact or commitment to improving the health of the ocean so the ocean can better support all life. International treaties have had success in the past at reducing some impacts on the ocean (e.g. Montreal Protocol, Stockholm Convention). As communications and technologies make the world feel like a smaller place and emphasise the interconnectedness of humanity and our environment, there may be openings to build global support for such an agreement. At a minimum, current declarations from the G7 and G20, as well as United Nations Environment Assembly of the United Nations Environment Programme and other UN initiatives, can be built upon.

Further Research
While much has been learned about the scope, scale and impacts of marine plastic pollution in recent years, there remain significant gaps that could help inform and prioritise solutions. There are multiple significant research efforts underway that were not published in time to be referenced in this paper. It is the authors' hope that these studies will be completed and released as soon as possible as they are expected to contribute significantly to the state of knowledge on this topic. Ongoing research on ocean plastic is also needed, and would be greatly facilitated by the creation of open data protocols to aggregate and share data globally for scientific scholarship.

Finally, just as we see synergies in the solutions to ocean plastic and other pollutants in the ocean, more research is needed to understand their other interactions in the ocean as well as their implications.

Acknowledgements The paper's technical reviewers, Grant Collins, Rob Kaplan, Chris Reddy and David Tickler, as well as its arbiter, Martin Stuchtey, all provided helpful technical comments.

The authors thank World Resources Institute for providing support as the Ocean Panel Secretariat.

The authors would also like to acknowledge Amy Brooks for GIS analysis and map images, Kathryn Youngblood for technical graphic assistance, and Connor Keisling for referencing assistance.

While our colleagues were very generous with their time and input, this report reflects the views of the authors alone. The authors thank Sarah DeLucia for copyediting and Jen Lockard for design.

Highlights

- Effective management of resources has been hindered by a lack of information about how humans are impacting the ocean.
- There is an explosion in new data and technology for the ocean at the moment, and with it enormous potential for advances in the understanding and stewardship of ocean resources.
- Coordinated efforts by industry, researchers and governments can create advanced sensor networks that provide high-resolution, real-time information about the ocean to anyone who needs it, an "Internet of Things" for the ocean.
- However, significant technical and non-technical barriers exist to creating an equitable, open and accessible digital ecosystem for the ocean. To capitalise on the revolution in data and technology, breakthroughs are needed on several fronts.
- Vast stores of ocean data are in the hands of governments, researchers and industry but are unstructured, inaccessible and unusable. These data should by default be made open and available through data tagging, federated networks and, where possible, data lakes.
- Technology can leverage vital innovations in management. Real-time information and automation can allow robust and nimble adaptation to changing conditions and create new accountabilities in government and in business. An urgent priority is to ensure that these new capabilities are available to all ocean stakeholders.
- Overcoming market barriers is critical to fostering successful innovation that supports science and management

in the future. Capturing the extraordinary potential of technology will require action by governments and others to foster the needed innovations for all those who have a role in ocean stewardship, by creating new market incentives for innovation, new public–private instruments for investment and new business models.

1 Introduction

We are in the middle of an explosion in new data on the ocean, creating enormous potential for advances in our understanding and stewardship of ocean resources. An exponential increase in the number and variety of ocean observing systems and other new data sources has created the prospect of a digital ocean ecosystem. Advances in processing techniques and visualisation are rapidly expanding our ability to extract information from those data, and are enabling a wide array of tools to provide real-time information in actionable form to decision-makers, such as policymakers, resource managers, resource users, consumers and citizens.

To capitalise on this revolution in data and technology, we will need breakthroughs on several fronts. A first imperative is to end the balkanisation of data to create a new era of open and automated data access—so that the data now locked in the servers of government agencies, businesses or researchers are much more broadly available—and to enable the flowering of an ocean Internet of Things (IoT). A second priority is to harness this revolution to support vital innovations in management. Real-time information and automation can allow robust and nimble adaptation to changing conditions and create new accountabilities in government and in business. A third priority is to create the incentives, investments and business models that will support the innovations that are needed not just by wealthy governments and resource users but by all who depend on the ocean and have a role in sustaining the ocean's future. In this paper, we outline the most promising avenues to create this open, actionable and equitable digital ecosystem for the ocean.

2 The Data Explosion

2.1 Fostering New Scientific Understanding of the Ocean

Walter Munk once said that the twentieth century would be known as "the century of undersampling" (Munk 2012). The ocean is 10 trillion times more opaque to light than the atmosphere. This means that we cannot observe the ocean system by looking at it, as we can with terrestrial ecosystems. Instead, we must place our devices inside the ocean itself. The ocean and its ecosystems change on both small and large scales in time and space. A typical phytoplankton growth rate is to double every 1–10 days, and while the average ocean depth is about 3700 m, most of its photosynthesis occurs in the upper 100 m. At the same time, ocean currents move slowly both horizontally and vertically, causing the ocean to act as the "memory" of the Earth system. Organic carbon that is created in the upper ocean may be buried in deep ocean sediments for millennia. Changes in our land and atmosphere will have an ocean signature for decades or centuries. To end "the century of undersampling" will require a fundamental transformation of our observing systems. We need to sample the ocean on its own intrinsic scales, not on the scales that are dictated by our current technical capabilities.

Over the last three decades, there has been an exponential increase in the number and variety of ocean observing systems. From profiling floats such as Argo (e.g. Freeland and Cummins 2005) to cabled observatories (e.g. Kelly 2014), our understanding of ocean dynamics has been transformed through these new tools. And these observing systems are not just in the ocean, but they are also in space. Beginning with the launch of SeaSat and the launch of the Coastal Zone Color Scanner on NIMBUS-7 in 1978, ocean remote sensing has moved from experimental missions in support of the research community to continuously operating systems that support a wide range of management and application needs.

New communication pathways are opening up a vision of a connected ocean, although the fundamental physical properties of seawater will never enable the same level of ubiquitous communications that we have with land and atmospheric observing systems. Cabled observatories, such as the US Ocean Observatories Initiative (Smith et al. 2018), now bring data ashore directly to the Internet. Acoustic modems, although limited in data throughput, can provide a level of connectivity that may eventually enable heterogeneous "swarms" of platforms to behave as a coordinated network. Hybrid systems of both underwater and ocean surface vehicles are now being tested, with the surface vehicles acting as data "mules," receiving low-bandwidth acoustic data streams from the underwater vehicles and converting them into high-bandwidth radio data streams for transmission to aircraft or satellites. With the emergence of high-bandwidth communications based on networks of hundreds to thousands of small satellites, there is promise of gigabit/second networks everywhere over the surface of the world ocean.

With advances in microelectronics and mechanical design, there has been a rapid increase in the type of measurements that can now be made in the undersea environment. Beginning with measurements of physical properties (temperature, conductivity, velocity, etc.), we can now measure a wide variety of chemical and biological properties in the ocean environment. For example, flow cytometry, which was originally designed as a tool for human blood cell analysis, is now being used in situ to identify a wide variety of microorganisms in the ocean (e.g. Lambert et al. 2016). These instruments are being used to identify harmful algal blooms (HAB), as well as in a wide range of ecological studies (Seltenrich 2014). Environmental DNA analysis is becoming a powerful tool for understanding ecosystem composition, and such analyses can now be made in situ, not just through laboratory analysis of water samples (Kelly et al. 2017).

These examples can be viewed as adapting traditional lab- based techniques to the ocean environment through processes such as miniaturisation, lowering power requirements and automation. However, there are also sensing tools that are fundamentally new. For example, new methods of manufacturing fibre-optic cables are enabling sensors to be embedded within the fibre (Rein et al. 2018). Undersea fibre-optic cables are critical conduits of global information flows, carrying over 95 percent of international data, and more are rapidly being added as bandwidth demands increase, creating huge opportunities to expand ocean sensing (Wrathall 2010). Designers are exploring the possibility of embedding both processing and communication semiconductors within these fibre-optic fabrics, thus creating a dense network of smart sensors and allowing fibre-optic cables to act as both sensors and platforms. Fibre-optic sensors in sea-floor cables are also being used for a wide range of environmental sensing, including seismic activity (Joe et al. 2018).

The variety and capability of these new sensing systems are continuing to increase, and they are now being deployed on a broader range of platforms. For decades, sensors were mounted on fixed buoys or attached on ships. With miniaturisation and power reduction, sensors are now being deployed on underwater passive platforms, such as Lagrangian drifters or buoyancy- driven gliders, or on self-propelled devices, such as the REMUS (Stokey et al. 2005). The same holds for platforms on the sea surface. The Wave Glider (Thomson and Girton 2017) can traverse entire ocean basins, and also remain in areas that are simply too hostile for conventional ships. Saildrone (Cokelet et al. 2015) is pursuing a different model for ocean data acquisition. Rather than sell individual vehicles that are managed by the end user, Saildrone provides "mission as a service," where the user defines the mission plan (types of data, location, etc.) and then Saildrone designs and manages the mission.

These new platforms have greatly expanded our sampling "footprint" in both time and space. We can sample over longer time periods and greater spatial distances than with fixed buoys and a few ships.

The "always on, always connected" ocean (Abbott and Sears 2006) could soon be a reality, with the decreasing costs, improved performance and increasing availability of data. Munk's "century of undersampling" could be drawing to a close. However, there remain both technical obstacles and opportunities.

On the technology side, power availability continues to be challenging. Slow-moving or passive devices, such as floats and gliders, can sample the ocean for many months but they can only cover a small area. Therefore, their ability to observe rapidly changing processes or to map large areas is severely limited. Self-propelled systems require significant power to move through the ocean, as power requirements increase non-linearly with speed. Such systems simply run out of battery power.

Power-harvesting systems are being developed for platforms that operate on the ocean surface, such as the Wave Glider or Saildrone. These platforms can harvest wind and solar energy as well, thus enabling them to remain working for months to years. Bottom- mounted systems that rely on microbial fuel cells are being deployed as well. These fuel cells harvest energy by taking advantage of the natural oxidation of organic material at the sea floor (Reimers and Wolf 2018). New approaches in battery technology, such as aluminium- based systems that use seawater, show promise for greatly increasing battery capacity.

Along with power, the undersea environment is challenging for communication and navigation. Unlike the terrestrial environment where radio frequencies can support WiFi and cellular networks as well positioning systems such as GPS, the ocean lacks such fundamental infrastructure. The ocean is nearly opaque to electromagnetic radiation, and therefore we must rely on acoustic signals and other approaches to provide the basics of communication and navigation.

Acoustic modems are increasing their capability to transmit data, but the amount of data that can be transmitted remains substantially smaller than what we can achieve on land. However, as microprocessors continue to decrease in size and power requirements, and increase in computational performance, we are beginning to develop on-board systems that process and analyse the data on the platform and transmit only the results rather than the entire observed data stream. For example, a resource manager may only need to know if a harmful algae species is present or not, rather than detailed information on every species of microbe in the water. Long fibre-optic cables may string together swarms of platforms that can then communicate with a single data "mule," which can carry the data to the surface. Next-generation Internet-capable microsats are capable of delivering high bandwidth anywhere over the world ocean. While the ocean will always be a difficult environment for high-bandwidth communication systems, distributed intelligence in undersea networks shows promise in overcoming this basic physical obstacle.

Navigation systems are showing similar signs of improvement. A small number of precisely located undersea beacons could serve as anchor points for platform swarms and networks that rely on relative distances from each other to create a precise "cooperative" map. Following Metcalfe's Law of networks, the value of the network increases non- linearly with the number of nodes in the network. Thus, such smart swarms show promise in delivering increasing value with regard to navigation and operational efficiency.

In addition to the technical obstacles to our vision of an always on, always connected ocean, there are many non-technical barriers as well. Our ability to sustain long-term ocean observing systems is always under threat. A recent report by the US National Academies of Sciences, Engineering, and Medicine (NAS 2017) documents both the importance of long-term ocean observing systems and the inability of governments to sustain these systems. Numerous reports on the global ocean observing system also highlight these issues. Long time series have enabled significant growth in our understanding of ocean processes, but every year is a struggle to sustain costly and often remote infrastructure. Even the Argo system, with roughly 3800 floats, must expend significant political and financial resources to try to make modest increases in the number and capabilities of these profiling floats (Roemmich et al. 2009).

The majority of ocean instrumentation is developed primarily to meet the requirements of the science community, and therefore the requirements of cost and schedule are often restricted with respect to the science needs. Most ocean instruments and platforms are expensive and often crafted by hand. There is only a small commercial market to counteract the pressures from the science community to build state- of-the-art, one-of-a-kind instruments. Even systems that are "transitioned" from the science lab to the commercial sector often remain focused on the small market of ocean science. There is little incentive (or pressure) for the funding agencies to engage in any sort of sustained design effort that would encourage an extensible architecture that supports the development of multipurpose instrument systems. Instead, solutions are generally monolithic, with their design focused on meeting the specific needs of a specific science question. Thus, technology lock-in and a relatively slow pace of instrument system evolution are characteristics of scientific ocean observing tools and the generally undercapitalised commercial instrument developers in the field.

Buck et al. (2019) describe a parallel environment in the world of data systems that are built around "portal and download," with little regard to how data will be used within a framework of user-driven services. They propose a fundamental rethinking of data systems architecture, where data are democratised, enabling users to build their own knowledge systems. In a sense, rather than a pre-defined data organisation structure, tagged data would reside in unstructured data lakes where the schema are written as the data are accessed. Much as data lakes are transforming machine learning and analytics, a similar development environment needs to be created for ocean observing systems that would enable knowledge services to be driven by the user.

There is considerable work to do to define and realise such a vision, but if we are to develop adaptive and flexible management approaches to our changing ocean, we will need to rethink how we both collect and deliver data. Much like natural ecosystems, these knowledge ecosystems will deliver critical services.

2.2 Monitoring Human Activity

Technology is changing our ability to understand ocean ecosystems, and how humans are using (and abusing) them. Effective management of resources has been stymied by a dearth of information about how humans are impacting the ocean. The big advances that are generating new opportunities for scientific data collection present parallel opportunities to improve oversight of human activity at global and local scales.

At the global level, increasing access to satellite technologies has enabled real-time, precise vessel tracking. Where once ships operated largely out of sight of regulators, the ubiquity of GPS has allowed governments to mandate that most commercial vessels carry Automated Identification System (AIS) devices, which automatically track and transmit their location. Knowledge products, such as Deep Sea Mining Watch and Global Fishing Watch, publish this information online, allowing anyone to look at what vessels are doing on the world ocean.

The proliferation of increasingly powerful imaging satellites has also been an important development in understanding global impacts on the ocean. Imaging satellites can track changes to coastal and ocean ecosystems, and can be used to understand coastal development patterns, monitor nutrient run-off and track pollution from ships.

Drones offer similar imaging at a more granular level. Drones are a cost-effective way of reaching offshore areas, allowing managers to see what is happening at a distance through real-time video streaming.

Drones can also be equipped with chemical sensors, supporting a wide variety of management uses. In Denmark, drones are being flown over the exhaust of shipping vessels, for example, allowing enforcement agencies to determine whether ships are using legally mandated low-sulphur fuels.

Drones are also being used in the water. Autonomous underwater vehicles and swarms of sensors can gather visual and chemical information on vessels. Drones and buoys equipped with acoustic sensors are particularly powerful in understanding human activity. Sound travels great distances in the ocean and different types of vessels have different acoustic signatures. Acoustic sensors can allow managers both to identify when vessels are operating in areas where no vessels are allowed, such as marine protected areas (MPAs), and to identify specific malefactor vessels.

Sensors on vessels provide another level of detail. Video cameras on fishing vessels and even on fishing nets can be used to monitor fish catch and potentially to identify labour abuses (Michelin et al. 2018). These cameras can be coupled with gear sensors that activate when fishing gear is deployed, giving regulators robust insight into where fishing is actually taking place.

Chemical sensors on smokestacks and in the water are being used to monitor water and air pollution to determine compliance with environmental regulations. These sensors also contribute important scientific data to world meteorological organisations, which use sensors on ships for critical in situ data from remote areas to support weather forecasting.

Connected sensors are also a building block for efforts to create traceability in supply chains. The IoT opens the door to robust tracking of all types of maritime goods from the moment they are harvested or produced through ports to their destinations throughout the value chain. Digital tracking will introduce critical efficiency and transparency in global supply chains.

Lastly, social media and the increasing connectivity between people give new insights into human actions. Mining social media data and the dark web can illuminate labour abuses and other illegal activity that historically has been nearly impossible to penetrate (Greenemeier 2015). Online forums can illuminate how and why resource users are flouting regulations, information not generally communicated accurately to regulators but critical for developing effective management (Shiffman et al. 2017). Social media is also providing new sources of data for scientists. Citizen science apps allow members of the public to submit photos for species identification, leading to updated species distribution maps as well as the discovery of new species (Silverman 2016). Photo submission can also help regulators target problem areas: in Los Angeles, citizen tracking of plastic pollution along the Los Angeles River identified the most important spots for intervention (Thompson 2019). Scientists are using Twitter reports of flooding to generate high-resolution urban flooding maps to improve model accuracy and forecasting (Wang et al. 2018).

2.3 A Vision of an "IoT" for the Ocean

The dramatic increase in intelligent, connected devices is enabling a vast array of new services on land. The IoT phenomenon is in its infancy, but the prospect of trillions of connected devices is driving technologies in both network communications (e.g. 5G) and microprocessors. This is not just a simple scaling up of the Internet; it will require a fundamental shift in our software design and network architectures. Developers will no longer think solely of "dumb" sensors feeding high-speed data ingestion systems. Instead, computational power will be pushed out to these "edge" sensors. Workflows will be intelligent, driven by the services being provided. The pressures of near real-time data flows and derived services will require that "time to insight" becomes a fundamental metric. While the traditional historical analyses (and associated data ingestion engines) will continue to be important, these new real-time flows will grow hugely in significance.

Thinking about an IoT for the ocean will still require new approaches to data communications and sensor location. Terrestrial systems can rely on satellite-based positioning systems and radio networks, whereas ocean systems cannot. But, over the next decade, we can expect that an IoT model will begin to become a reality (Fig. 6.1). The availability of powerful microprocessors that consume small amounts of energy will enable networks that transmit small, but information-rich messages (e.g. sensors that identify harmful algal bloom species on board and then transmit a simple presence/ absence message). And as the number of these sensing platforms increases, and they communicate with each other, Metcalfe's Law of networks, where the value of every node in the network increases with each new node added, will come into play in the ocean.

The vision of an IoT for the ocean will only be realised if the private sector, governments and researchers ensure that ocean sensors are interoperable and network architectures support connected, smart sensors (Cater and O'Reilly 2009). Without concerted efforts to achieve these goals, business as usual could lead to a plethora of disconnected sensors all generating proprietary data types that do little to achieve the potential of a connected IoT for the ocean. It is also essential that smart sensor networks are compatible with different types of data access regimes, including open access. New platform and sensor types may minimise the need for researchers and managers to gather their own data, but these platforms are often costly. Effort must be made to ensure that, where possible, the data generated by these platforms are available to relevant researchers and managers and not locked in high-cost proprietary systems.

IoT sensors are also vulnerable to attack. While the security and privacy concerns that are relevant for smart sensors located in the home are less pressing in the ocean, the vulnerability of sensor networks could make large-scale manipulation of data inputs relatively easy (Li et al. 2015). Governments, industry and researchers must work together to develop network architectures that overcome these concerns.

3 Tapping into the Explosion in Data Sources

The explosion in new data about the ocean has the potential to reshape how we understand and manage the ocean. Ocean management has long been impeded, and often defeated, by a lack of timely, accurate and relevant information on the condition of ocean resources (Cvitanovic et al. 2015) and on human activities and their impacts. New technologies are vastly increasing the collection of data, and the urgent challenge is to ensure that these data are available and useful to ocean management.

Data alone are not inherently useful (Kelly 2014). Relevant information must be extracted, combined with information from other sources, and translated into a form that is easily understandable, timely, actionable and accessible for decision-makers (Bradley et al. 2019). The importance of effective knowledge translation cannot be overstated amid the rise of "big data" in the ocean, but historically it has been a weakness in the science–policy interface (ELI 2014). The key challenge ahead is to create a "digital ecosystem for the ocean," which makes diverse ocean datasets available and translates that data into actionable information for decision-makers.

3.1 Making Data Available

"Water, water everywhere, nor any drop to drink." Although Coleridge was referring to the ocean, the same could be said about ocean data. We may be drowning in a sea of data but cannot find the information we need to increase our knowledge or to make science-informed decisions. Quantitatively, the amount of unstructured data gathered and managed annually by organisations within the government, research and business sectors is growing exponentially. Qualitatively, this shift is even more radical, as the conceptual framework for data management moves from a historic, disaggregated and static model to one that is based on dynamic, unstructured and collaborative use. Knowledge extraction will require new tools to enable new levels of collaboration, visualisation and synthesis—this is not just scaling up traditional workflows to accommodate greater volumes. Data will be broadly dispersed, as will the teams that come together to work on specific economic and science issues, and these many-to-many networks will constantly be changing as the needs for collaboration change. As a result, new frameworks are required that provide a systematic basis for data management, analysis and collaboration, rather than ad hoc aggregations of independent components (Buck et al. 2019.)

In the next 10 years, frontier efforts are aiming to create a "digital ecosystem for the environment" (Jensen and Campbell 2018), which aggregates many sources of data to provide timely and high-quality information to decision-makers. There are numerous initiatives that have set out to create this digital ecosystem, from the Global Ocean Observing System hosted by the Intergovernmental Oceanographic Commission of UNESCO (IOC-UNESCO) ("a truly integrated global ocean observing system that delivers the essential information needed for our sustainable development, safety, wellbeing and prosperity," GOOS

2019) to private sector efforts like REV Ocean's Ocean Data Platform ("a global, unifying ocean data platform [that] will enable unbiased research and facilitate a data-driven debate, leading to better decision-making and enable more successful conservation and utilization of ocean resources," REV Ocean 2019). Most current efforts focus on combining datasets into one centralised database, which is a more powerful version of the traditional portal–download data model (Buck et al. 2019).

Efforts to create unified data platforms have faced daunting challenges, however. Datasets are often not consistent or interoperable. Data holders are often reluctant to share data because, once data are combined, they lose control over how their data are accessed and used (Piwowar et al. 2007). Lastly, there are few incentives (either financial or professional) to expend the considerable effort necessary to make datasets available on a sustained basis.

Outside of the ocean, Google and other technology companies have created various tools, such as Google's BigQuery, that crawl the web combing and combining diverse datasets to mine insights. These tools provide new ways to access datasets that previously would not have been interoperable, but they face many of the same challenges as ocean-focused solutions. Researchers and governments do not share their data in ways that allow these tools to access the information, and the incentives needed to tailor these tools to ocean problems do not exist.

We must now rethink our fundamental strategy (and culture) and move decisively towards a data architecture that allows diverse datasets to be accessed automatically by researchers and managers. Universal data tagging standards are the essential foundation for this new wave of ocean data infrastructure, allowing data to be combined in federated data networks and data lakes that support verified and automated global access. Federated data networks offer the potential to liberate ocean data that are currently locked in private sector and government databases, while data lakes create new opportunities to combine data in ways that support real-time management needs and enable the development of new (and sometimes unanticipated) data-driven services.

3.1.1 Tagging Standards

Standardised data tagging and metadata protocols are the first step in making ocean data globally accessible. Standardised metadata include normal indicators, such as where and when data were collected, and how. Tags build on this, indicating whether and how data can be stored, transmitted and used, and its suitability for management and enforcement decision-making. Data tagged appropriately can be made automatically available to users that meet the criteria specified in the tags. Data owners can update data tags at any time, ensuring that access restrictions can be changed as needed. Some have raised concerns about reliance on federated networks for scientific purposes, namely that federating the data removes the connection between the data provider and user and may make it difficult to convey the nuances of how the data were collected (Buck et al. 2019). Tagging can overcome these concerns (Bar-Sinai et al. 2016; Crosas et al. 2015; Sweeney and Crosas 2015).

Creating data networks based on tagging may also allow new types of knowledge to be included more comprehensively in management decisions. Traditional knowledge that does not meet standardised scientific requirements, but which is increasingly recognised as an important part of management decisions, can be included with the appropriate tags (Berkes et al. 2010). Historical data from diverse sources, such as ships' logs, newspapers and menus, can be included to bolster understanding of historical baselines (Thurstan et al. 2015).

3.1.2 Federated Data Networks

Tagged data can be stored and connected through federated data networks, allowing researchers and managers access to diverse ocean data. Global standards allow disparate datasets to be queried and relevant information extracted (WEF 2019). A trusted broker creates and maintains the system, including access verification and other trust-promoting tools (Buck et al. 2019).

Federated data networks can be used to overcome commercial and other confidentiality concerns. They are currently being used successfully in several contexts. They have been particularly attractive to those in healthcare as they provide a way to access data without violating the many privacy laws that govern how health data are shared. Creating systems where the actual data are not shared, but instead external queries can gather the needed information from the data, allows researchers critical access to healthcare data while protecting the privacy of patients.

3.1.3 Data Lakes

Where users are willing to relinquish some control over their data storage, data lakes can be included as nodes within larger federated data networks. Data lakes move data onto cloud architecture, which is designed to scale and bring data closer to the processing pipelines. This type of computing architecture and the workflow pipelines running on top of these cloud solutions is not new. From early mainframes to the virtual machine operating system released by IBM in the 1970s, the concept of shared access to services has emerged and evolved because of the commodification of the entire Internet ecosystem (from microprocessors to services).

Data lakes rely on service-driven data schema rather than pre-defined schema used in "data warehouses" and are particularly promising for scientific data where compute needs are intensive and concerns over data privacy are low (Stein and Morrison 2014). This presents a significant change in the way data users access and use data by implementing, at scale, tightly coupled compute and storage, as well as services. This pipeline creates more efficient access to data and the ability to produce insights at scale.

Anticipated growth in observing technologies driven by advancements in radio telecommunications (5G, satellite and other radio technologies) pose significant challenges for data ingest and archive volumes that are growing exponentially. Distribution for the science community has become a logistics problem of moving assets in order to produce useable products. Efficient utilisation of a data lakes architecture places data close to compute and provides access to countless building block services that enable and expedite science discovery for data users.

Data lakes can enable new workflows that will change the way science is done across multiple domains. These new workflows will create new modelling approaches that help address algorithmic and analytical variability, which has led to reproducibility errors in the present system of science workflows. Adopting a cloud services approach through data lakes eliminates downloading and data transfers, thus allowing researchers and the public to interact and work with data directly, and move only the finished derived products or user experiences to achieve scale.

Data lakes present a path forward for the scientific community, and when built on universal tagging standards can be integrated into ocean data networks that allow automated data access and use for a diverse set of stakeholders. The United States Geological Survey (USGS) and National Oceanic and Atmospheric Administration (NOAA) have successfully transitioned some of their satellite remote sensing data into cloud-based data lakes, and have seen their user base rise exponentially as a result (NCE 2018). Data lakes can unlock new value by allowing users to analyse many data types and opening ocean data to a broader range of users.

Together, tagging, federated data networks and data lakes offer the promise of vastly expanding the ocean data available, and broadening access:

- **Access to more data:** Data tagging coupled with federated data networks enables the liberation of data that are currently locked away because of security, commercial or privacy concerns. The most notable of these data are those collected by defence departments and private sector companies, many of which have collected robust, long-term datasets on ocean conditions for decades. These data are sometimes classified (in the case of defence departments) or confidential (in the case of industry), even when much of the data are on oceanographic conditions with no associated security risk. New standards for data tagging could allow data collected by industry and militaries to automatically be available to researchers, for instance, after any security or time embargos have been met.
- **Accessible to more users:** Tagging allows automation of data access and thus makes it both simpler and more efficient (Sweeney and Crosas 2015). Currently, researchers and managers rely on one-off agreements between parties to allow access to needed data. In robust tagged systems, these agreements can be built into the data from the beginning. If parties are verified research institutions, for example, data tagged with "academic research" as an allowable use will automatically be available to these institutions on specified terms.

  This type of automated access also creates avenues for more equitable access to data. Currently, many marine datasets are in principle available to other researchers. In practice though, these datasets are often only shared with known research partners or top academic institutions. Executing complex Memoranda of Understanding (MOUs), which often take months to be agreed on, is an insurmountable barrier to entry for smaller institutions and resource- constrained managers.

  When combined with the reach provided by federated data networks, automating data use can provide managers with access to actionable information as they need it. Specialised apps can be built on top of data networks that are tailor-made to address common management questions and provide robust knowledge solutions.
- **Access globally:** Federated data networks and data lakes can enable global data access for scientists, managers, communities, consumers and others, but it is essential that they are built with these goals in mind. Without coordinated efforts by governments, research institutions and technology service providers, there is the danger of these solutions becoming additional siloed pieces in an already fragmented ocean data landscape.

As these solutions come online, governments and others must also ensure that data networks and lakes are accessible to everyone. Federated networks and data lakes are promising in part because of the business models they enable, which allow data to be stored for free while the knowledge services built on top of the data, or the increased speed generated by storing data closer to computations, generate revenue. These models, discussed further in Sect. 4, can support widespread, free access to data. Governments must work with web service providers to ensure that these systems are fulfilling this promise and not just providing data access to those that can pay (Borowitz 2019). The data-scarce areas where additional data are most needed to guide marine management are also the ones that are least likely to be able to pay for data access.

Beyond ensuring equitable access to data, governments also need to address the important privacy and security concerns raised by open data. Network architectures must ensure that data integrity is protected throughout the data lifecycle, including quality assurance mechanisms that prevent false data from being added to data networks (Buck et al. 2019). As personal devices, such as mobile phones, and video monitoring tools are increasingly sources of data for ocean management, it is essential that the privacy of users is built into management systems. Additionally, as governments open up access to ocean data, they need to be mindful of potential social and economic costs—open access may provide a de facto subsidy to some private sector actors, for example, or provide avenues for policy influence to those that are best equipped to make use of the data (Johnson et al. 2017).

Opening up access to data will require new incentives for governments, companies and researchers to make their data available. Government can lead the way directly—by taking bold steps to help create and contribute to federated data networks. Governments can also require that a condition of access to public resources—whether the resources are fish stocks and mineral deposits or funds for coastal management or for research—is a commitment to sharing the data produced.

International cooperation around the UN Decade of Ocean Science for Sustainable Development (2021–2030) provides a unique opportunity for concerted action to overcome existing barriers and make real progress towards integrated ocean data (Ryabinin et al. 2019; UNESCO and IOC 2019). It is essential that this opportunity is not wasted.

3.2 Extraction of Information and Translation

Recent innovations are improving our capacity to translate data into useful information. Advanced processing techniques coupled with new visualisation portals enable a wide array of digital decision support tools aimed at providing actionable information to decision-makers (Lathrop et al. 2017).

Rapid advances in artificial intelligence and machine learning (AI/ML), including the emergence of deep learning methods such as neural networks and machine vision, have great promise for ocean data (LeCun et al. 2015). As the variety and volume of ocean data increase, there are similar efforts to use AI/ML tools to derive insights and, more importantly, predictions regarding complex processes, such as large-scale rainfall patterns or severe storms, and eventually even more complex systems that involve ecosystem resilience and human activities. For these complex systems, where deriving mathematical formulations and collecting reproducible data are extremely difficult, big data and AI/ML have become especially appealing.

Within the physical domain, AI/ML have shown potential as a means to substantially improve traditional methods for systems predictions. For example, the US Bureau of Reclamation recently sponsored a contest on sub- seasonal climate forecasting for rainfall patterns in the western United States. The best-performing team relied on AI/ML methods to outperform the benchmark forecast model (Soeth 2019). NOAA is developing a comprehensive strategy to integrate its enormous volume of data with its numerical models using AI/ML approaches to tackle long-standing challenges in Earth system forecasting, such as hurricane tracks and intensity (Bayler 2019).

Much of the appeal of these new methods rests on the fundamental difficulty of developing a mathematical framework for complex, multiscale processes. For example, the microphysics of clouds cannot be resolved at the scales possible in global climate models. Moreover, the processes are difficult to measure as well. However, these processes cannot be ignored and therefore must be parameterised. New methods rely on stochastic formulations of these processes, which are then coupled with the deterministic models of larger- scale processes (e.g. Palmer and Williams 2008). With the advent of AI/ML techniques, it is a fairly straightforward intellectual leap to move from stochastic/deterministic models to AI/ML models.

Phenomenal improvements in AI/ML have enabled better understanding of complex processes, such as language, than is possible with traditional approaches. This has led some scientists to claim that "big data" represents a new scientific paradigm (e.g. Hey et al. 2009). In complex, multiscale processes, AI/ML appears to overcome the challenges in understanding the linkages between these processes, where traditional scientific approaches have been unable to provide any conceptual foundation or mathematical framework. In fact, some have asserted that this means the end of the scientific method, which is based on the connection between reason-driven experiment (or data collection) and analysis based on mathematics and modelling.

Coveney et al. (2016) and Succi and Coveney (2019) provide an extensive review of the interplay between big data and the scientific method. These authors argue that "big data" must work in partnership with "big theory," even when the work of mathematical formulations is difficult and slow. AI-based models are extremely fragile, rarely working outside of the specific data domain in which they are developed. Succi and Coveney (2019) note four key points:

1. Complex systems are rarely based on Gaussian distributions.
2. Complex systems are highly sensitive to small errors, so datasets are never “big enough.”
3. Correlation does not imply causation, especially as the links become more remote as the size of the datasets increase.
4. Too many data are as bad as no data.

While we can expect AI/ML to help guide our observing systems and our analyses, we must continue with the fundamental science and mathematics of complex systems.

Beyond better forecasting and analysis of scientific datasets, AI/ML have also unlocked new potential for management. Advancements in computer vision, for instance, allow marine species to be automatically identified from video footage. This opens the door to a new era of electronic management in fisheries, replacing human observers—who are often harassed and in some cases even killed—with video cameras. ML algorithms can automatically review the video footage captured by these cameras to determine what species are being caught and whether vessels are operating legally, at a much lower human and monetary cost than taking observers on board.

More powerful AI/ML analysis techniques also support the creation of advanced knowledge products to support key ocean management needs. Global Fishing Watch, for example, provides a global window on fishing, by providing visualisation of fishing activity through the GPS devices (AIS) required on large vessels. Using ML algorithms to analyse the large amount of data coming from these vessels, Global Fishing Watch can identify when and where a vessel is engaged in fishing activity, classify the type of fishing, and detect other behaviours such as trans-shipments and potentially illegal incursions into protected areas. Similar techniques are being employed by a large new class of enforcement tools that use ML to identify illegal behaviour on the ocean. AI/ML capabilities are foundational to analysing the volumes of data provided by emerging technologies and newly networked data, supporting a new generation of knowledge products for managers.

AI has enormous potential to translate the growing flood of ocean data into information that is relevant—and vital—for research, and for the use and management of ocean resources. To realise the potential will require better access to data, through the federated networks and data lakes described above. It will also require innovations in ML. While current methods to train neural networks require vast labelled datasets, emergent methods are able to learn from relatively few labelled points (Reichstein et al. 2019). These methods provide a path forward for many ocean problem sets where the quantity of labelled data are extremely low. As these new methods come online, predictive modelling for ocean management will become exponentially more powerful.

Beyond issues of data availability, current ML suffers from intensive computational requirements. The future will see exponential increases in available compute power, enabling more powerful understanding of our ocean. However, increases in compute are fuelled by significant energy expenditures. The future of ML compute must come from renewable sources.

AI/ML solutions are currently highly tailored to specific ocean problems. For instance, image recognition algorithms are trained to identify individual fish species and may be very difficult to adapt to recognise other fish species. Computational and methodological improvements unlock new possibilities to move beyond hyper-specific ML prediction to generate new cross- cutting understanding of ocean conditions. Advances in modelling that combine ML techniques with physical modelling can combine both data-driven and theoretical insights to generate robust, interpretable results that are testable against physical realities (Reichstein et al. 2019). Applying these methods to broad datasets can move beyond single-problem insights to demonstrate new relationships between diverse ocean conditions.

While ML shows promise, there are significant issues of bias that also need to be addressed before it is widely adopted in management. ML outcomes are only as good as the data they learn from. Existing inequity can be exacerbated in cases where complex machine learning algorithms are being used to identify illegal behaviour (such as in the case of many advanced tools for monitoring illegal fishing) (Sajin 2018). If, for instance, an algorithm looks at past enforcement actions to build a model that predicts the likelihood of future illegal activity, this algorithm will solidify any historical bias in which types or flags of vessels have been most often targeted for enforcement. AI/ML algorithms can also be susceptible to false or “spoofed” data. Small pieces of inaccurate or manufactured data can lead to erroneous results and inferences from these complex, but fragile, algorithms (Amodei et al. 2016). Emerging work in AI interpretability may help to overcome these issues by allowing managers to see into the black box of AI to identify systemic biases and to elucidate the basis for management outcomes so that they can be legally enforceable.

4 Harnessing the Technology Revolution to Transform Ocean Management

In recent decades, there have been important innovations in ocean management and in using markets to incentivise more sustainable use of ocean resources. Technological advances

Table 6.1 Technology enables innovations in management

		Management Innovations			
		Dynamic and automated management	Integrated ocean management	Rights based management	Harnessing the market
Enabling technologies	Sensors	In-situ, remote and vessel-based sensors enable highly granular observations of current ocean conditions	Autonomous vehicles, profiling floats and other new sensor platforms allow previously unreachable areas to be studied	Low cost sensors support community management of marine resources	DNA barcoding and other biotechnology tools can verify product identity throughout the supply chain
	Communication networks	5G networks and satellites enable real-time transmission of ocean data to managers and resource users	Acoustic networks, cabled observatories and satellite transmission can link distant sensors to shore	5G and cellular networks allow fishers and other resource user to access resource user to access management	Apps that use blockchain can create an immutable record of product movement
	Data systems	Data lakes and federated networks provide access to the data from different sources needed to support dynamic management	Data lakes can give scientists access to unstructured data that supports many different kinds of analysis	Local data networks allow resource users to share and access relevant data on resource use and conditions	Federated data networks allow industry to share relevant data while respecting privacy and ownership concerns
	Data processing	Advanced modelling analytics support near real-time data processing and analysis	Machine learning enables new analysis of large and previously disparate datasets	Modelling can better predict resource use and allocations	Machine learning can be used to analyze large volumes of industry information for compliance
	Knowledge tools	Blockchain combined with near real-time sensor data can be used to create smart contracts that automate management decisions	Near real-time vizualizations of ocean conditions provide critical information for managers	Daily maps based on new data and modeling are being used in fisheries to maximize catch and reduce protected bycatch	Apps and other tools illuminate the supply chain for consumers at the point of sale

offer the opportunity to leverage those innovations, creating new capabilities, new incentives and new accountabilities (Table 6.1).

4.1 Public Management

Historically, the ocean has been managed as a public good. Public management has had limited tools, and has been constrained by politics, practicalities and a profound lack of information. The result of these limitations has been a reliance on regimes that are static and often crude, and that sometimes create perverse incentives.

4.1.1 Innovations in Management

In recent years, there has been increasing emphasis on ecosystem-based management (EBM) for managing marine systems. EBM shifts away from traditional, siloed management of individual resources or uses to consider the ecosystem as a whole and the full range of human activities within it (Long et al. 2015). Successful EBM regimes require a wealth of scientific data to understand and predict the complex relationships and dynamics in marine systems. EBM must also be nimble in responding to changing ecosystems and stakeholder needs and interests, requiring an integrated approach to ocean management.

Two innovations in governance—dynamic management and rights-based management—have shown particular promise in aligning capabilities and incentives with sustainability. Emerging technologies can leverage these policy tools to increase the effectiveness of marine management.

Dynamic Management Ocean management has always been challenged by the fact that resources and conditions are constantly changing. With the increase in climate and other stressors, that challenge will only grow. Yet ocean management has typically been static—relying on fixed areas, seasons and catch limits. Dynamic management strategies allow managers to make near real-time adjustments as conditions change (Maxwell et al. 2015). In fisheries, this has meant a transition from, for example, static spatial limits on fishing that are set at the beginning of a season, to dynamic closures where the allowed fishing area can be adjusted based on the status of stocks, the presence of bycatch species and other key indicators. Dynamic management is the essential underpinning of a new generation of responsive, ecosystem-based marine spatial planning.

Technological innovations have made dynamic management possible. New tools for monitoring ocean conditions and for communicating with geographically dispersed resource users allow managers to make rapid decisions and disseminate them widely. In one striking example of dynamic management in action, a series of hydrophones were attached to buoys in the busy shipping lane approach to Boston Harbor. When the hydrophones detect the song of endangered right whales, this information is automatically transmitted to ships approaching the harbour and reduced speed limits are imposed (Laist et al. 2014). By allowing vessels to maintain high speeds when whales are not in the area, this approach reduces ship strikes on whales while maximising shipping efficiency. Other examples of dynamic management include the dissemination of real-time information on high-risk areas for turtle bycatch to fishers in Hawaii. A recent study found that in the California drift gillnet fishery, a highly dynamic fishery that is difficult to manage, implementing dynamic spatial closures could significantly reduce the percentage of total area closed to fishing to achieve the same conservation goals (Hazen et al. 2018).

Rights-Based Management Policies that focus on shifting incentives to achieve management goals represent another important frontier in marine policy (Lubchenco et al. 2016). For fisheries, many jurisdictions have taken steps to better align the incentives of resource users with long-term sustainability by instituting rights-based management (RBM). RBM regimes seek to eliminate the traditional problems associated with common pool resources by assigning property rights in the resource to the resource users (Nyborg et al. 2016), either through quota systems that assign a percentage of fish catch to each user (Individual Transferable Quotas) or through territorial rights that give stakeholder groups exclusive rights to fish in a specific area (Territorial Use Rights for Fishing (TURFs)).

When designed correctly, RBM has proven to be a highly effective management solution (Lubchenco et al. 2016). To succeed, leaders must build consensus among stakeholders before policies are implemented. They should develop a regime that combines strong property rights with reputational and behavioural incentives and ensure that rights are protected with enforceable sanctions (Crona et al. 2017).

RBM is not a silver bullet to solve fisheries management, however. Some note that giving fishers a quota of fish stocks is not the same as a true property right, and may lead to continuing management issues in the future as incentives for fishers are not fully aligned with the long-term viability of the fishery (Bromley 2016). Others note that inequity may be reinforced by the distributional choices made in allocating quotas, which are often based on historical catches, rewarding those with the most economic clout (Guyader and Thébaud 2001).

Some systems have found creative solutions to these challenges. In some industrial fisheries in the Bering Sea, for example, a percentage of the fish catch is allocated to coastal communities as Community Development Quotas (Haynie 2014). Coastal communities are able to fish or lease their quotas to fishing companies and invest the revenues. These programmes have been successful in helping to alleviate some of the largest equity concerns around the privatisation of fisheries (Carothers 2015).

These new models of governance—ecosystem-based, rights-based and dynamic—are helping managers meet the challenges of managing the many pressures on ocean resources. New technologies—from more powerful sensors to smart contracts—offer opportunities to build on these policy innovations, creating a new era in ocean management that transforms both capabilities and incentives.

4.1.2 Making Management Robust and Nimble

The years ahead will see significant advances in our ability to collect data on resource conditions and uses with high spatial and temporal resolution, and to translate those data into actionable information for users and managers. The continued proliferation of satellites and ocean-going drones will expand capability to monitor activities on and in the water. Video cameras on fishing boats and on nets will allow fishers to more precisely control their catch and will enable increasingly granular management and accountability. Flocks of communicating sensors in the water will be able to identify emergent problems and swarm to investigate (Jaffe et al. 2017).

These capabilities will become increasingly vital to effective, ecosystem-based ocean management as climate change and other stressors disrupt ocean systems. It will be essential to have real-time information on ocean conditions to be able to manage heatwaves, shifting fish stocks, harmful algal blooms and other upheavals.

New technologies enable a better understanding of how humans are using marine ecosystems. Monitoring data on human use can guide enforcement efforts, allowing more targeted deployment of enforcement solutions focused on providing data in near real time that meets legal evidentiary requirements. New options, from drones that allow visual monitoring of distant water areas (e.g. ATLAN Space) to mandatory tamper-proof GPS-enabled devices on fishing vessels, provide this information to enforcement officials.

Real-time data supports integrated approaches to ocean management. Integrated ocean management (IOM) creates comprehensive management plans to reconcile competing uses of the ocean and ensure ecosystem health (See Blue Paper 14 on "Integrated Ocean Management"). IOM tools, such as marine spatial planning, are important pieces of the ocean management landscape but require extensive data on both ecosystem baselines and human uses of the ocean.

Technological advances could have profound value for helping fishing communities manage their resources. In small-scale fisheries, for instance, small GPS trackers enable fishers to accurately track where they fish each day. Apps like mFish allow fishers to use their smartphones to receive critical data on weather, market prices and other conditions, while at the same time using their phones to collect key data about what they catch and where. Fishcoin allows buyers to compensate small-scale fishers for collecting data they need, paying them in mobile-phone minutes through a blockchain. Blockchain technology can also help small producers connect to global supply chains.

A future of robust management based on better information is not assured. Even when relevant data are available, managers often do not get the information they need because data are not available to them, or because they do not have scientists working with the data to address the most policy-relevant questions (McConney et al. 2016). Even decision-support tools designed explicitly for marine managers are often so technical that only programmers are able to use them (Stelzenmüller et al. 2013). Non-governmental organisations (NGOs) and interdisciplinary research organisations have been important players in bridging the science–policy divide, allowing research priorities to be developed collaboratively with scientists and managers (Sutherland et al. 2011).

4.1.3 Automating Management Through Smart Contracts

In the next decade, technology will not only expand the potential for dynamic management regimes, but also open new frontiers for completely automated management. Dynamic management still typically relies on the human process of translating data into management decisions. Coupling dynamic management with the possibilities opened up by smart contracts, among other technologies, creates the opportunity to automate some areas of marine management.

In other industries, smart contracts are the cutting edge of regulatory compliance efforts. Smart contracts rely on verification—once the agreed conditions have been met, smart contracts execute automatically (Le Seve et al. 2018). For instance, smart contracts for travel insurance can automatically send compensation to passengers when online flight trackers report that their flights have been delayed by a pre-agreed amount. These smart contracts are generally based on distributed ledger technologies, so that they are immutable and tamper- proof. Automatic execution reduces opportunities for corruption and fosters transparency.

When these contracts are connected to environmental sensors, there is the potential to automate aspects of environmental management (Jensen and Campbell 2018). Smart contracts have already been used to facilitate peer-to-peer water management in Australia (Le Seve et al. 2018). Water rights are notoriously complex to manage and transfer. Smart contracts allow for easy transfer of water quotas between users depending on agreed upon conditions (for example, if a user uses less than their monthly allotment, a sensor can automatically detect this and transfer the remainder immediately to another party at an agreed rate). In the case of ocean pollution control, for example, sensors placed on ship exhaust could automatically fine companies when the concentration is above allowable levels.

Combining the technological innovation of smart contracts with the policy innovation of dynamic management has the potential to reshape how marine management functions. Replacing tasks that currently require human verification with smart contracts and other tools can free up management resources to be spent in more critical oversight functions that require human attention.

In fisheries, governments and industry working could create near-automated port entry systems based on increasingly powerful monitoring capabilities. This "global entry" system could provide expedited entry into port for fishing vessels that meet predetermined transparency requirements, such as sharing of AIS data, electronic monitoring on board the vessel, and release of information on permits and ownership. Fisheries agencies can use these data to ensure that the vessels are at low risk of illegal, unregulated and unreported (IUU) fishing, and in turn provide preferential clearance and processing while in ports. This type of system can incentivise good behaviour by fishers, while at the same time reducing the impact of corruption by port officials.

Box 6.1: Case Study: Preventing Bycatch

Japan Agency for Marine-Earth Science and Technology (JAMSTEC) uses high-frequency (HF) radar data to understand the relationship between the sea state and the small Pacific bluefin tuna (<30 kg) catch by the setnet. The observations are acquired in quasi real time, every 30 min, and are posted immediately (usually within 1 h) as a surface current map on JAMSTEC website. These setnets are able to register when current patterns are likely to lead to mass bycatch of restricted tuna and alert the local fishers of the potential risk of young tuna entering their setnets in large numbers. The setnet fishers can, therefore, prepare themselves for releasing the young tunas based on the alert. See Appendix 1 for more detail.

Automated systems can also be used to strengthen mitigation measures. Timely detection and forecasting of environmental threats, such as storms, heatwaves and harmful algal blooms, can be directly linked to automated systems that preemptively protect ecosystems. These systems are already beginning to be used in storm water management: predictions of impending storms or detection of water quality parameters outside the normal range automatically trigger additional treatment measures to prevent nutrient loading (Klenzendorf et al. 2015; Lenhart et al. 2018), as well as in the power sector where heatwave predictions trigger cooling curtailments. This should be expanded to link real-time threat detection and forecasting to automatic mitigation action in other contexts. Threat forecasting for harmful algal blooms, for instance, has become highly advanced in order to prevent human health impacts. Linking bloom forecasts with automatic reduction in fertiliser application in neighbouring areas or increased water treatment could help to not just predict but mitigate these and other types of environmental threats.

Automated systems have the potential to make RBM an even more powerful, and more equitable, management tool by facilitating effective enforcement and efficient exchange of fisheries rights. Additionally, new tools like blockchain provide for new, more transparent and reliable ways to transfer quotas quickly without many of the transaction costs that have plagued these systems in the past.

Blockchain advocates go further, pointing towards a future of decentralised management and the complete disappearance of the state (Atzori 2015). With governance based entirely on smart contracts, they argue, managers are no longer needed to create regulations and ensure compliance. In the marine governance system a future where managers are completely removed from the picture is unlikely. Creating regulations is a complex process that involves negotiations among many stakeholders, coupled with an understanding of ecosystem dynamics, which requires human decision-making. Knowledgeable managers thus remain important. One can envision a future, however, in which much of the burden of implementation and enforcement is alleviated by automation.

There are hazards. Although blockchain-based options create immutable records, these records are only as good as the information put into them. Smart contract solutions thus must include robust measures for assuring the accuracy of the data upon which they depend. Stakeholder participation can be part of a data verification system (Jensen and Campbell 2018). If industrial permits, for instance, rely on the clean-up of certain environmental conditions, local stakeholders can verify that conditions have been met by submitting evidence such as photos.

Automated management also raises the spectre of a dystopian future where decisions are made based on complex and opaque algorithms with no human judgement. Governments should only adopt automated management when they have robust processes in place for dispute and review of automated decisions. Automated management should also only be applied to management problems where metrics are quantitatively verifiable (e.g. changes in ocean temperature) and results do not compromise fundamental civil liberties. These criteria need to be evaluated for each proposed application on a case-by-case basis. In the case of alterations to fishing areas or allowable gear types, for example, automated management can allow rapid, real-time changes as oceanographic conditions change without compromising protected legal rights. On the other hand, while AI algorithms can be used to identify probable illegal fishing vessels based on their behaviour, they cannot be a sufficient basis for automated enforcement action because the basis of the determination is unspecified and the consequences could be criminal liability.

Automated management can shift human management resources from routine, numerical determinations to more complex ecosystem-level analysis and decision- making. When coupled with stakeholder engagement, incentive-shifting and improved baseline data, automated and dynamic management will help to support successful ocean governance and integrated ecosystem-based management.

4.2 Harnessing the Market

In the private sector, the transparency and traceability enabled by technological advances can create new incentives for more sustainable practices.

Over the past 20 years, the Sustainable Seafood Movement has demonstrated the potential for market actors—including consumers, retailers, processors, fishers—to incentivise better management of fisheries. Independent certification of fisheries and chain of custody through supply chains, such as through the Marine Stewardship Council, and ratings systems, such as Seafood Watch, help buyers to identify seafood from well-managed fisheries. A growing number of multinational companies have taken increasingly active roles in promoting sustainable seafood, including: retailers such as Walmart and Tesco; the leading tuna processors, through the International Seafood Sustainability Foundation; and 10 of the largest seafood companies, through Seafood Business for Ocean Stewardship (SeaBOS).

In recent years, growing consumer concern over fish provenance, coupled with corporate interest in supply chain control, have sparked significant momentum towards supply chain traceability. In 2017, 66 companies signed the Tuna 2020 Traceability Declaration, pledging that all tuna they buy will be completely traceable by 2020. More than 30 major companies, including SeaBOS, have signed up to the Global Dialogue on Seafood Traceability, specifying the key data elements to be collected in their supply chains and creating standards for IT platforms to ensure interoperability.

Many are looking to blockchain and other distributed ledger technologies to support supply chain traceability. As noted above, however, these systems depend on the reliability of the data on the provenance of goods entering the system, and therefore depend on the market creating strong incentives for driving transparency through far-flung supply chains (Hardt et al. 2017). Emerging technology offers the prospect of increasingly robust transparency—providing near real-time information on where boats are fishing and what they are catching—and traceability from the moment of catch to the supermarket shelf.

Publicly available vessel tracking data are now being used to track larger vessels (Kroodsma et al. 2018). As more countries share the more granular data they already collect, and as satellite surveillance capabilities expand, a much larger proportion of the global fishing fleet will be tracked. Global Fishing Watch, for example, aims to expand its coverage from 60,000 vessels today to 300,000 by 2029. Continued progress in developing AI and ML tools to process data from video monitors and satellites will also expand the ability to monitor fishing activity. This growing transparency will be matched by continued improvements in traceability, through genetic tools, sensors and electronic tags or QR codes that can be used to track fish through supply chains and verify source and species.

These data systems have the potential to enable buyers, such as processors and retailers, to ensure that the fish they buy is legal and meets their environmental and social standards. Providing actionable information at the moment of the decision may also spur sustainable choices on the part of consumers. Apps at the point of sale can display these data for consumers, showing them where fish is caught and how it has been processed and shipped. Allowing consumers access to data on whether fish have been illegally caught or are contaminated with mercury or microplastics, for instance, could inspire more informed decisions.

Historically, fishers have closely guarded information about where they are fishing. High-level information on the most productive areas has been available for decades, however, leading to the globalisation of effort by the major fishing nations (McCauley et al. 2018). Global Fishing Watch and other platforms protect more granular information on where vessels are moving in response to daily fluctuations in fish stocks by placing a 72-h delay on the release of vessel location.

Stringent transparency and traceability requirements can make it harder for small-scale fishers to sell into global supply chains. The cost of vessel tracking systems is already out of reach for most small fisheries. Low- cost traceability apps built on smartphones provide a promising option for these small-scale fishers, but companies will need to accommodate these types of solutions in their traceability systems. Agreement on global standards, like the Global Dialogue on Seafood Traceability, can also facilitate the development of tools.

As technology continues to improve and leaders in the seafood industry act on their commitments, there is the clear prospect that full transparency and traceability will become the expectation of the marketplace and the cost of doing business, and usher in a new era of accountability.

4.3 Ensuring That Technology Promotes Sustainability

Over the course of history, advances in technology have generally led to increased exploitation of ocean resources—more powerful boats and fishing gear have transformed fishing from a coastal activity to a global industry and driven many fish stocks into decline; deep-water platforms and drilling innovations have enabled massive extraction of oil resources and soon, possibly, minerals on the seafloor. The rapidly expanding capabilities in information technology described above could similarly accelerate exploitation—helping fishers track down every last fish, for example. These new capabilities thus come with two imperatives. The first is management—as the ability to exploit resources expands, effective management of those resources will be ever more vital. The second is accountability—information on resource conditions and use must be public, so that users of public resources are accountable to governments, to markets and to the public.

To realise the potential of new technology to support sustainability, it will be essential that these new capabilities are available not only to well-funded governments, companies and institutions, but also to governments and communities with more limited means. This requires both that ocean data are widely accessible and that the hardware and software to access those data are available and affordable. Low-cost technologies based on smartphone capabilities are one promising avenue, taking advantage of the increasing ubiquity of smartphones to allow both access to global information and the generation of locally relevant data. This can enable better management and increased accountability, and facilitate access to global markets. However, capacity-building is needed to ensure that the physical and intellectual infrastructure exists to support these advances in all areas of the globe.

In this report, we have focused principally on the explosion in new data on ocean health, resources and resource use—from new sensors and other sources—and the increasingly powerful technologies for extractin action. Advances in genetics and biotechnology mean that those fields also have great potential to play a central role in sustaining ocean resources. Research on the genetics of coral, for example, is helping scientists identify species that are more resilient to heatwaves, and thus better equipped to thrive in a warming ocean. Researchers have developed new microbes that can break down plastics in the ocean or oil from oil spills.

Biotech may also have a role in mitigating the environmental impacts of aquaculture, including: the destruction of coastal habitats to build fish farms; pollution from the use of pesticides and antibiotics; and a massive increase in demand for fishmeal and fish oil, harvested from wild stocks, to use in feed. New strains of fish, bred to be resistant to disease can reduce the need for antibiotics. New plant-based feeds are reducing the need for fishmeal and fish oil.

Gene drives can eliminate invasive species and restore ecosystems by introducing altered genes that promote the inheritance of a certain genetic variant (in the case of invasive species, often a variant that makes organisms infertile) (Esvelt and Gemmell 2017). These solutions have the potential to eliminate invasive species populations that have wreaked havoc on ecosystems and been nearly impossible to control using conventional methods. However, introducing altered genes is akin to introducing another invasive species into an ecosystem—one that can invade any viable population with consequences beyond what we are capable of predicting.

Some innovators are now aiming to reduce overfishing by producing seafood without relying on fish. Companies, such as Finless Foods, Wild Type and BlueNalu, are cultivating tuna, shrimp and other seafood in laboratories. Cultured seafood has the potential to protect wild fish stocks while having a significantly lower overall environmental footprint and a reduced risk of contamination (a major problem in high trophic-level fish species due to the bioaccumulation of mercury and other heavy metals in wild populations) (Stephens et al. 2018).

5 Fostering Technological Innovations for the Ocean

Sustainable use of the ocean will require new technologies for researchers, managers, resource users, coastal communities, companies, consumers and others who have a stake and a role in ocean stewardship. Technologies that are important for ocean stewardship typically face significant barriers, however—debilitating start-up capital costs, regulatory constraints and lack of clear revenue streams (OECD 2019). Technological innovation in the ocean has therefore been largely driven by government and large-scale commercial interests. For some other needs, such as scientific instrumentation, small markets have often led to hyper-specific solutions that lack commercial applicability, creating an environment of technology lock-in. Many needs are simply unserved.

Overcoming these market barriers is critical to fostering successful innovation that supports science and management in the future. The landscape of innovation is complex. To capture the extraordinary potential of technology to enable ocean stewardship will require action by governments and others to create market incentives for innovation, as well as new public–private instruments for investment and new business models.

5.1 Creating Market Incentives for Innovation and Diffusion

Both governments and private actors have critical roles to play in incentivising the technological innovations that will be needed to safeguard the health and sustainable use of the ocean.

5.1.1 Governments

The history of environmental policy has shown that strong, technology-forcing regulations drive innovation. Regulations that place limits on pollution, such as automobile or power-plant emissions, for example, have repeatedly spurred technological innovation by industry to lower the cost of reducing emissions. In the same way, the International Convention for the Prevention of Pollution from Ships (MARPOL) has incentivised innovation across that sector. In addition, the recent International Maritime Organization mandate requiring the global shipping fleet to halve its greenhouse gas emissions by 2050 has already spurred major technological advances in vessel propulsion, creating the prospect that zero-emission vessels may enter into service by 2030. Similarly, government requirements for monitoring and safety provisions on vessels have created markets for technologies that enable companies to achieve and demonstrate compliance.

Government regulation can also be vital in driving the diffusion of new technologies into large-scale application. In recent years, for example, there have been many innovations that could significantly reduce bycatch in fisheries, but many have not been widely implemented. Stronger government restrictions on bycatch could quickly drive the widespread adoption of those solutions.

The ocean is a patchwork of regulatory jurisdictions, but experience in other sectors demonstrates that actions by individual authorities can nonetheless drive progress. Measures to promote the use of solar energy in Germany and a few other jurisdictions spurred massive innovation in that sector globally, for example. The US mandate that required shrimp catchers to use turtle exclusion devices (TEDs) led to global adoption and innovation in TEDs (Yaninek 1995). Individual governments can incentivise innovation in the ocean by adopting forward-looking technology-forcing regulations, without waiting for international action.

Specifically, governments should prioritise forward- looking technology-forcing regulations that target real- time monitoring of fishing, shipping emissions, mineral development, coastal development and pollution, and that create public accountability. Some technology solutions already exist in these areas. Government could radically increase innovation by building on these tools. In the case of fisheries, mandates by major seafood-catching countries (such as European Union countries, the United States and Japan) that all vessels use electronic monitoring, for example, could spur a wave of innovation, speeding up the translation of existing AI expertise from the technology sector to ocean management.

Governments can also drive innovation in less direct ways. The barriers to innovation are often information gaps: the technology community is unaware of the specific problems that managers need to solve, while managers do not have the technical expertise to know what solutions are possible. By bringing together managers and technology companies, governments can catalyse the development of innovative management tools that use readily available resources. For example, in the Caribbean, MPA managers and technology experts worked together to develop low-cost acoustic sensors that are being used, together with smartphones, to detect vessel activity in areas that are off limits to boats. When the sensors detect an acoustic signature, the mobile phones are programmed to send a text to local enforcement agencies, allowing effective, low-cost enforcement of MPAs.

Creating a national account for the ocean can make the economic benefits of innovation in the ocean clear. Current GDP-based models of national accounting do not effectively capture these benefits, and as a result ocean innovation is often undervalued. Using a suite of indicators to understand ocean production, income and sustainability can spur economic investment, innovation and stewardship (see Blue Paper 8, “National Accounting for the Ocean & Ocean Economy”).

Trade and import controls extend a government’s influence beyond its own territory. Requirements to ensure that imported products were legally produced or comply with labour or environmental standards spur innovations to create transparency and traceability in supply chains. The US Lacey Act, for example, has required importers to demonstrate compliance with the laws of producing countries. Under the EU 2008 IUU fishing regulation, the European Commission has blocked imports from countries with inadequate controls on illegal seafood products, and has issued “yellow cards” to others as a warning that imports will be blocked unless stronger measures are put in place.

5.1.2 Private Sector

Crucially, private sector action can often play a similar role in creating market incentives for innovation. Over the past two decades, many global companies have begun to address issues of environmental impacts and labour conditions in their businesses and in the far reaches of their supply chains. The Sustainable Seafood Movement, described above, is a leading example. The Global Plastic Action Partnership is another. As companies drive changes in their own operations and raise standards for their suppliers, they create opportunities for innovators to develop technologies that can improve environmental performance or provide greater accountability and sustainability across supply chains.

Commitments by companies to transparency and traceability in their supply chains illustrate the potential. Companies are beginning to capitalise on the rapidly expanding capabilities for monitoring activities on the ocean—through remote sensing, for example, and video or other monitoring on board vessels and in the water—in order to gain greater visibility and stronger accountability across their businesses. In this way, they can drive both improvements in technology and reductions in cost, and these capabilities will then become increasingly available to less-developed markets. Similarly, growing corporate interest in traceability spawns new solutions, such as the recently launched blockchain platform OpenSC. Tech innovators partnering with NGOs and big seafood companies can extend that capability to small-scale fisheries, as Fishcoin is now pioneering, using blockchain to compensate fishers for the collection of key data on their fishing and enabling traceability.

5.1.3 International Standards

Finally, both governments and the private sector can play important roles in setting the standards for technology that enable a fertile ecosystem for innovation. There are many examples of past collaborative efforts between the private sector, governments and academia to create new standards, but the Internet is one of the most useful examples (Abbate 1999). In this case, a government agency (the US Defense Advanced Research Projects Agency—DARPA) worked with a small number of academic researchers to create the basic structures of the Transmission Control Protocol/ Internet Protocol (TCP/IP) to serve ARPAnet, the forerunner of the Internet. TCP/IP was then widely adopted by the Internet community as a result of a DARPA mandate to all of its contractors to use ARPAnet. The initial standard- setting by government, and the subsequent buy-in by the private sector, was successful in launching a standardised Internet platform and unleashing a wave of innovation.

International agreements can also play a role in creating global market demand for new technological innovation for the ocean. The Port State Measures Agreement (PSMA) by the Food and Agriculture Organization of the United Nations (FAO), for example, creates new requirements for port monitoring and control that are applied globally and that will require technological innovation in data collection and sharing to achieve. Agreements like PSMA also often include goals for technology transfer and capacity-building that commit governments to ensuring that developing countries have the same access to promising management solutions (Harden-Davies 2017).

5.2 Mobilising Investment

The current landscape of ocean innovation is centred in highly capitalised private sector industries, such as oil and gas, industrial fishing and shipping, and government-funded defence departments. This has been the case for the past century, and consequently many of the technologies now used by scientists and managers were developed under government defence contracts or for marine industrial use. Examples of this include many deep-sea submersibles and autonomous vehicles, with technological underpinnings pioneered by defence departments before being adopted by scientists. Similarly, innovations in the oil, gas and fishing industry that allow companies to work on submerged infrastructure or increase detection abilities of fish schools have been widely adopted beyond these industries. As with government defence efforts, these profitable industries are able to support significant research and development (R&D) expenses beyond what is generally feasible for marine researchers or managers.

This model has been successful in many ways. Capitalising on the market power of industry and government to develop technological solutions for the ocean has allowed scientists and managers to take advantage of innovation without high capital expenditures. The government model of investing in early-stage technologies has led to important advances. This happens both with investments through R&D programmes as well as through direct investment in the innovations needed for government purposes, particularly the defence industry. Both of these avenues have yielded critical marine innovations without which managers would have significantly less technological capacity than they do today.

Relying on the trickle-down of commercial and defence technologies is not sufficient to fill the needs of marine managers and other ocean stakeholders. For instance, gaps in information about marine ecosystems that are not commercially valuable may not be filled by technologies aimed at efficient oil extraction or target detection. The development of technologies to fill these gaps lags behind those incentivised by the strong market forces of industry.

Overall, environmental innovations have been notoriously underrepresented in the new wave of technological innovation. In the United States, for example, total federal expenditure on R&D is about US $125 billion. Of these expenditures, the amount spent on space flight and space research is about $10 billion; less than $2 billion is spent on the ocean sciences. Moreover, in the United States and elsewhere, government funding tends to go to early-stage research and dries up in later stages of development (OECD 2019).

In recent years, private investment has expanded beyond traditional marine industry R&D, with venture capital funding and start-up accelerators focused on ocean innovation. These avenues lag far behind the funding available in other industries, such as energy and healthcare, but provide potential avenues for scaling up technology solutions with strong business models.

Several specialised technology accelerators focused on the ocean are providing early-stage funding to innovative technologies that advance the sustainable use and management of marine resources (e.g. Katapult Ocean and the Sustainable Ocean Alliance). The start- ups funded are tackling issues ranging from seafood traceability to the development of bioplastics and wave energy. These solutions present important steps towards solving ocean issues in cases where innovation offers the potential for strong market returns.

Large prizes are also incentivising ocean technology innovation. These prizes are funded by a mix of individuals, companies and large foundations. XPRIZE, for instance, has been successful in incentivising the development of breakthrough technologies such as private spaceflight and autonomous ocean mapping robots. While these prizes have spurred important progress technologically, there are significant concerns about whether these developments will be able to scale given current market constraints (Kremer and Williams 2015).

Considerable academic research has been devoted to identifying the driving frameworks for innovation. These frameworks are complex, adaptive systems that rely on the participation of a wide range of actors, including public, private and research institutions. Other sectors provide a roadmap for what this ecosystem could look like. Agriculture has faced many of the same problems in technology innovation and adoption as the ocean has, including a fragmented producer landscape, lack of technology incubation support and high resource investment requirements. Partnerships that bring together a mix of institutions, from private sector investment to government incubators and philanthropic efforts, are able to overcome many of these barriers (WEF 2018).

For the ocean, the Organisation for Economic Co- operation and Development (OECD) has specifically recommended bringing together a diverse group of actors to spur innovation in "ocean economy innovation networks" (OECD 2019). These networks provide many potential benefits by leveraging complementary innovations at different points in the innovation stack and by providing technology transfer to developing countries. These multisector approaches are more likely to foster complementary innovation that increases the potential impact and uptake of new technologies. By combining multiple technologies in layered systems, the impact of technologies can be exponentially increased (OECD 2019). For example, innovation ecosystems that allow developments in sensor processing to happen in parallel with new communication and platform tools both unlocks unique collaboration but also ensures that emerging technologies are plugged into larger ecosystems of innovation.

Technology clusters such as those recommended by the OECD have already been successful in moving innovation in ocean industries from early, government- funded stages to thriving multi-commercial markets. The Norwegian Centres of Expertise Maritime CleanTech cluster, for example, has been pivotal in driving the adoption of clean energy innovations in cruise and ferry lines. By creating a platform for collaboration between emerging players innovating in the clean energy space, established industry, and government and academic researchers, this cluster drove the development of the first fully electric car ferry, among other innovations in zero-emission and hybrid vessels. Moving forward, similar blue technology innovation clusters should be created to help emerging technology solutions achieve adoption and market penetration. On the other hand, although there is a plethora of these clusters, many of them have struggled to achieve sufficient momentum to be self-sustaining. In these early days, it is essential that governments focus on enabling market demand as well as market supply. Too often these innovation clusters rely solely on a "build it and they will come" model. Creating partnerships between market pull and market push is a role that government should be encouraged to perform.

Box 6.2: Case Study: Creating New Market Opportunities

In Japan, the declining number of operational fishing boats together with the declining number of fishers—due to ageing and other factors—is emerging as an important issue, especially for sustaining the exploration-type fisheries on the coast and offshore. For this reason, it has become more difficult to search for fishing grounds, and the fishers are forced to continue with their inefficient fishing operations. One of the solutions for bringing back the efficiency in the operation is to deliver highly accurate information about fishing grounds to reduce fuel consumption. With that aim, JAMSTEC started research and development on the advancement of fishery forecasting technology for squid, which is one of the most important species for the fisheries of Aomori Prefecture. The outcome was a squid fishing ground forecasting system that provided fishing ground information in real time, and was so successful with fishers that it was transferred to the private sector for routine operational distribution of the information.

5.3 Creating New Business Models

Beyond investment and regulation, innovation in business models can also create new ways to make the economics work to support data access and collection by marine managers and other stakeholders. There are also opportunities to further exploit existing market opportunities that are currently underdeveloped. Research in energy and other markets has shown that the pace of innovation is highly related not only to public investment in R&D, but also to market growth (Bettencourt et al. 2013).

The provision of ocean data by governments is viewed as an important public good, but the costs associated with this can be significant. In addition to the direct economic costs, additional indirect costs of open data include the potential subsidy of private sector activities and the creation of inroads for corporate influence, and the need to be considered in relation to the purpose and potential benefits of open access data (Johnson et al. 2017). For ocean and environmental data, several models exist to help support research and management databases.

Most existing research databases rely on public funding, from governments, universities or other research institutions, with a minority also generating revenue through use and access fees (OECD 2017).

The cost of storing large quantities of data can be prohibitively high. Several creative solutions exist though. NOAA, for instance, reached an agreement with Amazon Web Services (AWS) for storage of key ocean data. Having NOAA data on AWS servers brought data significantly closer to the computation needed to support key knowledge services—for example, weather forecasting—and drove traffic to AWS (Barr 2015). In return, NOAA was able to store petabytes of data on the AWS servers at no cost to the taxpayer.

Innovation in business models can create solutions that are able to meet both management and industry needs. Several approaches are showing promise.

5.3.1 Segmentation

Existing commercial markets for satellite data, for instance, are strong. Many new companies, such as Planet Labs and others, provide slightly degraded data free of cost to researchers. The cost of collecting these data is borne by the commercial entities paying for the data, and the degraded data are of sufficiently high quality to support research use. These secondary markets are important opportunities for ocean management and other uses.

5.3.2 Data Services

Data networks can be supported by the knowledge products built using them. Already, ocean and climate data are being used as the basis for complex insurance decisions, targeted weather forecasts for precision agriculture, and other lucrative knowledge products. Companies like Descartes Labs and others have been successful in this model (Jensen and Campbell 2018). These "data as a service" models can also create opportunities to sustainably support research databases over time (OECD 2017).

Markets for data and knowledge services can also support new innovations for gathering data. Low-cost and distributed sensor systems that are able to gather data at very high resolutions, which directly support commercially valuable knowledge outcomes, for example, have clear market use.

5.3.3 Innovations in Payment

Innovations in payment can drive data collection and traceability throughout the supply chain. Fishcoin, described above, is one example—paying fishers for their data with mobile-phone minutes. Other blockchain- based solutions in agriculture show promise in linking consumers directly to small-scale producers, allowing consumers to directly pay small-scale farmers, for instance, that use desired production techniques. Coupling these payment innovations with new data services can allow citizens to participate more directly in environmental conservation. In China, a tree planting app that allows citizens to donate money to reforestation efforts and then track their growth over time using satellite imagery has already planted over 13 million trees (Thompson 2019).

6 Opportunities for Action

We are poised on the threshold of a digital ocean. To realise that vision, and to enable a flowering of new capabilities to understand and steward ocean resources, governments, companies, researchers and civil society must each do their part. There are six critical steps:

1. **Capitalise on the UN Decade of Ocean Science for Sustainable Development to create a global data network that provides broad and automated access to ocean data.**

   Vast stores of ocean data currently in the hands of governments, researchers, industry and others can be made available to all through data tagging, federated networks and, where possible, data lakes.
   (a) UNESCO should build on existing efforts to establish global standards for metadata, query and data tagging that allow existing datasets to be interconnected and automatically accessed.
   (b) Governments, industry and research institutions should use those standards to make their data broadly available in a global federated data network.
   (c) Data holders and cloud service providers should collaborate to create data lakes within that network to facilitate access to large scientific datasets and enable development of new data services.
   (d) Investment in capacity-building should ensure that these data are available, useful and affordable to all ocean users.
2. **Liberate ocean data.**

   Enabled by federated networks, data holders should establish a new default—that ocean data are broadly available to other users unless there are compelling security, proprietary or other interests.
   (a) Governments should:
   - provide public access to all data collected by defence and security agencies that can be shared without compromising security interests;
   - mandate use of AIS and share essential data on fisheries, including vessel ownership, licences and tracking for all fishing vessels; and
   - require that any user of ocean resources, such as fisheries, minerals or coastal land, is required to make their environmental data available to the public.

(b) Industry should make the environmental data they collect accessible to scientists, managers and the public.
(c) Scientific researchers should, by default, make their data available to all.

3. **Create an "Internet of Things" for the ocean.**

Coordinated efforts by industry, researchers and governments can create advanced sensor networks that provide high-resolution, real-time information about the ocean to anyone who needs it.

(a) Governments should develop new open standards for underwater communications and positioning.
(b) The private sector should work with governments and researchers to ensure that sensors are interoperable and data are generated in standardised formats.
(c) Security and privacy standards need to be developed for terrestrial IoT systems, and these should be adopted for marine IoT systems as well.

4. **Automate ocean management based on near real-time data on ocean conditions and resource use.**

(a) Governments should expand use of dynamic management and, where possible, automate management with smart contracts. These solutions are particularly promising in fisheries management, where stock limits, fishing areas and allowable gear types can be automatically updated based on changing conditions.
(b) Governments should automate mitigation measures to create immediate responses to acute environmental threats, from storms to heatwaves to nutrient fluxes. Forecasts that show impending harmful algal blooms or storms, for instance, could automatically trigger reductions in fertiliser application and increased storm water treatment to proactively protect ecosystems.
(c) Governments and companies should collaborate to create mechanisms for data-based proof of compliance. A voluntary "global entry" system for fishing vessels, for instance, could allow expedited access to ports for vessels that provide information on their ownership, permits and activities to managers—creating incentives for transparency and compliance.

5. **Create incentives for innovation.**

Existing markets do not incentivise many of the technological innovations that are needed for ocean stewardship and research. Governments and companies can change that.

(a) In regulating ocean activities, governments should design regulations to spur innovations that will enable more effective management, such as requiring real-time monitoring of fishing, shipping emissions, mineral development, coastal development and pollution.
(b) Companies should require full transparency and traceability in their operations and supply chains—to spur both better management of resources and innovation in technology, and enable consumers to hold producers accountable and reward better management.
(c) Governments should partner with the private sector to create innovation clusters in areas of market demand that support cross-sectoral collaboration and link emerging technology research and innovation with established industry players.
(d) Governments and companies should support innovative business models that combine commercial viability with support for management, such as governments and large companies who are buying data from, for example, private satellite and drone providers, making that data available in delayed or slightly degraded form for research and management uses.

6. **Mobilise capital for technologies for under-served markets.**

Many markets for ocean technologies do not offer commercial returns. We thus need innovative financial instruments that can leverage the different expectations and risk tolerances of different investors. Governments, philanthropies and private investors should join forces to:

(a) create blended finance facilities that combine risk reduction, impact capital and market capital; and
(b) invest in the development of low-capital technologies and training for developing countries, coastal communities, citizens and consumers to conserve, manage and sustainably use ocean resources.

Acknowledgements The authors thank Annie Brett for her extensive contributions to the research and writing of this report. The paper's technical reviewers, Zainal Arafin, Geir Huse and Sergio Lillo, as well as its arbiter, Peter Haugan, all provided helpful technical comments. The authors also thank the World Resources Institute for providing support as the Ocean Panel Secretariat.

While our colleagues were very generous with their time and input, this report reflects the views of the authors alone. The authors thank Sarah Chatwin for copyediting and Shannon Collins for design.

Appendix 1: Case Studies of Technology Deployment by JAMSTEC

The ocean, seas and coastal zones have diverse and vibrant ecosystems as well as other resources vital for the sustenance of human lives on Earth. In the spirit of sustainable management of these resources, scientists at the Japan Agency for Marine-Earth Science and Technology (JAMSTEC) have conducted a few pilot studies. In a specific case study, high-frequency (HF) radar data were applied to understand the relationship between the sea state and the small Pacific bluefin tuna (<30 kg) catch by the setnet. JAMSTEC has been observing the spatial distribution of surface current velocity in the eastern Tsugaru Strait and the surrounding area since 2014 with an HF ocean radar system (Fig. 6.2).

The observations are acquired in quasi real time, every 30 min, and are posted immediately (usually within 1 h) as a surface current map on the JAMSTEC website (http://www.godac.jamstec.go.jp/morsets/e/top/). The data are publicly available and the maps can be accessed by desktop or mobile/smartphone devices. An analysis of the website's access logs suggests that the fishers working in this area might be the main users of this website.

In the fall of 2017, mass bycatch of small tunas was registered by just two setnets near the HF radar measurement area. The surface current pattern observed by the HF radar at the time indicated a typical current pattern in this area. The catches of such small tunas are strictly restricted to maintain the stocks of the prized fish. Based on this pilot study, the local current data along the coast from the HF radar are now routinely used for safely releasing small tunas from the setnets. For example, when a surface current pattern similar to 2017 was observed in August 2018, a researcher at a local fisheries research institute, Hakodate Research Center for Fisheries and Oceans, immediately alerted the local fishers of the potential risk of young tuna entering their setnets in large numbers. The setnet fishers could, therefore, prepare themselves for releasing the young tunas based on the alert.

JAMSTEC researchers also try to apply the numerical simulation techniques to fisheries using a super- computer. The declining number of operational fishing boats together with the declining number of fishers—due to ageing and other factors—is emerging as an important issue, especially for sustaining the exploration-type fisheries on the coast and offshore. For this reason, it has become more difficult to search for fishing grounds, and the fishers are forced to continue with their inefficient fishing operations. One of the solutions for bringing back the efficiency into the operation is to deliver highly accurate information about fishing grounds to reduce fuel consumption. With that aim, in the financial year 2010, JAMSTEC started research and development on the advancement of fishery forecasting technology for squid, which is one of the most important species for the fisheries of Aomori Prefecture. In this research, JAMSTEC developed a squid fishing ground forecasting system and provided fishing ground information in real time. JAMSTEC conducted a demonstration experiment to deliver ocean forecasts to fishers through a web-based system. An ocean circulation forecast was conducted every week for two fishing seasons (June–August and January– March), a mathematical model was applied to estimate the fishing ground based on a statistical relationship between the ocean environment and the fishing ground and catches, and the results were provided to fishers through our website (Fig. 6.3). In addition, fishing ground positions and fish catches reported by fishers in real time every day were used to fine-tune the model to reproduce the information in our predictions. This demonstration experiment made us realise that there is a strong aspiration from fishers to continuously receive fishing ground forecast information in real time. In order to meet the operational demand in real time and to maintain sustainable

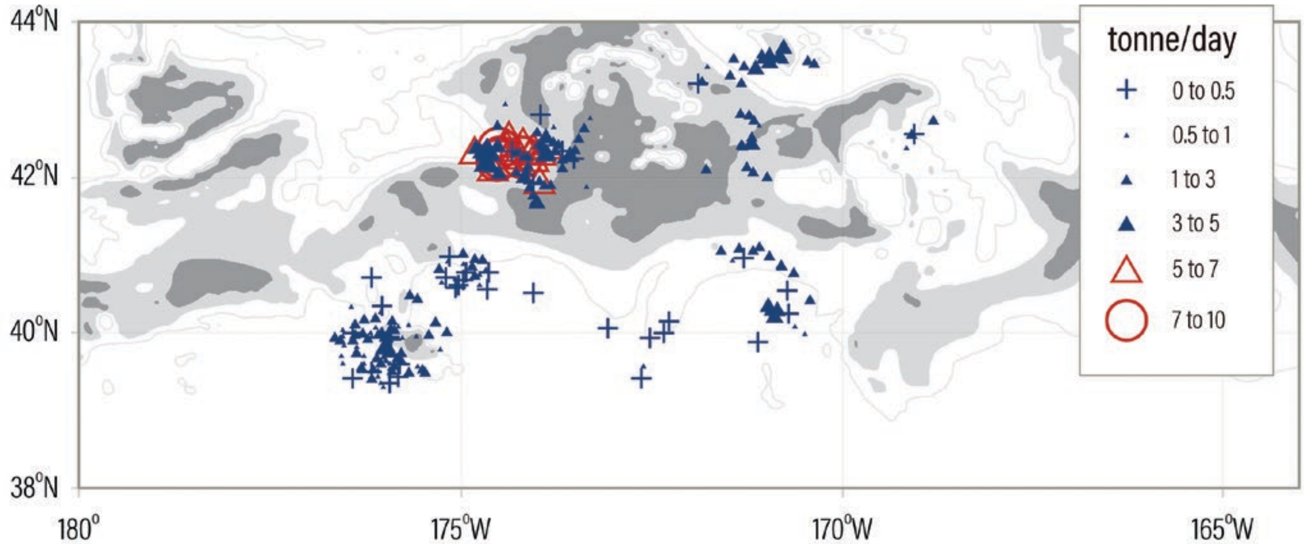

Fig. 6.3 Map of the potential fishing ground on 20 July 2012. *Notes: The potential fishing ground and fishing points in the central North Pacific from 38 degree North to 44 degree North in latitude, from 164 degree West to Dateline in longitude. The fishing point and the amount reported by fishing vessels are denoted by symbols (plus, triangle and circle). The potential fishing ground is shown as the Habitat Suitability Index (HSI, contours), which is normalised between 0 and 1. The contour interval is 0.2. Light grey shading indicates HSI values over 0.6 and dark grey shading indicates those over 0.8. (Source: Information Engineering Program (IEP)/VAiG/JAMSTEC*

fishing, the developed technologies were transferred to the private sector for routine operational distribution of the information.

JAMSTEC is also operating a set of ocean state forecasting models on a super-computer targeting a wide range of spatio-temporal scales from global/seasonal to nearshore/hourly for various other marine applications. The seasonal forecast aims at representing the effects of global climate modes, which are important for seasonal forecasts of basin-scale sea surface temperature variations, obtained from several atmosphere–ocean coupled model forecasts. Nowcast/forecast operations of the ocean currents and the mesoscale eddies are performed by high-resolution ocean circulation models driven by atmospheric weather forecasting products. A main target region of the ocean current forecast is the North Western Pacific around Japan. Detailed behaviours of the major ocean currents, including the Kuroshio/ Oyashio path variations, are predicted every day, and the resulting information is provided to shipping companies for planning optimal ship routes and safe navigation. In addition, currents in some of the targeted areas are highly resolved by utilising downscaling techniques. Figure 6.4 shows an example of downscaling applied to Sukumo Bay, which is located in the Shikoku region of the western part of Japan. The local ocean currents in the bay are forecast every day with a 200-m resolution, and the forecast information is directly provided to the local fishers for their use (In Japanese) (http://www.jamstec.go.jp/jcope/vwp/sukumo500/).

JAMSTEC has from time to time held meetings with the fishers of the area, to exchange views and to explain the coastal environment based on our research results. Based on the outcome of these discussions on such occasions, it became apparent that local fishers wish to stabilise their profit rather than maximise the catch; in other words, they wish to ensure production consistency. More specifically, some of their desires are to:

- reduce the number of days with no catch, which would prevent wasting fuel;
- avoid extreme over-catch to avoid the fall in prices; and
- avoid catching juveniles to increase cost- effectiveness.

All these desires are key to sustainable fishery and it is very impressive that fishers have already recognised them through personal experience. To achieve such a sustainable direction, fishers have requested that JAMSTEC provide the following information and data in real time for their operations:

- Three-dimensional distributions of temperature, currents and current-rip from a few hours ahead for coastal fishers to a few days ahead for offshore fishers, to avoid going to an unsuitable area for fishing
- Positions of “hot spots” of specific fish species to avoid over-fishing
- Details of spawning grounds and juvenile habitats to avoid fishing there

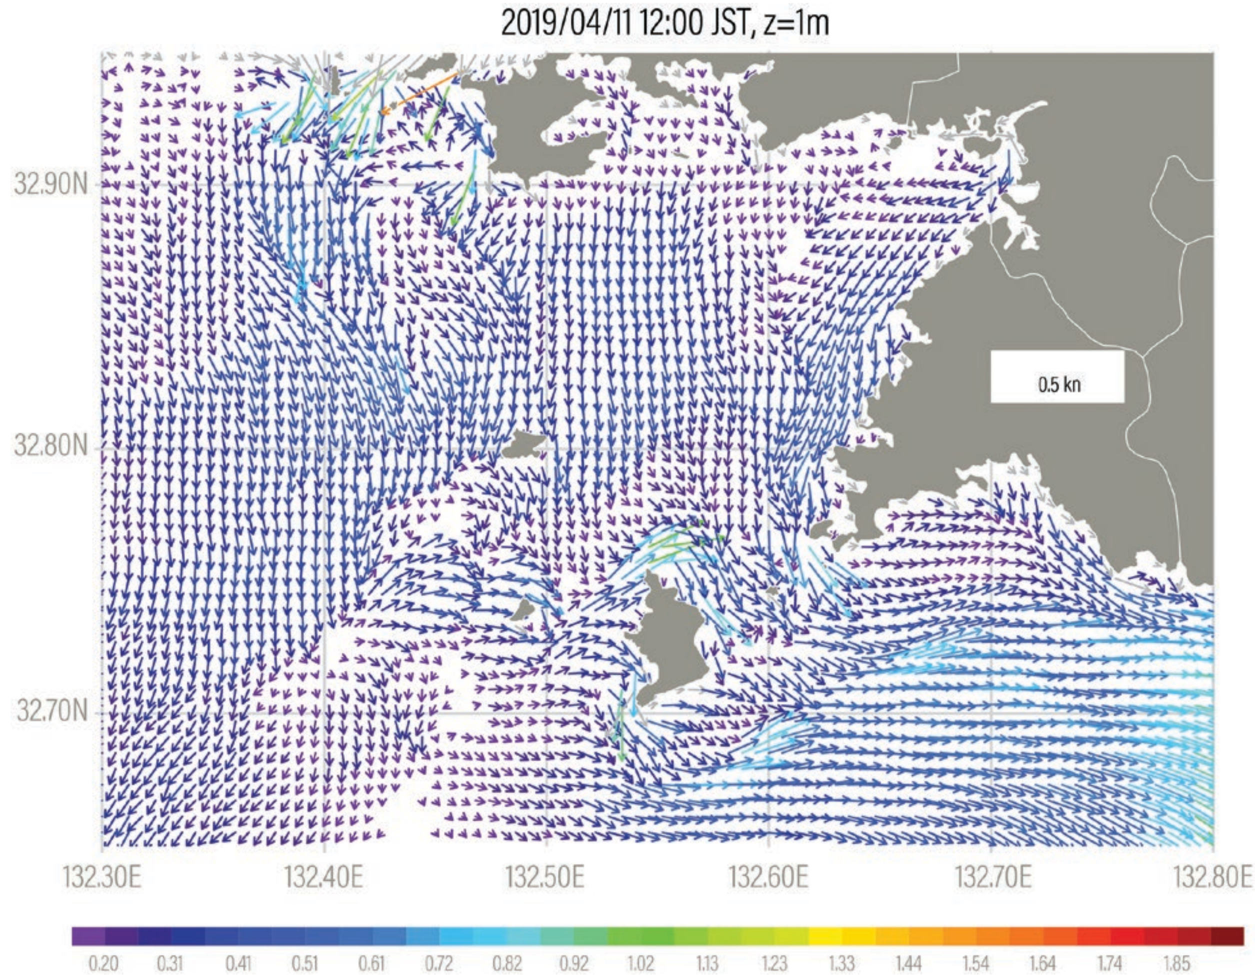

Fig. 6.4 Map of the potential fishing ground on 20 July 2012. *Notes: Arrows and colours indicate direction and magnitude (in knot) of surface ocean currents, respectively. The figure shows surface current. Source: APL/VAiG/JAMSTEC*

JAMSTEC is now at the initial stage of such R&D to meet these requirements and hopes to provide those data and information to the fishers in the near future. In spite of the enormous scientific and technical challenges, research towards such a sustainable goal should be one of the most important missions for science and societal well-being. Therefore, JAMSTEC researchers are now exploring the possibility of forecasting surface current velocity several hours ahead in the Tsugaru Strait by harmonic and pattern analyses as the first step to respond to the requests of local fishers.

A more comprehensive real-time data acquisition system from wider areas of the ocean, as well as advanced simulation models, is required to produce practically useful forecasts. In order to realise such a system, the development of lightweight automated observational instruments (sufficiently easy to use that they can be mounted on fishing boats) and the improvement of technology in data aggregation, processing, large-scale high-speed computation and information distribution services are indispensable. Furthermore, there is a scope to develop overseas non-commercial and commercial applications in the future after domestic operationalisation of the system and its nationwide adoption.

About the Authors

Lead Authors

Jim Leape is William and Eva Price Senior Fellow and Co-Director of the Center for Ocean Solutions at the Stanford Woods Institute for the Environment.

Mark R. Abbott is President and Director of Woods Hole Oceanographic Institution.

Hide Sakaguchi is Executive Director at Japan Agency for Marine-Earth Science and Technology (JAMSTEC).

Contributing Authors

Annie Brett is an André Hoffmann Fellow at Stanford Center for Ocean Solutions and the World Economic Forum Centre for the Fourth Industrial Revolution.

Ling Cao is Associate Professor in Marine Habitat Conservation and Fisheries at the Shanghai Jiao Tong University (China).

Kevin Chand is a Legal Fellow at the Stanford Center for Ocean Solutions and a Lecturer at Stanford University.

Yimnang Golbuu is CEO at the Palau International Coral Reef Center.

Tara Martin is a Research Group Leader in the Oceans and Atmosphere Business Unit of the Commonwealth Scientific and Industrial Research Organisation.

Juan Mayorga is a researcher with the Sustainable Fisheries Group at UC Santa Barbara, and with National Geographic Society's Pristine Seas project.

Mari S. Myksvoll is a senior researcher at the Institute of Marine Research (Norway).

Highlights

- Resilient coastal ecosystems are central to the realisation of a sustainable, inclusive, prosperous, and equitable ocean economy, as coastal areas are home to more than 40% of the world's population and host most of the transport, commercial, residential and national defence infrastructure of more than 200 nations and territories.
- Coastal ecosystems are undergoing profound changes, as they are challenged by climate change, threatened by urbanisation and poor upstream agriculture and extractive industry practices, increasing sprawl of coastal infrastructure, and over-exploitation of resources.
- Failure to properly manage our coastal ecosystems will result in continued environmental damage, compromised development of established and emerging ocean sectors, disadvantaged nations and peoples, as well as inadequate infrastructure to meet the demands of changing demographics and climate change impacts.
- To ensure the environmental, economic and social sustainability of our space-constrained coastal ecosystems, ongoing development of our coasts must be balanced across multiple competing uses.
- The full range of economic, social, cultural and environmental values of coastal ecosystems must be balanced through enduring partnerships and active stewardship from government, industry and communities, and supported through innovation and research.

J. Lubchenco, P. M. Haugan (eds.), *The Blue Compendium*, https://doi.org/10.1007/978-3-031-16277-0_7

- This Blue Paper focuses on how to enhance coastal ecosystem resilience and enable sustainable pathways for economic, infrastructure and social development, without compromising the integrity and benefits of coastal ecosystems, or disadvantaging the people who rely upon them.
- This paper identifies opportunities for nations to cooperate by building upon past success to realise a sustainable ocean economy through championing the following four coastal opportunities for action: build ecosystem resilience; mitigate impacts of terrestrial and extractive activities on coastal ecosystems; advance sustainable, future-proofed blue infrastructure; and enhance community resilience, equity and access.
- With COVID-19 creating an imperative for stimulating economic activity, there is a unique window of opportunity to ensure that relevant policy and investment decisions address the challenges faced by coastal ecosystems and communities, as well as foster sustainable economic pathways. This involves supporting the recovery and development of impacted communities, building the resilience of coastal ecosystems and safeguarding the services they provide and future-ready built infrastructure.

1 Introduction

More than 200 countries have a coastline, and this forms the basis for their claims to territorial waters and exclusive economic zones (EEZs). Globally, about 40% of the world's population live within the "near coastal zone"—the area below an elevation of 100 metres (m) and closer than 100 kilometres (km) from the coast (Kummu et al. 2016). The vast majority of resources for current and emerging sectors that comprise the "ocean— or blue—economy" are concentrated along coastal areas within these EEZs and must operate within a complex, multiple-use and often space-constrained context. The near coastal zone is also where the majority of many coastal nations' commercial, residential, transport and national defence infrastructure is situated, and it is the backbone to domestic and international supply chains that deliver the marine goods and services upon which we increasingly rely.

Coasts sustain livelihoods for hundreds of millions of people in work that ranges from artisanal small-scale fisheries and aquaculture to transnational fishing, shipping, energy and tourism industries. Our increasingly urbanised societies are highly dependent upon coastal resources for food, energy, minerals and pharmaceuticals. Consequently, the coastal economy—which is much broader in its accounting than the ocean economy because it includes not only the sum of outputs from ocean resources but also employment on or near the coast—makes a disproportionately high contribution to the economies of many countries, and to the global ocean economy (He et al. 2014; Mohanty et al. 2015; NOEP 2016; Voyer et al. 2018). A significant, but mostly unquantified, informal or grey economy also occurs within coastal settings and underpins the livelihoods of some of the most disadvantaged populations. In addition to providing these important provisioning goods, the biodiversity and natural functions of intact coastal ecosystems provide regulating, supporting and cultural services that also underpin the ocean economy. These services are recognised as nature's contributions to people (NCP), as they are central to links between nature and people and their culture knowledge systems (Pascual et al. 2017; Diaz et al. 2018; IPBES 2019).

Coastal environments occur where the land and the ocean meet, and they are the place where, historically, people have concentrated and prospered. These environments are intrinsically dynamic—shaped as they are by the interaction of marine, terrestrial and atmospheric processes. However, they are also profoundly changing across human timescales, as they are challenged by extreme climate events that are escalating in frequency and severity, and threatened by increasing population growth and urbanisation, poor upstream land practices, conversion of coastal habitats, and environmental impacts from industry, pollutants and over-exploitation of resources. These changes are direct and physical through the loss, fragmentation and alteration of many ecosystems, but also functional, through a loss of resilience that diminishes the capability of coastal environments to resist and recover from such perturbations. Poorly designed and operated infrastructure can also create harmful environmental and social impacts, increase vulnerability to natural disasters and can sometimes leave an unserviceable burden of debt.

Future projections over the coming decades of our accelerating use and dependence on the coastal zone for living space and resources highlight that, unless we change the way we manage and adapt our use of coastal environments, there will be profound consequences for the resilience of coastal environments and the communities that rely upon them. To avoid the realisation of these projections requires innovative approaches to increase the resilience of coastal environments, and to ensure that the services they provide are sustained. Nature-based solutions are increasingly being adopted as complementary approaches to bridging this adaptation gap, to make infrastructure more resilient to climate change effects and add longer-term value to infrastructure assets.

They are also critical to our aspirations for achieving a sustainable ocean economy and many of the Sustainable Development Goals (SDGs). To realise a sustainable ocean economy that protects, produces and prospers, fundamental issues of equity, inclusion and access must be addressed by developing better governance, participatory, finance and capability-enhancing mechanisms. While COVID-19 has had a profound impact on the economies and social fabric of many nations, under the banner of "build back better", there are significant opportunities to address many of the challenges confronting coastal environments, by adopting approaches that support both a sustainable ocean economy and associated livelihoods to create win-win outcomes for governments and coastal communities. For example, promoting natural infrastructure and grey-green infrastructure nation-building projects provides jobs and builds coastal resilience, while establishing local supply chains for fisheries supports community resilience in low-income countries.

This Blue Paper reviews the major human activities that have increased pressure on coastal ecosystems and reduced their resilience. Our focus is principally on reviewing and identifying practicable solutions that can be implemented to enhance coastal ecosystem resilience and enable sustainable pathways for economic and infrastructure development, without compromising the integrity and benefits of coastal ecosystems or disadvantaging the people who rely upon them. Thus, we use the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) conceptual framework, which rationalises inclusive valuation of nature's contributions to people in decision-making, and we consider resilience not only in physical and ecological contexts but also in terms of social, institutional and financial resilience (see Table 7.1).

We have drawn upon a number of recent intergovernmental reports, notably the Intergovernmental Panel on Climate Change (IPCC) *Special Report on the Ocean and Cryosphere* (IPCC 2019) and the IPBES *Global Assessment Report* (2019), which provide comprehensive global assessments of current and projected conditions of coastal environments.

Likewise, there are a number of other excellent reports that develop solutions spanning a number of fields: innovation, finance, engineering and material science, and behavioural psychology. Many of the coastal issues and their potential solutions can only be briefly considered here, and several companion Blue Papers provide more detailed analysis.

Table 7.1 Coastal resilience definitions adopted for this report

Type of resilience	Characteristics
Physical resilience	Resilience of existing and planned infrastructure, including through risk-sensitive land-use planning, incorporation of structural resilient measures into infrastructure projects, investments in structural risk reduction measures, and improved operation and maintenance of infrastructure as pathways to building physical resilience
Financial resilience	Improved financial management and timely provision of adequate flows through contingency financing, increased availability and coverage of insurance and capital market risk transfer solutions. Comprehensive risk financing solutions and enhanced capabilities to use financing effectively
Social and institutional resilience	Governance and the promotion of poverty reduction and social protection programmes that build community resilience and channel support to affected poor households. In particular, building women's resilience through greater access to technologies and finance, diversification of livelihoods, and increased participation in women-led solutions
Ecological resilience	Natural ecosystems play multiple roles in conferring resilience. Examples of this type of resilience are enhancing support for nature-based climate and disaster solutions, including upper watershed restoration, wetlands restoration, mangrove rehabilitation, and installation of detention basins and retention ponds to reduce flooding, storm surges and coastal erosion

2 Coastal Changes and Challenges

For millennia, coastal environments have been the location of many civilisations, providing resources and materials for local use, as well as trade along sea routes with other nations (Paine 2014). Today, however, the scale of coastal use and resource demand, driven by rapid population growth and increasing urbanisation, is unprecedented and has been referred to as the *blue acceleration*—a race among diverse and often competing interests for ocean food, material and space (Jouffray et al. 2020). Concurrently, coastal environments, which have always been shaped by climate processes, are now the frontline of anthropogenic climate change, with these environments and their dependent human communities already experiencing the impacts of both extreme climate events and slow-onset changes, such as sea level rise. Together, these climate-induced changes and the accelerating demand for coastal space and resources, as well as the forms of pollution that result (e.g. litter, wastewater), are threatening the extent, condition and biodiversity of many coastal ecosystems, and the goods and services we derive from them. Below, we briefly summarise global patterns of change in climate conditions and human demand for coastal resources and space over the last 50 or so years, and projections for the coming three decades that will profoundly shape and alter our coastal environments.

2.1 Climate Changes and Coasts

Rising carbon dioxide (CO_2) and greenhouse gas emissions have led to well-documented global increases in sea level and sea temperatures, which have resulted in stormier and more extreme sea conditions. The IPCC *Special Report on the Ocean and Cryosphere* (IPCC 2019; and key chapters: Bindoff et al. 2019; Magnan et al. 2019; Oppenheimer et al. 2019) provides the most current and authoritative analysis of recent (1950–present) observed changes in the climate system, and future projections (to 2100) based on low and high Representative Concentration Pathway (RCP) emission scenarios (RCP2.6 and RCP8.5, respectively). Table 7.2

Table 7.2 Summary of key observation and trends in climate change

Parameter	Observed trends	Near-term (2030–2080) and end-of-century projections	Physical effects on coastal ecosystems and settlements	Key references
Global mean sea level	Rate change from 1.38 mm/year during 1901–1990 to 3.16 mm/year during 1993–2015	Up to 2050, global mean sea level will rise between 0.24 m and 0.32 m In 2100, the numbers are 0.59 m and 1.10 m, respectively	Permanent submergence, flood damage, erosion, saltwater intrusion, rising water tables/impeded drainage, ecosystem loss (and change)	Storlazzi et al. (2018), Vitousek et al. (2017), Donnelson Wright et al. (2019a, b), Becker et al. (2020), Oppenheimer et al. (2019)
Regional mean sea level	Rising and accelerating	Increased regional relative sea level nearly everywhere (RCP8.5)	Coastal flooding, submergence, erosion, salinisation	Oppenheimer et al. (2019), Minderhoud et al. (2020)
Extreme sea levels	Increase due to increase in storm intensity	More frequent extreme sea level events as a consequence of sea level rise at many locations by the end of the century (RCP8.5)	Coastal flooding, erosion, saltwater intrusion	Mentaschi et al. (2018)
Waves	Small increases in significant wave height with larger increases in extreme conditions and largest increase in the Southern Ocean	Low confidence for projections overall but medium confidence for Southern Ocean increases in wave height	Coastal erosion, overtopping and coastal flooding	Young and Ribal (2019), Reguero et al. (2019a), Camus et al. (2017)
Winds	Small increases in wind velocity with larger increases in extreme conditions and largest increase in the Southern Ocean	General trend of reduction in wind velocity in summer, autumn and spring, but increase in winter in Northern and Central Europe. General increase in extreme conditions	Wind waves, storm surges, coastal currents, land coastal infrastructure damage	Young and Ribal (2019), Zheng et al. (2019)
Storms, tropical cyclones, extra-tropical cyclones	Regionally variable but increase in annual global proportion of tropical cyclones reaching Category 4 or 5 intensity	Decrease in global tropical cyclone frequenc but proportion of cyclones that reach Category 4 or 5 intensity will increase by 1–10% (RCP8.5)	Higher storm surge levels and storm waves, coastal flooding, erosion, saltwater intrusion, rising water tables/impeded drainage, wetland loss (and change). Coastal infrastructure damage and flood defence failure	Kossin et al. (2020)
Sea surface temperature	SST warming rates highest near the ocean surface (>0.1 °C per decade in the upper 75 m from 1971 to 2010) decreasing with depth	0–2000 m layer of the ocean projected to warm by 900 zettajoules (ZJ) (RCP2.6) and 2150 ZJ (RCP8.5)	Increase in number of coral bleaching events, number of coastal bottom dead zones due to density stratification, harmful algal bloom events, altered ecosystem structure, increased stress to coastal ecosystems	Bindoff et al. (2019)
Marine heatwaves	Doubled since 1980s	Projected to increase (high confidence)	Changes to stratification and circulation, reduced incidence of sea ice at higher latitudes, increased coral bleaching and mortality, increased poleward species migration, decrease in the abundance of kelp forests, massive sea bird die-off and harmful algal bloom	Bindoff et al. (2019), Oliver et al. (2019)
Freshwater input	Declining trend in annual volume of freshwater input	Increase in high latitude and wet tropics and decrease in other tropical regions	Altered flood risk in coastal lowlands, water quality, salinity, fluvial sediment supply, circulation and nutrient supply	Wang et al. (2019), Llovel et al. (2019)
Sea ice and perma-frost thaw	A loss of soil carbon of 5.4% per year across the site Arctic sea ice loss of over 40% over the last last 40 years	By 2100, thaw-affected carbon increase 3-fold (RCP4.5) to 12-fold (RCP8.5)	More storm surges, increasing ocean swells, coastal erosion and land loss in the Arctic and Antarctica regions	Nitzbon et al. (2020), Plaza et al. (2019), Rignot et al. 2019
Ocean acidification	Ocean surface water pH is declining by a very likely range of 0.017–0.027 pH units per decade, since 1980	pH drops of between 0.1 (RCP2.6) and 0.3 (RCP8.5) pH units by 2100, with regional and local variability, exacerbated in polar regions	Increased CO_2 fertilisation, decreased seawater pH and carbonate ion concentration. Enhancing coral reef dissolution and bioerosion, affecting coral species distribution and community	Bindoff et al. (2019), Agostini et al. (2018), Gao et al. (2019)

summarises the historical changes and future projections for climate drivers and ocean and coastal conditions, while below, we focus on the consequences and implications of rising sea levels, warmer and more acidic water, and a greater frequency of extreme climate events, for coastal environments.

Changes in the observation record—which extends back to the early 1900s for tide gauges and more recently for measurements from satellites—from the ocean around the world are clear: sea surface temperatures, wave energy, storminess and acidity have all risen, in many cases doubled, and have continued to accelerate, particularly in the last 30 years (Table 7.2). Near-term and end-of-century model projections all predict, with a high degree of certainty, that these trends will continue to increase and to accelerate. What is unclear is the magnitude, extent and timing of slow-onset climate drivers, such as global mean sea level rise (GSLR), and the frequency of occurrence and magnitude of extreme climate events, including inundation and marine heatwaves.

These changes in ocean state result from both changes occurring directly within the ocean, such as the changes in heat content, density stratification and circulation patterns, and cryosphere changes that include the melting of glaciers, particularly in Greenland and the Antarctic, and sea ice. Both of these factors can act to dilute the salinity of seawater, leading to changes in density and circulation patterns, but only glacial melt will increase the volume of the ocean.

Changes in ocean condition and state are magnified in shallow coastal environments, where tidal and wave energy have their greatest impact on shorelines, and extend across the regional tidal range, and can result in: increased frequency of inundation and subsidence, changes in wetlands, increased erosion of beaches and soft cliffs, and the salinisation of surface and groundwater. Here, the local or relative sea level is complicated and compounded by activities occurring within the coastal zone that affect land elevation, such as subsidence, as well as prevailing winds and water circulation.

While there are significant regional variations, GSLR over the coming century (to 2100) could increase by between 0.43 m (c.4 millimetres (mm)/year) under RCP2.6, and 0.84 m (c.15 mm/year) under RCP8.5. Locally high sea levels, which historically only occurred once per century (historical centennial events or HCE), are projected by 2050 to occur at least annually in many locations, inundating many low-lying areas, including deltaic regions (e.g. Bangladesh and the Mekong Delta), coastal megacities (e.g. Jakarta and Manila) and small islands (e.g. Oceania), impacting their coastal ecosystems, economic development and habitability (Vitousek et al. 2017; Storlazzi et al. 2018; Minderhoud et al. 2019; Oppenheimer et al. 2019; Donnelson Wright et al. 2019a, b; Becker et al. 2020).

In conjunction with sea level rise, greater wave action (wave height, period) and changes in direction and intensity, and more frequent and intense storm surges will affect many coastal areas that were previously never, or infrequently, exposed to such events. These changes can result in cascading impacts on coastal infrastructure and communities living in coastal areas, which are considered further in Sect. 3.3. Projected changes in sea level and wave action, and storm surges will be important considerations for how we build future climate-ready coastal infrastructure (Bhatia et al. 2018; Morss et al. 2018; Abram et al. 2019; Bindoff et al. 2019; Fernández-Montblanc et al. 2019; Kim et al. 2019; Marcos et al. 2019; Magnan et al. 2019; Morim et al. 2019; Oppenheimer et al. 2019; Reguero et al. 2019b).

Coastal shelf waters, from polar regions to the tropics, are also undergoing profound changes as a result of changes in patterns of water circulation and stratification, warmer sea surface temperatures, deoxygenation and more acidic conditions. Rising sea surface temperatures have led to well-documented and rapid changes in the distributions of many marine taxa, including fish, birds and mammals, while changes in circulation and upwelling events have affected the productivity of many eastern boundary systems of the Pacific and Atlantic (Bakun et al. 2015; Champion et al. 2018).

Prolonged extreme ocean warming events—also known as marine heatwaves—over the period 1982–2016 have doubled in frequency and have become longer lasting, more intense and more extensive. Climate models project further increases in the frequency of marine heatwaves, notably in the Arctic Ocean and tropical oceans. Marine heatwaves can severely impact marine ecosystems, resulting in losses of species and habitats from ecosystems as varied as coral reefs, kelp forests, seagrass meadows and mangrove forests, and indirect effects like disruption to sediment-nutrient dynamics and carbon storage (Hughes et al. 2017, 2018; Arias-Ortiz et al. 2018; Hoegh-Guldberg et al. 2018; Oliver et al. 2019; Smale et al. 2018, 2019; Babcock et al. 2019; Garcias-Bonet et al. 2019; Hebbeln et al. 2019; Holbrook et al. 2019, 2020; Sanford et al. 2019; Thomsen et al. 2019; Wernberg et al. 2019).

Deoxygenation in coastal regions results not only from rising sea temperatures but also over-fertilisation and associated runoff from agriculture and from sewage outputs into coastal waters, which leads to algal blooms that consume oxygen once they die and decay. Since the mid-twentieth century, over 700 coastal sites have reported new or worsening low-oxygen conditions. Such oxygen minimum zones can cause widespread changes to marine ecosystems, including loss of invertebrate and fish species and changes in biogeochemical cycling.

Climate models confirm this decline and predict continuing and accelerating ocean deoxygenation (Breitburg et al.

2018; Laffoley and Baxter 2018; Oschlies et al. 2018; Limburg et al. 2020; Rodríguez-Martínez et al. 2020).

Over the last 25 years, the pH in the surface waters of the ocean has reduced as they have absorbed more CO_2, and it is projected to decline further during this century, leading to under-saturation of the carbonate system in the Arctic Ocean, major parts of the Southern, North Pacific and Northwestern Atlantic Oceans (Orr et al. 2005; Hauri et al. 2015; Sasse et al. 2015; Bindoff et al. 2019). As a result, primary productivity of calcifying and non-calcifying plankton species are projected to decrease, while the calcification of corals and bivalves can be impeded, making them more brittle and susceptible to damage, which causes higher mortality, reduced recruitment, increased vulnerability to disease and increasing sensitivity to warming (Fabricius et al. 2011; Doropoulos et al. 2012; Nagelkerken and Connell 2015; Mollica et al. 2018; Gao et al. 2019; Hall-Spencer and Harvey 2019; Liao et al. 2019). In coastal waters, carbonate chemistry is also affected by freshwater runoff which lowers pH due to leachate from acid sulphate soils and humic acids from groundwaters. The extent of coastal acidification can be exacerbated by sea level rise, catchment driven flooding and land runoff, and has had significant impacts on the shellfish industry—a US $19 billion global industry—and can lead to intermittent fish-kills (Salisbury et al. 2008; Barton et al. 2015; Gledhill et al. 2015; Fitzer et al. 2018).

2.2 Changes to Coastal Environments and Ecosystems

Coastal ecosystems are diverse, forming a mosaic of interconnected seascapes, which vary latitudinally from the tropics to the poles, across intertidal and cross-shelf gradients from land to ocean, and in relation to the amount of tidal and wave energy. These coastal ecosystems are most often classified by their geomorphic landform (e.g. estuaries, sandy beaches and rocky shores) or by their foundation species, which can be wetland vegetation (e.g. saltmarshes, seagrass meadows, mangrove forests) or biogenic structures such as coral and shellfish reefs. Many of these ecosystems, particularly over the last 50 years, have undergone massive worldwide reductions in their extent and in their functional resilience, which are the combined consequence of various human activities (clearing and fragmentation of vegetation, hydrological alterations, decreased coastal sediment supply, pollution and emplacement of coastal infrastructure) as well as climate change. Combined with other coastal pressures, such as pollution, most countries are experiencing increased cumulative impacts in their coastal areas, with islands in the Caribbean and mid-latitudes of the Indian Ocean experiencing the greatest impacts (Halpern et al. 2015, 2019). In this section, we summarise observed global changes to these ecosystems, while Fig. 7.1 represents the global extent of these

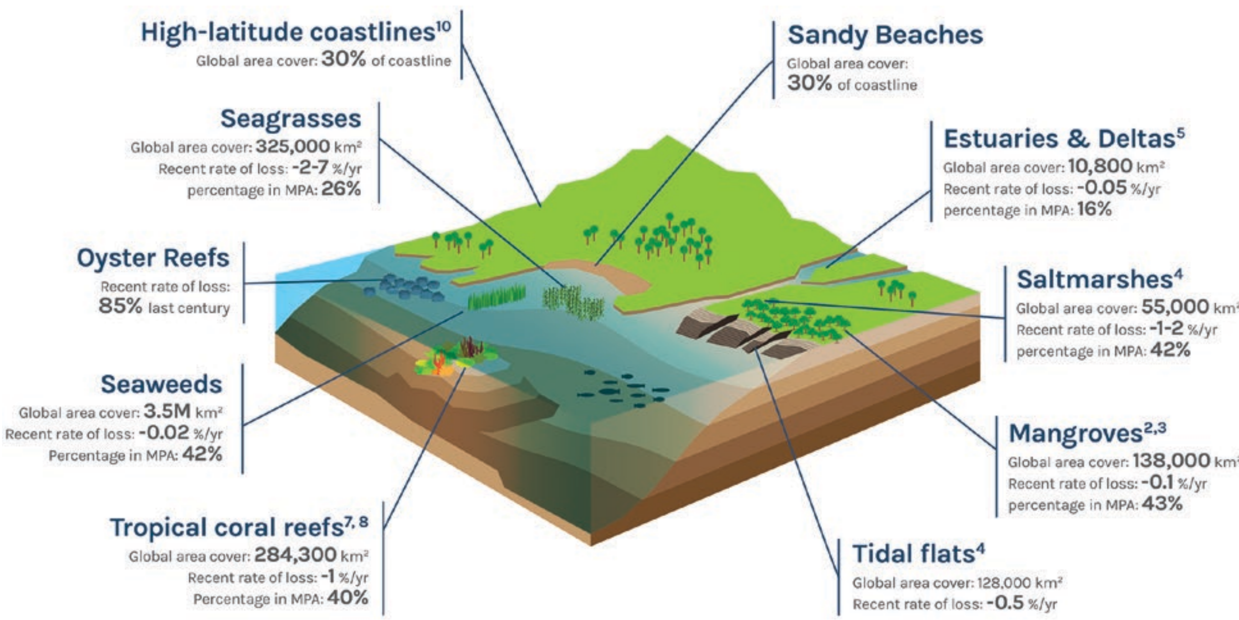

Fig. 7.1 Areal extent and historical and projected losses of major coastal ecosystems. (Source: CSIRO. (1) Beck et al. (2011); (2) Bunting et al. (2018); (3) Goldberg et al. (2020); (4) Mcowen et al. (2017); (5) Murray et al. (2018); (6) Nienhuis et al. (2020); (7) Rogers et al. (2020); (8) UNEP (2020); (9) Vousdoukas et al. (2020); (10) Wernberg et al. (2019))

changes. The companion Blue Paper *Critical Habitats and Biodiversity* (Rogers et al. 2020) provides comprehensive analyses of these changes in habitats and biodiversity.

2.2.1 Coastal Landforms

Coastlines comprise a variety of coastal landforms—beaches, dunes, cliffs, reefs, estuaries, rias, fjords, bays and headlands—that have developed at the dynamic interface of land and sea and have evolved over multiple timescales from quasi-cyclical patterns of erosion and accretion that occur under varying climatic, oceanographic and geological conditions.

Along exposed open coasts erosion is the dominant process weathering these environments. About 50% of the world's coastlines are rocky and sandy beaches. Rocky coasts form where harder more stable substrates predominate, forming reefs that are often covered subtidally by seaweeds and shellfish beds, which in turn support biodiverse communities. Intertidal areas are exposed to strong environmental gradients and these ecosystems are highly sensitive to ocean warming, acidification and extreme heat exposure during low tide emersion. While rocky coastlines form a physical barrier between the land and the sea, softer lithologies are more susceptible to both physical and biological erosion, with significant morphological changes often following extreme events such as storms or tropical cyclones (Hawkins et al. 2016; Ciavola and Coco 2017; Young and Carilli 2019).

Muddy depositional environments, such as estuaries, deltas and tidal flats, are highly dynamic as they are affected by natural and/or human-induced processes originating from both the land and the sea. In addition to GSLR, changes occurring in adjacent catchments that affect sediment supply can result in land subsidence or coastal erosion, or introduce pollution. This in turn can lead to flooding, land loss, salination of coastal aquifers and river reaches, with consequences for properties, agricultural production and food security, especially in agriculture-dependent coastal countries (Khanom 2016).

Shoreline erosion leads to loss of coastal habitats and can, together with sea level rise, contribute to "coastal squeeze" when the intertidal region is constrained by infrastructure built above high water. Shoreline erosion increases the risk of increased flooding and damage to coastal infrastructure and anthropogenic activities, such as upstream dam construction, and river and coastal sand mining, while coastal infrastructure development can significantly alter depositional processes that lead to increased erosion and subsequently diminish the resilience of coastal habitats and increase risks to infrastructure (Naylor et al. 2010; Brooks and Spencer 2012; Pontee 2014; Koehnken and Rintoul 2018).

Satellite-based observational records, from the 1980s to the present, demonstrate changes in the global extent of coastal landforms and show strong regional patterns—with some areas eroding and others accreting—that reflect a dynamic balance between prevailing sea conditions and the extent of catchment and hydrological modification. When globally aggregated, these patterns can be less discernible, which belies the significance of regional changes. Over the last 40 years:

- The loss of *permanent land* in coastal areas is almost 28,000 km^2, which is almost twice as large as land gained within the same period; more than 50% of this net loss of 14,000 km^2 occurred along Asian and Caspian coasts (Mentaschi et al. 2018).
- Twenty-four percent of the world's *sandy beaches* have eroded at rates exceeding 0.5 m/year, but other areas either accreted (28%) or were stable. It is projected that by 2050 13–15% of the world's sandy beaches could face severe erosion, but in low-elevation coastal zones the figure is more than 30%. A number of countries, including the Democratic Republic of the Congo, Gambia, Jersey, Suriname, Comoros, Guinea-Bissau, Pakistan, could face extensive sandy beach erosion issues by the end of the twenty-first century (Luijendijk et al. 2018; Vousdoukas et al. 2020). Worldwide, sandy beaches show vegetation transformations caused by erosion following locally severe wave events with the original dense vegetation being replaced by sparser vegetation and often resulting in a regime shift in the beach morphology and shifts in the associated fauna composition. Coastal dunes are extensive along the world's sandy shorelines and back the majority of beaches forming a linked system. Human disturbances, especially tourism and recreation that have increased foot and vehicular traffic, have increased erosion rates on sandy beaches and dunes, while coastal squeeze has constrained sediment supply and accretion capacity. Paradoxically, vegetation cover on sand-dunes has increased substantially on multiple, geographically dispersed, coastal dune fields on all continents in the period 1984–2017 and points to enhanced dune stability and storm buffering effects (Jackson et al. 2019; Nayak and Byrne 2019).
- *Tidal flats* are intertidal, muddy, sedimentary habitats, often flanking estuaries, and are widely distributed, with a present global extent of 128,000 km^2, of which 70% occur in three continents (Asia 44%; North America 15.5%; South America 11%). Since 1984, it is estimated that 16% of tidal flats have been lost, principally from coastal development and coastal erosion due to reduced sediment delivery from major rivers and sinking of riverine deltas. In China, massive losses of tidal flats have resulted from reclamation, or conversion to other activities, principally aquaculture (Murray et al. 2018).
- *Deltas* account for less than 1% of global land area, yet are home to more than half a billion people and some of

the largest cities. Deltas have a dynamic and evolving geomorphology, formed by the accumulation of unconsolidated river-borne fine sediments (mud, silt and clay) and so are particularly sensitive to anthropogenic activities which influence the mobilisation, delivery, deposition and erosion of sediment to and from a delta. Over the past 30 years, despite sea level rise, deltas globally have experienced a net land gain of 54 km^2/year with deltas being responsible for 30% of all net land area gains that result principally from deforestation-induced increases in fluvial sediment supply. Yet, for nearly 1000 deltas, river damming has resulted in a severe (more than 50%) reduction in anthropogenic sediment flux, resulting in global deltaic land loss of 12 km^2/year. In many of the major deltas (e.g. Mekong, Irrawaddy, Ganges-Brahmaputra), this decline of sediment supply due to upstream dam construction, combined with land-use changes, river sand mining and over-abstraction of groundwater, has led to deltaic subsidence rates at least twice the concurrent rate of GMSL rise (3 mm/year). As a consequence, flooding now routinely occurs in many deltas around the world, with an estimated 260,000 km^2 of delta temporarily submerged in the 1990s/2000s, and leads to saline or brackish water intrusion that increases residual salinity of potable and irrigated water. Intensive human activities around estuaries and river deltas have also substantially increased nutrient and organic matter inputs since the 1970s resulting in eutrophication (Ericson et al. 2006; Nicholls et al. 2020; Nienhuis et al. 2020).

- Some of the most significant effects of climate change are occurring along *high latitude* (polar) coastlines that occur to the north and south of 60° (IPCC 2019). Whereas Arctic coastlines represent about one-third of the world's coastlines and occur over a range of geological and oceanographic settings, Antarctic coastlines are often permanently covered in ice. Rapid and accelerated Arctic sea ice loss, which has averaged 10% per decade over the last 40 years, is attributed to the impacts of land–ocean warming and the northward heat advection into the Arctic Ocean. The possibility of a nearly ice-free Arctic summer within the next 15 years has led to speculation as to whether this will create new shipping channels between Asia and Europe. With longer open-water periods during summer, extra wave activity is expected to result in higher erosion rates along many high-latitude shorelines, while warmer temperatures and increased frequencies of extreme storms may trigger landscape instability, increase sediment and nutrient supply, change carbon fluxes, affect the structure and composition of pelagic communities and benthic habitats and the well-being of dependent human populations. Given the rapidity of these changes, adequate governance frameworks need to be urgently implemented (Moline et al. 2008; Krause-Jensen and Duarte 2014; Kroon et al. 2014; Bull et al. 2019; Gardner et al. 2018; Bendixen et al. 2019b; Oppenheimer et al. 2019; Rignot et al. 2019; Ouyang et al. 2020; Kumar et al. 2020; Hugelius et al. 2020; Peng et al. 2020).

2.2.2 Vegetated Coastal Ecosystems

Vegetated coastal ecosystems, including saltmarshes, mangroves, seagrasses, and kelp and other seaweed, are wetland systems that form important interconnected habitats which support high biodiversity and provide valuable ecosystem services, such as fisheries production, sediment and nutrient trapping, storm protections and carbon storage. Mangroves typically grow between the low and high tide, and reach their highest abundance and diversity in the tropics, predominantly in the Indo-Pacific region. Saltmarshes occur particularly in middle to high latitudes but often overlap with mangrove distributions, resulting in dynamic transitions between these two communities. Seagrasses rooted in unconsolidated sediments grow in shallow coastal waters to 60 m depth and have a global distribution. Seaweeds attach to solid reef substrates, with some species such as kelp—a brown algae—forming large canopies present in more than 40% of the world's marine ecoregions.

However, these ecosystems have been extensively modified by human activities and must also adapt to accelerating rates of climate change. For example, it is estimated that eustatic sea level rise could result in the loss of 22% of the world's coastal wetlands by 2080, and in the Indo-Pacific region, where sediment delivery has declined due to damming of rivers, existing mangrove forests at sites with low tidal range and low sediment supply could be submerged as early as 2070 (Waycott et al. 2009; Duarte et al. 2013; Blankespoor et al. 2014; Copertino et al. 2016; Lovelock et al. 2016; Kelleway et al. 2017; van Oosterzee and Duke 2017; Besset et al. 2019; Serrano et al. 2019a, b).

The current extent and historical loss of these ecosystems are summarised in Fig. 7.1, and below.

- Globally more than 6000 km^2 of mangroves were cleared between 1996 (142,795 km^2) and the present (137,000 km^2). Contemporary (2000–present) global losses (0.2–0.6%/year) of mangroves are an order of magnitude less than losses during the late twentieth century, and have resulted primarily from land-use change, usually through conversion but also fragmentation. In Southeast Asia, mangrove loss has been recorded at twice the global rate, where conversion of mangroves to shrimp aquaculture accounted for more than 50% of losses, while more recently oil palm plantations and coastal erosion are leading to further losses. In Brazil, Puerto Rico, Cameroon, China and Singapore, large areas of mangroves have been lost to urban development. Significant declines in the delivery of upstream sediment supply have further diminished the ability of mangroves to expand and to keep pace with rising sea levels (Richards and Friess 2016; Woodroffe et al. 2016; Hamilton and Casey 2016; Bunting et al. 2018; Romañach et al. 2018; Worthington and Spalding 2018; Agarwal et al. 2019; Friess et al. 2019; Goldberg et al. 2020; Richards et al. 2020; Turschwell et al. 2020a).

- Saltmarshes, with a present global extent of c.56,000 km^2, are declining around the world, having lost between 25 and 50% of their global historical coverage through conversion to agriculture, urban and industrial land uses. Many saltmarshes are also being squeezed between an eroding seaward edge and fixed flood defence walls, and agricultural grazing has a marked effect on the structure and composition of saltmarsh vegetation, reducing its height and the diversity of plant and invertebrate species (Bromberg Gedan et al. 2009; Crooks et al. 2011; Mcowen et al. 2017; Thomas et al. 2017).
- Seagrass meadows, with a present global distribution of about 300,000 km^2, are estimated to have been lost at rates of 110 km^2 per annum between 1980 and 2006. Current losses are particularly high in East and Southeast Asia, principally as the consequence of coastal development: poor water quality resulting from watershed siltation, physical disturbance such as dredging and coastal reclamation, and the degradation of food webs from aquaculture and fisheries (Waycott et al. 2009; Short et al. 2011; Erftemeijer and Shuail 2012; McKenzie et al. 2020).
- Loss of macroalgal forests over the last half-century has been significant, although spatially variable; kelps have declined by 38% in some ecoregions, but have either grown or remained stable in other regions such as southern South America. Temperature is a key determinant of the biogeographic distribution of many seaweeds, so increases in sea temperatures have led to changes in range and abundance. Kelp die-off from marine heatwaves has been reported along the coasts of Europe, South Africa and Australia, and the kelp is replaced by a less diverse turf-dominated ecosystem (Ling et al. 2015; Krumhansl et al. 2016; Vergés et al. 2016; Wernberg et al. 2016; Piñeiro-Corbeira et al. 2018; Filbee-Dexter and Wernberg 2018; Smale et al. 2019; Wernberg et al. 2019; Wernberg and Filbee-Dexter 2019; Friedlander et al. 2020).

2.2.3 Coral and Shellfish Reefs

Coral reefs occur throughout tropical latitudes and are one of the most diverse and productive ecosystems, providing services that support almost 30% of the world's marine fish species fisheries, and 500 million people who depend on them for work, food and coastal protection in more than 100 countries across Australasia, Southeast Asia, the Indo-Pacific, the Middle East, the Caribbean and the tropical Americas. Coral reefs throughout the world are today one of the most endangered habitats, threatened by a combination of climate change and human activities that weaken the natural resilience of coral reefs.

Activities such as over-exploitation and destructive fishing, watershed and marine-based pollution, and coastal infrastructure development have had an impact on reef population structure and biodiversity by reducing coral recruitment, survival and growth, and hindering community recovery (Fabricius 2005; Roff et al. 2012; Otaño-Cruz et al. 2017; Lam et al. 2018; MacNeil et al. 2019; Vo et al. 2019).

Since 1998, marine heatwaves have bleached, or killed, corals on many reefs across the Indo-Pacific, Atlantic and Caribbean. In 2016 and 2017, heat stress associated with consecutive El Niño events triggered the third major global coral bleaching event, resulting in severe coral bleaching of around 70% of the world's reefs throughout all three tropical ocean basins; in the Great Barrier Reef, the world's largest reef system, half of the corals died. Further projected increase in sea level, storm intensity, marine heatwaves, turbidity, nutrient concentration due to floods may contribute to the degradation trend of a majority of coral reefs worldwide and require comprehensive management and intervention responses (Hoegh-Guldberg and Bruno 2010; Hughes et al. 2017, 2018; Magel et al. 2019; Morrison et al. 2019, 2020).

Shellfish reef ecosystems have, until recent times, been overlooked as an important estuary habitat. Historically, dense aggregations of bivalves, their shells, associated species and accumulated sediments were a dominant habitat in temperate and subtropical estuaries around the world. Oyster reefs provide numerous ecosystem services, such as improvements to water quality through filtration, shoreline stabilisation and fisheries productivity. Dredging, habitat degradation, including poor water quality and altered species interactions, disease outbreaks and habitat loss, have contributed to the drastic decline in bivalve habitats with an estimated 85% of oyster reefs lost over the last century, as well as largely unquantified losses of other habitat-forming bivalves, such as the formerly widespread green-lipped mussel (*Perna canaliculus*) beds in New Zealand, which now occur at less than 1% of historical levels (Lenihan and Peterson 1998; Newell and Koch 2004; Piehler and Smyth 2011; Scyphers et al. 2011; Beck et al. 2011; Grabowski et al. 2012; Paul 2012).

2.3 Coastal Development Changes

The key global economic trends relevant to maritime sectors are increasing energy demand, increasing food and water demand, and increasing population growth and urbanisation, all of which depend on coastal infrastructure. Factors such as adaptation to climate change, developing economies seeking an increasing share of global growth, growing expectations around health and safety and human rights, and technological innovations are also relevant to maritime and coastal development trends and coastal infrastructure. Energy production, food production and water demand, as well as urbanisation and population growth, represent over a third of the global economy and provide up to two-thirds of jobs. While natural resources make human development possible and underpin economic growth, our accelerating demand for coastal space and resources, as well as the forms of pollution that result (e.g. litter, wastewater), threatens the extent, condition and biodiversity of many coastal ecosystems (IPBES 2019; WEF 2020a). Below, we summarise the major trends in coastal development and discuss the potential consequences.

2.3.1 Population Growth and Urbanisation

About 40% of the world's population lives within 100 km of the coast and 11% live in low-lying coastal areas that are less than 10 m above sea level. While the majority of these populations are based on continental coastal areas, small island developing states (SIDS) are home to 65 million people, while 4 million people live within the Arctic region. Coastal population growth has been increasing at around twice the rate of national growth and is the result of population and demographic changes, as well as migration from rural areas to cities, and displacement of some indigenous and other disaffected communities. Over the next decade, population growth will occur most significantly in Africa (380 million) and Asia (373 million), where the urban population is expected to grow by 2.5 billion over the next 30 years (Creel 2003; McGranahan et al. 2007; Ford et al. 2015; Neumann et al. 2015; Kummu et al. 2016; Jones and O'Neill 2016; Merkens et al. 2016).

Population growth has been accompanied by rapid urbanisation, and today 55% of the global urban population lives in coastal settlements, and 16 of the world's 31 megacities—those with over 10 million inhabitants—are coastal, including New York City, Tokyo, Jakarta, Mumbai, Shanghai and Lagos. Asia has the greatest intensification of coastal population, property and infrastructure, with 10 of the world's megacities, and 20 of the top 30 most populated coastal cities. Even in many SIDS, urbanisation is a growing concern, where 38 million (59%) already live in urban settlements. Globally, from 1985 to 2015, urbanisation expanded on average by 9687 km^2/year, with nearly 70% of this development occurring in Asia and North America (Small and Nicholls 2003; Jongman et al. 2012; UN-Habitat 2015; Liu et al. 2020).

2.3.2 Infrastructure Development

Coastal infrastructure systems form the backbone of every society, providing essential services that include coastal defence, trade, tourism, fisheries and aquaculture, energy, water, waste management, transport, telecommunications and other industries. Urbanisation is, however, not only a land-based problem, and coastal development has led to a proliferation of coastal infrastructure, commonly referred to as "ocean sprawl", that is occurring worldwide along coastlines and in near-shore waters, and is more recently expanding offshore as industries seek to utilise new resources and access space to operate. Along and adjacent to coastal foreshores, infrastructure for defence, residential and commercial developments, transport and tourism/ recreation are common, while moving further offshore infrastructure for aquaculture, oil and gas, offshore renewable energy, mineral extraction and desalination occur.

Although this proliferation of structures provides a suite of economic, social and even ecological benefits, it also replaces natural habitats and can modify environmental conditions critical to habitat persistence at regional scales. Catchment-based infrastructure, such as dams, that affect the natural patterns of hydrological discharge and sediment transport to the coast, can also affect downstream coastal ecosystems.

As of 2018, the physical footprint of built structures was at least 32,000 km^2 worldwide, and is expected to increase by at least 23% (7300 km^2) to cover 39,400 km^2 by 2028. The global area of seascape that is modified around these structures is estimated to be in the order of 1.0–3.4 million km^2 globally, an area comparable to the global extent of urban land (Bugnot et al. 2020). This concentration of structures close to the shore means that many coastal habitats are affected by multiple structures.

There are also substantial regional differences in the amount of different types of marine infrastructure. Proportionally, China, Democratic People's Republic of Korea and the Philippines have the largest marine infrastructure footprints; nearly half of all oil and gas rigs are located in the US Gulf of Mexico, while wind and tidal farms are spread along the coasts of North America, India, the United Kingdom, Germany and in the Asian North Pacific (Bugnot et al. 2020).

Table 7.3 represents the current extent and projected growth of various infrastructure and activities occurring in, and adjacent to, coastal environments. There is also a growing number of regional-scale transnational infrastructure projects under way that will fundamentally change the use of the coastal zone and marine water offshore and in areas beyond national jurisdictions and, unless carefully managed, these present serious threats to biodiversity (see Box 7.1).

Table 7.3 Crowded coasts: global growth of major coastal infrastructure

Category	Type	Footprint	Category	Type	Footprint
Reclamation	Coastal reclaimed land[2]	Area: 3370 km^2	Water Infrastructure	Large dams[8]	Number: 58,000

Since investment in infrastructure is at an all-time high globally, an ever-increasing number of decisions are being made now that will lock in patterns of development for future generations (Bromberg Gedan et al. 2009; Aerts et al. 2011; Sekovski et al. 2012; Jennerjahn and Mitchell 2013). Such infrastructure, unless carefully planned to account for future climate conditions, constructed using environmentally sensitive methods, and operated with appropriate regulations, can pose significant environmental risks to coastal environments, including: changes in coastal morphology from disruption to natural sedimentary processes, destruction and fragmentation of coastal habitat, and impacts on resident and migratory wildlife through disruption to established connectivity pathways or from "accidents" with infrastructure (Dafforn et al. 2015; Firth et al. 2016; Hughes 2019; Hughes et al. 2020). Below, the major forms of infrastructure, their extent and projected growth, and known impacts on coastal ecosystems are summarised.

Coastal defence structures: With increased urbanisation, rising sea levels and stormier seas, shorelines worldwide have dramatically changed as they become increasingly "hardened" with a proliferation of coastal armouring infrastructure, constructed to protect coastal populations and their property, transport infrastructure, industry and commerce, and amenity and recreational areas. Seawalls, breakwaters, jetties, piers and related infrastructure have replaced once natural shorelines by more than 50% in some cities and countries; for example, wetlands along China's 34,000-km coastline have been replaced with 13,830 km of hard engineering structures (Luo et al. 2015). Such coastal defence structures can have a variety of negative effects on adjacent coastal ecosystems. These structures are typically designed to reflect waves and reduce coastal flooding and erosion; consequently, they can alter wave exposure, interfere with the spatial dynamics of sediment transport, and impede animal movement and connectivity between habitats. Over the longer term, this can cause changes in sediment, current and wave dynamics that accelerate erosion, leading to the loss of beaches and other coastal habitats they were intended to protect. Artificial structures may also produce larger-scale impacts through their alteration of ecological connectivity, which restricts the movement or dispersal of organisms, and which may in turn, influence the genetic structure and size of populations, the distribution of species, community structure and ecological functioning (Bulleri and Chapman 2010; Nordstrom 2014; Bishop et al. 2017; Leo et al. 2019).

Box 7.1. Regional Coastal Infrastructure Projects

Belt and Road Initiative and the Maritime Silk Road: The Belt and Road Initiative is a long-term Chinese government vision for improved global connectivity, expanded production and trade chains, and closer overall cooperation. Potentially spanning 72 countries, the Belt and Road Initiative is the largest infrastructure project of all time (valued at over $8 trillion by 2049) and seeks to create connections between core cities and key ports across Eurasia, Asia and parts of the African continent through infrastructure development in the transport, energy, mining, IT and communications sectors. First announced in 2013, the twenty-first Century Maritime Silk Road is the maritime/coastal component of the Belt and Road Initiative, and focuses on creating a network (string of pearls) of ports, through construction, expansion or operation, and the development of portside industrial parks and special economic zones that link China's coastal ports through the South China Sea to the Indian Ocean, extending to Africa and Europe; and potentially to the Pacific Ocean (Fig. 7.2). To date, deep-water ports projects have been initiated in Africa (Tunisia, Senegal, Tanzania, Djibouti, Gabon, Mozambique, Ghana), Asia (Pakistan, Sri Lanka, Myanmar, Indonesia) the Middle East (Oman, Israel) and Europe (Greece). Studies looking at the potential environmental impact of the Belt and Road Initiative have identified that over 400 threatened marine species, including mammals, could be affected by port infrastructure, while over 200 threatened species are at risk from an increase in shipping traffic and noise pollution (Huang 2016; Hughes 2019; Hughes et al. 2020; Narain et al. 2020; Turschwell et al. 2020b).

LAPSSET Corridor, Africa: The LAPSSET Corridor Program is a regional project intended to provide transport and logistics infrastructure aimed at creating seamless connectivity between the eastern African countries of Kenya, Ethiopia and South Sudan. The project connects a population of 160 million people in the three countries and is part of the larger land bridge that will connect the East African coast (at Lamu Port) to the West African coast (at Douala Port). The LAPSSET Corridor is intended to operate as an Economic Corridor with the objective of providing multiple eastern African nations access to a large-scale economic trade system, thereby promoting socioeconomic development in the region. The LAPSSET Corridor Program consists of several subsidiary projects, including the development of deep-water ports, railway lines and highways connecting cities in Kenya, South Sudan and Ethiopia, oil refineries and pipelines, and international airports and resort cities (LAPSSET Corridor Development Authority 2016; Okafor-Yarwood et al. 2020).

Bangladesh Delta Plan 2100: The Bangladesh Delta Plan 2100 is the combination of long-term strategies and subsequent interventions for ensuring long-term water and food security, economic growth and environmental sustainability. It aims to effectively reduce vulnerability to natural disasters and build resilience to climate change and other delta challenges through robust, adaptive and integrated strategies, and equitable water governance. Six hotspot areas were identified: coastal zone; Barind and drought-prone areas; Haor region (flash-flood areas); Chittagong hill tracts and coast; major rivers and estuaries, and urban areas (Bangladesh Planning Commission 2018).

The Red Sea Project: The Red Sea Project is a large-scale luxury tourism development that will extend over 28,000 km^2 along the shores of the Kingdom of Saudi Arabia. The area includes the Al-Wajh lagoon, a large lagoon area with 92 islands, valuable ecosystems and rich biodiversity, including species of global conservation importance. The Red Sea Development Company, responsible for the execution of the Red Sea Project, has committed to achieving a net-positive impact on biodiversity. To grow tourism, which currently represents only 3% of the economy, it will create a special economic zone that is expected to attract 1 million people every year, create 70,000 new jobs and add $5.9 billion to the Saudi GDP (Chalastani et al. 2020).

Ports and harbours: Seaports are nodal hubs in the maritime transportation network, enabling more than 90% of world trade. A growing reliance on marine transport for international trade has led to the construction of more ports and harbours, and the expansion and deepening of existing facilities to accommodate larger vessels. Today, there are more than 4700 commercially active ports worldwide, which are used by more than 50,000 international merchant ships, manned by over a million seafarers, and carry more than 90% (>10 billion tonnes in 2015) of global trade by weight. The development and operation of ports and harbours have been associated with a number of negative environmental and social impacts on coasts, including principally altering regional coastal processes which disturb the sediment balance and exposing down-drift areas to increased erosion. Oil, sewage and noise pollution can result from port operations and can seriously impact surrounding marine life and disrupt social amenity (Zanuttigh 2014; Lee et al. 2015; Johnston et al. 2015; IAPH 2016; IMO 2017; Camus et al. 2019; Leo et al. 2019; Santana-Ceballos et al. 2019; Vaughan 2019; Valdor et al. 2020).

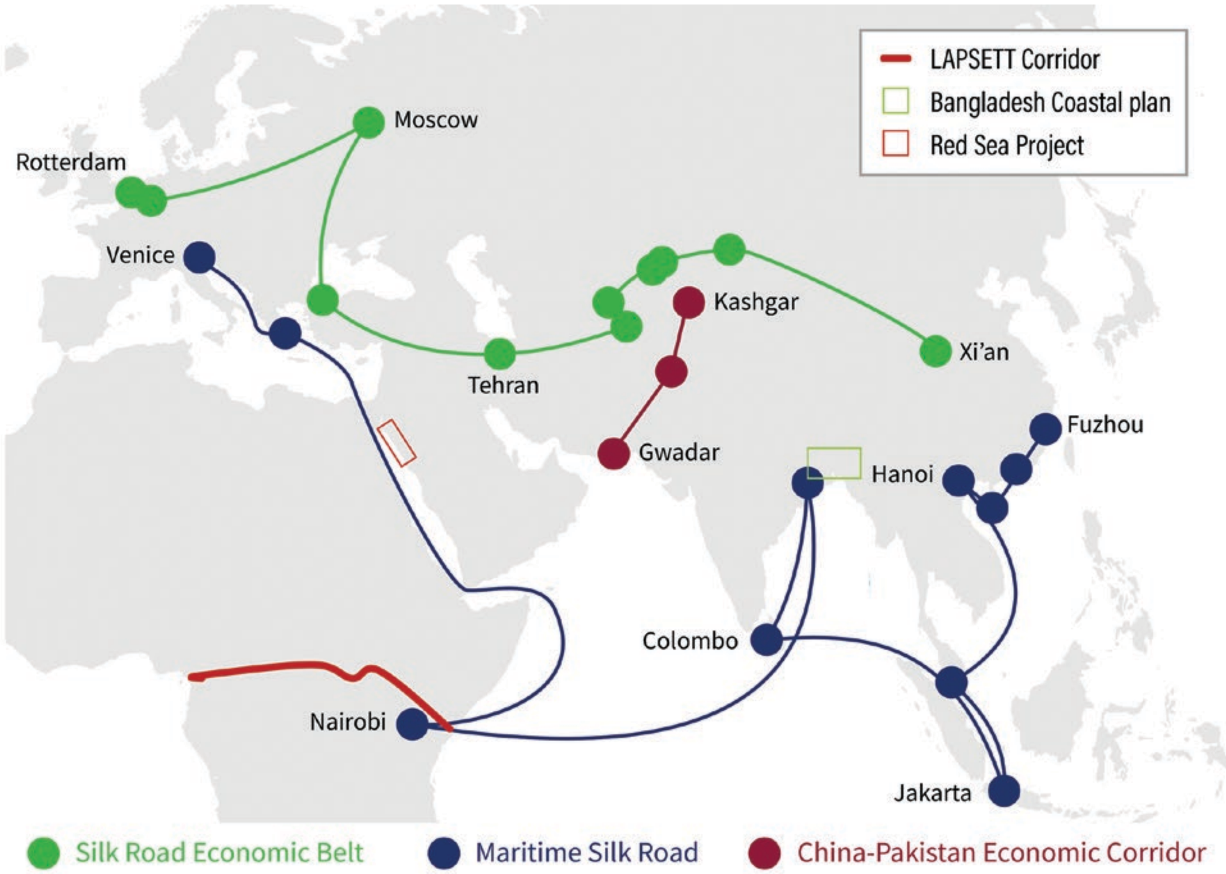

Fig. 7.2 Map of belt and road initiative and twenty-first-century maritime silk road

Energy infrastructure: Conventional oil and gas platforms and associated pipelines, and increasingly offshore renewable energy technologies, including wind farms and tidal power, are common infrastructure in coastal and offshore environments. Tidal farms are located closest to the shoreline, with 41% closer than 2 km in 2018, while nearly half (47%) of all wind farms were located within 10–50 km of the coast, and half of all oil and gas fields were located within 40 km of the shoreline.

Catchment infrastructure: Infrastructure such as dams and weirs for the impoundment of water, irrigation, hydroelectric power generation and flood protection results in hydrologic alteration of the quantity and timing of river flow. Decreased fluvial sediment transfer to coastal regions can lead to sand-starved beaches, and accelerated coastal erosion of deltas and loss of mangrove forests. Construction of embankments and navigation structures can result in rivers becoming disconnected from their floodplains, disrupting natural sediment fluxes, reducing marine and ecological connectivity. Coastal aquifers are more vulnerable to groundwater extraction than to predicted sea level rise under a wide range of hydrogeologic conditions, and over-pumping has led to saltwater intrusion, subsidence and loss of the water supply for future use. Lack of appropriate sewage processing facilities in coastal areas can increase the nutrient pollution and consequent degradation of coastal ecological systems (Poulos and Collins 2002; Giannico and Souder 2005; Al-Bahry et al. 2009; Dafforn et al. 2015; Reopanichkul et al. 2009; Ferguson and Gleeson 2012; Martínez et al. 2014; Rovira et al. 2014; Firth et al. 2016; Chee et al. 2017; Smith et al. 2017; Appeaning Addo et al. 2018; Tessler et al. 2018; Silva et al. 2019; Luijendijk et al. 2020).

2.3.3 Competition for Coastal Space

Today, coasts are an increasingly crowded space, where various sectors of the economy vie for access to areas within territorial and EEZ waters, not only for food and materials, but for a number of other activities, including tourism and leisure, transport and telecommunications. Other activities, such as aquaculture and renewable energies, seek to produce rather than extract seafood and energy, but require coastal space with environmental conditions conducive to their operation. The growth and success of these emerging industries are central to the predicted growth and significance of the ocean economy over the next few decades (see Box 7.2) and will place further demands on access to coastal space.

The allocation of space and the management of associated resources is the responsibility of various government entities, often with overlapping jurisdictions and sometime incompatible mandates, which results in a struggle to balance conservation and sustainable use, to set appropriate operational limits for individual sectors, to resolve conflicts between overlapping incompatible uses and to properly assess the cumulative impact of activities.

Competition and conflict over access to coastal space and resources have often led to allegations of "ocean grabbing" by powerful actors to secure exclusivity or dominance over a resource, and have often disadvantaged other groups, particularly livelihood-dependent local communities, indigenous and artisanal peoples, or those seeking to undertake recreational and cultural activities. In many nations today, coastal developments and industries face greater scrutiny of their environmental and social performance than in the past, and many businesses now seek "social licence" through local environmental and social responsibility programmes that create benefits for the local community, but this is sometimes viewed negatively as nothing more than "green-washing".

To accommodate increasing urban and industrial development, agriculture, silviculture (notably oil palm) and aquaculture (notably shrimp), coastal space has been created by both the clearing of existing coastal vegetation, including mangroves, saltmarshes, coastal dunes and tidal flats, and the reclamation of intertidal and subtidal areas. Urban land expansion rates are significantly higher in coastal areas than in adjacent hinterland, and it is estimated that by 2030, global urban land cover will increase to 1,527,000 km^2 (Brown et al. 2013; Seto et al. 2011; Liu et al. 2020).

Coastal infilling, dredging and reclamation have been the primary means of expanding the coastal foreshore or creating artificial islands, and produce direct loss of marine habitat. While reclamation of coastal wetlands and tidal flats has been practised for millennia, the current scale to meet increasing demands for land is unprecedented. Globally, it is estimated that 33,700 km^2 of land has been added to coastal areas over the last 30 years, with more than 1250 km^2 of land being reclaimed from 16 megacities between the mid-1980s and 2017. Further ambitious land reclamation projects are under way in many regions of the world (see Box 7.1). China, in particular, is leading the world in large-scale reclamation projects, extending its coastline by hundreds of square kilometres every year, while the Netherlands and India have reclaimed areas of 7000 and 1500 km^2, respectively. As well as removing valuable habitat, reclamation of coastal areas contributes to land subsidence in coastal areas. Many of the world's coastal cities—built in low-lying areas where soft sediments can compress under the weight of infrastructure as cities grow—are now sinking (see Box 7.5). This results in increased risk of flooding, with consequences including structural damage and high maintenance costs for urban infrastructure and risk to human livelihood (Waltham and Connolly 2011; Wang et al. 2014; Donchyts et al. 2016; Reyna et al. 2016; Tian et al. 2016; Sengupta et al. 2017).

Box 7.2. Key Coastal Growth Sectors of the Ocean Economy

Coastal (beach-based) and maritime (water-based) tourism is the second largest employer in the ocean economy, providing 1 in 11 jobs worldwide and generating more than $1.5 trillion in trade income or 9.2% of global GDP, and it is the dominant sector in an increasing number of national economies. For some island states, tourism can comprise 25% of national GDP. Globally, over 350 million people annually travel to the coral reef coast, and the coral reef tourism sector has an estimated annual value of $36 billion globally, with over 70 countries and territories having "million dollar reefs"—reefs that generate over $1 million in tourism spending. Cruise-ship tourism has been growing (at least until the COVID-19 pandemic, see Box 7.3) at 7.7%, and can account for more than 90% of international visitors to some destinations. By 2030, coastal and maritime tourism is expected to comprise 26% of the total ocean industry value-added, and will employ c.1.5 million more people than it does at present. Coastal and maritime tourism generates indirect land activities linked to infrastructure construction that are responsible for pollution and destruction of natural habitats, as well as for pressure on natural resources, such as water, but also sand, limestone and wood (OECD 2016; Spalding et al. 2017; Tonazzini et al. 2019; WTTC 2019; UNWTO 2020a, 2020b).

Aquaculture, the farming of aquatic animals (e.g. finfish, molluscs and crustaceans) and seaweeds, is the fastest-growing food production sector in the world, with an average annual growth rate of 5.8% during the period 2000–2016. In 2016, global aquaculture production reached 80 million tonnes of food fish, with coastal aquaculture and mariculture (i.e. aquaculture in a marine environment) producing 28.7 million tonnes or 36% of this production. Aquaculture is mainly practised in tropical and subtropical regions and globally more than 60,000 km^2 of coastal areas is used for aquaculture. Asia accounted for 89% of global aquaculture production in 2016, much of which is produced in areas of former tidal flats and near-shore areas; China ranked first, followed by India, Indonesia, Viet Nam, Bangladesh, Egypt, Norway, Chile and Myanmar. Comparatively, Africa contributes the least of any continent to total global aquaculture production, yet the continent's aquaculture sector is growing faster than anywhere in the world, and accounts for 8% of the 12.3 million Africans employed in the fisheries sector.

Globally, the potential for onshore and offshore mariculture is large, and seafood production is expected to be predominantly sourced through mariculture by 2050. Significant areas of coast have been identified as areas that are suitable for further aquaculture development, including environmentally sensitive areas such as southern Patagonian coastal waters. The environmental impacts of aquaculture are well recognised and include the clearance of mangroves for shrimp ponds, eutrophication leading to disruptions to the surrounding benthic communities and increased phytoplankton and harmful algal blooms and disease (Kapetsky et al. 2013; Waite et al. 2014; Tenório et al. 2015; FAO 2018, 2020a; Obiero et al. 2019; Agarwal et al. 2019; Ahmed and Thompson 2019).

Offshore renewable energy, particularly offshore wind, is projected to grow significantly over the next decades. Under the International Energy Agency's (IEA) Stated Policies Scenario, installed capacity of global offshore wind is set to expand by at least 13%/year, increasing more than 15-fold over the 2018 installed capacity of 23 GW by 2040 (IEA 2019). Further extension of policy targets and falling technology costs may drive even greater uptake with over 560 GW installed capacity, accounting for 5% of global electricity supply, by 2040 in the Sustainable Development Scenario (IEA 2019). The UK Government 2020 levelised costs update shows continual reduction of offshore wind costs, being now lower than new gas and other fossil fuel generation, and projected to be less than onshore wind by the mid-2030s, owing to the relative strength and consistency of resource, and the large-size turbines able to be deployed offshore (BEIS 2020). Technical resource potential in shallow (<60 m) water depths, accessible to current fixed-bottom foundation wind technologies, is more than 87,000 terawatt-hours (TWh)/year. The emergence of floating foundation wind technologies removes depth constraints, and could provide access to another 330,000 TWh/year; 70% of the most accessible wind resource (20–60 km from shore) is located in water depths greater than 60 m (IEA 2019), which reflects the size of the opportunity to floating technologies. Other ocean-based renewable energy sources, including tidal, wave, floating solar and others, are less developed than offshore wind but also have significant potential for many regions where other drivers or advantages occur (see Haugan et al. 2020).

Over the coming decades, a number of industries are seeking to move further from the coasts in search of space to operate, or additional or more stable energy resources. Aquaculture, common in many inshore areas, will be much more prevalent offshore where larger, more complex, infrastructure designed to withstand the rigours of these environments will be required. Likewise, marine renewable energy infrastructures to harness wind waves and tidal power will become much more common.

2.3.4 Resource Extraction

The demand for food and materials—some traditional and others novel—from coastal environments has expanded rapidly in the last 50 years and will continue to do so over the coming decades, as growing coastal populations and a rising middle class seek greater protein in their diets, increased fresh water and more materials to build infrastructure. Box 7.2 briefly summarises three sectors—aquaculture, tourism and offshore renewable energy—that will see significant growth in coastal regions throughout the world over the coming decade.

The growing demand for global seafood still relies predominantly on coastal fisheries—those that occur less than 50 km from inhabited coastlines, or in waters less than 200 m deep. Despite significant declines over the last 60 years in a large number of exploited fish and invertebrate populations, coastal fisheries (see Gaines et al. 2019) still accounted for 55% (50–60 million tonnes/year) of global marine fisheries in the period 2010–2014. About 36% of this catch is from small-scale fisheries, undertaken mainly in developing countries and engaging more than 47 million people, nearly 50% of whom are women. These statistics not only highlight the global importance of coastal fisheries, but also the prominent role of small-scale fisheries in supporting coastal livelihoods, food security, nutrition and human well-being (World Bank et al. 2012; Monfort 2015; FAO 2020a, b; Palomares and Pauly 2019; Palomares et al. 2020).

Demand for fresh water for human consumption and agricultural and industrial use has rapidly increased and led to greater impoundment and extraction from coastal rivers and aquifers in drier areas, or where there is no longer sufficient water, the use of desalination plants has become commonplace. In 2000, there were c.45,000 reservoirs installed, and, as of 2014, at least 3700 major dams, each with a capacity of more than 1 megawatt (MW), were either planned or under construction, primarily in countries with emerging economies in Southeast Asia, South America and Africa.

While this construction will increase the present global hydroelectricity capacity by 73% to about 1700 gigawatts (GW), these impoundments will reduce the number of free-flowing large rivers by about 21% and trap 25–30% of the total global sediment load—and all of the bed load—that might otherwise be delivered to the coasts. Desalination facilities worldwide include about 16,000 operational plants with a global capacity of more than 95 million m^3 per day and the majority of these are from seawater or brackish water (21%). New ocean-water desalination projects are on the rise, including floating desalination plants constructed on ships and offshore structures, which have the advantage of being mobile (Vörösmarty et al. 2003; Syvitski et al. 2009; Grill et al. 2019).

Over the next 30 years, greater areas of irrigated agricultural land will be required, which, unless carefully managed, will have negative consequences for downstream coastal ecosystems. While today c.70% of irrigated areas are in Asia, under business-as-usual scenarios, by 2030 the total harvested irrigated area is expected to increase by at least 12%, to 394 million hectares (ha) (and perhaps as high as 1.8 billion ha), with approximately 9% of this growth expected to be in developing countries, especially those in Sub-Saharan Africa, but also South Asia and Latin America and the Caribbean. Irrigation is responsible for significant groundwater depletion in many regions, with about 11% of this resource embedded in the international food trade (Dalin et al. 2017; Ringler 2017; Puy et al. 2020).

Aggregates, such as sand—a key ingredient of concrete, asphalt, glass and electronics—and gravel, are the largest proportion of primary material inputs used in building and transport infrastructure (79% or 28.6 gigatonnes/year in 2010) and are the most extracted group of materials worldwide, exceeding fossil fuels and biomass. In most regions, sand is a common-pool resource, and even when sand mining is regulated, it is often subject to illegal extraction and trade. As a result, sand scarcity is an emerging issue with major sociopolitical, economic and environmental implications. Continued urban expansion and large infrastructure projects, as well as increasing trade and consumption, are pressuring sand deposits, causing conflicts, and compromising environmental and human systems. Activities such as unregulated sand mining of riverbeds, particularly in developing countries, can accelerate erosion and destabilise riverbanks and shorelines, and can harm benthic habitats, either through direct removal during dredging operations or from sedimentation. Transport of sand may also lead to increased biosecurity risks (Torres et al. 2017; Schandl et al. 2018; Koehnken and Rintoul 2018; Bendixen et al. 2019a; UNEP 2019).

More than 30% of current global energy demands are met by marine oil and gas reserves, and collectively the oil and gas sector accounts for one-third of the total value of the ocean economy. There are currently more than 6000 offshore and a few coastal (<200) platforms in service worldwide. As shallow-water fields become depleted and novel technologies emerge, production is moving towards greater depths and new territories. Other unconventional forms of gas, such as shale and natural hydrates, are also being increasingly exploited, as the technology to cost-effectively extract these reserves develops (Arthur and Cole 2014; US Department of Energy 2015; OECD 2016).

Despite the rhetoric of a sustainable ocean economy, there is growing scepticism that a business-as-usual scenario, favouring industrial and economic expansion of established and emerging industries, is being progressed without adequately addressing the equity, inclusion, access and benefit-sharing rights of those who also hold rights to the same resource (Selig et al. 2019; Bennett et al. 2019; Cisneros-Montemayor et al. 2019; Cinner and Barnes 2019; Hodgson et al. 2019; Cohen et al. 2019; Lau et al. 2019).

2.4 Summary

Large-scale declines in the extent of coastal landforms, vegetated ecosystems and biogenic structures over the last 40 years have occurred in many regions, and these declines have diminished coastal ecosystems' natural resilience to recover from a range of climate and anthropogenic threats, and to the biodiversity and services they support. The primary agents occurring on local to regional scales are the direct consequences of land-clearing and fragmentation, the degradation of these ecosystems from pollution, and imbalance in natural sediment supplies. Most of the remaining regions with a natural coastline are found in Africa and Asia, and these regions are also projected to experience the highest coastal population and urbanisation growth in the decades to come. Coastal ecosystems have been affected to varying degrees by sea level rise, ocean warming and acidification, and extreme weather and these effects are projected to be more significant in the future. Over the coming decades, further urbanisation and adaptation to rising sea levels and intensified storms will require even more coastal infrastructure.

This will require more material extraction, such as for aggregates to build infrastructure, new methods of environmentally sensitive construction with designs capable of withstanding future climate conditions. New forms of coastal infrastructure will also be required over the coming years to meet increased demand and access to coastal space. In an era of scarcity and increasing demand for fresh water, desalinisation plants will become much more common.

3 Risks to Coastal Resilience

Globally, coastal systems are undergoing profound, rapid and undesirable environmental changes, driven by the combined consequences of climate change, coastal development pressures and pollution, which leads to habitat loss and fragmentation—subdivision of habitat into smaller and more isolated patches. This degrades the ability of these ecosystems to provide essential ecosystem services. Anthropogenic threats to coastal systems can be exacerbated due to connectivity between marine, freshwater and terrestrial ecosystems, complicating the task of governance across the land–sea interface. Likewise, coastal settlements, their people, infrastructure and economies are increasingly at risk, as they struggle to adapt to these changes. In this section, we summarise the potential impacts on coastal ecosystem and services that arise from activities related to coastal development and industries, and review the risk to human populations, settlements, infrastructure and economies.

3.1 Threats to Coastal Ecosystems

3.1.1 Habitat Clearing and Fragmentation

The globally significant net loss of coastal landforms and vegetated and biogenic habitats that has occurred over the last half-century was summarised in Sect. 2.2, and includes erosion of depositional coastlines, loss of coastal vegetated ecosystems (50% of saltmarshes, 35% of mangroves), and coral (30%) and shellfish reefs (85%). These losses vary between regions, with some of the greatest losses occurring in Asia and Africa. While some of these changes have been incremental—although cumulative over time—in other cases, rapid/abrupt and potentially irreversible changes have also occurred. In some cases, such as mangroves and saltmarshes, the rates of loss in recent decades has decreased relative to changes that occurred 40–50 years ago, but other habitats, notably coral reefs and kelp forests, faced with the likelihood of more frequent and severe marine heatwaves in the future, are likely to see further significant and widespread losses.

However, the primary factor responsible for losses to date has been the clearing of coastal vegetated habitats to make way for agricultural, urban and industrial uses, and the reclamation of intertidal and subtidal areas (see Sect. 2.2 for more details). Less obvious, but equally pervasive, are the consequences of incremental fragmentation of these habitats, which, as has been highlighted in a number of recent publications, accrues significant cumulative net losses, impairs a number of ecosystem functions and services, and leads to declines in biodiversity for a range of taxa that rely on large intact areas for their home range, or as wildlife corridors on migratory routes. Patterns of fragmentation do not necessarily correlate with deforestation, or clearing, and relate to differing land-use and extractive activities. For example, in Ca Mau province, Viet Nam, over a 24-year period, the number of mangrove patches increased by 58% but the mean patch size decreased by 52%, and fish diversity was 1.8 times lower than in less fragmented mangrove forests (Tran and Fischer 2017; Jacobson et al. 2019; Bryan-Brown et al. 2020).

Other human activities, most notably alterations to natural patterns of river and surface water discharge, and the sediment, nutrients and pollutant loads that these carry to the coast, can have detrimental impacts on adjacent coastal habitats. While ecosystems, such as seagrass, oysters and coral reefs, are particularly sensitive to too-much sediment, in depositional coastal areas an adequate supply of sediment from upstream will be required to ensure the stabilisation of shorelines and the ongoing accretion of mangrove and saltmarsh habitat.

3.1.2 Pollution

An estimated 80% of pollution load in coastal environments originates from industrial, agricultural, urban/rural and other land-based activities, and is a key threat to biodiversity (IPBES 2019). While sediment and nutrients (principally nitrogen and phosphorus) occur naturally in the environment, excessive levels released from point sources (wastewater effluent, storm-water outfalls and runoff from waste storage) and nonpoint sources (deforestation, land conversion and runoff from agriculture or ranching) into rivers and estuaries, or directly into coastal and marine ecosystems, are considered serious threats.

Among developed nations, it is estimated that more than 70% of wastewater is treated with discharges to sewered connections centralised in wastewater treatment plants, where remedial technologies improve the quality of the effluent to differing standards—tertiary treatment, which removes nutrients, being the best. The quality of the discharge is often regulated by the setting and reporting of established concentration or load-based criteria. Over recent decades, this has resulted in significant reductions in nutrient loads from major coastal cities discharged into rivers, estuaries and coastal waters. However, among developing nations only 8% of generated wastewater is treated and most people rely on some form of decentralised or self-provided services. With increasing urbanisation, especially in Africa and Asia where the urban population is expected to grow by 2.5 billion over the next 30 years, there is an urgent need to better treat urban waste (Sato et al. 2013; Gallego-Schmid and Tarpani 2019).

As detailed in the companion Blue Paper, *Leveraging Multi-Target Strategies to Address Plastic Pollution in the Context of an Already Stressed Ocean* (Jambeck et al. 2020), marine litter is a global environmental concern, entering the ocean largely through storm-water runoff, but is also dumped on shorelines or directly discharged at sea from ships. Between 61 and 87% of this litter is plastics, and since the 1950s this has increased dramatically, with current estimates of between 4.8 and 12.7 million tonnes of land-based plastic waste ending up in the ocean every year, while in the next two decades, the amount of plastics produced is expected to double (Jambeck et al. 2015, 2020; Geyer et al. 2017; Löhr et al. 2017; Barboza et al. 2019; Walker et al. 2019; Galgani et al. 2019).

3.1.3 Bio-invasions and Disease in Coastal Ecosystems

In an increasingly tele-coupled world, invasive alien species—most commonly introduced via shipping and associated coastal infrastructure—threaten global biodiversity, economies and human health. Shipping is the primary vector for 60–90% of marine invasions globally, transporting marine species, including plankton, crustaceans and molluscs, in ballast water or attached to ships' hulls. Terrestrial pest species can also be transported in carried goods and their packaging, and upon arrival at destination ports can be rapidly spread inland along transportation chains. Once introduced, alien species can rapidly establish, particularly in areas that have already been disturbed, displacing native species, altering ecosystem structure and functions such as nutrient cycling and carbon sequestration. Well-known examples include invasions of coastal wetlands, dunes and saltmarshes by vascular plant species, marine algae and plankton, which increasingly result in occurrences of harmful algal blooms, by molluscs such as the Asian green mussel (*Perna viridis*) and by echinoderms such as the Northern Pacific seastar (*Asterias amurensis*). Projected increases in global maritime traffic of 240–1200% by 2050 are forecast to lead to a 3- to 20-fold increase in global invasion risk and this will occur mainly in middle-income countries. Significantly, Northeast Asia will not only be disproportionally affected but will also be the primary vector source to other geo-regions (Pyšek et al. 2008; Early et al. 2016; Seebens et al. 2015; Carrasco et al. 2017; IPBES 2019; Sardain et al. 2019).

Marine organisms serve as hosts for a diversity of parasites and pathogens affecting not only the host population that can include vertebrates, invertebrates and plants, but can also cascade through ecosystems altering the structure and function of marine ecosystems. Marine diseases can become emergencies when they result in significant ecological, economic or social impacts, so understanding the factors responsible for the genesis and timing of diseases will be increasingly important as our use of coastal and marine resources accelerates. The billions of dollars lost in the early 1990s as a result of a global pandemic of white spot syndrome in penaeid shrimp aquaculture, and the environmental and economic impacts of coral diseases that led to widespread mass mortality in Caribbean reefs and reduced ecotourism, are salient examples.

Marine disease emergencies can also have significant social impacts, capable of disrupting public safety, threatening human health, or decreasing the resilience of local human communities. The probability of humans acquiring infections from marine mammals, avian influenza from marine birds, and cryptosporidiosis and vibriosis from consumption of shellfish is also expected to increase unless carefully managed, with better surveillance, impact mitigation, and adaptive and responsive strategies. It should be noted that COVID-19 is not considered infectious to marine organisms (Ward and Lafferty 2004; Groner et al. 2016; Mordecai and Hewson 2020).

3.2 Risks to Coastal Ecosystem Services

Coastal ecosystems, their biodiversity and functions provide important provisioning goods, as well as regulating, supporting and cultural services that underpin the ocean economy and that also have values that are not explicitly economic. Provisioning goods, such as the harvesting of fish or timber from coastal habitats, represent products that are consumed. Growing demand for these products is a key driver in the conversion of habitats for these provisioning goods. Regulating services represent intangible benefits provided when ecosystems are left intact, such as flood and erosion reduction, and underpin provisioning goods such as fisheries production. Coastal areas also provide for uses that are considered aesthetic, spiritual and cultural services, such as sacred sites or points of historic interest. Such services are not easily valued in economic terms and thus lead to questions as to whether the concept of ecosystem services is an overly transactional view of nature, and whether the benefits that people receive can be represented better by frameworks that are less anthropocentric.

A central dilemma facing coastal ecosystems, and achieving a sustainable ocean economy more generally, is reconciling the competing demands for provisioning goods and services with the need for regulating, maintenance and cultural services (HM Treasury 2020). Loss or impairment to coastal ecosystems can result in a concomitant, although often non-linear, loss of service(s). It is notable that the most recent IPBES Global Assessment Report and World Economic Forum Global Risks Report both ranked biodiversity loss and ecosystem collapse in the top five risks to the global economy (IPBES 2019; WEF 2020a).

While provisioning services can be readily measured and valued, regulatory, supporting and cultural services are much harder to quantify and only rarely are they directly accounted for in coastal management because their services are not quantified in terms familiar to decision-makers, such as (loss of) annual expected benefits (Beck et al. 2018a). There are several competing lines of thought about this conundrum. Some argue that we should accept that some values cannot, and perhaps should not, be measured and monetised, and that we need to invoke other frameworks to accommodate the different types of values (Sagoff 2008). Others argue that incorporation into systems derived from economic accounting is an efficient way to ensure that resources are devoted to conserving the ecosystems. From the latter are emerging global standards, such as the System of Environmental-Economic Accounting (SEEA), which uses natural capital accounting frameworks and associated methodologies to classify and place a monetary value on even intangible services. These frameworks can be integrated with traditional economic national accounts, allowing them to be explicitly considered in resource and environmental decision-making. They might also facilitate development of financial instruments, such as payments for ecosystem services (PES), to incentivise the conservation or repair of natural assets. More details are provided in the companion Blue Paper *National Accounting for the Ocean and Ocean Economy* (Fenichel et al. 2020), while below we briefly summarise the key coastal services, the value they provide and the risks if they are diminished or lost.

3.2.1 Coastal Protection

Coastal vegetation and reefs can contribute significantly to coastal protection by absorbing the energy of wind and waves and providing a buffer that helps to minimise erosion and limit the intrusion of storm surges and damaging floodwater. As such, they provide significant annual flood protection savings for people and property, particularly from the most frequent storms. Globally, and averaged across these ecosystems, it is estimated that they can together reduce wave heights between 35% and 71%, with mangroves and reefs providing annual storm and flood protection benefits exceeding $65 billion and $4 billion, respectively.

Along the Northeastern seaboard of the United States, saltmarshes avoided costs of $625 million in direct flood damages resulting from Hurricane Sandy in 2012. In the Philippines, it is estimated that annually mangroves reduce flood-risk for more than 613,500 people, 23% of which live below the poverty line, and avert damages of $1 billion to residential and industrial property. Coral reefs protect more than 18,000 people from flood damage and avoid costs of $272 billion.

Without mangroves, it is estimated that a further 15 million people would be potentially exposed to flooding annually across the world, while the absence of reefs would more than double the expected damage from flooding, and costs from frequent storms would triple. Many countries (notably Bangladesh, Cuba, China, India, Indonesia, Malaysia, Mexico, Philippines, USA and Viet Nam) are estimated to gain annual expected flood savings exceeding $400 million, while some small (20-km) coastal stretches, particularly those near cities, receive more than $250 million in flood protection benefits from nearby mangrove forests (Spalding et al. 2014; Narayan et al. 2016, 2017; Beck et al. 2018a, b; Reguero et al. 2019b; Storlazzi et al. 2019; Menendez et al. 2020).

3.2.2 Carbon Sequestration

Coastal vegetated wetlands, including saltmarshes, mangrove forests and seagrass meadows, are considered to be the main blue carbon habitats, due to their ability to sequester and store large amounts of carbon within their root systems and in the underlying soil in which they grow. Despite their relatively small global extent (equivalent to 0.2% of the ocean surface), these vegetated coastal ecosystems contribute approximately 50% of the carbon sequestered in marine sediments, absorb CO_2 up to 40 times faster than terrestrial forest and consequently are globally equivalent to c.10% of the entire net residual land sink. Consequently, it is now well recognised by many nations and organisations that the conservation and restoration of these blue carbon ecosystems is an effective climate solution that could deliver substantial mitigation of CO_2 through storage and sequestration, as well as delivering other important benefits, like enhancing livelihoods and reducing risks from storms. Other research commissioned by the Ocean Panel estimates that coastal blue ecosystems could, by 2030, contribute avoided emissions of 0.32–0.89 billion tonnes of CO_2e per annum and this would increase to 0.50–1.38 billion tonnes of CO_2e by 2050. However, impairment or loss of these blue carbon ecosystems can contribute significant emissions. For example, as a result of global net losses in mangrove ecosystems between 1996 and 2016, global mangrove carbon stocks have declined by 1.5% (0.16 billion tonnes) with greatest losses occurring in Indonesia, which has the largest areal extent of mangroves, but also in countries such as Myanmar, where mangrove clearing rates today still remain high. Internationally, many countries with large blue carbon stocks seek to recognise the mitigation potential as part of their national emission reduction commitments. For example, preventing mangrove deforestation in Indonesia could reduce emissions from land-use change by 30%. Efforts to halt and reverse this trend could be supported by the private sector, as many companies look to offset their carbon emissions though investments in blue carbon protection or restoration (McLeod et al. 2011; Atwood et al. 2017; Serrano et al. 2019b; Spivak et al. 2019; Lovelock and Reef 2020; Richards et al. 2020).

3.2.3 Fisheries Productivity

Another important service of mangroves, marshes, reefs and seagrass beds is that they provide breeding and nursery habitat for a number of commercially important inshore and offshore fisheries. The complex structure of these habitats provides juveniles with refuge from predators and access to a variety of food sources that sustain their growth into adulthood. The fisheries value can be highly site specific and often more than one of these habitats may contribute to the life cycle of the fishery, including larval dispersal and migration to offshore habitats. The economic values of these fisheries also vary according to specific costs associated with each fishery, proximity to economic markets and levels of utilisation. Inshore, small-scale fisheries target a variety of mollusc, crustacean and fish species, often for domestic use or in local markets, and are of relatively low economic value relative to offshore fisheries harvested mainly by industrial-scale operations. In many tropical coastal communities, gleaning—fishing for invertebrates such as sea cucumbers in water that is shallow enough to walk in—is often done by women and children, and provides a source of essential protein, micronutrients and income. Mangrove habitats adjacent to large river mouths, where freshwater and high nutrients enhance productivity, generate the highest numbers of juvenile fish (e.g. mangrove jack, *Lutjanus aregentimaculatus*) and commercially important species like shrimp. While many coastal small-scale fishers are fully aware of their reliance on mangroves, larger commercial fisheries, such as the shrimp industry, operating in offshore waters often overlook the mangroves on which they depend.

Box 7.3. Enabling Coastal Resilience in a COVID World

COVID-19 is having serious and significant impacts on national economic growth trajectories, including coastal economies. The hardening of borders, limited movement of people, shrinking income opportunities, disruption of globalised supply chains and rise in restrictive trade policies are emerging as early consequences of the global pandemic that are relevant to coastal economic sectors. Poor urban coastal communities are most vulnerable to the pandemic since they live in crowded areas in low sanitary conditions often at the water's edge. The reduction of income for coastal residents, social distancing and quarantine, and even the provision of basic food supplies to coastal communities, are proving difficult. The impacts are most profound for marginalised groups and increase the social and environmental stressors, as well as exacerbating the challenges of disaster response in coastal contexts (CIRAD 2020; UNCTAD 2020a; WEF 2020b).

Coastal and ocean economy sectors, such as fisheries, aquaculture and seafood processing, tourism and recreation, maritime transport and logistics, are most impacted by the pandemic. Restrictions to ship docking, limited road transport and access to ports, falling demand for fish products and for tourism and recreation all reduce the income of the coastal and ocean economy sectors and associated jobs, as well as impacting on those who work on board vessels, with accounts of crew being stranded at sea for months (Bennett et al. 2020; Gössling et al. 2020; OECD 2020a, b).

COVID-19 has exposed weaknesses in the complex global fisheries and seafood production system and supply chains. Impacts on the hospitality sector and live export markets has led to international demand for fresh fish dropping dramatically and prices dropping accordingly. At the same time, demand for canned tuna has been maintained as it is seen as desirable as a source of shelf-stable protein, and some markets have seen increased demand (FAO 2020c, d; OECD 2020a, b).

The small-scale fisheries sector has been particularly hard hit, especially where perishable product is dependent on being sold through wet markets and then processed locally. Small-scale fisheries and fish processing are high-employment, low-wage sectors, with a high proportion of women working in fish processing facilities, and where proximity puts workers at risk of COVID-19. Entrepreneurial vendors are using digital technology to connect directly to customers, but the closure of wet markets and the closure of processing facilities has meant that a large proportion of product has no pathway to market (Bennett et al. 2020; CIRAD 2020; Davey and Steer 2020; FAO 2020c, d; OECD 2020a, b).

Positive stories have emerged from several Pacific Island nations, where practices such as food sharing have restarted and local food networks have been revived, and where collective actions have worked to safeguard rights. There are also stories of increased pressure on natural resources, through more fishing effort, regulations being relaxed and areas being opened up to fishing, including as people move back to their home communities from major cities, because of the loss of jobs. Using coastal resources as a social safety net, and relaxing rules during times of economic crisis is a high-risk strategy and could lead to greater problems in the long term (Bennett et al. 2020; CIRAD 2020; Davey and Steer 2020).

Tourism is one of the economic sectors hardest hit by COVID-19. Economies and communities with a high dependence on international tourism receipts have been badly affected by travel bans and restrictions. Tourism is a high-employment, low-wage sector, often employing large numbers of young people, and is particularly important as a source of GDP for many SIDS economies. Many coastal hotels and recreation facilities are facing bankruptcy, and stimulus options are urgently needed for this sector to preserve the long-term potential and to engage the affected workforce. Reskilling in digital technologies, engagement in natural resource recovery programmes or mobilising the workforce into nation-building sustainable natural infrastructure programmes are all options that could be explored (Gössling et al. 2020; OECD 2020a, b; Vianna et al. 2020; WEF 2020b).

Seagrasses also support substantial fisheries, both from small-scale fisheries that target species that rely on seagrass for most of their life (e.g. rabbitfish) or species that rely on seagrass in early life stages before they move offshore (e.g. northern Atlantic cod). Seagrass meadows are also popular locations for small-scale mariculture, like sea cucumbers and seaweeds (Benzeev et al. 2017; Carrasquilla-Henao and Juanes 2017; Worthington and Spalding 2018; Waltham et al. 2019; Jinks et al. 2020; Vianna et al. 2020; Waltham et al. 2020).

3.3 Risks to Coastal Populations, Infrastructure and Economies

Coastal communities, built infrastructure, and established and emerging economic sectors are significantly affected through the disruption of coastal physical processes resulting from climate change and coastal and upstream development. Globally, around 10 million people experience coastal flooding due to storm surges, cyclones and heavy rainfall every year with impacts ranging from displacement of households and destruction of sources of livelihoods, to disruption of national economies. The World Economic Forum's two most recent Global Risks Reports ranked extreme weather, preparing cities for sea level rise biodiversity loss, and ecosystem collapse in the top five risks.

While the consequences of COVID-19 (see Box 7.3) on the resilience of coastal ecosystems will continue to unfold over many years, the immediate impacts on coastal-dependent industries, such as tourism, and the flow-on effects on the economies of nations and livelihoods of local communities, are profound (Vitousek et al. 2017; Bergillos et al. 2019; Hino et al. 2019; DasGupta and Shaw 2015; Betzold and Mohamed 2017; Kramer et al. 2017; Hagedoorn et al. 2019; WEF 2019, 2020a).

3.3.1 Populations

An estimated 310 million people, and $11 trillion in GDP, are exposed globally to the risk of a 100-year flood event. Risk is expected to increase, due to rising sea levels and other climate-related threats concurrent with population growth. If no mitigation measures are undertaken, by 2050, c.9 million of the world population, concentrated in more than 570 coastal cities, situated in low elevation areas, notably in China, Bangladesh and Indonesia, could suffer from enhanced inundation and increased coastal erosion. By 2060, up to 411 million people could be exposed to the risk of a 100-year flood event (Ericson et al. 2006; Hallegatte et al. 2013; Hinkel et al. 2014; Wong et al. 2014; Neumann et al. 2015; Reguero et al. 2015; Arnell and Gosling 2016; Lumbroso 2017; Brown et al. 2018; Barnard et al. 2019; Nicholls et al. 2020).

Both sea level rise and extreme coastal events cause massive and existential displacement of populations. Sea level rise has already affected many low-lying islands, such as Kiribati, and Isle de Jean Charles in Louisiana, USA, and resettlements of populations are either under way or planned. After the Indian Ocean tsunami, in the coastal areas of the provinces of Aceh and North Sumatra in Indonesia, over half a million people, including some 300,000 living in severely damaged areas, were displaced. The task of resettling these residents, while keeping their sense of community, serves as a test case for future events (UNDP 2005; McGranahan et al. 2007; Birkmann et al. 2013; Gray et al. 2014; Wilkerson et al. 2016; Oliver-Smith 2019; Visessri and Ekkawatpanit 2020).

The risk posed to coastal populations depends not only on the exposure to the hazard, but also on social conditions (susceptibility) and capacities to respond (resilience) and together describe the vulnerability of societies. As a result, countries have different risks, with tropical states and SIDS in the Caribbean and Oceania and coastal areas in Southeast Asia (Bangladesh, Myanmar, Papua New Guinea and Timor-Leste) being most at risk (Fig. 7.3). Countries in Africa have high overall risk, as vulnerability scores are high and exposure to coastal hazards and adaptation are generally low; in contrast, countries like the Netherlands and Japan have high exposure rates but are more resilient (Beck 2014).

Coastal indigenous peoples, particularly those inhabiting islands or archipelagos, are some of the most vulnerable populations to coastal hazards. Often their traditional and customary use areas are not recognised and their access to cultural and spiritual sites of importance is not upheld, including where national and multinational interests seek access to the coast (see Box 7.4).

To mitigate the impacts of the pandemic, government and industry need to address the immediate economic and social hardships caused by the pandemic and enable coastal communities to maintain their resilience and rapid after-pandemic recovery, while maintaining their long-term goals of protecting coastal natural resources, the coastal environment and ecosystems. This can be done by supporting the incomes of and providing healthcare to the most vulnerable groups and ensuring that evidence-based management remains in place and is enforced. It is estimated that $10–20 trillion of public funding will be mobilised into the world economy in the next 2–3 years to support and stimulate economic recovery, including the recovery of coastal economic sectors. Therefore, a unique window of opportunity exists to engage and influence relevant policy and investment decisions and ensure stimulus funds foster sustainable ocean economic pathways and support the recovery and development of impacted communities. For example, coastal restoration can be used to help economic recovery from the COVID-19 pandemic while providing co-benefits of ecosystem services, community cohesion and climate adaptation (ADB 2020; OECD 2020a).

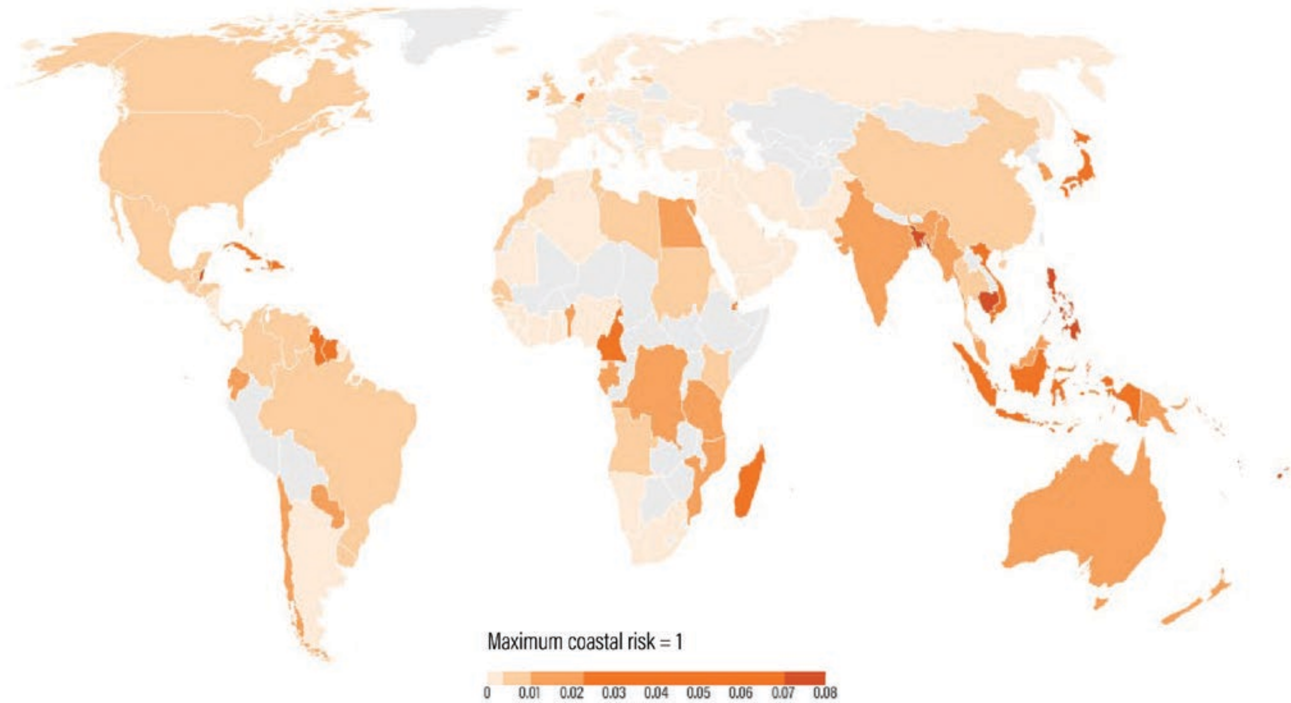

Fig. 7.3 Coastal risks to nations and geo-regions. (Source: Beck (2014). Data from The Atlas of Ocean Wealth (https://oceanwealth.org))

Box 7.4. Vulnerabilities of Coastal Indigenous Peoples and People from Traditional Communities

Coastal indigenous peoples, including those of SIDS, comprise some 370 million people, or 5% of the global population. As they rely on ocean resources and are highly vulnerable to ecosystem and economic change, the exploitation of fish resources and climate hazards pose distinct threats to these communities (Cisneros-Montemayor et al. 2016). Coastal indigenous peoples consume approximately 1.9 million tonnes of fish per year, approximately 2% of the global catch, and this seafood demand is concentrated around equatorial regions in Africa and Asia, and in the Arctic. In many of these areas' fisheries, stocks (e.g. of Pacific tuna; Bell et al. 2015) are changing migration and distribution patterns in response to global environmental changes, and traditional fisheries areas are under mounting pressure from foreign and domestic fishing fleets. Already, people in the 22 small island nations and territories of the southwest Pacific have increased their reliance on imported foods, including canned meats and packaged products, in part because of depleted fish stocks. Food imports to countries such as Samoa and Tonga now exceed total exports. These societal shifts have strong negative implications for the health and well-being of indigenous peoples. For instance, deaths in the Pacific from preventable non-communicable diseases, such as diabetes, cardiovascular disease and cancer, have risen, in part because of the dietary and lifestyle changes that have accompanied people's increased reliance on food imports (Morrison et al. 2019).

Coastal indigenous peoples are some of the most vulnerable populations to coastal hazards, such as storms, cyclones and tsunamis. While efforts to mitigate the impacts of these hazards mainly focus on defence infrastructure development, or early warning systems, the traditional and local knowledge of these communities has been found to increase their resilience and help them to manage crises—be it natural hazards, economic problems or political conflicts (Hiwasaki et al. 2014). Furthermore, many indigenous communities live in regions without strong governance, although a number of international agreements and bodies (e.g. United Nations Declaration on the Rights of Indigenous Peoples; Convention on Biological Diversity; Intergovernmental Panel on Climate Change) recognise preferential access rights for indigenous peoples, their vulnerability to climate and food security, and the value of traditional ecological knowledge (Cisneros-Montemayor et al. 2016; Vierros et al. 2020).

3.3.2 Infrastructure

Building resilient communities is a shared challenge for the world's population living along the coast now and in the future. To address this challenge, communities typically engineer barriers along the coast. However, there is growing understanding that traditional approaches to coastal protection (e.g. seawalls, bulkheads) are unsustainable. Hardened shorelines can be expensive to build and maintain, and can lead to unintended shoreline erosion, degradation or loss of habitat, impacting on communities that depend on healthy coastal ecosystems for protection, subsistence and livelihoods. However, decision-makers often lack basic information about where and under what conditions ecosystems reduce risk to coastal hazards and who would benefit from the protective function conferred by those ecosystems (Adger et al. 2005; McGranahan et al. 2007; Kron 2013).

The proportion of the world's gross domestic product (GDP) annually exposed to tropical cyclones has increased from 3.6% in the 1970s to 4.3% in the first decade of the 2000s. Flood assessment of 136 major coastal cities shows that average flood losses in 2005 were about $6 billion/year, and in the last 10 years insurers have paid out more than $300 billion for coastal storm damage. Considering the risks from sea level rise and sinking land, both the World Bank and the Organisation for Economic Co-operation and Development (OECD) estimate that, by 2050, global flood damage in large coastal cities could cost $1 trillion a year, while climate-induced declines in coastal and ocean health will cost the global economy $428 billion/year, and global infrastructure investment of more than $94 trillion will be required to reduce these risks (UNISDR 2011; Hallegatte et al. 2013; Diaz 2016; Oxford Economics 2017; IPCC 2019; ORRAA 2019; WEF 2019).

Box 7.5. Sinking Cities

Land subsidence is one of the world's under-rated problems, yet its impact on many coastal cities is increasingly apparent. Many of the world's sinking cities are built on low-lying marshes, flood plains or river deltas, where soft sediments compress under the weight of infrastructure, and this is exacerbated by groundwater or oil/gas extraction for human use, as well as reductions in sediment supply due to dams and impoundments. The increased frequency and magnitude of extreme weather events and changing sea levels further increase the risk of flooding, the consequences of which include structural damage to infrastructure, drains and sewage systems and high maintenance costs for roads and railways.

Cities that have grown rapidly, or have failed to curb groundwater usage, are particularly at risk, most notably in Asia (e.g. Jakarta, Guangzhou, Shanghai, Dhaka, Ho Chi Minh, Bangkok), but also on other continents, including the Americas (e.g. Mexico City, Houston, New Orleans), Africa (e.g. Lagos) and Europe (e.g. London, Rotterdam, Venice). Jakarta is the world's fastest-sinking city, at a rate of c.25.4 centimetres (cm)/year.

Around 40% of the city now lies below current sea levels and some coastal districts have sunk as much as 4.3 m in recent years. With further population growth, urbanisation, intensification of economic activities in deltas, and climate change, the problem is set to accelerate. Stopping the pumping of groundwater is one of the practical and local actions that can be readily implemented. A century ago, Tokyo was sinking at a greater rate than Jakarta is now. Following the Second World War, laws limiting pumping and a programme to re-inject water back into the ground has stabilised land subsidence such that, by the early 2000s, the city's subsidence slowed to 1 cm a year (Sato et al. 2006; Kramer 2018).

3.4 Summary

Coastal environments and dependent human communities are already experiencing the impacts of climate-related changes from extreme events and slow-onset changes, and the consequences of rapidly growing and urbanising populations that demand great access to greater resources, built infrastructure and services, and space. These climate and development changes can act synergistically and result in cascading and hard-to-predict impacts, as the world has seen with the global COVID-19 pandemic, in which core vulnerabilities have been exposed with devastating consequences.

While across the globe there is regional variability in how coastal environments will be affected, these changes will continue for many decades irrespective of actions taken, while no action will result in disproportionately higher risks, and a return to previous conditions should not be expected.

4 Building Coastal Resilience

To effectively manage the challenges wrought by coastal development and climate change, there are four main management strategies that can be used to secure the integrity and resilience of coastal ecosystems and their contributions to people:

1. *Protection strategies* use regulations and area-based management, to designate where and how much of specified activities can and cannot occur in coastal environments and in the adjacent catchment, and legislate areas for conservation such as marine protected areas (MPAs) or implement area, habitat and species-specific conservation plans.
2. *Mitigation strategies* aim to reduce local stressors caused by human action through the use of technology, regulation and the promotion of stewardship to minimise the introduction of pollutants, the over-exploitation of resources or activities that will otherwise harm coastal environments.
3. *Adaption strategies* explicitly consider the coastal social-ecological system and are implicitly related to resilience; adaptation leads to resilience and resilience is a property needed for having capacity to adapt (Nelson 2011). They use principles of ecosystem-based adaptation and ecological engineering to incorporate natural infrastructure into existing grey infrastructure, relocate at-risk activities and populations away from the coast, and also use incentives to change behaviours and practices.
4. *Repair strategies* seek to restore damaged ecosystems by restoring the composition and/or function of lost or fragmented habitats, restoring (reinstating) the natural hydrology, sediment and nutrient balance entering and cycling through coastal ecosystems, or by assisted evolution.

Figure 7.4 represents 17 actions that can be taken under these four strategies and highlights the enabling conditions needed to ensure their success.

All four strategies broadly fall under the umbrella framework of nature-based solutions (NbS), which are defined by the IUCN as "actions to protect, sustainably manage, and restore natural or modified ecosystems, that address societal challenges effectively and adaptively, simultaneously providing human well-being and biodiversity benefits" (Cohen-Shacham et al. 2016). NbS is an area that covers a range of ecosystem-related approaches to protect (i.e. area-based conservation), to manage holistically (e.g. integrated coastal management or ICM), to address specific issues and to repair and restore ecosystems.

NbS approaches are now being used to reframe policy debates on biodiversity conservation, climate change adaptation and mitigation, and sustainable use of natural resources, to address conflicts and trade-offs associated with use and management of ecosystem services, and to invest in blue infrastructure and ocean finance (World Bank 2008; United Nations 2013; Nesshover et al. 2017; Thiele et al. 2020; WEF 2020c). But not all strategies are applicable in a given situation, and evaluating a broad range of actions, and combinations of actions, can help decision-makers to estimate the trade-offs of different management approaches and to maximise the co-benefits. In fact, comprehensively tackling issues, such as reducing pollution or preventing clearing of mangroves and saltmarshes, will require a mix of all four strategies.

The success of any of these strategies is predicated on the presence of a number of enabling factors or conditions that encompass the dimensions of technical readiness, social equity, economic viability and environmental sustainability. Some of these are shown in the outside ring of Fig. 7.4 and are summarised in Sect. 4.6; they also form the basis for many of the opportunities for actions outlined in Sects. 5.2 and 5.3. In particular, integrated management is listed here as an enabling factor as it provides the framework with which these various strategies can be applied across the terrestrial-coast ocean continuum, between institutional lines of responsibility, as well as integrating with other relevant agendas, such as those for climate action and urban transitions. Approaches to coastal integrated management are discussed below but are considered in detail in the companion Blue Papers *Integrated Ocean Management* (Winther et al. 2020) and *The Ocean Transition* (Swilling et al. 2020).

As part of the four strategies outlined above, the approaches and activities most useful to ensuring coastal resilience are evaluated below and form the basis for the opportunities for actions presented in the following sections: area-based measures for protecting coastal ecosystems; mitigating terrestrial impacts on coastal environments; adapting infrastructure; and restoring coastal habitats.

Fig. 7.4 Four strategies and actions for building coastal resilience and the enabling conditions to achieve them. (Source: CSIRO)

4.1 Protecting Coastal Ecosystems

The first line of defence in ensuring coastal resilience is to provide adequate protection of coastal habitats from inappropriate forms, or unsustainable levels, of human use, and to secure the rights of peoples with recognised tenure and customary access rights. Protecting coastal habitats is more cost-effective and has better ecological outcomes than rehabilitating lost habitat. For example, protection of mangroves provides an immediate benefit–cost ratio of 88, compared with restoration activities which have a ratio of 2, because they require higher logistical costs and take decades to realise the benefits (Konar and Ding 2020).

Protection can only occur where there is a clear, effective and enforceable regulatory framework in place, with national and subnational policies and regulations that, among other things, forbid the clearance of natural coastal lands for other activities, designate appropriate human activities that are allowed to occur within defined coastal areas while minimising harm, and set limits to levels of resource extraction or activity. In all cases, such regulations are most effective when ownership is clearly established. However, as many of these regulations pertain to single areas, sectors or individual developments, a priority for further enhancing protection of coastal ecosystems is to improve legislation, policies and planning frameworks to better consider multiple pressures and cumulative impacts from marine and land-based activities. Ensuring there is a comprehensive monitoring program and research agenda in place to assess and predict potential impacts and develop effective management strategies is also required (Griffiths et al. 2019).

There are a number of international conventions and agreements that relate to various aspects of coastal management, including conservation of coastal environments and biodiversity (e.g. Convention on Biological Diversity (CBD), Ramsar Convention on Wetlands) and controlling pollution (MARPOL Convention, United Nations Framework Convention on Climate Change (UNFCCC)), which can be built upon to provide greater levels and greater breadth of protection for coastal ecosystems and their services. Both the SDGs (14.5) and the CBD Aichi Targets (11) commit nations to conserve at least 10% of their coastal and marine areas by 2020; and it is now being advocated that at least 30% will need to be protected by 2030, with the remaining areas also under environmental management (World Conservation Congress 2016; Laffoley et al. 2019; Roberts et al. 2020). The UNFCCC nationally determined contributions (NDCs) for greenhouse gas emission reductions under the Paris Agreement and the Sendai Agreement for Disaster Risk Reduction 2015–2030 may secure better protection of coastal ecosystems through recognition of their carbon sequestration and climate protection services. However, many of these agreements are usually voluntary and non-binding and, as Winther et al. (2020) note, “it is failure to implement these existing international instruments at national levels that is one of the most important weaknesses of ocean governance”.

Over the last 30 years, a number of integrated planning frameworks, conservation and spatial management tools and processes have been developed and implemented to protect coastal ecosystems, and minimise multi-sector competition for resources or space. Best known is integrated coastal management (ICM), also known as integrated coastal zone management (ICZM), which aims to balance the complexities and potential conflict of growing uses of the coastal zone through the use of relevant legislation and policy and spatial and conservation management tools to integrate planning, decision-making and management across sectors and across land and sea estates, and aspires to consider cumulative effects and trade-offs (Álvarez-Romero et al. 2011; Bernal 2015; Cicin-Sain 1993; Katona et al. 2017; Stephenson et al. 2019).

ICM principles and frameworks have been implemented at global, regional and national scales. Many countries have sought to implement ICM in several forms and with various degrees of success. For example, many countries in East Asia, including Viet Nam, the Philippines, China, and the Republic of Korea, have institutionalised ICM in national legislation, and this has supported countries in the region to improve coastal management and to enhance the effectiveness of use and conservation of coastal natural resources and environment. Regionally, intergovernmental cooperation, such as the Partnerships in Environmental Management for the Seas of East Asia (PEMSEA), has for more than 25 years applied ICM solutions in dozens of sites across East Asia, covering around 38% of the region’s coastline, across 12 countries (see Box 7.6).

Success in implementing ICM in some countries has been hindered by the absence, or limited presence, of key enabling factors, including inadequacies with legal frameworks, poor cooperation between different sectors or government departments, lack of personnel, capacity and access to knowledge (White et al. 2006; Shipman and Stojanovic 2007; Borja et al. 2008; Nguyen and Bui 2014; Elmgren et al. 2015; Candel 2017; Liu and Xing 2019; PEMSEA 2020).

ICM is a dynamic process and continues to evolve, with greater emphasis on better management across the catchment–coast–ocean continuum, coupling coastal, water and urban frameworks, integrating climate and disaster risk reduction and management. A terrestrial–ocean integrated climate policy is part of a larger changing narrative about the ocean and the recognition of its untapped potential for climate regulation, mitigation and adaptation, and our aspirations for a sustainable ocean economy. There are significant opportunities for alignment with Integrated Water Resources Management initiatives, including the UN’s 2018–2028 Water Action Decade and the urban sustainability agenda (discussed further in Sect. 4.2).

Today, an integrated management framework, coupled with an ecosystem-based approach to management and supported by marine spatial planning, including the use of MPAs and other effective conservation measures (OECMs), is recognised as best practice. Ecosystem-based approaches and management are based on the application of scientific methodologies, focused on levels of biological organisation, which encompass the essential structure, processes, functions and interactions among organisms and their environment. These approaches have been most widely applied and institutionalised into fisheries management. For example, Indonesia and the Philippines have both recently adopted ecosystem-based fisheries management and spatial closures by designating a number of Fisheries Management Areas (Mokhtar and Aziz 2003; Levin et al. 2009; Saad et al. 2012; Ureta et al. 2016; Altenburg et al. 2017; Gelcich et al. 2018; Muawanah et al. 2018; Alexander et al. 2019; Alexander and Haward 2019; Kirkfeldt 2019).

MPAs are one of the most widely implemented area-based management tools used by countries to protect valuable or representative coastal and marine areas, and, increasingly, areas of the high seas. MPAs vary in levels of protection, from marine reserves and parks that provide full protection to multiple-use areas that restrict some activities in some areas, such as no-take areas. In most countries, multiple-use MPAs are the most common form (>75% in 2013). More than 40% of mangroves and warm water coral reefs are placed within gazetted MPAs, while seagrasses and estuaries are the habitats with the lowest proportion of area (<30%) contained within MPAs (Toonen et al. 2013; Costello and Ballantine 2015; Jacobsen 2019; Bryan-Brown et al. 2020; Rogers et al. 2020; UNEP 2020).

Box 7.6. Regional Coastal Management Strategies

Partnerships in Environmental Management for the Seas of East Asia (PEMSEA): PEMSEA is an intergovernmental organisation operating in East Asia to foster and sustain a healthy and resilient ocean, as well as coasts, communities and economies across the region. PEMSEA serves as the regional coordinating mechanism for the shared regional coastal and marine strategy, Sustainable Development Strategy for the Seas of East Asia (SDS-SEA), adopted by 14 countries (Brunei, Cambodia, China, DPR Korea, Indonesia, Japan, Lao PDR, Malaysia, the Philippines, RO Korea, Singapore, Thailand, Timor-Leste and Viet Nam) (Fig. 7.5). The strategy is a package of applicable principles, relevant existing regional and international action programmes, agreements and instruments, as well as implementation approaches, for achieving sustainable development of the Seas of East Asia. It offers a regional framework for the interested countries and other stakeholders to implement, in an integrated or holistic manner, the commitments they have already made, without assuming new legal obligations. It addresses linkages among social, cultural, economic and environmental issues and embodies the shared vision of the countries and other stakeholders for the Seas of East Asia, and the ways by which they will achieve that shared vision. PEMSEA has developed an ICM system that addresses complex coastal management concerns, covering governance and various sustainable development aspects. In November 2015, PEMSEA country partners committed to scale up the ICM to cover 25% of the region's coastline by 2021. To date, PEMSEA has exceeded that target and secured about 37.9% of the region's coastline, having a significant impact on 86,284 km of coastline and over 150 million people living in coastal and watershed areas. As part of ICM implementation towards achieving blue economies in the region, PEMSEA is committed to improving coastal and ocean governance, and implements programmes on climate change mitigation, disaster risk reduction, habitat protection restoration and management, water use and supply management, food security and livelihood management.

West Africa Coastal Areas Management Program (WACA): WACA was established by the World Bank in 2015 in response to demands from countries in the region to manage their growing coastal erosion and flooding problems. Countries already participating in the programme include Benin, Côte d'Ivoire, Ghana, Mauritania, Sao Tome and Principe, Senegal, and Togo, and discussions are under way with other countries. WACA is designed to improve the livelihoods of coastal communities in West Africa by reducing the vulnerability of its coastal areas and promoting climate-resilient integrated coastal management. The programme's mix of technical assistance and investments will seek to preserve and rehabilitate the natural coastal resources essential for livelihoods; spur economic development and increase social welfare; and support the sustainable development of key growth sectors, such as agro-industry, fisheries, offshore petroleum exploration and production, and tourism. WACA is also a convening platform to help countries obtain the finance and expertise they need to sustainably manage their coastal areas. It also serves as a forum within which countries and regions can share lessons learned.

Southeast Pacific Data and Information Network in Support to Integrated Coastal Area Management (SPINCAM): SPINCAM is an IOC-UNESCO/Flanders and Permanent Commission for the South Pacific (CPPS) initiative, created in 2008 to develop a framework of indicators in various pilot sites of the southeast Pacific (Chile, Colombia, Ecuador, Panama and Peru). SPINCAM supports the development of decision-making tools and implementation of ICM through regional and national investment for improved data and information management capacity, knowledge, communication and networking at national and regional level (COI-UNESCO and CPPS 2016). Main outputs so far have been the development of information systems, in the form of substantial ICM atlas and web-based portals for the associated metadata. The main outcomes expected from SPINCAM include: institutionalisation of coastal and marine governance at national and regional level; improved regional networks on coastal and marine issues; regional strategic recommendations on marine spatial planning, sustainable blue growth, monitoring systems and decision support tools; reduction of national technical disparities on capacity development; and improved communication and participatory processes.

Fig. 7.5 PEMSEA ICM sites

There is now a recognition that conservation is enhanced when the people and communities dependent on resources take on some of the responsibility for managing (making decisions about) those resources. The most widely used OECM is locally managed marine areas (LMMAs), whereby coastal communities limit or prohibit extractive or destructive practices within a defined area. One example is the Territorial Use Right for Fisheries (TURFs), where local communities, or associations or cooperatives, of fishers have exclusive property rights to harvest resources within defined areas.

TURFs, in combination with no-take-areas, are now being implemented throughout the Americas, Oceania and Southeast Asia, and demonstrate a range of positive effects, including increased yields, ancillary biodiversity conservation, and social and ecological enabling conditions for local stewardship. For example, in Chile, the combination of TURFs and small-scale aquaculture are showing promising results for livelihood diversification, production and food security. LMMAs generally operate on more limited spatial (1–10 km^2) scales than contemporary MPAs, potentially reducing their conservation effectiveness. There are also, however, a number of less-encouraging aspects, including biases towards only reporting positive results and focusing on sedentary biota, lack of effective enforcement, misalignment between yields and sharing agreements, and operating as isolated silos that can't meet ecological and economic expectations (Christy 1982; Jupiter et al. 2014; Afflerbach et al. 2014; Albert et al. 2016; Viana et al. 2017; Andrachuk et al. 2019; Sepulveda et al. 2019; Villaseñor-Derbez et al. 2019; Aceves-Bueno et al. 2020; Halim et al. 2020; Nguyen et al. 2017).

Recognition of indigenous rights to, and ownership of, significant coastal estate in some countries (e.g. Australia, Canada, New Zealand) is having a growing role in marine governance and conservation and aspirations for blue economy livelihood opportunities. Across many cultures, traditional owner communities have often long practised conservation of coastal ecosystems and resources through application of traditional ecological knowledge, such as spatial and seasonal closures, and there is growing recognition of the need to incorporate such knowledge within modern conservation practices (Kerr et al. 2015; Charles 2017; Ban and Frid 2018; von der Porten et al. 2019a, 2019b; Rist et al. 2019; Reid and Rout 2020).

To empower and to incentivise local communities as custodians to protect and restore local coastal areas, the application of payments for ecosystems services (PES) is increasingly being adopted. With this approach, stewards (traditional owners or community groups generally) of a coastal area are incentivised (paid) to carry out activities that preserve or enhance the provision of ecosystem services. Those who pay for PES are motivated by direct benefits (e.g. environmental protection helps a business) or indirect benefits (e.g. offsetting carbon footprint), and PES transactions are generally regulated by independent organisations who certify that measurable units of benefit (e.g. carbon sequestered) have been created by the project's activities and allow the resulting credits to be sold or traded in relevant marketplaces (UNEP 2020).

Beyond designating areas with a level of protected status, many factors can define success or failure of individual MPAs. Without careful governance, planning and execution, MPA designations can amount to little more than "paper parks". Multi-stakeholder engagement is considered a critical factor affecting success, as is whether zoning and plans identify and resolve conflicts among users, and whether effective performance monitoring and evaluation occurs. Even when MPAs are effective, issues can arise with unmet expectations by communities, upfront costs from decreased fishing in new protected or regulated grounds, loss or change of cultural uses, and unequal distribution of resources (Cinner et al. 2012; Fox et al. 2012; Ehler 2018; Giakoumi et al. 2018).

Marine Protected Area design continues to evolve as it seeks to meet a range of emerging challenges. Irrespective of the level of protection afforded from human-use impacts, effective MPA management must now also consider the consequences of a changing climate (recurrent coral bleaching, for example) and the role of MPAs in addressing the impacts on biodiversity—for example, through creating refugia and connected networks of "bright spots" and incorporate projected future distributions of coastal ecosystems rather than focusing on past conditions.

4.2 Mitigating Catchment Impacts Through Terrestrial Reform

Achieving a sustainable ocean economy relies on the adequacy of upstream urban and hinterland infrastructure to provide the transport, energy and water services required to support ocean industries and their supply chains. Equally important, however, is addressing the downstream impacts of inappropriately designed and operated infrastructure and activities on coastal ecosystems. The activities of concern are those that clear, convert or modify coastal ecosystems to other land uses; extract resources such as surface water, groundwater and sand; and introduce land-based pollutants, such as excessive nutrients, sediments and manufactured chemicals (e.g. agricultural, industrial pharmaceuticals and personal care products), and litter.

In relation to the last of these, the companion Blue Paper *Leveraging Multi-Target Strategies to Address Plastic Pollution in the Context of an Already Stressed Ocean* (Jambeck et al. 2020) proposes several relevant interventions that would reduce pollutant inputs: improve wastewater and storm-water management, adopt green chemistry and new materials, recover and recycle materials, implement coastal zone improvements, and build local systems for safe food and water.

Given growing water scarcity worldwide, there is also opportunity for better reuse of wastewater to meet these demands as well as to reduce impacts on coastal environments. There are well-established technologies that can be deployed to increase the amount of wastewater that is recycled and reused. As a result, cities across the globe are establishing ambitious targets and developing policies to support zero discharge concepts (UN Water 2017).

As noted in Sect. 4.1, there are significant opportunities for closer integration with current global water, urban and climate agendas and initiatives.

The High Level Panel on Water articulated an agenda for water reform that encompassed: establishing a *foundation for action* based on better understanding, valuing and managing water; *leading an integrated agenda* to provide sustainable and universal access to safe water and sanitation, build more resilient societies and economies, invest more and more effectively in water-related infrastructure, and build sustainable cities and human settlements; and *catalysing change, building partnerships and international cooperation* to encourage innovation, promote partnerships and strengthen cooperation, and leverage finance and institutional support. The High Level Panel on Water highlighted the need to consider "urban deltas, coastal areas and other environmentally sensitive areas" and "to integrate appropriate measures into sustainable urban and territorial planning and development" (High Level Panel on Water 2017).

To support these efforts, the UN General Assembly proclaimed the period 2018–2028 as the Water Action Decade, which—given that it overlaps with the 2021–2030 UN Decade of Ocean Science for Sustainable Development—means that there are considerable opportunities to harmonise initiatives to develop a "source-to-sea" approach that explicitly considers downstream impacts of terrestrial infrastructure and activities on coastal ecosystems. The strength of source-to-sea management is that it considers the entire system, highlighting upstream and downstream environmental, social and economic linkages, and stimulating coordination across sectors and across different authority levels. Source-to-sea approaches have been implemented in many countries, often under different names (e.g. catchment-to-coast, ridge-to-reef), while globally this approach is recognised as essential to addressing SDG implementation by ensuring that linkages between the different goals and their targets are considered (Mathews et al. 2019; Singh et al. 2020).

Mitigating the impacts of diffuse land-based sources of pollution, including the application of nutrient fertilisers and agricultural chemicals (pesticides and herbicides), as well as the erosion of sediment on sensitive adjacent coastal ecosystems (seagrass beds and coral reefs), is now the principal concern among developed nations, and globally. For example, in Australia, management of activities to mitigate the loads on nutrients, sediment and pesticides discharged from catchments adjacent to the Great Barrier Reef have been in place since the 1990s and encompass regulations that range from setting end-of-catchment load reduction targets to regulating and incentivising land-practice activities, such as precision and regenerative farming that retain soils on-farm, and minimise the use of agrochemicals. Further downstream, the retention of vegetative buffer strips along the banks of rivers, estuaries and shoreline, and the use of natural and constructed wetlands to trap sediments and filter nutrients, are also effective ways of minimising discharges to coastal environments (Brodie et al. 2012; Day 2018; Adame et al. 2019; Saderne et al. 2020).

While ecosystems such as seagrass, oysters and coral reefs are particularly sensitive to too much sediment, in depositional coastal areas an adequate supply of sediment from upstream will be required to ensure the stabilisation of shorelines and the ongoing accretion of mangrove and saltmarsh habitat. Regulation of the amount of water used by upstream activities, removal of unnecessary impoundments and barriers, sustainable sediment management in reservoirs, and the setting of dedicated natural environmental hydrological flows that can reach the coast unimpeded are needed to ensure that deltas and estuaries can keep pace with sea level and erosion (Kondolf et al. 2014; Anthony and Goichot 2020).

The carbon sequestration and storage of areas of mangrove, saltmarsh and seagrass is now widely considered by many countries with large blue carbon stocks as part of their national emission reduction commitments, and they are now active in conserving and restoring these ecosystems (see Sect. 4.4).

Emerging initiatives are focusing attention on the importance of action to curb the over-extraction of sand from rivers and coastal areas and stop critical deltas from "sinking and shrinking". For example, WWF's Resilient Asian Deltas initiative (WWF 2019) focuses on Asia's six largest delta systems—Ganges–Brahmaputra–Meghna, Indus, Irrawaddy, Mekong, Pearl and Yangtze—with an emphasis on the importance of building with nature and the benefits nature provides as a key solution for delta and coastal resilience. From restoring fluvial and coastal sediment flows to creating more room for rivers, from reconnecting floodplains to restoring mudflats, mangroves and other wetlands, from minimising the impact of new infrastructure on river flows to creating ponds and sponge cities to compensate for expanding areas of impermeable concrete, building with nature across their river basins would transform the future of these deltas.

Likewise, over-abstraction of groundwater, leading to subsidence in low-lying areas and cities, requires a comprehensive approach to better manage these resources. Given that these abstraction and extraction activities can occur

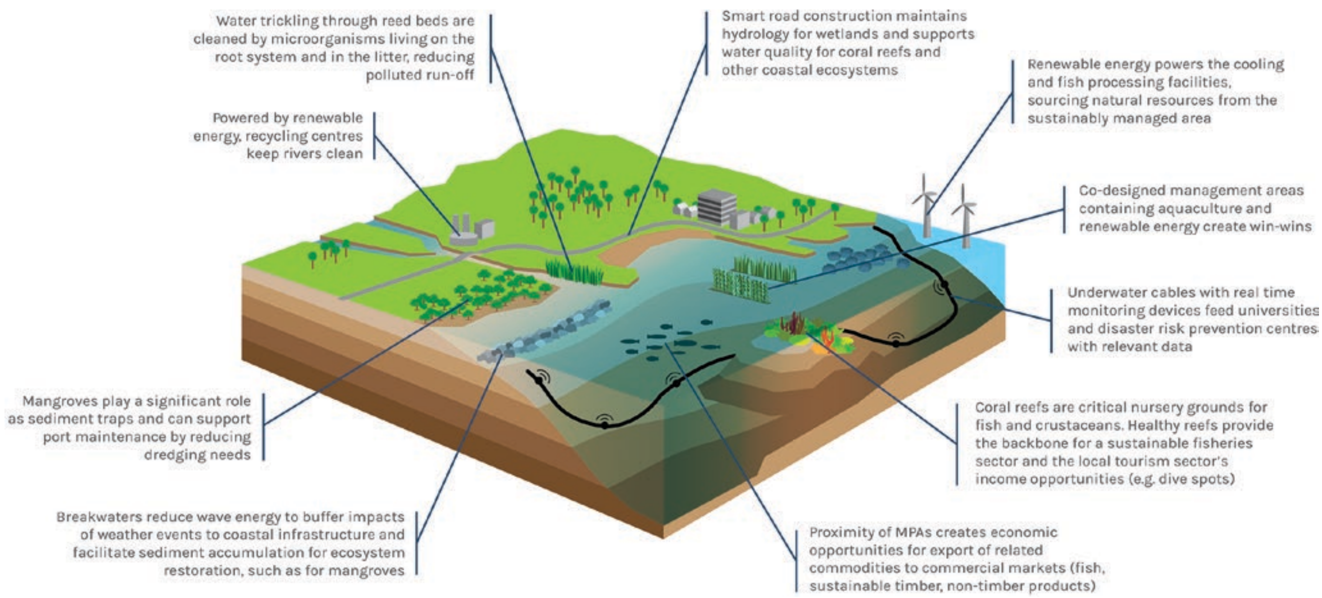

Fig. 7.6 Benefits of implementing blue infrastructure. (Source: Thiele et al. (2020). IUCN)

many hundreds of kilometres from the coast, and sometimes in adjacent countries, regional, or transnational source-to-sink approaches are required.

4.3 Adapting Coastal Infrastructure

The coastal adaptation strategies considered here are principally concerned with using nature-based approaches to adapting infrastructure to increase resilience to changing conditions, and to minimise the loss of ecosystem services. This also requires a change in behaviours or practices by which we make use of coastal environments and the resources they provide, and the way in which we value the direct and indirect benefits derived from these ecosystems.

Traditional coastal infrastructure is typically built with "hard" or "grey" engineering techniques and materials (e.g. concrete, steel) and designed to specifications for withstanding probabilistic exceedances that are based on the assumption that the past can reliably predict the future; as discussed in Sect. 2.1, this is no longer the case and puts many low-lying settlements at risk. These hard approaches have also left a legacy of environmental impacts affecting the structure, function and connectivity among adjacent coastal habitats and diminishing biodiversity. The next generation of coastal infrastructure will have a critical role in meeting these increased climate-driven challenges, as well as accommodating continued urbanisation and the needs of blue economy industries. To ensure that the right infrastructure is built, we must adopt resilient approaches, and policymakers will need to establish long-term visions for sustainable national infrastructure systems, informed by the SDGs (Thacker et al. 2019).

Softer, natural approaches—often labelled "green" for terrestrial or "blue" for marine—that apply ecological engineering principles are increasingly being used to build coastal defence structures that "mimic" natural coastal areas, including dynamic coastal landforms, such as beaches, barrier islands and dunes; coastal vegetation, such as mangroves, seagrasses, dune vegetation, saltmarshes and kelp forests; and reef systems, such as mussel beds, oyster reefs and coral reefs. Figure 7.6 illustrates the cbenefits of implementing blue infrastructure, and Table 7.4 summarises the advantages and disadvantages of each form of infrastructure.

The direct benefits of natural infrastructure are principally protection from flooding and from erosion. Consequently, such approaches are now recognised as a way of balancing continuing development with solutions that deliver climate change resilience and adaptation benefits, alongside multiple ecosystem benefits, including enhancing biodiversity and carbon sequestration and improving water quality by filtering storm water (Francis 2010; Lai et al. 2015; Perkins et al. 2015; Sutton-Grier et al. 2015; Firth et al. 2016; Vikolainen et al. 2017; Gracia et al. 2018; Burt et al. 2019; Browder et al. 2019; Conger and Chang 2019; Liu et al. 2019; Thacker et al. 2019).

Table 7.4 Summary of selected management approaches advantages and disadvantages

Advantages	Disadvantages
Grey infrastructure	
• Significant expertise exists on how to design and build such approaches at large scales	• Does not adapt with changing conditions such as sea level rise
• Decades of experience with implementation	• Weakens with time and has a built-in lifetime
• Excellent understanding of how these approaches function and what level of protection will be provided by different types of structures built to specific engineering standards	• Can disrupt longshore coastal sediment transport and cause downdrift coastal erosion
• Infrastructure is ready to withstand a storm event as soon as it is constructed	• Can cause coastal habitat loss and have negative impacts on the ecosystem services provided by nearby coastal ecosystems
	• May sustain more damage during small storm events
	• Only provides storm protection benefits when a storm is approaching; no co-benefits accrue in good weather
	• Needs continuous monitoring and regular maintenance
	• Barrier to dispersal and movement of fauna and flora, resulting in loss of ecosystem connections
Natural and hybrid infrastructure	
• Capitalises on best characteristics of built and natural	• Little data on how well these systems perform to date
• Allows for innovation in designing coastal protection systems	• Does not provide the same benefits that natural systems provide
• Provides some co-benefits besides coastal protection	• More research is needed to design the best hybrid systems
• Can provide a greater level of confidence than natural approaches alone	• Growing but limited expertise in the coastal planning and development community on which approaches to use
• Can be used in areas where there is little space to implement natural approaches alone	• Hybrid systems, due to the built part of them, can still have some negative impacts on species diversity
• Balances conservation with development	• Uncertainty in cost-effectiveness and long-term performance
	• Permitting for hybrid projects can be a more difficult process than for built projects
	• Response to native species colonisation is unpredictable
Ecosystem restoration	
• Provides many co-benefits in addition to coastal protection, including fishery habitat, water quality improvements, and carbon sequestration and storage, and can provide these benefits to coastal communities all the time, not just during storm events	• The development of best practices for how to restore ecosystems is needed, according to a set of starting criteria
• Ecosystem grows stronger with time as establishes	• Provides variable levels of coastal protection (non-linearity of the provisioning of coastal protection benefits), depending on the ecosystem, geography and also on the type and severity of storm events; more research is needed to better understand how to estimate or predict the coastal protection provided
• Has the potential to self-recover after a storm or other disturbance event	• In the case of restored ecosystems, it can take a long time for ecosystems to get established so that the natural systems can provide the necessary level of coastal protection
• Can keep pace with sea level rise	• Likely requires a substantial amount of space to implement natural approaches (such as ecosystem restoration or protection of existing ecosystems), which may not be possible in highly urban or industrial contexts
• Can be cheaper to construct	• Uncertainty in cost-effectiveness and long-term performance
• Increased CO_2 storage capacity in created, maintained or restored ecosystems; reduction of urban heatwave island effect; improvement in water quality	• Permitting for natural projects can be a more difficult process than for built projects
• Can enhance tourism, recreational and local employment opportunities included in establishment and maintenance	• Uncertainty over responsibility for ownership and maintenance
• Enhances the natural environment and implicit value	• Uncertainty in assessing levels of risk for insurance cover and premiums for coastal assets
• Saves raw materials and improves public health	

However, as the design and performance of this natural infrastructure is often influenced by local ecological, social and political conditions, increasingly *hybrid* approaches blending strategic use of natural assets and ecological principles with grey-engineered techniques and existing infrastructure are being adopted. Hybrid approaches provide cost-effective hazard protection solutions and are increasingly being adopted in urban areas where green approaches may be insufficient to meet the rising impacts of climate change, or where space is limited. There are now numerous examples and guidance on applying these approaches to applications that range from the landscape scale to individual breakwaters. Restoration of wetlands, sand-dunes and beaches can be integrated with supporting grey structures for flood or erosion management (e.g. levees, breakwaters and seawalls), providing a solution that is more comprehensive, robust and cost-effective than either solution alone. Small-scale engineering interventions to coastal defence structures can be implemented at relatively low cost, in intertidal and shallow subtidal zones to increase faunal and algal abundance and diversity. The modification of these structures, by adding grooves, pits, ledges and texture, can be incorporated into the design of coastal defence structures or retrofitted to existing structures. For example, the Living Seawalls project (see Box 7.7) is fitting seawalls with various shaped tiles—made with 3D printing technology—that enhance relief and facilitate settlement of a variety of benthic organisms, or create habitat for small cryptic fishes (Borsje et al. 2011; Depietri and McPhearson 2017; Strain et al. 2018a, b; Browder et al. 2019; Conger and Chang 2019).

Another area of adaptation is the development and use of building materials that are more environmentally benign. There are now a number of green concretes—made with waste material as a partial or complete replacement for cement or aggregate, including recycled demolition waste aggregate, blast furnace slag, manufactured sand, glass aggregate and fly ash. While green concrete requires less energy for its production and produces less CO_2, the higher cost of reinforcement, and the shorter life of buildings constructed with green concrete are limitations that are being addressed (Zhang et al. 2014; Khazaleh and Gopalan 2019; UNEP 2019).

Many cities around the world are now developing and implementing green urban infrastructure plans and demonstrating that urban transitions integrating green, blue and grey infrastructure are possible and affordable, and lead to more efficient, multipurpose infrastructure. Recognition that these solutions can be applied in other parts of the world has led to a number of international city networks, notably the C40 Cities Climate Leadership Group, the World Mayors Council on Climate Change and the Urban Climate Change Research Network, now actively collaborating and learning from each other to improve their adaptive capacity.

Similarly, many seaports around the world, facing growing environmental concerns about their construction and operation, have sought to align their performance with sustainability considerations, as well as planning protection from the impact of climate change. A shift to greener, integrated ports is now recognised as a long-term economic choice, and an increasing number of ports now implement a range of in-port operations, including energy conservation, environmental protection and development planning that considers the adjacent environment, other coastal operations and nearby cities. A range of incentives are also used to reduce emissions, such as using shore-based electricity for ships at berth, requiring slow vessel speeds, and incentivising rail and barge transport, rather than roads, from ports. Some ports also reduce fees based on indices that assess the environmental performance of individual vessels, such as the Environmental Ship Index. However, the voluntary nature of such schemes means that progress on significant emission reductions remains slow. Consequently, regulators and policymakers must be prepared not merely to nudge and incentivise but to take more concrete action (PIANC 2014; Gonzalez et al. 2018; Bergqvist and Monios 2019; Psaraftis 2019; de Boer et al. 2019; Dundas et al. 2020; WPSP 2020; UNCTAD 2020b).

With growing offshore sprawl, there are opportunities to find synergy in sharing infrastructure between industry sectors that might previously have been in conflict. For example, combining aquaculture with wind or solar operations, and even conventional oil and gas platforms, is now increasingly common. Such multifunctional use is, however, still very much in its infancy and requires technical and economic feasibility as a basic prerequisite, as well as alignment among sectors and national jurisdictions of environmental, safety and regulatory regimes and practices. Similarly, a growing legacy of ageing marine (e.g. oil and gas platforms and pipelines) and catchment (e.g. small dams) infrastructure that must be decommissioned in the near to medium future is driving the development of policy and science that seeks to minimise environmental harm while ensuring cost-effectiveness (Buck and Langan 2017; Buck et al. 2018).

Multilateral funding and investment agencies and the insurance industry now recognise that integrating blue and grey infrastructure can help to fill the need for the next generation of climate-resilient infrastructure solutions and allow for the devising of new risk financing for nature-based solutions, such as the recent insurance for the Mesoamerican Reef (Reguero et al. 2019b). There is a large and growing pool of funding for natural infrastructure—although the availability is geographically uneven—with the largest opportunities in the redirection of post-disaster recovery funds to pre-disaster investments in risk reduction. However, the largest barriers for securing adequate resources are identifying locations where natural infrastructure can play a significant role in flood risk reduction, developing the experience and standards to overcome institutional biases that favour grey infrastructure, and developing institutional arrangements capable of matching available funding with the needs of individual situations (Colgan et al. 2017).

Policy support for green/blue/hybrid infrastructure can make good politics and has an important social dimension, as adoption will be most successful when it meets the needs and interests of local stakeholders and communities. However, much clearer integrated policy pathways to promote adoption of blue and hybrid infrastructure are required, and while "green" and "blue" are often used to delineate terrestrial and marine approaches, in fact, "teal" approaches are what is required to effectively address coastal development (Browder et al. 2019; Dundas et al. 2020).

A body of policy and practitioner guidance has emerged in recent years that provides tools to enable integration and the use of natural infrastructure solutions, lessons from implementation, and policy recommendations to ensure that infrastructure meets sustainable development objectives (Browder et al. 2019; Conservation International 2019; Thiele et al. 2020). At a macro level, the 2019 G20 Principles for Quality Infrastructure Investment provide clear policy guidance for the consideration that needs to be taken around infrastructure planning, including that in the coastal zone. The principles include a focus on maximising the positive impact of infrastructure on achieving sustainable growth and development through the positive economic, environmental, social and development impact of infrastructure and encourages the use of a virtuous circle of economic activities, including the use of ecosystem-based adaptation where possible. They highlight the need for comprehensive disaster risk management planning in the design of infrastructure, including in terms of considering the re-establishment of essential services, as well as the need to ensure long-term adaptability and to build for infrastructure resilience against natural disasters and the slow onset of environmental changes. Finally, they highlight the importance of finance and insurance mechanisms, including well-designed disaster risk finance, to help incentivise resilient infrastructure through the financing of preventive measures, and the need to make transparent the additional benefits of sustainable infrastructure projects to enable the use of green finance instruments, including in the delivery of NDCs (G20 2019).

Box 7.7. Living Seawalls: A Green Engineering Solution with Global Significance

The Living Seawalls project enhances the ecological value of seawalls by using modular habitat panels, constructed using 3D design and printing technology, to mimic features of natural shorelines (SIMS 2020). Panels with crevices and ridges, in New South Wales, Australia, enhance native biodiversity and the survival of Sydney rock oysters, a native habitat-forming and economically important species (Strain et al. 2018a, b). Individual panels can be designed to mimic the natural habitat features of a locality, and panels of multiple designs can be configured in mosaic arrangements to provide a variety of habitats to maximise diversity.

To date, panels of multiple designs have been installed at six locations in Sydney Harbour to create "living seawalls". Within hours of installation, panels were inhabited by microbes and mobile macro-invertebrates, and within just a few months, the complex panels supported more diverse and abundant marine communities than flat surfaces. This project, a collaboration between marine biologists, designers and engineers, was made possible by a forward-thinking local council (North Sydney), which has long supported seawall greening and provided access to their seawalls (Fig. 7.7).

Urban stakeholders are supportive of green engineering initiatives and local stakeholders reported a greater sense of well-being associated with these initiatives. The enormous potential of the Living Seawalls habitat panels to transform seawalls around the world has captured the attention of local and state governments, consultants, marine managers and ecologists from around Australia and abroad. At present, the main barriers to implementation are the lack of clarity on seawall ownership due to jurisdictional boundaries within the intertidal and shallow subtidal environment, confusion around required documentation for the permitting process, and the slow rate at which these questions are resolved.

4.4 Repairing Coastal Ecosystems

It is now widely accepted that protection is not enough to reverse trends in coastal habitat loss and degradation, and efforts to repair these ecosystems, through at-scale habitat restoration efforts and by re-establishing natural coastal and hydrological processes, are required. It is also increasingly accepted that these efforts can deliver substantial environmental co-benefits (Sect. 4.5), including biodiversity protection, coastal protection, coastal carbon storage and fisheries production, as well as direct and indirect employment co-benefits related to installation, maintenance, recreation, tourism and education. Several studies have begun to quantify the singular and bundled value of the direct and indirect benefits that accrue from repairing coastal ecosystems, and demonstrate substantial economic gains and cost avoidance relative to business-as-usual scenarios.

Restoration science and practice is also fundamental to creating new nature-based infrastructure for coastal defence (Sect. 4.3). Recent analysis commissioned by the High Level Panel for a Sustainable Ocean Economy notes that restoration activities provided a benefit of four dollars for every one invested, but due to higher logistical costs and the longer

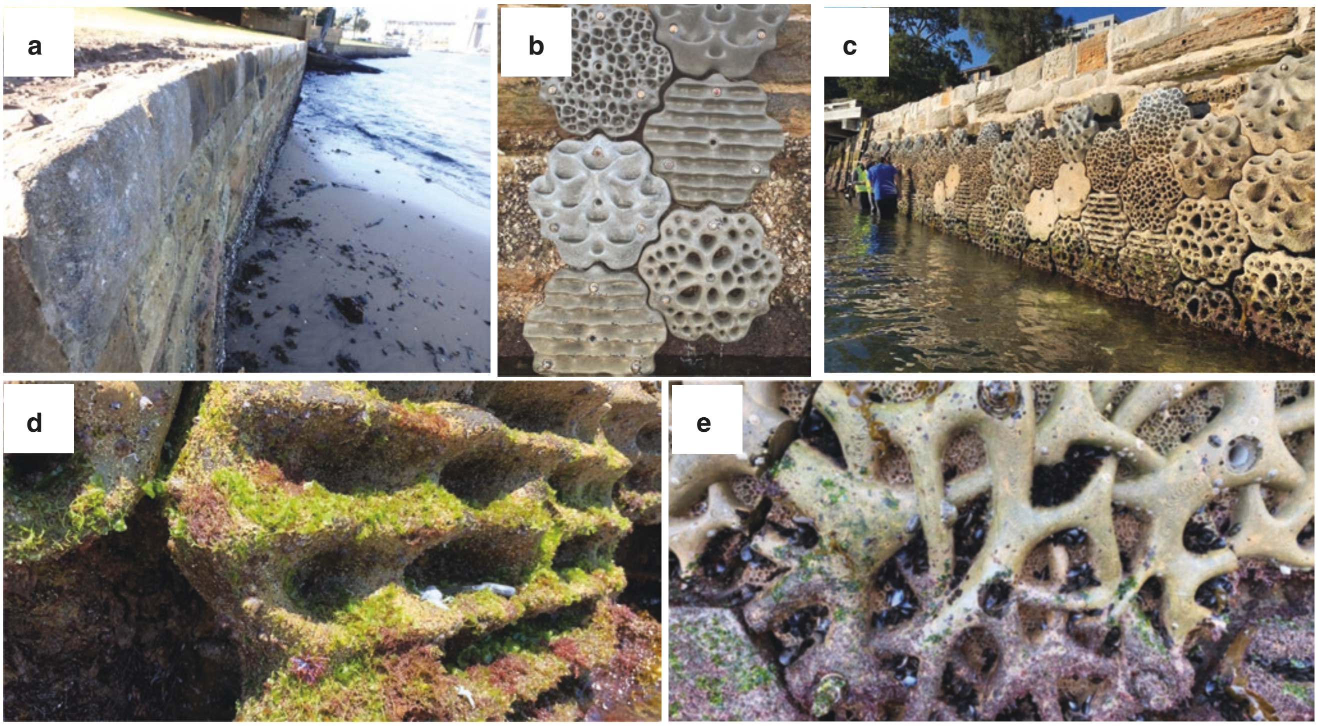

Fig. 7.7 Living seawalls. Living Seawalls panels can be affixed to existing seawalls that are generally flat and featureless, and otherwise provide little protection for marine life (**a**). Panels have been designed using 3D printing technology to incorporate complex texture and a variety of micro-habitat features (**b**). Seawalls can be retrofitted in a variety of configurations to suit site conditions, ecological objectives or aesthetic preferences (**c**). Within months, the complex panels were colonised by a variety of invertebrate and macroalgae and fish (**d**, **e**). (Source: Maria Vozzo)

timescales taken to realise the benefits, this ratio is at least 20-fold less than implementation of protection measures (Konar and Ding 2020).

Globally, there are a number of initiatives actively seeking to scale up restoration. The UN General Assembly has declared 2021–2030 the UN Decade on Ecosystem Restoration, promoting global cooperation on the restoration of degraded ecosystems to combat climate change, protect biodiversity, assist with food security and deliver clean water for the planet. The Bonn Challenge seeks to restore 350 million ha of the world's degraded and deforested lands by 2030, while the Global Mangrove Alliance has set a target of increasing global mangrove extent by 20% within this time period.

While the reasons for restoration are varied, it should be understood that the aim of restoration activities is not to return degraded coastal ecosystems to any particular past reference point, but rather to focus on increasing the extent and abundance of key habitats and keystone species, and use metrics that include presence of structure, functions, resilience and ecosystem services to evaluate success (Bayraktarov et al. 2016, 2019, 2020a; Friess et al. 2019; Duarte et al. 2020).

Depending on the habitat to be restored, as well as local conditions, a variety of restoration methods have been used and there are now numerous examples of successful and unsuccessful projects that have allowed the development of extensive practical guidance on restoration (Gann et al. 2019). Box 7.8 summarises some of these principles and learnings, and Boxes 7.10–7.13 provide relevant examples of mangrove, seagrass, coral and shellfish reef restoration.

For coastal marine ecosystems, mangrove restoration is the most well established and is widely undertaken throughout the world. Mangrove restoration occurs predominantly by planting seedlings and saplings in projects that vary from small (<1 km^2) to large (1000 km^2) scale, and by 2010, nearly 4000 km^2 had been restored. Online tools, such as the Mangrove Restoration Potential Map (maps.oceanwealth.org/mangrove-restoration/), allow users to explore at global, regional and national levels the opportunities for mangrove restoration.

The map identifies c.8120 km^2, or 6%, of former mangrove area as restorable, with the greatest opportunities in Southeast Asia (Worthington and Spalding 2018). The Global Mangrove Alliance (http:// www.mangrovealliance.org/gma/) provides practical advice on mangrove restoration.

The reinstatement of natural hydrological conditions for rivers, as well as tidal areas that have been restricted, is an important pre-condition for restoration in coastal marine habitats. In many cases, the removal of bunds and other structures restricting natural tidal flows can be sufficient to assist revegetation of coastal areas that had previously been cleared for other land use, including agriculture and aquaculture (Kelleway et al. 2020).

Technically, to improve the success of restoration efforts, the rigorous application of science to design and select areas that are suitable for restoration is needed, and the use of "big data" can be utilised for such assessments. Continual evaluation of project progress with metrics that assess effectiveness rather than effort will help to ensure that lessons are learned from past failures and successes so that restoration practices are improved and resources can be maximised in the most cost-effective manner. Harnessing knowledge of the life histories of the habitat-forming organisms, using technologies such as drones to identify suitable areas for restoration and to disperse pods into ideal locations, or using commercial vessels equipped with oil booms to collect wild coral-spawn slicks for re-seeding target reefs (see Box 7.11) are just a few examples to help achieve the scale of restoration required (Fairhead et al. 2012; Baker and Eckerberg 2013; Doropoulos et al. 2019a, b; Vanderklift et al. 2020; Worthington et al. 2020; Waltham et al. 2020).

Apart from the technical challenges of undertaking restoration at ecologically meaningful scales, restoration must operate within a complex and dynamic interplay between technical decision-making, legal constraints, social licence to operate, ideologies and politics. As a result, many efforts are considered value-laden, context-driven and prone to disagreement and compromise. In developing countries, restoration projects must also operate and respect the cultural norms and traditional ownership/rights issues relevant to the project area, while at the same time addressing perceptions of "green grabbing". Governance and institutional issues can also hamper rehabilitation if there is poor coordination among agencies, many of whom often have conflicting production/development and environmental protection mandates.

In addition to the ecosystem services that restoration of coastal habitats can provide, there are also significant flow-on benefits through the creation of new jobs and supporting local economies. Marine habitat restoration is recognised as a "jobs-intensive" industry and strong driver of economic growth, creating immediate employment in transport, construction, marine engineering, project management, science and aquaculture. For example, the economic impact of 50 coastal habitat restoration projects funded through the American Recovery and Reinvestment Act (2009) created on average 17 jobs per million dollars spent, which was higher than traditional industries, including coal and gas, roads and energy generation. Many jobs are created in rural and regional coastal areas and offer a range of skilled and low-skilled positions, considerably enhancing economic opportunities in regional areas. Longer-term employment can be created through the flow-on benefits of these ecological improvements to new and increased opportunities for fishing, aquaculture and tourism and their service sectors (Edwards et al. 2013; Powell et al. 2018).

Marine habitat restoration is also almost unparalleled in its capacity to deliver collaborative, partnership-based approaches for restoration. Active involvement and meaningful consultation between practitioners, local communities and the science sector that leads to integration of best-practice science and local knowledge is essential for effective implementation. Factors for success include local government support, community involvement, property rights, education and preparation, and supplementary livelihoods. Citizen science activities are regularly incorporated into projects to reduce costs and expand community participation and education. Engagement with traditional landowners can result in shared learning, application of traditional ecological knowledge and improved coastal management and indigenous engagement (Diefenderfer and Adkins 2003; Stojanovic et al. 2004; Ismadi and Yamindago 2014; Dharmawan et al. 2016; McLeod et al. 2018; Powell et al. 2018; Waltham et al. 2020).

Box 7.8. Success Factors for Coastal Restoration

1. Planning: Careful planning is necessary and should include identifying the causes of degradation and conducting preliminary small-scale interventions to test effectiveness prior to applying any full-scale restoration activities.
2. Create the right preconditions: Removal or mitigation of stressors, such as poor water quality, and limiting conditions, such as lack of suitable substrate or inadequate supply of propagules, is necessary before natural recovery can occur. Stressors that enhance mortality, such as disease and predation, particularly during early stages of growth, also need to be minimised.
3. Consider the right scale and context: The need to scale up restoration activities means that the patch-based approaches must consider processes at the broader landscape and regional scales—for example, movement of water or dispersal of biota.
4. Location: Ensuring restoration takes place in the locations that maximise success for the system being

restored, in terms of considering scale, access, disturbance history and forecasting, and downstream benefits, is vital.

5. Focus on tangible outcomes, not targets: While ambitious area-based targets (e.g. size of area planted, number of seedlings planted) for restoration are being widely advocated, these should be reframed to focus on success criteria linked to environmental outputs (e.g. percentage survival, vegetation densities similar to natural forests) and incorporate social-ecological outcomes of restoration.
6. Engage partners and community: Active involvement and meaningful consultation between practitioners, local communities and the science sector—that leads to integration of best-practice science and local knowledge—is essential for successful implementation and longevity.
7. Harness technology: Technology must be developed and utilised to effectively scale up restoration efforts. Remote sensing technology opens new ways to monitor and inform conservation and restoration.
8. Long-term monitoring and adaptive management: It is important to plan for, commit to and invest in long-term monitoring, so that small issues can be quickly rectified.
9. Investment: Besides public investment, restoration efforts clearly need private investment, and this investment could be accessed via new financial instruments, including payment for ecosystem services, green bonds, biodiversity offsets, carbon credits, debt-for-nature swaps, and water quality credit markets.

Box 7.9. Mangrove Protection and Restoration: Nature-Based Solutions to Multiple Problems

Mangrove conservation—including actions that both protect and restore—is becoming a priority for international policy, in part because mangroves provide multiple benefits, including carbon sequestration, coastal protection and fish habitats. Currently, around 36% of the world's mangroves have some form of legal protection, and they are also implicitly or explicitly included under multiple international policy frameworks, including the Ramsar Convention on Wetlands of International Importance.

Many nations are developing policies and legislation that afford increased protection. For example, the island nation of Sri Lanka—one of the countries most affected by climate change—has implemented legal protection for all of its mangrove areas, as well as a policy to rehabilitate 10,000 ha of mangrove forest, while Indonesia aims to restore 50,000 ha of mangroves by 2024. However, policy frameworks still include incentives (such as expansion of aquaculture) that contribute to mangrove degradation and loss, and removing such perverse incentives is key to reversing decline.

Efforts to restore mangroves have taken many forms, from using seedlings grown in pots or directly inserting mangrove propagules into the soil, to simply allowing the tide to return and letting nature take its course. The approach has varied, depending on the purpose, such as whether the focus is on stabilising an eroding coast or generating carbon credits. Many of these initiatives often fail completely (for example, all the seedlings die), or they do not achieve the intended result. However, many successful initiatives exist, which shows the enormous potential of restoration. For example, in Bali, Indonesia, restoration of abandoned aquaculture ponds has yielded excellent results over more than a decade, including high rates of carbon sequestration. Breaching the barriers around the ponds (i.e. pond walls and gates) has allowed the tide to return, promoting rapid natural mangrove regeneration and accumulation of carbon-rich soil (Fig. 7.8).

In southwest Madagascar—a nation that lost 21% of its mangroves in the 20 years from 1990 to 2010 alone—coastal communities are almost entirely reliant on the resources they get from the sea. Blue Ventures has worked with these local communities using participatory approaches to develop a suite of activities designed to encourage sustainable use of mangroves, including development of sustainable alternative ways of generating income. Among the activities is the implementation of a locally managed marine area, alongside local regulations (Dina) to prevent overharvesting mangroves. The project also includes mangrove restoration by directly inserting into the soil the viviparous propagules of *Rhizophora mucronata, Ceriops tagal* and *Bruguiera gymnorhiza*, which are collected from parent trees nearby. The survival rate of planted mangroves is high, and measurements also include the carbon content of mangroves and the underlying soil, to develop carbon credits for sale in the voluntary carbon market, and so generate an additional source of income for local people.

Box 7.10. Seagrass Protection, Adaptation and Restoration

Seagrasses globally have been degraded over recent decades, and there is ample evidence from well-studied parts of Australia, North America and Europe showing that millions of hectares of seagrass meadows have died around the world (Waycott et al. 2009).

Can we begin to reverse this pattern through restoration? Advances in seagrass restoration techniques suggest that we can. Broadly, there are two main ways of restoring seagrass, which take advantage of the way that seagrasses (like grasses on land) can multiply both asexually and sexually. In asexual growth, seagrasses send out rhizomes (structures like horizontal stems) that colonise new areas; sometimes parts of an adult plant can break off and be transported to a distant area through sea currents, where it can then establish and grow. This characteristic of seagrass has been harnessed for decades in attempts at seagrass restoration, by methods which involve taking shoots from a healthy meadow, and planting them elsewhere. It can be laborious, and sometimes survival is low. But, if circumstances are right, it can be very successful. One example is Oyster Harbour, an enclosed embayment on the southern coast of Australia. After the original causes of seagrass death were ameliorated, efforts were made to transplant rhizomes of *Posidonia australis*, it with its characteristic large leaves attached. These were replanted in areas that once hosted seagrass, taking care to bury the rhizomes below the sediment surface, holding them in place with a wire hook. Survival was high, and the transplanted seagrass began to extend outwards. After 8 years, individual transplants could not be distinguished and meadows of transplanted *Posidonia* had begun to merge with existing natural meadows. When rates of carbon burial were measured 18 years after the original planting, rates inside meadows that grew from transplanted seagrass were similar to those in natural seagrass—further demonstration of the success of that project (Bastyan and Cambridge 2008; Marbà et al. 2015; Serrano et al. 2020).

Another restoration method yielding promising results harnesses the use of the seeds that seagrasses produce. In this method, seeds are dispersed into areas where seagrass once grew. Although only a small proportion survive and grow, many seeds can be dispersed, so that the overall chances of success are improved. In coastal bays of Virginia (USA), a project started in 1999, which involved scattering seeds of eelgrass (*Zostera marina*) from a boat across 125 ha over several years, had, by 2010, formed seagrass meadows covering greater than 1700 ha (Orth et al. 2012). Similar successes are now being reported at multiple locations around the world, highlighting that this method offers considerable promise (Fig. 7.9).

Box 7.11. Restoration and Adaptation of Coral Reefs

With widespread and more frequent bleaching events, it is now widely held that conventional management approaches are not enough to protect coral reefs, and that restoration at ecologically meaningful scales is urgently needed to aid and accelerate recovery of damaged reefs.

Restoration methods developed over the last 40 years have traditionally involved transplanting coral fragments or adding artificial substrate, with other approaches such as larval addition, rubble stabilisation or algal removal infrequently applied (Boström-Einarsson et al. 2020). The coral gardening approach was pioneered in the 1990s and programmes using this approach now operate in more than 150 coral nurseries across 20 countries. Most interventions have traditionally been small, labour intensive and costly (replanting coral fragments grown in a nursery costs between $1 million and $4 million per ha) and have had mixed results (Rinkevich 1995; Edwards and Gomez 2007; Lirman and Schopmeyer 2016; Bayraktarov et al. 2016, 2019, 2020b; Anthony et al. 2017; van Oppen et al. 2017; Ladd et al. 2018; National Academies of Sciences, Engineering and Medicine 2019).

Some recent studies have begun to demonstrate longer-term and larger-scale (around 1–2 ha) successes (Fox et al. 2019; Williams et al. 2019; Bayraktarov et al. 2020a, b). One promising approach shown below is the harvesting, culturing and release of wild coral-spawn slicks to targeted reefs. Recent studies in Australia have demonstrated the feasibility of such large-scale restoration, and have been accomplished by incorporating technologies used in oil spill remediation, dredging operations and land-based aquaculture. Such an approach allows for long-distance translocation of corals and maintenance of coral diversity, and has virtually no impact at source (Doropoulos et al. 2019a, b).

Assisted evolution, such as selective breeding, assisted gene flow, conditioning or epigenetic programming, and manipulation of microbiome could also help coral reefs, which are particularly sensitive to warmer water temperatures (van Oppen et al. 2017). Moreover, including strategic decision science (Doropoulos and Babcock 2018) alongside novel interventions (Anthony et al. 2017) is necessary to maximise the long-term effectiveness of restoration activities (Fig. 7.10).

Box 7.12. Shellfish Reef Restoration

Shellfish restoration has been successfully undertaken in several countries at scale and has employed approaches ranging from natural regeneration, assisted regeneration and reconstruction approaches. Shellfish reef restoration now frequently occurs at large scales (>10 ha), engages across government, non-governmental organisations (NGOs) and local communities and is innovative in addressing financing options. Examples of shellfish restoration around the globe include:

- In the United States, the Chesapeake Bay Executive Order requires oyster populations of 20 Chesapeake Bay tributaries to be restored by 2025. Three estuaries have been restored thus far, including 390 ha of restored reef at a projected total cost of $72 million. The economic investment was returned in less than 5 years through the increased catch of commercial fish and crab fisheries as a result of increased productivity from restored reefs (Knoche and Ihde 2019).
- In China in 2004, over 20 tonnes of hatchery-reared seed oysters were successfully transplanted onto two around 50-km concrete dykes previously constructed in the Yangtze River (Quan et al. 2009).
- In South Australia in 2018, a 20-ha native flat oyster reef was restored at a cost of c.$3 million, to support recreational fishing tourism and regional jobs at an employment ratio of 8.5 jobs per million invested. Key success factors included using case studies of the environmental and social benefits of reef restoration (particularly from the United States) to help educate the community and government stakeholders on the benefits of natural habitat restoration compared with artificial reefs; identifying a clear social beneficiary stakeholder (i.e. recreational fishers) and economic beneficiary stakeholder (i.e. local service businesses that financially benefit from the predicted increase in recreational fishers in the region); and successfully articulating marine ecosystems as natural infrastructure, which is synonymous with built infrastructure in terms of providing a beneficial service to communities and which can be quantified like other types of infrastructure (Econsearch 2016).

The benefits of restoring shellfish reefs to coastal communities and industries are well quantified, with the economic value of the full suite of ecosystem services derived from natural oyster reefs in North America estimated to be as high as $100,000 ha per annum (Grabowski et al. 2012) and including job creation and economic development, fish production, water filtration and dentification, coastal protection and providing habitat for many other marine species (Fig. 7.11).

Fig. 7.11 Shellfish Reef Restoration at Windara Reef in South Australia. (Source: Chris Gillies)

Box 7.13. Promoting Gender Equality for Coastal Resilience

Promoting gender equality is essential for ensuring coastal resilience, as women play key roles in many marine sectors and are important negotiators and decision-makers. Women can make up more than half of the workforce in some marine industries, especially small-scale fisheries, aquaculture and processing plants. However, women, particularly in developing countries are often disadvantaged through gender inequalities caused by unequal power relations and structures, lack of training, discriminatory laws and customs, and unequal access to and control of resources, and as a result, there are very few women in leadership positions. Women are also more vulnerable than men to climate change and natural disaster impacts.

Many examples from developing countries show that, where women are empowered and can contribute to decision-making processes, social well-being is enhanced and conflict reduced, the health and education of children is improved, and the environment is better protected. Thus, developing and implementing education programmes and capacity building, not only for women but men in the community as well, and establishing women's cooperatives and advocacy groups are needed (Tschakert and Machado 2012; Alston 2013; Monfort 2015; CARE 2016; Dah-gbeto and Villamor 2016; Smucker and Wangui 2016; Tran et al. 2016; de la Torre-Castro et al. 2017; MFF 2018; UNFCCC 2019; Stacey et al. 2019; Ravera et al. 2020).

Box 7.14. Incentivising Coastal Development and a Sustainable Ocean Economy

The Asian Development Bank (ADB) gives us an example of how a multilateral development bank is moving to incentivise coastal development and a sustainable ocean economy. In its operational plan, ADB highlights the importance of building resilience as part of its overarching vision for a "prosperous, inclusive, resilient, and sustainable Asia and the Pacific". Many Asia Pacific countries, particularly low-lying nations and SIDS, are highly exposed and vulnerable to natural hazards and the impacts of climate change. Disaster losses are already growing due to insufficient regard for climate and disaster risk in either the design or location of new infrastructure. A clear priority is planning and delivering infrastructure that builds resilience in a climate and disaster risk resilience context, with a number of different categories of resilience being identified (see Box 7.1).

ADB's Action Plan for Healthy Oceans and Sustainable Blue Economies, launched in 2019 (ADB 2020), is an example of an integrated approach to promoting ocean health and sustainable coastal development. It includes a commitment of $5 billion in investments and technical assistance in focus areas that include sustainable infrastructure, blue economy livelihoods, ecosystem management and pollution control management, supported by an ocean financing initiative.

4.5 Coastal Co-benefits and Trade-Offs

4.5.1 Co-benefits

All too often coastal management strategies are undertaken in order to meet a single objective, without recognising the multiple other benefits that can result from an action. Only by accounting for these can we truly place the full value of ecosystem services into a planning and management context. Value can be expressed in many ways other than direct monetary metrics, including food security, health and cultural values. The benefits that people receive from ecosystems may accrue far from where they are produced. In the last decade, there have been significant advances in developing methods to quantify non-market benefits of coastal ecosystems and to map additional benefits that cascade from them.

Today, ecosystem service valuation is increasingly being used as a tool to assist coastal planning and management to achieve better informed and more holistic decision-making about resource use, and identify opportunities for effective conservation. For example, ecosystem-service approaches can help to inform coastal and marine planning by modelling the likely outcomes of management strategies for objectives expressed in terms of value to people, whether monetary or otherwise.

A number of studies demonstrate that spatially explicit scenario modelling of ecosystem services allows stakeholders and policymakers to better refine zones of human use, identify how different regions may contribute to the flow of services on a larger scale, and test the efficacy of different management strategies. One such recent global analysis finds that, under business as usual, the biggest economic impacts that could result from the loss of nature would be increased coastal vulnerability, followed by loss of carbon sequestration potential, while a "global conservation" scenario would deliver economic gains that result principally from improved natural coastal defences (Johnson et al. 2020). These results suggest that one clear opportunity for action is to focus on protecting and rehabilitating natural infrastructure. These types of nature-based solutions are increasingly being viewed as critical actions to reduce societal risk regarding a number of complex problems, from coastal protection to food security (Whelchel et al. 2018).

4.5.2 Trade-Offs

A key challenge in coastal marine conservation and management is how to manage trade-offs between social and ecological goals, so that both benefits and costs can be distributed equitably across individuals or communities (Halpern et al. 2013). For example, the decision to protect a mangrove to avoid carbon emissions or to slow erosion may have an impact on current timber harvesting or future opportunities to develop the coast for aquaculture or urban expansion. For the people who rely on these for their livelihoods, there is no obvious benefit and therefore little incentive, unless alternative sources of income can be provided.

Globally, climate and coastal development projections over the coming decades mean that we are inevitably faced with compelling circumstances requiring trade-offs to maintain viable environmental conditions and standards of living (Whelchel et al. 2018). Navigating these trade-offs will require thoughtful consideration of the distribution of costs and benefits, and development of mechanisms that protect the livelihoods of those least able to bear the cost. For example, in southwestern Madagascar, efforts to reduce mangrove deforestation have involved developing partnerships with local communities that include finding alternative fuel sources, and alternative ways of generating food and income (Rakotomahazo et al. 2019).

Understanding trade-offs can be complex and cannot be limited to assessing only quantifiable costs and benefits, but needs to consider less obvious factors that can result from complex social-ecological interactions, or that arise because the trade-offs affect marginalised individuals. Concepts of social equity, justice and human rights need to be incorporated in assessing these trade-offs and co-benefits, especially within the wider global discourse on governing the blue economy. While efforts to meet SDG 14 will typically be compatible with those for other SDGs, protecting and conserving coasts to meet SDG 14 targets can also lead to social and economic trade-offs and the downstream effects of such trade-offs can be especially pronounced in low-income coastal communities (Allison et al. 2012; Daw et al. 2015; Galafassi et al. 2017; McClanahan et al. 2016; Nippon Foundation–Nereus Program 2017; Gattuso et al. 2018; Kittinger et al. 2017; Davies et al. 2018; Singh et al. 2018; Bennett 2019; Cohen et al. 2019; Lombard et al. 2019).

To avoid these effects, consideration of trade-offs requires a deliberative approach engaging stakeholders through participatory processes, and harnessing marine spatial planning and scenario modelling tools that allow multiple perspectives and objectives to be considered. As a result, final decisions may reflect open debates about trade-offs and can inform solutions that balance multiple objectives—and surprising synergies may occur (e.g. developing infrastructure to meet multiple uses) that transform a trade-off to a co-benefit (Arkema et al. 2015).

It is important to adopt a long-term perspective when considering trade-offs. For example, short-term losses of livelihoods or income resulting from the creation of MPAs can lead in the long term to ecological, socioeconomic and cultural benefits upon the recovery of fish populations and marine habitats. Intergenerational equity must also be an essential criterion when balancing short-term trade-offs and long-term benefits.

Unintended consequences can also arise. For example, a focus on gross area targets for MPAs may promote the creation of very large marine protected areas, which, by virtue of their size, are generally located in offshore areas, where space is available, tenure arrangements are less complicated and the numbers of stakeholders involved are lower. This may, however, discourage the further protection of mangroves, saltmarshes and seagrass, as their coastal location, often fringing and disjunct distributions, and their location along coasts with multiple land uses and stakeholders make it more complicated to create large protected areas (Friess et al. 2019).

4.6 Enabling Conditions

The coastal zone is crowded, jurisdictionally complex, contains an extremely diverse set of user and interest groups and is subject to multiple competing demands, particularly for space and access. It is a complex socioeconomic system, where achieving sustainable ocean economy outcomes that are resilient to current and future shocks will depend on strong institutions, clear and appropriate governance and finance, an inclusive and equitable approach, and a set of information and science needs. These enabling elements are by nature cross-cutting and are listed below.

- *Strengthening governance and recognising customary rights:* A key influence on the choice and likely success of management options is the existing regulatory framework, through which management authorities, such as permitting and other approvals, are distributed across local, regional, state and/ or federal entities. Most coastal landscapes in the tropics have complex and unclear land tenure and sea use arrangements, especially for indigenous peoples and traditional communities. Furthermore, in many countries indigenous peoples and traditional communities have traditional and customary tenure and rights to significant coastal assets, often defined by LMMAs. Ensuring that these rights are respected and indigenous peoples and traditional communities are engaged in the stewardship of these coastal assets and the creation of alternative livelihood opportunities will be essential.
- *Multilateral partnerships:* Any decision pathway necessarily involves multiple stakeholders who will be interested and involved in the decisions surrounding interventions that sustain or repair coastal ecosystems: practitioners, science and engineering, regulators, industry, investment community, traditional owners and local communities. Developing ecological engineering solutions will require much closer collaboration between scientists and engineers, plus the funding for and a commitment to scientifically test a range of bold innovations at sufficient scale. Where successful, this knowledge should be shared to understand how these innovations could be applied in other settings. Globally, the private sector is seen to have a major role in the implementation of the SDGs and in conserving coastal ecosystems. The International Chamber of Commerce has explicitly stated that sustainability is no longer a luxury business investment, but a core driver of business productivity and growth.
- *Valuing and accounting for coastal assets and ecosystem services:* Coasts and coastal natural infrastructure are essential to the economies of countries and the livelihood of their inhabitants. Impairment of coastal ecosystems that leads to a reduction in resilience or productivity can be a significant cost to the economy. Many ecosystem assets and services remain unquantified. Better methods for valuing non-market assets and services, and applying these consistently within national Systems of Environmental-Economic Accounting (SEEAs), will better inform choices relating to what areas or assets can be developed and what needs to be protected.
- *Quantify co-benefits and trade-offs:* As discussed in Sect. 4.5, analysing trade-offs requires a deliberative approach,

with stakeholder values at the centre. Obtaining full stakeholder involvement through participatory integrated and ecosystem-based marine planning is an important component of assessing trade-offs because it allows for the articulation of multiple perspectives that can inform solutions that balance multiple objectives (Galafassi et al. 2017; Gattuso et al. 2018; Lombard et al. 2019).

- *Science, technology and innovation:* Implementing these various strategies and actions must be underpinned by multidisciplinary science that informs wise decision-making. Although many of these issues encompass the complexity of human decision-making, institutional structures and governance arrangements, science is pivotal to developing more sophisticated and evidence-based policy and management. Integrated management must be underpinned by a deeper understanding of how biophysical and human systems are coupled and an understanding of singular and cumulative impacts. Technological innovation underpins the emerging "science of solutions" that will guide the choice of interventions chosen to safeguard and restore coastal ecosystem resilience. Novel approaches have originated from the growing understanding of biology and ecology, inspiring new theories (e.g. positive species interactions) on which new interventions can be built and tested at scale. There is an important role for the social sciences to be included in future intervention study design, implementation efforts and the collection of evaluation effectiveness metrics.
- *Monitoring and assessment:* Ongoing synoptic and finer-scale observations are required to assess changes in the coastal ecosystems and the surveillance of activities that are occurring within and adjacent to coastal zones. A new generation of in situ sensors, observational platforms, environmental satellite capabilities and informatics provide unprecedented capability and are increasingly accessible and affordable.
- *Capacity building and sharing knowledge:* Supporting the capacity and adaptability of nations—especially least developed and small island states—to successfully implement these strategies requires ongoing, not one-off, capability development that includes both training and access to best-practice information.
- *Financing the future:* Financing for green and grey-green infrastructure is in an exciting growth phase as private investors and development banks increasingly recognise the high potential of this type of infrastructure to tackle development challenges. Initiatives such as the WWF's Sustainable Blue Economy Finance Principles (WWF 2018) lay the groundwork for such investments and need to be broadly and full adopted by public and private sector finance organisations. Strong and effective national sustainable blue economy strategies or plans, based on a clear vision for and definition of a sustainable blue economy, help to foster an enabling environment that reduces risk and builds investor confidence. *The* creation of targeted finance and investment opportunities, such as blue bonds, blended finance, public–private partnerships, insurance payments for risk reduction and corporate stewardship, have emerged as novel ways to build resilience, restore natural capital, and reduce environmental, social and economic risks and investor risk (Herr et al. 2015; Colgan et al. 2017; Niehörster and Murnane 2018; Sumaila et al. 2020; Thiele et al. 2020).

5 Conclusions and Opportunities for Action

5.1 Conclusions

The coastal zone has the world's highest population density, is where the vast majority of resources that underpin the world's ocean and maritime economic sectors are located, and where the majority of many coastal nations' commercial, residential, transport and national defence infrastructure is situated. Coasts sustain livelihoods for hundreds of millions of people in endeavours that range from artisanal small-scale fisheries and aquaculture to transnational fishing, shipping, energy and tourism industries.

Over the last 30–50 years, there have been significant, and, in many cases, rapid/abrupt and irreversible, changes across all of the world's coastal ecosystems. These have included erosion of depositional coastlines, loss of coastal vegetated ecosystems (50% of saltmarshes, 35% of mangroves), and coral (30%) and shellfish reefs (85%), and significant reduction in system resilience.

Coastal ecosystems have evolved in dynamic spatial contexts and many are adapted to disturbance and perturbation or perform a stabilisation and energy dissipation function. Climate change impacts are increasing the physical stress and damage to coastal habitats from storms, flooding and inundation, and are also directly affecting ecosystems through warming and changing ocean chemistry on the abundance and distribution of species and ecosystems.

Humans are also directly affecting coastal ecosystems, with pressures from increasing population growth and urbanisation, poor upstream land practices, alteration of freshwater and sediment flows, habitat conversion, water quality degradation, litter, pollution and over-exploitation of resources. Agriculture operations in catchments can lead to alteration of flows, and increased sediment, nutrient and chemical loads, while coastal fisheries and aquaculture can have direct and indirect effects on coastal ecosystems and habitats. Energy production and resource extraction infrastructure have high freshwater requirements, while urban infrastructure growth leads to habitat conversion, hardening of coastlines, channelisation of flow, and sand-mining in upstream catchments altering sediment budgets at the coast. The result is direct physical loss, fragmentation and alteration of many ecosystems, as well as a functional loss of resilience—which diminishes their ability to resist and recover from such perturbations—that is unprecedented historically. The drivers of this change in coastal ecosystems are complex and interconnected and result from unsustainable levels of human modification to, and resource extraction from, coastal ecosystems.

A rapidly growing and urbanising coastal population, and expansion of existing and new industries, has generated additional demand for coastal space and resources, while incompatibility between different uses—and sometimes ideologies—has also led to conflict in coastal environments. Coastal population growth and increasing urbanisation, catchment degradation and mismanagement, loss of coastal foreshore amenities, environmental impacts from industry, incompatible or unsustainable resource use, and climate change are some of the major challenges that can result in conflict and require careful management.

The physical loss of ecosystems and habitats leads to the loss of their ecological function within the coastal zone socioeconomic system, including provisioning and protection functions. Coastal communities, especially those that are poor and vulnerable and that rely directly on coastal resources for food security, nutrition and livelihoods, are often those most at risk of climate impacts or disasters. COVID-19 has shown us the vulnerabilities that exist in many coastal economic sectors, and again it is those who are poor and vulnerable who appear to be most at risk.

If current trends continue unabated, or without significant interventions, projections over the next 10, 30 and 80 years comprehensively demonstrate the widespread and potentially catastrophic risks to coastal ecosystems, human populations, built infrastructure and economies that will result. The rapid population growth that will occur across Asia, and, even more significantly, Africa, will increase demand for coastal resources and services, and potentially expose coastal cities and settlements to increased impacts. It is here, as well as in the many small island nations spanning the Indo-Pacific and in the Caribbean, that the greatest risks occur.

Failure to properly manage our coastal resources will result in further significant environmental damage to coastal environments, loss of economic well-being for existing industries that operate in the coastal zone (and disincentive for new industries to invest), and inadequate infrastructure development to meet the demands of changing demographics and climate change impacts.

Actions that aim to deploy protection as the "first line of defence" are no longer enough; strategies and technology solutions that mitigate threats, assist in the adaptation of human activities, infrastructure and behaviours, or seek to repair coastal natural systems through restoration and facilitated adaptation will be required. Over the coming decade, implementing these actions *at scale* must be accelerated and assistance to less-developed countries will need to be stepped up.

There are, however, a range of positive policy, planning and coastal infrastructure developments that are cause for cautious optimism as we look towards 2030. Nature-based and hybrid approaches are increasingly being used to adapt existing, and design new, infrastructure to increase resilience to changing climate conditions, and to minimise the loss of ecosystem services. There is great interest, and a large pool of funds, from the investment, insurance and business sectors to implement natural and hybrid approaches for the next generation of climate-resilient infrastructure, and to empower nations and communities to protect coastal ecosystems through a range of financial mechanisms that remunerate for the protection and enhancement of ecosystem services. Intergovernmental bodies, funding agencies (the World Bank, Global Environment Facility, Green Climate Fund), the insurance industry and investment banks all recognise the need for investing in nature-based solutions. However, the availability of support is geographically uneven and there are many barriers to implementation of such approaches at scale.

Building the socioeconomic resilience of those who are most vulnerable, and empowering and engaging natural resource users and coastal communities, especially those who rely directly on coastal resources for food security, nutrition and livelihoods, are critical aspects of ensuring healthy coastal ecosystems and realising a sustainable ocean economy.

5.2 Opportunities for Action

To ensure environmental, economic and social sustainability of our space-constrained coastal systems, the great challenge will be to balance ongoing development and multiple competing uses. By realising the following opportunities for action, it will be possible to reverse the trend of degradation, including from terrestrial and extractive activities, and instead optimise the benefits of healthy ecosystems, natural infrastructure, and inclusive and equitable approaches, to build a coastal zone and coastal economy that is robust, sustainable and resilient.

5.2.1 Building Coastal Resilience

The resilience of coastal ecosystems, and the people who rely upon them, can be enhanced through actions that increase their ability to withstand pressures, and actions that help them to recover when damage occurs.

- Coastal ecosystems must be better protected by strengthening regulations and increasing area-based conservation to halt the net loss, increase the extent and improve the condition of critical coastal habitats, such as sand-dunes, saltmarshes, mangroves, seagrass, and coral and shellfish reefs.
- At-scale habitat restoration, and re-establishing natural coastal and hydrological processes, are required in order to repair many damaged coastal ecosystems and restore functional resilience.
- Restoration also delivers significant co-benefits that extend beyond ecosystem goods and services by creating jobs related to restoration activities, and once established, livelihood opportunities from tourism, enhanced fisheries and payment for ecosystem services, such as carbon sequestration and storage.

5.2.2 Creating Coastal Community Resilience, Equity and Access

Actions that build the socioeconomic resilience of communities, including gender equity and social inclusion, are important in mitigating and recovering from climate and disaster risks and shocks, such as COVID-19, where the impacts are greatest among the poor and vulnerable.

- The multiple benefits coastal communities derive for ocean and coastal services should be included in the valuing and accounting of the ocean economy.
- Communities and coastal fishers should be recognised as legitimate resource users and also stewards of marine ecosystems. This is particularly true for SIDS and remote coastal regions, where communities are often isolated from major governance centres and where marine tenure has remained or is being reinvigorated.
- Governance approaches must be inclusive, incorporating indigenous and local knowledge in planning and decision-making processes.
- It is vital to ensure that business processes are inclusive and that incentives exist to protect and restore coastal ecosystems and enhance local livelihood opportunities.
- Local supply chains should be prioritised, so that pregnant women and infants, and those at risk of malnutrition or hunger, gain access to the nutritional benefits from locally sourced sustainable fish.
- Governments should prioritise poverty reduction and social protection programmes that build community resilience, including to climate change and disasters, and channel post-disaster support to affected poor households. In particular, they should build the resilience of those who are most vulnerable, especially by promoting gender equality and empowering women.

While the consequences of COVID-19 for the resilience of coastal communities will continue to unfold over many years to come, as nations begin to rebuild their economies, there is a unique window of opportunity to ensure relevant policy and investment decisions also address these coastal challenges. In addition, they must foster sustainable economic pathways that support the recovery and development of impacted communities and build the resilience of coastal ecosystems, safeguarding the services they provide.

- Coastal fiscal and economic stimulus and recovery packages must be designed with a sustainable and equitable ocean and coastal economy outcome as a primary objective, and meet multiple SDGs.
- High-employment sectors should be prioritised if they are essential services, or support sustainable ocean economy opportunities. Options include micro-canneries for domestic consumption, mangrove restoration for disaster risk reduction, and investments in effective waste management systems that reduce disease prevalence.
- Vulnerabilities in coastal economic sectors and supply chains should be prioritised for investment and innovation. Examples include the development of product alternatives that have a longer shelf life, using digital means to connect to customers and local markets, and adopting electronic and digital verification systems in supply chains.
- Climate change projections and impacts should be incorporated into all aspects of COVID-19 recovery planning and sustainable infrastructure design. This includes the protection and restoration of coastal ecosystems and fisheries as part of building resilience.

5.2.3 Mitigation of Terrestrial and Extractive Activities on Coastal Ecosystems

The impacts of terrestrial and extractive activities on coastal ecosystems may be cumulative and may be amplified by climate change effects, while the downstream impacts of upstream activities can lead to conflicts among user groups.

- Integrated management underpinned by good spatial planning and coastal ecosystem planning must be fully integrated into urban, catchment and land-use planning frameworks.
- Urban and agriculture water use should be managed to ensure that coastal ecosystems receive healthy surface flows and that coastal groundwater reserves are maintained.
- Upstream catchment diversions and dams should be managed to ensure that adequate freshwater flow and adequate sediment supply is maintained to the coast. Promotion of

alternatives to mega dams, such as building small dams with sediment release facilities, is a priority.
- Regional multi-sector dialogues should be initiated to address upstream sand extraction and sand scarcity, particularly in relation to coastal city subsidence and stability of urbanised deltas.
- Closer integration should be pursued between the current global water, food and energy nexus, and the water, urban and climate agendas and initiatives, including the High Level Panel on Water, and the overlapping UN decade initiatives for Oceans, Water, and Ecosystem Restoration.

5.2.4 Sustainable, Future-Ready Blue Infrastructure

The following opportunities for action are designed as ones that industry, government, scientists and communities can take to promote the uptake, resourcing and deployment of natural infrastructure.

- Identify locations where natural or hybrid infrastructure can play a significant role in natural hazard risk reduction, and adapt and upgrade existing coastal infrastructure through the adoption of nature-based approaches for more sustainable designs, including retrofitting coastal defence structures.
- Develop and scale cost-effective, hybrid approaches that enhance resilience by integrating nature into mainstream infrastructure systems. Encourage closer collaboration between scientists and engineers, and dedicate funding to develop eco-engineering opportunities.
- Build the skills and capacity of government staff in the design of sustainable ocean economy recovery programmes and in the design and maintenance of sustainable green coastal infrastructure, such that there is a common understanding of the benefits and opportunities.
- Embed opportunities for future-ready blue infrastructure and nature-based solutions within existing planning and management approaches, including within spatial management tools such as marine spatial planning, ecosystem-based integrated ocean management, marine protected areas and community-based natural resource management tools and approaches.
- Support the restoration of coastal ecosystems, including mangrove forests, saltmarshes, seagrass meadows, kelp and other seaweed forests, and coral and shellfish reefs, to optimise their function for coastal defence, coastal stabilisation or as part of hybrid coastal defence structures. Recognise that coral reef and mangrove restoration in particular offer cost-effective options for risk reduction of climate hazards.
- Develop the experience and standards to overcome institutional biases that favour grey infrastructure, and develop institutional arrangements capable of matching available funding with the needs of individual situations.
- Design new and innovative financial instruments to provide the pathways for investors to direct private finance into nature-based solutions, including through public–private investments.
- Establish standards and principles for developing and financing blue infrastructure and appropriate blended finance instruments, a good example of which are the Sustainable Blue Economy Finance Principles.
- Enable the use of green finance instruments, including in the delivery of NDCs, and use them to promote the uptake of natural infrastructure and sustainable infrastructure projects, including in developing and low-income countries seeking financing from multilateral development banks.

5.3 Enabling Conditions to Support Coastal Resilience

For any of the above actions to be successful in delivering coastal resilience, a number of enabling conditions need to occur. These were summarised in Sect. 4.6, while enabling actions specific to the coastal context are given below.

Strengthening governance and recognising customary rights: The enabling conditions for inclusive and effective local governance must be put in place, so coastal communities can effectively advocate for their rights to access coastal resources. Power imbalances must be acknowledged and addressed, to allow coastal communities the necessary influence and impact in governance and policy fora. As suggested in SDG 14, Target 14.b, the will and needs of coastal communities should be recognised, respected and reflected in policymaking and decision-making, and in the implementation of the SDGs. Local and national policies recognise the role of communities in the management of coastal resources, incorporate advice from community members in decision-making, and facilitate more equitable and inclusive access of communities to natural resources and markets.

Science, technology and innovation: The cross-disciplinary nature of grey-green infrastructure and natural infrastructure brings together ecology and engineering in the emerging discipline of ecological engineering, in designing societal services such that they benefit society and nature. As the implementation of hybrid and grey-green infrastructure solutions grows, there needs to be a body of research on all aspects and at a range of scales, in order to optimise the design of individual projects and to facilitate scaling. It is an area that is ripe for the application of technological innovation, consistent with the use of intelligent and smart building design in green buildings. COVID-19 has stress-tested contemporary coastal economic and logistical systems, and identified weaknesses and vulnerabilities that need to be prioritised for research, innovation and technological solutions.

Multilateral partnerships: Ensuring traditional owners and local communities have a voice and are engaged in the co-design and development of strategies and plans will be essential for gaining social licence. Ensuring a role in the stewardship and day-to-day management of activities that use these coastal assets and creation of alternative livelihood opportunities must be a priority.

Capacity building and sharing knowledge: Translating coastal research to best practice and "how to" guidance on coastal issues, such as dredging, coastal modelling, water and sediment quality standards, restoration methodologies, coastal and eco-engineering, and emergency preparedness, is required. Making this information available through a clearinghouse of coastal information will encourage adoption by regulators, environmental consulting and analysis sectors and organisations, and communities seeking to undertake restoration activities.

Financing the future: Green infrastructure and hybrid infrastructure designed with co-benefits in mind opens up a range of possible finance options in addition to the standard government financing model. It allows projects to be promoted to governments, the private sector or development agencies as stand-alone investment opportunities, matched to particular motivations. The private sector has the ability to provide substantial investment to support nature-based solutions, including through bonds and other novel instruments. However, the amount they currently invest is small because of constraints such as limited evidence of the returns on investment and lack of appropriate financial instruments. Development agencies with core mandates of climate resilience, poverty reduction and environmental sustainability also have a strong motivation to invest in such projects. The next decade should see significant growth in green and grey infrastructure, as investment pipelines grow, the capacity for designing and managing such investments is increased in target countries, and as challenges to scaling are overcome.

Acknowledgements We wish to thank the many people who generously provided material, advice and review for the report: Russ Babcock, Elisa Bayraktarov, Melanie Bishop, Katherine Dafforn, Dorothee Herr, Alexander Goad, Mariana Mayer-Pinto, Peter Steinberg and Torsten Thiele. The paper's technical reviewers, Audrey Legat, Borja Reguero, Julien Rochette, Alan Simcock and Sharon Tatman, as well as its arbiter, Jane Lubchenco, all provided helpful technical comments.

While our colleagues were very generous with their time and input, this report reflects the views of the authors alone, and is not necessarily the views of their organisations. Thank you to Em Muirhead, Lauren Hardiman and Derek Fulton for providing administrative, editing and graphic design support.

The authors thank Sarah Chatwin for copyediting and Romain Warnault for design.

Glossary

Ecological engineering The design of sustainable ecosystems that integrate human society with its natural environment for the benefit of both. The approach has developed over the last 30 years, rapidly over the last 10 years, and its goals include the restoration of ecosystems that have been substantially disturbed by human activities and the development of new sustainable ecosystems that have both human and ecological values.

Green grabbing The appropriation of land and resources for environmental ends, where "green" credentials are called upon to justify appropriations of land, and the restructuring of rules and authority in the access, use and management of these resources may have profoundly alienating effects.

Green infrastructure Green infrastructure (also sometimes called natural infrastructure or engineering with nature) intentionally and strategically preserves, enhances or restores elements of a natural system, such as forests, agricultural land, floodplains, riparian areas, coastal forests (such as mangroves), among others, and combines them with grey infrastructure to produce more resilient and lower-cost services.

Grey infrastructure Traditionally used to manage coastal hazards, often constructed out of concrete with a uniform and smooth texture, often costly to install and maintain, usually has low flexibility, and when it fails can generate catastrophic impacts on social and ecological domains.

Nature-based solutions (NbS) Actions to protect, manage and restore natural or modified ecosystems, which address societal challenges, effectively and adaptively, providing human well-being and biodiversity benefits. IUCN defines nature-based solutions as actions to protect, sustainably manage and restore natural or modified ecosystems, that address societal challenges effectively and adaptively, simultaneously providing human well-being and biodiversity benefits.

Ocean economy Also known as the blue economy, encompasses a sustainable economy for the ocean-based marine environment, related biodiversity, ecosystems, species and genetic resources, including marine living organisms (from fish and algae to microorganisms) and natural resources in the seabed, while ensuring their sustainable use and hence conservation.

Rehabilitation The replacement of structural or functional characteristics of an ecosystem that have been diminished or lost.

Resilience The capacity of social, economic and environmental systems to cope with a hazardous event or trend or disturbance, responding or re-organising in ways that maintain their essential function, identity and structure, while also maintaining the capacity for adaptation, learning and transformation.

Restoration The process of assisting the recovery of an ecosystem that has been degraded, damaged or destroyed.

Social-ecological Refers to systems that emphasise humans as part of nature and stress that the delineation between social systems and ecological systems is artificial and arbitrary. While resilience has somewhat different meanings in social and ecological contexts, the social-ecological approach holds that social and ecological systems are linked through feedback mechanisms, and that both display resilience and complexity.

Source-to-sea A source-to-sea system is the land area that is drained by a river system, its lakes and tributaries (the river basin), connected aquifers and downstream recipients, including deltas and estuaries, coastlines and near-shore waters, as well as the adjoining sea and continental shelf and the open ocean. A source-to-sea system can also be defined at a larger scale to include a sea and its entire drainage area, which may include several river basins.

About the Authors

Co-authors

Andy Steven is the Research Director of Coasts at the Commonwealth Scientific and Industrial Research Organisation (CSIRO), Australia.

Kwasi Appeaning Addo is an associate professor in Coastal Processes and Delta Studies and the Director of the Institute for Environment and Sanitation Studies, University of Ghana.

Highlights

- Organised information provides the power to make good decisions and justify them. National accounts contain and organise the information that describes our economies and helps decision-makers, and the public, understand near-term policy outcomes and long-term sustainability. However, currently only a small fraction of the information in national accounts is used because the focus has been overly narrow—producing a gross domestic product (GDP) metric.
- Planning for and managing a sustainable ocean economy requires tapping into the rich information that national accounts can provide. A system of national accounts can provide information in three critical areas to ocean economy decision-making: output or national means—a measure of production; outcomes or policy ends—a measure of real income and its distribution; and sustainability—indicated by changes in the national balance sheet.
- Many countries already produce an ocean GDP, but ocean GDP is usually the wrong metric for measuring the outcomes of ocean policy or the sustainability of the ocean economy. Efforts to calculate ocean GDP or measure the ocean economy with GDP will often be misleading because of fundamental features of GDP.
- This paper discusses a system of national accounts with multiple indicators and how they should be applied to the sustainable ocean economy. The paper emphasises the need to develop the underlying data structures to anticipate unintended consequences of decisions such as inequity and resource depletion.
- The paper proposes four principles of accounting for a sustainable ocean economy, including a set of Opportunities for Action for unlocking the information from national accounts needed to secure a sustainable ocean economy.
  - Assess policy options and decisions about the ocean and ocean economy in terms of their impacts on (1) real income and its distribution, (2) ocean production and (3) changes in ocean wealth, including ecosystems. Changes in ocean wealth are the most important indicator of sustainability.
  - Develop ocean accounts that build on the existing internationally agreed framework and standards for national accounting.
  - Avoid overreliance on GDP, which is not a sustainability indicator or measure of benefits to people from economic activity.
  - Lead or contribute to collaboration efforts to improve national ocean accounting systems, including global partnerships to share best practices and build capacity.
- The paper concludes that developing national accounts to guide economic development for the ocean is critical but not as daunting as it may seem. Many of the data already exist in national accounts, in government agencies or in scientific databases. The knowledge to build the connections also exists but is dispersed throughout government, academia, business and nongovernmental organisations (NGOs). Furthermore, most governments have already committed to many of these steps, with the gaps largely in implementation.

1 Introduction

Realising the goal of the High Level Panel for a Sustainable Ocean Economy (Ocean Panel) to catalyse the transition to a sustainable ocean economy depends on coordinating and

managing humanity's relationship with the ocean and the broader environment. This task requires organising information that currently is often disorganised, spread across multiple government agencies or in a few cases not yet available. National ocean accounts would provide countries with the information needed to guide ambitious and broad- based plans to develop ocean economies and to capitalise on marine opportunities (European Union Directorate-General of Maritime Affairs and Fisheries and Joint Research Centre 2018; Economist Intelligence Unit 2015), while protecting the ocean for generations to come in accordance with the Sustainable Development Goals, most notably SDG 14, 'Life below Water'. The 'blue-ing' of the ocean economy—or making the ocean economy sustainable—requires ensuring that the ocean continues to provide at least the current levels of opportunity; 'measuring the ocean economy gives a country a first-order understanding of the economic importance of the seas' (Economist Intelligence Unit 2015). The old adage goes that 'what gets measured, gets managed', or more accurately, that 'if you cannot measure it, you cannot improve it'. Sound decision- making requires organised information.

National ocean accounts provide a system to organise and process information to guide sustainable development. They can be characterised as a specific application and extension of the existing standardised System of National Accounts (European Commission et al. 2009) used by most countries, whose main objective is 'to provide a comprehensive conceptual and accounting framework that can be used to create a macroeconomic database suitable for analysing and evaluating the performance of an economy. The existence of such a database is a prerequisite for informed, rational policymaking and decision-taking.'

Box 8.1 Ocean or Marine to Blue

We use ocean, but marine could be used in its place throughout this report, to refer to large aquatic systems. This could include large lake systems. A sustainable ocean economy, or "blue economy" for short, accounts for biophysical processes and may include production outside of current national accounting boundary. A blue economy is one potential form of an ocean economy.

The ocean must be fully accounted for in this system to enable decision-makers around the world to balance between using the ocean today and conserving, restoring or enhancing it for the future to strengthen productivity, create jobs and reinforce food security and regional stability. Something as complex as the ocean economy cannot be managed by a single indicator. A complete set or 'sequence' of national ocean accounts provides three key high-level indicators: ocean product, changes in the ocean balance sheet and ocean income (Fig. 8.1):

1. **Ocean product** measures the 'outputs' of human efforts on the ocean to provide 'means' or 'inputs' into achieving other social and economic goals; monetary components of the ocean product account aggregate to ocean 'gross domestic product (GDP)' or 'net domestic product (NDP)'. In environmental accounting standards, physical accounts are also important.
2. **Change in the ocean balance sheet** provides a sustainability indicator. A stable or increasing balance sheet is necessary for sustainability. This is because the balance sheet reports current and future potential for the ocean to provide products and benefits. The ocean balance sheet includes 'natural capital' like live fish populations, coastal wetlands and seabed minerals, which fall under the heading of 'non- produced' assets, in addition to 'produced assets', such as port infrastructure. Changes in the balance sheet integrate physical and monetary changes.
3. **Ocean income** measures benefits to nationals (people of a nation) from the ocean, the 'ends' or 'outcomes' of policy; income accounts aggregate to net national income (NNI), though in practice national statistics offices usually produce gross national income (GNI). Importantly, income measures can be disaggregated to show the importance of the ocean for different segments of the population. Furthermore, income can include non-monetary types of income, though these are often expressed in monetary equivalents.

The most important thing world leaders can do is to request reports on all three indicators and discuss information on national income and changes to national balance sheets along with changes in GDP in public addresses and policy meetings. All three indicators are important for directing a sustainable economy, in the same way that altitude, airspeed and fuel in the tank are important for flying a plane (Matson et al. 2016). Certainly, the ocean economic system is at least as complex as an airplane. The primacy of GDP dates to the World War II crises and a need to measure means to carry out the war and rebuild after (Pilling 2018). If a plane is crashing, one would focus only on altitude for a short time, but flying from crisis to crisis is not the way to direct an economy. It is important to track relatively rapid changes in production. Changes in the balance sheet tell the story of sustainability, but balance sheets need to exist for a period of time before this information truly becomes useful. Few people would invest in a company without inspecting its balance sheet, yet countries' balance sheets are often an

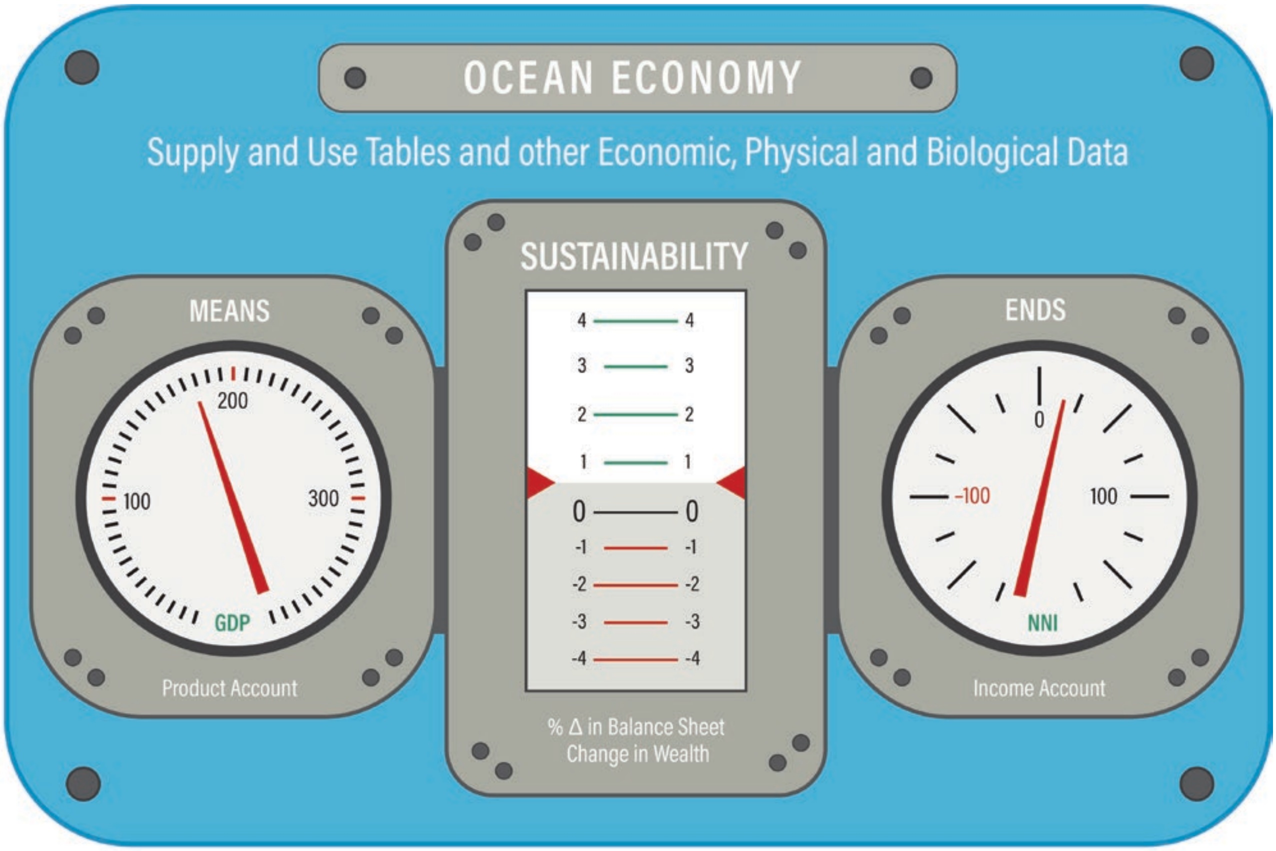

Fig. 8.1 National Accounts: a dashboard for assessing the ocean economy. (*Source: Jamie Ficker with input from the authors*)

afterthought, and few include ocean assets. This is despite agreement that national balance sheets should include produced and non-produced assets. Greater leadership in asking about the ocean in national accounts and on the national balance sheet can change this.

National accounts connect information about the processes of generating, producing, consuming, saving and building wealth within an information system. The strengths of the System of National Accounts lie in its data, as well as the data's organisation and consistency, which enable comparisons, especially through time within a country. While imperfect, national accounts are uniquely able to connect existing ocean-related data systems so they can provide information on economic activities and guide decisions. This is a logical place to use the information generated as part of the UN Decade of Ocean Science and similar initiatives. Ocean accounts can support coherent and holistic assessment and reporting on a wide range of social, economic and environmental conditions related to the ocean. National accounts for the ocean provide information in a form consistent with the needs of macroeconomic decision making to achieve sustainable development.

National ocean accounts provide three services. First, national accounts are a nation's information system. Aggregates such as GDP are representative of this information system, but GDP is just the tip of the iceberg. **It is important to avoid overreliance on GDP.** Second, national accounts provide a structured set of data about relationships among entities that provides the information needed to analyse policy, including ocean policy. For the ocean, many of these data exist, but they are currently distributed across different government agencies and international repositories. Third, the valuation component of national accounts facilitates analysis of policy trade-offs by organising ocean biological and physical data, many of which currently exist in disparate units, into a harmonised structure, evaluated in monetary terms with other economic data. Economic valuation helps answer important value related questions such as the following:

- How is the value stored in the ocean changing through time?
- What is the expected net present value associated with current and alternative management of the ocean?
- How is income generated in an ocean sector interconnected with other ocean and non-ocean income?
- How could changes in ocean policy impact tax revenue?

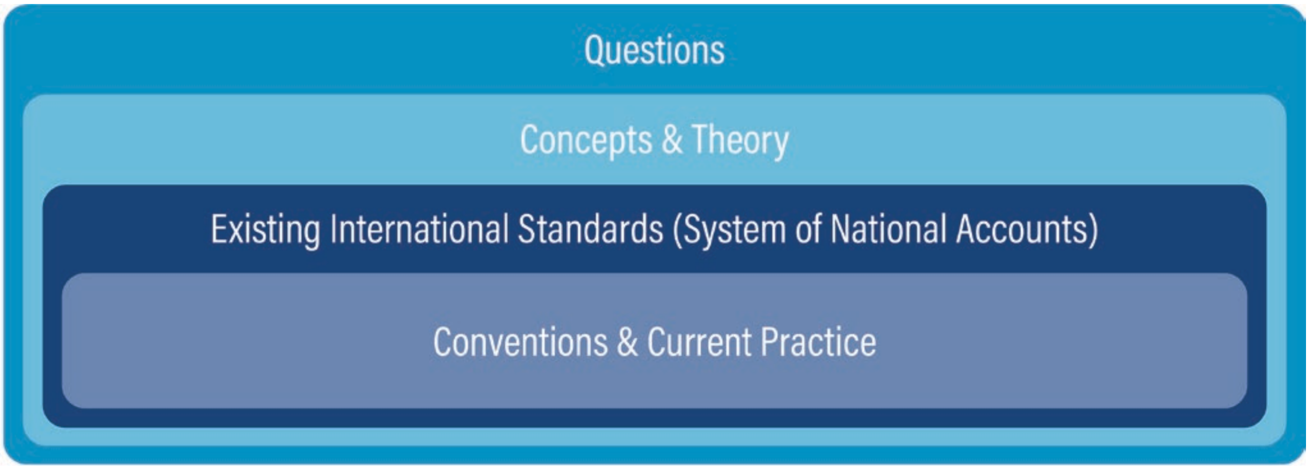

Fig. 8.2 Nesting from needs to practice. (*Source: Authors*)

However, it is important to stress that **the idea of a total value of the ocean is neither meaningful nor useful in practice**. Without the ocean, life on Earth would be fundamentally different. To paraphrase World Bank economist Michael Toman (1998), attempting the find the total value of the ocean would be 'a serious underestimate of infinity'.

Existing economic and national accounting theory and concepts inform many sustainable development policy questions. However, there are questions that economic and accounting theory do not answer. Moreover, the current existing international standards for national accounts—the 2008 System of National Accounts (SNA) and System of Environmental Economic Accounting (SEEA)—only partially address the concepts and theory. Some limitations result from economic questions that are not accounting questions, but others stem from design decisions in national accounts that merit revisiting. Furthermore, accounting practice often only partially implements the agreed international standards (Fig. 8.2). This Blue Paper identifies the gaps between these layers to provide Opportunities for Action.

Section 2 of the paper reviews questions about the ocean economy that national accounts can inform. It then turns to concepts and theory and how these are, or are not, addressed in the existing, internationally agreed System of National Accounts (European Commission et al. 2009). This helps identify formal changes needed to the SNA and SEEA to guide a sustainable ocean or blue economy. At the end of Sect. 2, we address some important ancillary issues such as the role of technology and concerns about equity. In Sect. 3, we examine the gaps between the formal SNA and current convention and practice in order to understand the need for leadership to modify norms and practices. Section 4 provides Opportunities for Action.

Now is the time to upgrade national accounting to provide information about the sustainability of economic activities. A focus on the ocean can lead the way. Economies are changing. Policy is concerned with outcomes and sustainability, not simply managing monetary inflation, and '21st century progress cannot be measured with 20th century statistics' (Agarwala 2019). On the one hand, bringing the environment, natural resources and ecosystems into national economic assessments and planning is critical for future human well-being and the persistence of natural systems, and all parts of the ocean are now impacted by human activities (Díaz et al. 2019). On the other hand, the SEEA is being revised, there is discussion of revising the internationally agreed system of national accounts to focus on sustainability (UN Stats 2019), the 'valuation of natural resources' is an active area of discussion within national accounting (UN Stats 2017), and the development and pilot testing of technical guidance for ocean accounting is underway (UN-ESCAP n.d.).

2 Questions, Concepts and Standards for Ocean Accounting

'What is the value of the ocean?' There are many reasons to ask this question, from concerns about specific ocean- related sectors to international commitments such as:

- The 2030 Agenda for Sustainable Development, including Sustainable Development Goal (SDG) 14 on 'Life below Water'.
- SDG Target 15.9, which calls for the integration of ecosystem and biodiversity values into national and local planning, development processes, poverty reduction strategies and accounts by 2020.
- SDG Target 17.19, which calls for efforts building on existing initiatives to develop measurements of progress

on sustainable development that *complement gross domestic product* and support statistical capacity building in developing countries by 2030.

However, this question it is far too imprecise for national accounts to answer. Notions of 'value' and 'ocean' are variable. National ocean accounting, in contrast, can answer specific questions like the following six, which we will return to throughout this paper:

1. How do industries, somehow connected to the ocean, create resources and products for use elsewhere? What jobs do these industries provide?
2. How do biological, chemical and physical ocean processes contribute to products for use elsewhere?
3. How does the ocean contribute to livelihoods and for whom?
4. How does the ocean provide welfare directly and for whom?
5. Is the ocean economy being developed sustainably?
6. How will a policy change affect aspects of the ocean economy? How will changes in the ocean affect the economy, or how will a use of the ocean in one location influence other industries and residents?

Questions 1–6 align with the dashboard in Fig. 8.1. Questions 1 and 2 relate to ocean production and GDP metrics, though they require some disaggregation, with the difference between these two questions reflecting the gap between the 'ocean economy' and the 'blue economy'. Questions 3 and 4 relate to national income and welfare metrics, which are closely connected, but they also require disaggregation in some cases. These are questions about 'development'. Question 5 relates to future opportunities—sustainable development, which is a question about the national ocean balance sheet. Addressing Question 6 requires understanding relationships within and between ocean processes and the economy, which depend on information in national supply-and-use tables and the broader national information system.

Fortunately, there is a full a set, or 'sequence', of national accounts rather than a single, all-encompassing account. There are sub-accounts and satellite accounts to help answer all of these questions. It is easiest to focus on the four pieces illustrated in Fig. 8.1: a product account, an income account, a balance sheet and an information structure derived from the economy itself. The actual system of national accounts has even more pieces that facilitate the reliable creation of these accounts. What is and what is not in measures differs somewhat from account type to account type. This, in theory, allows the different accounts to address different questions: questions about means, ends or outcomes, sustainability and forecasting the impact of changes. All but Question 6 are retrospective in nature. It is important to ask the questions of the right pieces of the system of national accounts, otherwise the answers can be misleading.

Focusing on questions such as the six above narrows the question 'What is the value of the ocean?' For example, one could mean, 'How important is the ocean to indigenous cultures?' or 'What opportunities are being lost by current ocean management?' The first question is beyond the scope of economic theory and national accounts. The second requires assumptions about alternative ocean management. National accounts will reflect changes in the economic sphere made to address non-economic concerns, such as cultural preservation. Furthermore, national accounting information is useful for assessing the forgone economic opportunities associated with policies that advance non-market policy priorities. The accounts will not tell decision-makers what the correct trade-off is, but national account data help leaders to identify trade-offs and make informed, purposeful, defensible decisions by holding a mirror to past decisions. They do not tell leaders what choice to make, anymore than an airplane dashboard tells a pilot what the destination should be.

Many of the issues of national ocean accounting bring broader national accounting and national sustainability assessment issues into focus. However, the fact the ocean often contains the physical boundaries between countries leads to a unique challenge for developing national ocean accounts. In the context of production, gross domestic product is different from gross national product (GNP). GDP uses the physical boundaries of a country, whereas GNP uses its people as the basis for calculations. This raises the question of how to account for activities on the high seas or other areas beyond national jurisdiction. In practice, this can lead to confusion about how to account for activities within countries' exclusive economic zones (EEZs). These conceptual and practical challenges extend across the sequence of accounts. Furthermore, areas beyond national jurisdiction influence ocean processes within national ocean waters (Popova et al. 2019). This makes it hard to know where national data begin and end, which suggests the need for international cooperation to develop data systems.

A seemingly natural place to start is by asking, 'What is the ocean economy?' and 'What needs to be included and what does not for a sustainable or blue ocean economy?' These questions, however, are rooted in an early twentieth century reporting paradigm in which computing sums and aggregates was a major bottleneck to statistical reporting. Modern technology is changing this. Computing power, algorithmic development and new data-management structures make it increasingly possible to align the exact sectorial boundary with the question being asked. Apportioning certain industries into and out of the ocean economy is challenging; for example, should a seaside coffee shop be included? This concern is secondary and addressed at the end of this section. A modern national accounting infrastructure makes it easy for decision-makers to ask if such an apportioning decision is material to a specific policy question. Developing the information system so that it is robust to these shifts addresses this challenge.

2.1 Production as Means

Simon Kuznets, Lillian Epstein and Elizabeth Jenks (1934) compiled one of the earliest modern national accounts in focusing on the 'industrial branches' of the U.S. economy during the Great Depression.[1] Given, the dominance of Keynesian monetary policy in the 1940s, the system focused on the balance between total supply and demand and investment in produced or man-made capital (Maler 1991). This effort evolved into modern GDP. Formally, the gross domestic product is the monetised value of new goods and services that could in principle be exchanged in a market—value added. In other words, it is the means a country has at its disposal at a point in time, but it says nothing about the ends. Product measures are used to understand a country's tax base, how sectors are changing in relation to other sectors in the economy, how productive certain sectors are and how demand for capital in various sectors might influence available money supply and inflation. These are all important questions, but aside from the ones about how the ocean sectors change in relationship to others, influencing potential tax bases, none of these questions are unique to the ocean or relevant to ocean policy.

Question 1 focuses on 'ocean-linked' market-like production, and Question 2 focuses on 'ocean-based' environmental contributions to market-like production. Neither is about outcomes for people or households. Colgan (2016) documents and discusses the confusion in various ocean accounting efforts between these two questions. Question 1 is the most common. It focuses on a group of firms or industries in an 'ocean' cluster and asks what means these firms generate. One can think of this as creating an ocean-affiliated industry class. The challenge is that often these firms are tangentially related to ocean processes (e.g. law firms provide maritime law services), and how much of any one industry to include is challenging. In practice, Question 1 is commonly used by industries for lobbying purposes—something along the lines of, 'We are an ocean industry, ocean industries are X percent of GDP, so the government should or should not enact a specific policy that will impact ocean industry.' The logic chain here is weak. First, means are not ends, and GDP measures the production or mobilisation of means. Public policy is concerned with means and ends. Second, ocean industries often are differentially influenced by policy. The purpose of lumping them together can, at times, be to inflate any one industry's perceived importance. It is often possible to analyse the affected industry directly and to examine changes to other influenced sectors. This errant lumping effect is even more perverse when nongovernmental organisations (NGOs) use aggregate ocean GDP to argue for the conservation of ocean biodiversity, which is not included in GDP at all. This use confuses the distinction between ocean based production that is dependent on environmental processes and mere ocean-linked production, which may or may not depend on environmental processes. Most ocean GDP calculations focus on the latter.

Question 2 is harder to answer and less commonly asked. It addresses how production based on the condition of the ocean ripples through the economy to create means during a certain period of time. Answering this question requires connecting the detailed information contained within national accounts with biophysical data.[2] Few national statistics offices or marine affairs offices have the capacity to do this on their own—they often must collaborate. Such collaboration requires removing barriers between agencies with ocean and biophysical data expertise and national statistics offices with expertise and access to often sensitive economic data. This leads to two interconnected challenges, beyond the principal challenge of increasing collaboration. Marine affairs agencies may have a regulatory role that access to private economic data (e.g. tax returns) could enhance, therefore there is a need to (1) develop confidentiality protocols and (2) establish clear institutional separation between measurement and reporting functions, on the one hand, and regulatory functions, on the other.

In practice, the product account records activities producing goods and services—this piece of the account provides information for GDP. The scope of product accounts is defined by a 'production boundary', which is 'understood to be a physical process, carried out under the responsibility, control and management of an institutional unit, in which labour and assets are used to transform inputs of goods and services into outputs of other goods and services' (European

[1] In 1947 the United Nations began chairing the design of a standardised system of national accounts to measure the total product and income of a nation over a specific period of time (the first release was in 1953). Subsequently, the system, adopted by virtually all UN member states, has been used (often erroneously) to make broader statements about social progress. The international system has been revised multiple times. The current version is the 2008 System of National Accounts (European Commission et al. 2009).

[2] These include biological, ecological, physical and chemical data.

Commission et al. 2009). This definition creates a challenge for ocean products. According to the SNA,

> *A necessary condition for an activity to be treated as productive is that it must be carried out under the instigation, control and responsibility of some institutional unit that exercises ownership rights over whatever is produced. For example, the natural growth of stocks of fish in the high seas not subject to international quotas is not counted as production: the process is not managed by any institutional unit and the fish do not belong to any institutional unit. On the other hand, the growth of fish in fish farms is treated as a process of production in much the same way that rearing livestock is a process of production.*

This illustrates the need for national accountants to pair with ocean specialists to understand relevant governance structures that often bring marine resources within the scope of the production boundary. Most national waters have an institutional unit that regulates and 'exercises ownership rights over' marine resources, putting these resources inside the production boundary (Obst et al. 2019). For areas beyond national jurisdiction, the activities of regional fisheries management organisations like the Inter-American Tropical Tuna Commission arguably move relevant marine resources within the production and asset boundary.

An example of how ocean product enters a national account is helpful. The value added of harvested ocean resources, like wild fish, is measured using resource rent (Table 8.1). The basic value of production is equivalent to total revenues generated by fishers. The intermediate uses are the values of goods and services consumed or used up as inputs in production, such as fuel costs. Taxes on products are regarded as a part of the value that is created by the industry when the resource is extracted, while a product-specific subsidy is considered part of the costs of extracting the resource. A product specific tax paid by the specific resource industry is added to the resource rent, while product-specific subsidies, including price supports, are subtracted. Industry-specific taxes and subsidies are not included in the calculation of the resource rent because they are a transfer of the resource rent between the government and the industry and do not affect the bottom-line value of the resource rent.

Table 8.1 Calculation of the realised resource rent

Sign	Term
+	Basic value of production
–	Intermediate uses
+	Taxes on products
–	Subsidies on products
=	Gross product
–	Non-industry-specific taxes
+	Non-industry-specific subsidies
–	Compensation of employees
–	Return on fixed capital
–	Capital consumption
=	Resource rent of the sector

Singular focus on the production account can be misleading. Repeated illegal fishing is formally within the scope of production accounts (European Commission et al. 2009). This is because illegally caught fish provide additional means in the current period, and if the illegal fishing is ongoing national accountants understand this as if the government, acting as a trustee, were voluntarily (implicitly) giving up fish to the unlawful fishers. Irregular piracy is not included in the production boundary because piracy does not create new means but shifts them involuntarily. However, defensive government expenditures preventing piracy are production in the current period. If increases in piracy increase government expenditure, then piracy indirectly adds to the product account. Increasing piracy or illegal fishing are not policy goals. These are just a few cautionary examples of why measures of means are not equivalent to measures of ends or outcomes.

2.2 Income as Ends

Economists—such as Dasgupta (2001); Jorgenson (2018); Kuznets (1973); Nordhaus and Tobin (1972); Solow (1993); Stiglitz et al. (2010); and Weitzman (1976)—have long understood the shortcomings of GDP for measuring human welfare or the ends or outcomes of policy. GDP is merely production, a 'means'. It is not an 'end' (Nordhaus and Tobin 1972), such as consumption or benefits to people, or sustainability (Solow 1993). Income is often associated with livelihoods. Livelihoods support household consumption (see Question 3 above). This is closer to the outcome goals of modern policy.

The standard starting place for considering the role of national accounts in measuring well-being is Nobel laureates William Nordhaus and James Tobin's (1972) 'measure of economic welfare', which responded to Kuznet's earlier calls to complete the consumption or well-being portion of national accounts (Jorgenson 2018). The renewed efforts by Joseph Stiglitz, Amartya Sen and Jean-Pierre Fitoussi (2010) to expand national accounts to provide welfare measures, 'beyond GDP', in their report to former French president Nicholas Sarkozy, are summarised by Marc Fleurbaey and Didier Blanchet (2013), both members of the Stiglitz commission. However, to our knowledge none of these efforts explicitly focused on ocean well-being, income, consumption or expenditure. If country leadership wants to link the ocean to well-being, then it is important to (1) support beyond GDP efforts and (2) prioritise their construction in a way that enables a disaggregation focused on ocean-related activities. Doing so may require more individual and time-use surveys along with expansion of the income or expenditure boundary.

Most scholars (e.g., Heal 1998) and national accountants define income following John Hicks's (1939) income concept, which applied to the ocean would define 'blue income' as the maximum amount a society can take from the ocean 'and still be as well off at the end of the week as at the beginning'. This includes 'nonmonetary' benefits to being 'well off' (Krutilla 1967). Question 4 differs from Question 3 by acknowledging that services not acquired through market or market-like production matter. The ocean contributes many such services, such as leisure. Most economic theory related to national measures of income accommodates these services (Fleurbaey and Blanchet 2013).[3] This creates a challenge in accounting theory because it means that the 'boundary' of the income account is broader than the production account, yet the two are expected to balance. Nevertheless, it is possible to create balancing items to address this challenge. National accountants already face this challenge when calculating gross national income in comparison to gross domestic product.

Continuing with the wild harvest fishery example from the end of Sect. 2.1, when calculating compensation of employees, it is a goal to use wage rates that reflect the alternative value of the fishers. This analysis uses the likely wage of fishers if they had to find a job elsewhere at the start of their working career, such as the average wage rate on the mainland. Clearly, this creates a challenge in subsistence settings, and it imposes a set of highly restrictive assumptions about labour mobility. The compensation of employees is calculated as the number of hours worked times this wage rate. Vessel owner income is included as the number of hours worked multiplied by the employee wage rate. This illustrates the current shortcomings of national income accounts. Payroll taxes and other finely resolved data are used by countries that have those data.

To capture the contribution of the ocean to national welfare or income requires including market and non-market benefits to people. Yet the divide between the market and the non-market is often the boundary for national accounts, leaving out economic activities, such as home production and flows from environmental public goods, that are often thought of as services. Insofar as these activities represent substitutes for market activities, their inclusion is necessary. Nordhaus (2006) writes, 'Probably the most difficult issue in design of augmented accounts is, where to draw the border.' Expanding the income boundary is important in enabling national ocean accounts to capture many of the services that lead people to care about the ocean. If the boundary is adjusted, then various methods to estimate the implicit income from non-market ocean services exist (Freeman 2003; Phaneuf and Requate 2017). It is more complicated to apply these methods than to use market data. Furthermore, the data analysis is often highly localised, and transferring results from one region to another is challenging (Boyle et al. 2010). Finally, the current version of income accounts is not a true measure of social welfare or economic well-being because they do not address distributional concerns (Fleurbaey 2009). Nevertheless, completing these accounts, with a broader boundary, would represent a substantial advance, and new technologies are enabling disaggregation. Dale Jorgenson (2018) argues that much greater information on distribution is needed for income, consumption and expenditure accounts. This is true for non-market services like many important leisure opportunities provided by the ocean and in cases where the ocean provides substantial subsistence opportunities. What is in and out of the account imposes a binary equity weighting. The ability of dashboards to enable disaggregation goes a long way towards addressing, or at least enabling informed discussion of, distributional concerns of 'fair allocation' of benefits associated with the ocean.

Leaders interested in policy outcomes, or 'ends', should be more interested in net national income (NNI) than GDP. NNI calculations require attention to the valuation of often hard-to-value assets, and NNI over a period of time is expected to balance with changes in national wealth reflected on a balance sheet.

2.3 Sustainable Development and the Balance Sheet

Production provides means, income is ends, but a sequence of balance sheets provides information to assess whether development is sustainable (Arrow et al. 2004; Hamilton and Clemens 1999; Maler 1991) and whether ocean development is sustainable or 'blue'.[4]

The balance sheet shows a country's wealth—the present value of the country's current and future economic opportunities conditioned on the current or most likely future institutional arrangements. Changes in national balance sheets are

[3] The 2008 SNA admits to the arbitrary nature of including household produced goods but excluding household produced services. This is done to support traditional monetary and fiscal policy concerns.

[4] It is often suggested to reformulate non-declining wealth as non-declining per capita wealth. However, it is unclear that per capita is the "correct" normalisation (Jorgenson 2018), for two reasons. First, some ocean services are non-rival, and all individuals experience the same service level. Therefore, the more people, the more service, the more wealth, and in such a case we should not divide by the total population. Second, per capita normalisation carries a certain distributional element that implies that distribution of access to ocean capital takes a certain form, but it is possible to increase per capita measures while reducing the most common (median) experience.

expected to balance with net changes in net national income. Ocean balance sheets reflect current and future economic opportunities afforded by the ocean. **Changes in balance sheets provide the sustainable development report card**, that is, 'meeting the needs of current generations without compromising the ability of future generations to meet their needs' (World Commission on Environment and Development 1987).[5] Kirk Hamilton and Michael Clemens (1999) put it succinctly, 'Achieving sustainable development necessarily entails creating and maintaining wealth.' A physical account complements the balance sheet that shows the current stock of assets.

Infrastructure and environmental assets, including natural resources, belong on national balance sheets (European Commission et al. 2009; Hulten 2006). This includes marine capital. Port infrastructure falls under the heading of produced assets. Other ocean assets from live fish populations to coral reefs to deep-water oil reserves are non-produced assets. The inclusion of natural capital in national accounts is not a novel or controversial idea. The idea of natural capital was well established by the early 1900s, long before the term natural capital was used. Irving Fisher (1906) used an ocean asset, Newfoundland fish stocks, as the first example of capital in his seminal 1906 text. U.S. president Theodore Roosevelt (1910) spoke of natural resources as assets as early as 1910. The current system of national accounts makes frequent mention of natural resources as capital (European Commission et al. 2009). Many Nobel laureates in economics, including William Nordhaus, Joseph Stiglitz, Robert Solow, James Tobin, Amartya Sen and Kenneth Arrow, have advocated greater inclusion of the natural environment in national accounts. Comprehensively completing the balance sheet is currently being piloted as 'wealth accounting' by the World Bank and UN Environment (Lange et al. 2018; Managi and Kumar 2018). The key innovation in these comprehensive wealth measures is that human and natural assets are given equal footing with produced assets. Recent versions of these reports include some ocean assets. The indicators for a sustainable ocean future will be contained in an ocean account balance sheet. Canada, Australia and other countries are already producing wealth reports, but we are unaware of any that are well developed for ocean sectors.

The boundary of the balance sheet is one of the most challenging pieces of national accounts (Hulten 2006). The 2008 SNA (European Commission et al. 2009) states that 'natural resources such as land, mineral deposits, fuel reserves, uncultivated forests or other vegetation and wild animals [fish] are included in the balance sheets provided that institutional units are exercising effective ownership rights over them, that is, are actually in a position to be able to benefit from them.'

Most countries exercise effective ownership over their marine assets, by virtue of their assertion of national maritime zones, and related management activities. It is telling, however, that in the current system of national account documents (European Commission et al. 2009, §10.167), 'ocean' only appears in the mention of 'certain naturally occurring resources, however, maybe such that it is not feasible to establish ownership over them, for example air, or oceans.' This suggests that informal conventions within national accounting require amendment to improve their consistency with prevailing realities of ocean governance.

Producing comprehensive balance sheets, including non-produced assets, is a first step to verifiable sustainable development. In the ocean economy, non- produced assets are especially important given the role of non-produced ocean assets in growing food, storing minerals, sequestering carbon and generating many other services. It is also not possible to calculate net measures or income or production without measuring changes in stored wealth.

An important challenge to creating balance sheets is the valorisation of ocean assets. National accounts primarily focus on the consumption of fixed capital, which is the amount of an asset used to produce a good or service (Obst et al. 2019). For produced capital, consumption of fixed capital is often computed using market prices or the perpetual inventory model, and consumption of fixed capital does not include depletion or degradation of nonproduced capital (European Commission et al. 2009).

In the fishery example from Sect. 2.1, what capital makes it to the balance sheet? The focus is on port infrastructure, the fishing vessels and other 'fixed capital'—not the fish population. When there are no market prices, the perpetual inventory method works by adding capital each year based on the cost of new investments (e.g. spending on boats or port maintenance), and capital is subtracted based on an estimate of the lifetime and depreciation profile. In practice for fishery capital, the lifetime is set to 20 years, and the depreciation profile is geometric, with a 10% annual rate. This is assumed to reflect the wear of this kind of capital. The claim is that the analysis takes a long-term perspective and essentially asks what the return on the capital would have been if it were not invested in the fishery sector in the first place. However, this is inconsistent with assessing the current state of the world. For something like fishing capital, this clearly ignores complementarities with the non-produced capital, which is the

[5] Nobel laureate Kenneth Arrow et al. (2004) formalise the definition of sustainable development as requiring constant or increasing opportunities, where the concept of wealth has evolved to be a measure of future opportunities. Wealth itself is the net present value of income.

fish stock. Ignoring marine non-produced capital can lead to errors in valuing marine-produced capital, such as port infrastructure. New Zealand has introduced a novel solution by creating a market place for the rights to use non-produced capital, that is, fish stocks, known as individual tradable quotas or catchshares. These programs were developed to align fisher incentives with regulatory goal (Grafton et al. 2000), but they create the added benefits of enabling the living fish population to be tracked on the national balance sheet (Hammond 2005).

The 2008 SNA provides little guidance for valuing non-produced assets, but methods exist. Fenichel et al. (2018) and Fenichel and Obst (2019) provide guidance for valuing non-produced assets in the form of natural capital, which can be applied to ocean non-produced assets. Yun et al. (2017a) provide a software package, called capital asset pricing for nature (capn) to facilitate implementation of these techniques. These techniques use observed behaviours but do not assume a constant flow of services. The approach accounts for economic and ecological feedbacks in the valuation process. The core challenge is to group strongly interacting pieces of the ocean ecosystem and economy to capture the most important feedbacks. Yun et al. (2017b) apply these techniques to develop balance sheet components for the Baltic Sea cod-herring-sprat fishery based on Polish data. When all data are not available, simplifying assumptions may be used that are as reasonable as those used in the perpetual inventory model.

Charles Hulten (2006) makes the real problem clear: ‘When it comes to capital, however, it is more a question of what to do than how to do it.’

2.4 Analysing Policy and Marine Planning

Headline indicators, the gauges in Fig. 8.1, are retrospective measures. They can provide lessons from the past, but ‘past performance is no guarantee of future results’. National accounts organise data to enable analyses that can inform future decision-making. This is the main goal of national accounts (European Commission et al. 2009). Question 6 above is about the future. A national ocean account can provide information to develop economy-wide models, including economy- wide models with fine spatial resolution. This is because national accounts are the system for processing information to coordinate national activities, provide business forecasts and evaluate policy outcomes.

National accounts provide a commonly agreed set of facts for shared understanding and decision-making. These accounts are built on extensive data, with high resolution, potentially down to a beachside ice cream parlour’s tax reports. New technologies and reporting paradigms are making data increasingly easy to access and disaggregate to answer questions about specific sectors of the economy—including the ocean economy.

The three gauges in Fig. 8.1 report the condition of the national (ocean) economy. The detailed data are stored in many structures, chief among them a set of supply- and-use tables. These tables provide the material to produce the aggregated, sector-level input-output tables commonly used in economic analysis and projects.

These are critical for understanding the interconnections within an economy and connecting the science of ocean processes with the traditional economy. Furthermore, supply-and-use tables are regularly produced at fine spatial scales. Indeed, in many countries the limits of publicly available spatial disaggregation are set by ethical and confidentiality concerns rather than data resolution.

The supply-and-use tables record the production and demand structure of an economy by describing the goods and services brought in through domestic production or through imports from outside the economy. The tables describe how those goods and services are used, such as through intermediate consumption, final consumption at the household or government level, gross capital formation or exports (Department of Economic and Social Affairs 2018; Kazemier et al. 2012). The tables provide the foundation for developing input-output (IO) tables. IO tables and supply-and-use tables may be in physical or monetary units. Supply-and-use tables allow analysts to verify that the underlying data used in national aggregate calculations are consistent, complete and balanced.

IO tables aggregate goods and services to industry or sector levels and track value flows between and within industries or sectors for intermediate consumption and final expenditure. Therefore, the IO tables are used in all sorts of economic analyses and forecasts. The supply-and-use tables can be expanded to include services and consumption currently outside of the income or production boundary to get a better handle on true national income and on ocean income and can ultimately be linked to similar structures for environmental processes taking place in the ocean. Natural production from the ocean could be treated as an economic sector.

Analysis to support sustainable ocean economic policy requires reducing the barriers between experts and data generators from different agencies. **Connecting assets with supply-and-use tables will make it easy for analysts to analyse how economic activity changes the ocean and how changes in the ocean influence economic activity.** Scientists already build models of the marine environment, such as Atlantis and EcoPath/EcoSim (Audzijonyte et al. 2018; Collie et al. 2016; Steenbeek et al. 2016), that use structures similar to IO tables. Establishing a central accounts structure could enable macro-environmental-economic policy analysis based on an integrated platform that links data and models and brings the environment into standard macroeconomic modelling frameworks (Finnoff and Tschirhart 2003). Currently, the expertise for much of this work sits outside national statistics offices, while those with biophysical knowledge struggle to connect their data and understanding to macroeconomic models.

Connecting ocean and economic experts is imperative because the ocean economy is strongly influenced by the performance of non-produced assets. Many natural assets may directly interact and influence each other's value, just like firms interact in an economy where automobile manufacturers influence the market value of suppliers—predators affect the value of prey. The value of services or the value of assets depends on substitutes and complements to those services or those assets. The ocean generates many services, but these services are produced through interconnected processes, and some of these services are regenerating assets. These connections can enable substitutions or create complementarities. Interactions can be physical or biological (such as ecosystem interactions between species), technical or market-driven. In an era of globalisation, markets connect the incentives for using various components of the ocean worldwide (e.g. fisheries, tourism). For example, coastal resources enable swimming and recreational fishing, which may be complements in producing tourism services. Sites that enable both may be of greater value than the sum of sites that only enable swimming or recreational fishing. In another example, unharvested prey fish biomass may seem of little value but actually have great value in supporting a harvested predator fish (Yun et al. 2017b). At the same time, one species of prey fish may be a good substitute for another species of prey fish, so the value of that prey fish species in a system with many species may be lower than if that prey fish species were the only prey source. This means that changes in the value of ecosystems may not be the sum of the changes in the value of the parts if the parts are measured independently. Measuring the parts independently may lead to double counting or undercounting. It is important to account for interactions, which often depend on policy decisions and institutions as well as ecology and natural processes.

2.5 Satellite Accounts

The term *satellite account* is used for separate accounts of interest that are not part of the central structure of the System of National Accounts. Most satellite accounts are rearrangements of items already included in a central account. They do not influence national aggregates. However, some satellite accounts allow items to be treated differently, such as with a different boundary than the central accounts.

One important system of satellite accounting is the System of Environmental Economic Accounting (SEEA), which is coordinated by the UN Statistical Division. The SEEA Central Framework (SEEA-CF) is an internationally agreed standard for accounting for environmental assets and their supply to and use in the economy. It provides guidance for services from non-produced assets, such as fisheries, in greater detail than the System of National Accounts. The SEEA-CF provides the specific guidance on fisheries, forests and agriculture, which reflects the SNA guidance with additional details for natural resources. The SEEA also has a system of Experimental Ecosystem Accounting (SEEA-EEA) that is currently being revised, with the goal of establishing an international standard by 2021. The experimental ecosystem accounts focus on the biophysical condition of ecosystems and interactions among non-produced assets. The SEEA-EEA will likely also provide guidance on ecosystem services that can be counted as income beyond the current income boundary, though this guidance is still in development. The revisions working groups have produced working papers, which are available on the SEEA webpage, https://seea.un.org/.

A second important set of satellite accounts consists of satellite ocean accounts developed by individual countries with guidance from the Organisation for Economic Co-operation and Development (OECD), EuroStat or in coordination with the UN Economic and Social Commission for Asia and the Pacific (UN-ESCAP). The UN-ESCAP program is also associated with ongoing efforts, coordinated by the UN Statistics Division, to maintain and develop the SEEA. Some countries also produce satellite transportation and tourism accounts with ocean-related components or coverage.

2.6 Related Issues

Before assessing the current state of national ocean accounting, we should examine some common issues that we have not yet addressed. These include boundaries and existing discussions of the ocean economy, data and technology, and equity concerns.

2.6.1 Conceptual and Spatial Boundaries

Ocean accounts need to address three types of boundaries: (1) accounting boundaries, which determine what types of services to include and which we have already discussed, (2) the marine economy boundary and (3) spatial boundaries within the marine system. This section focuses on the second and third boundary types.

Of the six established and five emerging blue sectors outlined by the European Union Directorate-General of Maritime Affairs and Fisheries and Joint Research Centre (2018) and by the OECD (OECD 2016), three major sectors—extraction of marine living resources, coastal tourism and biotechnology—are likely impacted, in some cases severely, by changes in the ocean's biological condition. These sectors depend critically on the biological natural capital of marine ecosystems. All sectors may be impacted by physical changes that alter access to the ocean by changing the distribution of storms, waves, wind and so on. Therefore, all sectors depend on physical natural capital, but it is less clear that the physical capital is ocean capital as opposed to climate.[6] It is likely that all sectors influence changes in the biological and physical condition of the ocean, which ultimately influence the accounting price of critical forms of ocean capital. Finally, 'marine and coastal' protection is often included as a sector of the blue economy. But this sector would be better thought of as investments or maintenance of ocean natural capital, which is how the current System of Environmental Economic Accounting treats this sector.

From shipbuilding to biotechnology to clean energy, the ocean spurs innovation and encourages human capital formation. Of course, the ocean is one of many contributors. More work is needed to partition the incremental contributions of the ocean to knowledge generation. Ocean accounting initiatives should be integrated with accounts that cover broader sections of the economy. Experiences with individual tradable permits for fisheries suggest there are regulatory structures that increase the value of natural capital (Fenichel and Abbott 2014) while increasing the value of human capital through safety improvements (Birkenbach et al. 2017; Pfeiffer and Gratz 2016). Such property rights may be important in marine mining and other extractive industries as well (Libecap 1994).

The issue of national boundaries, made acute by the ocean, is a somewhat unique issue for national accounts. Currently there is no institution maintaining a balance sheet for ocean areas beyond national jurisdiction. Many countries do not even include assets in their own EEZs on their balance sheets. Another concern is vessels operating in the territorial waters of other countries. The production and income are usually attributed to the vessel's home country, while any impacts to the balance sheet would occur to the geographic location. This could lead to the changes in wealth not balancing with NNP.

[6]The Blue Paper on "The Expected Impacts of Climate Change on the Ocean Economy" discusses the strong link between the ocean and climate.

A global emerging issue is marine spatial planning.[7] National account data are useful to marine spatial planning in ways that parallel regional development modelling—a common use of national account data. National account data enable input-output, integrated assessment and computable general equilibrium modelling. These sorts of models have a role in marine spatial planning.

2.6.2 Data and the Digital Revolution

The key strength of national accounts is their organisation of data. The digital revolution is changing the way people interact with data, and this is especially relevant for national ocean accounts.[8]

National accountants already use 'big data' and detailed business statistics from multiple sources, and they are experimenting with remote sensing. Aggregates are often built from very fine scale measurements, such as business receipts. This is important because environmental data will likely also not come from a single source. However, the national account reporting paradigm, with a heavy focus on headline GDP, is based on 1930s technology, now in the early stages of a radical update involving online digital dashboarding that makes headline numbers less essential (Fig. 8.3).

Marine conditions and activities are often 'far away' from observers, but remote sensing and in situ techniques are making it easier to observe the ocean. There is substantial untapped potential to monitor and measure the biophysical condition of the ocean through 'earth observation' (Ramirez-Reyes et al. 2019), and technology exists for these data to flow directly into national ocean accounts. Earth observation is defined as the union of diverse data sources, including from satellite, airborne, in situ platforms and citizen observatories (GEO 2015), for improved monitoring and forecasting of Earth's physical, chemical and biological conditions. The Group on Earth Observations (GEO) provides physical, chemical and biological information at increasingly fine scales, including at a few metres and hourly. Earth observation provides rapid, repeated and long-term synoptic observations that provide a platform for a nested ocean observing framework at global, basin, regional and local scales.

The Framework for Ocean Observing (Lindstrom et al. 2012), implemented under the auspices of the Intergovernmental Oceanographic Commission of the United Nations Educational, Scientific and Cultural Organization and coordinated by the Global Ocean Observing System, seeks to meet the need for ocean data that support governance, management, science and other ocean uses. It

[7]The Blue Paper on "Integrated Ocean Management" focuses on marine spatial planning.

[8]The Blue Paper on "Technology, Data and New Models for Sustainably Managing Ocean Resources" focuses on data and emerging technologies.

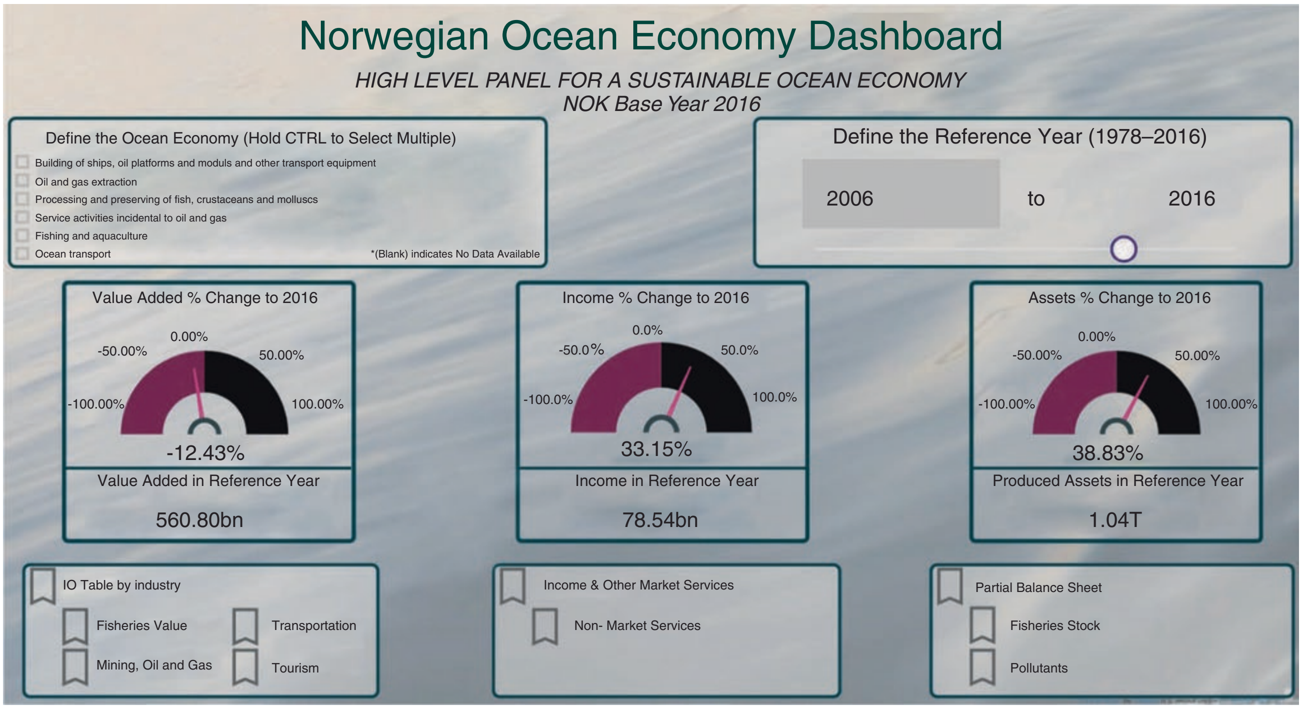

Fig. 8.3 Example of a Live Interactive Digital Dashboard for Norway. (*Source: Working version at* https://environment.yale.edu/data-science/norwegian-ocean-economy-dashboard/)

proposes the coordination and integration of routine and sustained observations of physical, biogeochemical, geological and biological essential ocean variables (Bojinski et al. 2014).

Through its marine and coastal (GEO Blue Planet) and biodiversity observatory network initiatives, the international Group on Earth Observations is working to improve the availability, access and use of ocean-related Earth observations. This includes work on a framework for a set of essential biodiversity variables for use in monitoring programs to understand patterns and changes in Earth's biodiversity (Navarro et al. 2017; Pereira et al. 2013) as well as on ecosystem essential ocean variables, a set of observable ecological quantities that contribute to the assessment of the ocean ecosystem (Miloslavich et al. 2018).

These efforts categorise specific ocean parameters that should be monitored continuously in order to identify key processes and determine the sustainability of the ecosystem as a whole, thereby addressing the challenge of evaluating the ocean's status in a synergistic way (Muller-Karger et al. 2018).

The biophysical data present two main challenges. First, expertise for working with Earth observations (which include ocean and coastal data) often resides outside national statistical offices, though some national statistics offices do possess this expertise (e.g. Canada's). It is imperative that national accountants collaborate with Earth observation experts to acquire physical data of ocean flows and measures of non-produced ocean assets. Coverage can vary, and some countries lack capacity for accessing these data altogether. Many habitats, including the deep sea, ocean trenches, ice- bound waters, methane seeps and even coral reefs, remain poorly studied at the global scale. Costello et al. (2010) shows that geographic gaps in biodiversity data are particularly acute for many parts of the global ocean, including coastal areas of the Indian Ocean, the southern and eastern Mediterranean Sea, polar seas and much of the South American coastal ocean.

There is a critical need to inventory data to quantify natural stocks, audit the data's usability for accounting for non-produced assets and identify priority data gaps. Data gaps need to be articulated with clear measurable and feasible observable units; such measures should be prioritised over derived measures like biodiversity. Data quality needs to be checked against academic data sets such as 'The Sea around Us' (http://www.seaaroundus.org/) (Pauly and Zeller 2017), and discrepancies should be documented, explained or remedied. Physical measures need to be linkable to human transactions and decisions for valuation. As part of the UN System of Environmental Economic Accounting, substantial progress has been made in defining the extent of ecosystem and other natural assets within basic spatial units (BSUs).[9] But data must go beyond spatial delineation to track condition through time. For example, the spatial extent of the Great Barrier Reef has not changed much over the last 30 years, but the reef's biological condition has.

Second, the amount of Earth observation data leads to computation challenges. The Copernicus Earth Observation Programme Sentinel satellites of the European Union (EU) produce approximately 20 terabytes of data per day (Esch et al. 2018). The geospatial community has developed solutions that 'bring the user to the data instead of the data to the user'. Technological advances in cloud technologies, the development of data cube technologies, the availability of analysis-ready datasets and the development of web- based platforms providing access to these services make this possible. These solutions may not work for national statistics offices that may need to match ocean data with confidential microeconomic data. National accountants and statisticians, led by economy and finance ministers in cooperation with transportation, marine affairs and fishery ministers, need to negotiate a platform that serves the needs of ocean accounts.

The digital revolution is aiding the understanding of human activity on the ocean and the implicit income that people gain or lose as the ocean changes. Many vessels are tracked by satellite. The International Maritime Organisation monitors maritime traffic through a regulation requiring the Automated Identification System (AIS) on all ships over 300 gross tonnes on international voyages, on cargo ships over 500 gross tonnes and all passenger ships irrespective of size. AIS reports the ship's identity, type, position, course, speed, navigational status and other safety-related information—automatically to appropriately equipped shore stations, other ships and aircraft. Vessels engaged in fisheries activities also report their locations. The vessel monitoring system (VMS) is a satellite-based monitoring system that provides data to the fisheries authorities on the location, course and speed of vessels (https://globalfishingwatch.org/). AIS and VMS data are key elements for measuring maritime transport.

Human transactions increasingly involve a digital footprint, and these data are increasingly useful for imputing the non-market income received from the environment, such as social media posts, administrative time-use surveys, voluntary recording on recreation, activity tracking and digital consumption of complement and substitute market goods. A number of difficult ethical concerns must be addressed with these data, but national accountants already grapple with these issues for business reporting data. All of these data could greatly improve determination of the precise value of non-market services provided by the ocean and nature more broadly. Digital transactions are already improving the precision of market data, and in some countries national accountants and economists are already working with these sorts of data for measuring the ocean economy. National statistics offices increasingly invest in the infrastructure and algorithms to support information from the digital world and lower barriers to bring in data from other data-collection agencies without loss of resolution. In the context of the ocean, this means that agencies must find ways to incorporate biophysical data and associate shore-based transactions with the marine physical environment. It is also important that national statistics agencies draw on the expertise of marine sector experts to understand the complex institutional arrangements and assignments of 'economic ownership', which often differs from 'physical ownership' in the marine context.

New technology makes national account data more accessible and more useful for policy analysis. For instance, an ocean proto-account for Norway can be displayed as an interactive dashboard (Fig. 8.3), and the United States hosts an interactive ocean proto-account (https://coast.noaa.gov/digitalcoast/tools/enow.html). Such dashboarding aligns with the recommendations of Stiglitz et al. (2010) for going beyond GDP. New interactive dashboarding technology makes decisionmakers less dependent on specific aggregates like gross or net ocean product and enables them to drill down quickly to indicators of interest.

2.6.3 Equity and National Accounts

Equity and inclusion are cornerstones of the sustainable development agenda, and distributional concerns are a limitation of only focusing on national income aggregates—though when used with care these can be an important piece of addressing equity (Fleurbaey 2009; Jorgenson 2018; Jorgenson and Slesnick 2014).[10] 'Equity' refers to the distribution of benefits and costs of resources (distributional justice). Conservation and changes in wealth are central to intergenerational equity (Dasgupta 2007; Solow 1974).[11] Intragenerational equity is also important (Adler 2013; Hart 1974; Sikor 2013; Stiglitz et al. 2009), and the ocean can contribute to poverty alleviation, especially for small island developing states and coastal least developed countries, providing food, jobs, livelihoods and cultural spaces (World Bank and UN-DESA 2017). It is a reasonable aspiration for ocean accounting to support 'equity measures', while being agnostic as to the 'correct' distribution or measure.

[9] Ideally, BSUs covering marine and coastal locations should designate a three-dimensional volume including the ocean, the seabed and subsoil, combined with a shoreline vector delineating the ocean from land. Conditions that can be assigned to and accounted for within BSUs include, for example, acidification (pH), eutrophication (BOD), temperature (°C), and plastics (T), and the abundance of various species.

[10] Fair sharing of the ocean is addressed in the Blue Paper on "How to Distribute the Benefits of the Ocean Equitably".

[11] Measuring sustainability with balance sheets requires considering access to assets and going beyond per capita measures (Jorgenson 2018).

National accounts are denominated in national monetary currencies and thus depend on the distribution of money income and wealth. While not reporting directly on equity, national accounts can provide some data to generate equity indicators and help countries meet international sustainable development reporting commitments. In order to do so, it is important to be able to disaggregate and apply politically chosen equity weights. Microeconomic and survey data are also important (Jorgenson 2018). The boundary of the account limits potential equity weights. Anything left out of the account is implicitly weighted at zero.

A clear limitation for policy analysis concerned with distributional outcomes is the ability to disaggregate reporting. Current national accounts vary from country to country in this respect, but technology is making it easier and easier to disaggregate data. The technical challenge is to build the data structure in a way that it can be disaggregated and recalled quickly. However, perhaps the greater change will ultimately be balancing ethical issues that emerge from the identifiability of fine-scale disaggregation (e.g. linked to data protection) with the ethical imperatives of using disaggregation to address equity concerns.

2.7 Aspirations for the System of Ocean Accounts

The ocean plays a major role in market and non-market services. The ocean unites and divides countries, and it links people through a common heritage and regulated climate. It also brings people together through trade and travel. A substantial number of services from the ocean rely on production underpinned by natural capital. In principle, much of this natural capital should already be on national balance sheets and within national accounts. The asset and production boundaries of national accounts may require adjustment to justify adding other stocks of natural capital to the balance sheet. **However, of first-order importance is generating balance sheets with the produced and non-produced ocean assets currently within the production and asset boundaries. This is not being done, but it would provide an immediate gauge of the ocean economy's sustainability.**

Furthermore, many ocean-provided services are not traded on the market. Therefore, they are missing from production and income accounts. Account boundary adjustments are required to provide clearer measures of the 'ends' in terms of economic well-being. It is **important to work towards a broader income boundary that includes broader ocean services**, such as household-produced services, leisure services and carbon sequestration and storage. The money boundary is a subset of this broader boundary.

Finally, the accounts must be more than summary statistics. Analysts must be able to get into the details of the data. Integrating the economic and biophysical data into a single platform will make it easy for economic analysts to consider the role of the ocean and perhaps help physical scientists better understand the economic trade-offs with biophysically based recommendations. Turning attention towards the data structures and away from the aggregates is imperative to address environmental concerns while answering forward looking policy and business questions.

3 Current State of Accounts for the Ocean

It is not enough to review concepts and investigate official guidance for national accounting for the ocean. We must also look at what countries are doing with respect to ocean accounting. This section surveys the current state of ocean accounting and relates practices to frameworks for ocean accounting and the suite of actors implementing frameworks. The goal is to identify gaps between the formal structure and practice. Assessing the current state of the accounts helps (a) show what is currently feasible, (b) identify important gaps where alternatives may exist or where resources are required and (c) identify areas where novel approaches to ocean accounting are needed.

There are three main components to the current practice of ocean accounting:

1. The set of internationally agreed frameworks for national accounting systems.
2. Countries that engage with these frameworks to provide national accounting information related to the ocean.
3. Programs and outside actors who link, filter or otherwise engage and support the set of existing frameworks and/or countries that are producing these national accounts.

3.1 Internationally Agreed Frameworks

A growing range of ocean accounting initiatives, frameworks and studies exists. It is useful to think about their articulation with the System of National Accounts (European Commission et al. 2009). Most countries' national accounts comply with this system. Relevant frameworks developed through intergovernmental systems include the following:

- The System of Environmental Economic Accounting (SEEA) Central Framework, developed through a UN Statistics Division process.
- The SEEA Agriculture, Forestry and Fisheries (AFF), which applies and expands on the SEEA–CF. This system is developed through the Food and Agriculture Organization of the United Nations (FAO).
- The SEEA Experimental Ecosystem Accounting (SEEA-EEA), which incorporates physical indicators of ecosystem conditions and services, as well as measures of ecosystem value. This system is developed through a UN Statistics Division process.
- The UN Technical Guidance on Ocean Accounting for Sustainable Development, which applies the SNA and SEEA, with additional guidance focusing on accounting for ocean governance and social circumstances within an integrated Ocean Accounts Framework. This guidance is developed through the UN Economic and Social Commission for Asia and the Pacific (UN-ESCAP), in collaboration with several governments and other actors.
- The Integrated Maritime Policy Database, a proposal/pilot refinement of ESA 2010 guidance that is a European-tailored version of the SNA.

The broadest of the international accounting frameworks is the System of National Accounts (European Commission et al. 2009), developed through the Inter-secretariat Working Group on National Accounts. The SNA aims to provide a framework for creating a sequence of national accounts that is 'comprehensive', 'consistent' and 'integrated'. Much of Sect. 2 focused on this system, and the SNA is clearly relevant for the ocean economy. Sections 6.136–42 address the output produced by sectors that operate in part within the marine economy. Many of the same challenges addressed by the SNA—for example, those having to do with home production—apply in the marine economy.

The SEEA-CF informs monetary measurement of economic activity related to the environment as well as physical measurement of environmental stocks and flows. The SEEA-CF complements and expands the SNA. Physical asset accounts are a key way in which the SEEA-CF expands the boundaries defined by the SNA. The SEEA-AFF provides more specific standards for physical and monetary accounting and measurement of fish and other aquatic products within the SNA. SEEA-CF adopts the notion of countries, firms or asset owners as economic units. The SEEA-EEA, in contrast, takes an ecosystem-centric perspective focusing on spatial units grounded in ecological rather than administrative boundaries (Chow 2016; FAO n.d.). The UN Technical Guidance on Ocean Accounting for Sustainable Development, developed through UN-ESCAP, focuses on the application of the SNA and SEEA in marine and coastal contexts, providing methods and approaches for developing satellite accounts for the ocean environment and economy that allow for spatial disaggregation. It also provides experimental guidance on accounting for contextual factors such as ocean-related social circumstances and current modes of governance. Ocean systems, given variation in depth, currents and boundary types, present specific challenges to the notion of an ecosystem-based spatial unit for a given terrestrial system. The UN-ESCAP guidance includes ecological and technological detail needed to define ocean spatial units and physical measurement standards tailored to measure marine assets. The community of practice surrounding UNESCAP ocean accounts includes Australia, Canada, China, Fiji, Indonesia, Malaysia, Portugal, Samoa, Thailand, Vanuatu and Vietnam. These accounts can be constructed at the national or subnational level. Together, the SNA, SEEA-CF and SEEA-AFF guidance constitute the internationally agreed framework applicable to ocean accounting. The SEEA-EEA and UN-ESCAP provide more detailed guidance produced through the same mechanism, but they have not yet been adopted as international standards.

3.2 Implementation of Ocean Accounting

The conceptual design of national accounts suggests that it should be possible to extract substantial information about the state of the ocean and the ocean economy. Greater detail requires more complex national accounts. It is important to develop a consistent framework for categorising economic activities to prevent double counting of flows from economic activities. Double counting and undercounting are surprisingly easy traps because of the many ways countries can group these activities. Increasing the level of detail in national accounts exposes important linkages across industries and early indicators of economic health.

The Ocean Panel member countries are diverse and clearly invested in the ocean, but not all have high-profile national ocean accounts. Therefore, they constitute a useful sample to examine the state of national ocean accounts. We focus on these 14 countries in this section and in the following section review other selected high profile efforts. A survey of the Ocean Panel countries' treatment of the ocean in their national accounts provides a representative, if optimistic, view of the state of national ocean accounting. We provide specific examples, so that practitioners can find examples of steps being implemented. We investigate four questions:

1. Do member countries explicitly account for the ocean economy? If so, to what extent?
2. Which accounting tools—production, income, balance sheets and supply-and-use tables—are produced? Are the

	Production Accounts Disaggregated to Ocean Economy	Physical Production Accounts Only at Level of Ocean Economy	Physical/Monetary Production Accounts Somewhat Disaggregated	Contribution of Ocean Economy to Production Unable to be Reported
Fisheries	13	1	0	0
Tourism	10	1	2	1
Transportation	3	4	1	6
Mining, Oil and Petroleum	2	1	0	11

Fig. 8.4 Ocean sector aggregates for ocean panel countries. (*Source: Authors' tally based on publicly available national count data*)

accounts usable to inform services, sustainability, and conduct economic analysis or are only production accounts produced?

3. How are non-produced ocean assets (ocean natural capital) treated in the accounts?
4. Is the current level of national account detail sufficient to produce a set of satellite accounts and aggregate statistics for the ocean economy?

We were able to find ocean-related data in national accounts for all 14 Ocean Panel member countries.[12] National ocean accounting is not starting from zero in any of these countries. Nevertheless, Ocean Panel member countries' national ocean accounting data vary greatly and are only comparable at a broad level. A variety of specialised reporting is already evident.

For example, Fiji's national accounts maintain detailed reporting on the *bêche-de-mer* (sea cucumber) industry and have an extensive structure for the harvest of biological organisms from the ocean. The same economic activity in other countries' national accounts in principle may only exist in an aggregate of the entire agriculture, fishing and forestry sector. Harmonising ocean accounting would facilitate inter-country comparison; more important, it would also facilitate capacity building and knowledge sharing.

3.2.1 Product and Income Accounts

Macroeconomic *production aggregates* exist across three of the four principal ocean-related sectors: (1) fisheries and (2) mining/oil and gas and (3) transportation or commerce (Fig. 8.4). Many, but not all countries report aggregates for tourism or hospitality, however, these estimates are often provided in a satellite account given the potential for double counting. Furthermore, the existing data are reorganisations of data from the countries' main sequence of national accounts and do not extend the income boundary. Therefore, accounting for the ocean does not change countries' headline GDP. Countries with explicit ocean accounts include additional sectors in their 'ocean accounts' beyond the four we focus on. These may include all coastal activities, maritime law, research on the ocean, restoration activities, ocean governance, bio-prospecting, and the list goes on. Such accounts aim to answer Question 1 in the initial set of 'value of the ocean' questions.

Some countries use spatial data on reporting location to partition marine-related coastal tourism and hospitality. Some countries, such as Portugal and Canada, go a step further and provide dedicated satellite accounts for the ocean (see INE n.d.; and Fisheries and Oceans Canada n.d.-a). Other countries, such as Fiji and Indonesia, have expressed interest in or are in the process of developing ocean satellite accounts. The production accounts are relatively complete, sufficient to provide marine GDP, if the boundary of the marine economy can be defined and data can be disaggregated. Marine GDP can be, and often is, created by reorganising items contained in standard national accounts, and many countries already produce a marine GDP.[13] The statistical offices for countries such as

[12] Our analysis is based on data we could locate online, so gaps in the analysis may reflect that the data are not easily located through the internet rather than that they are missing.

[13] See volume 2, issue 2, of the Journal of Ocean and Coastal Economics for country-specific experiences.

Norway have computed a statistic that is essentially marine GDP as a onetime exercise. In the marine affairs agencies of other countries, such as Canada, the Department of Fisheries and Oceans generates this sort of calculation. These marine GDP aggregates do not account for depreciation or degradation of marine produced assets (e.g. port infrastructure) or non-produced assets (e.g. fish stocks), because GDP calculations do not consider capital depreciation or degradation of any kind. Existing marine GDP statistics leave out changes in ocean capital because of the design of GDP and not necessarily because of a lack of information or an effort to conceal or ignore these changes. GDP is the wrong tool for assessing the sustainability of the ocean economy.

There are supply-and-use tables for the included sectors products, but these seldom connect to underlying ocean processes. It is not clear how ocean processes influence tourism, but ocean processes likely influence fisheries, and physical ocean processes may influence transportation.

With respect to the ocean, most national accounting effort goes into the national production account. Marine GDP does not provide insights into the well-being people derive from the ocean or ocean sustainability. This is insufficient for the accounts to inform how ocean policy is or is not contributing to well-being or whether or not ocean policy ensures a sustainable ocean future. Including the non-market contribution to welfare, which would generally sit in the income, consumption or expenditure account, is important for understanding well-being, even if it is not part of 'economic production'.

The Australian Bureau of Statistics (ABS) has presented headline indicators for the environment, characterising trends in terrestrial biodiversity, the atmosphere and land use for 2006. Yet, for the marine and coastal regions, the ABS (2007) simply states that 'these regions are also important to Australian society and the economy. Many of the ways in which we use the ocean, beaches and estuaries can affect the quality of the ocean's water and the diversity of life within it.' However, no headline indicator is reported for this sector through the program's reporting, which ends in 2012. There are national accounts efforts to track wages in industries that can be identified as ocean-related, such as in Portugal. Other sectors, such as tourism, can be difficult to disaggregate. Furthermore, it is often impossible to tell what fraction of the wage is attributable to various attributes of the ocean. For example, even if beachfront resources were their own category, it would be impossible to tell how much the ocean's biological capital was contributing to wages or revenue without greater survey data that exist in national accounts.

Furthermore, the few attempts to measure income beyond the current boundary (Jorgenson 2018) have not focused on the ocean or have taken place outside the purview of formal national accounts, and often not at a scale sufficient for national accounting.

3.2.2 Balance Sheets, Natural Capital and Supply-and-Use Tables

Balance sheets are essential for national ocean accounting. All 14 countries make an official national balance sheet available online. Six countries include non-produced assets, and Japan and Mexico include non-produced assets that are potentially non-produced ocean assets (Fig. 8.5) (OECD 2019). However, a number of other countries reference programs that might involve natural capital accounting or mea-

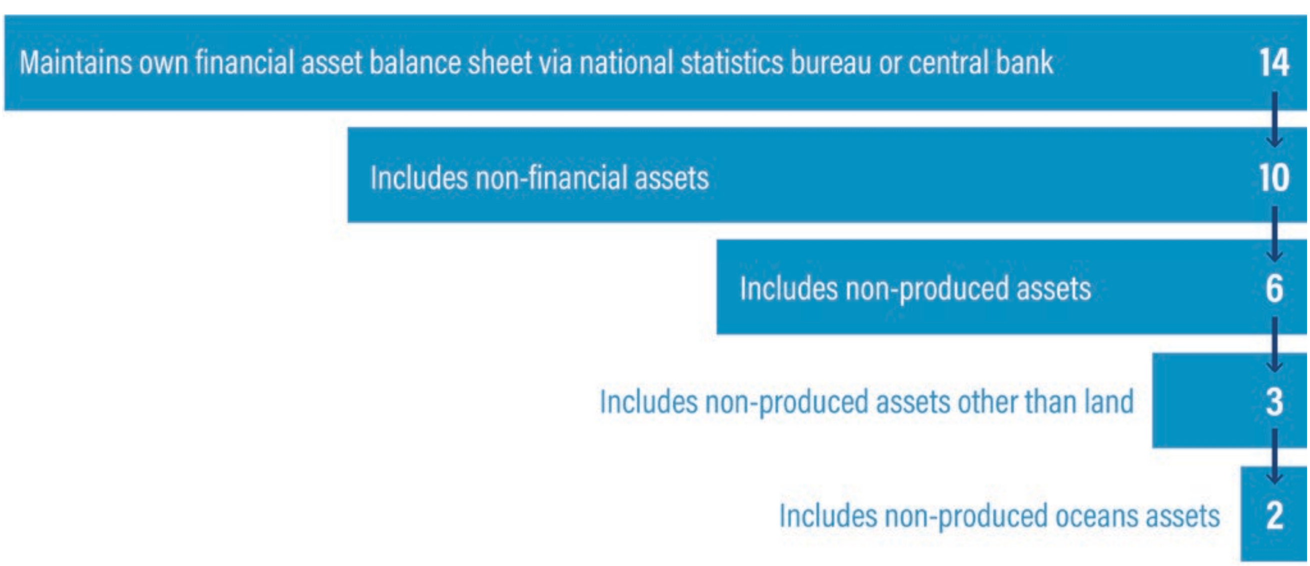

Fig. 8.5 Balance sheets among ocean panel countries. (*Note: Descriptions are not sufficiently precise to classify fully all non-produced assets. There may be some misclassification, but the pattern appears robust to misclassification. Source: Authors tally based on publicly available national count data*)

sure non-produced assets (e.g. Jamaica and Canada). However, these efforts do not appear to make it to the official statistics on the national balance sheet.

Half of the 14 Ocean Panel countries have some form of physical account paired with their monetary accounts—physical production sheets—for these aggregated sectors, but we found no complete balance sheets with ocean assets. For example, Kenyan fisheries accounts track physical and monetary flows that are disaggregated by freshwater fisheries, marine fisheries and aquaculture. Ideally, physical accounts would be paired with indicators of the quality or condition of the assets on balance sheets. These are typically not included in national accounts but are critical for natural capital accounts and are part of the UN System of Environmental Economic Accounting guidance.

Indicators, such as those for environmental quality, can provide a missing link between physical and monetary accounts. Ocean acidity, for example, can impact oyster biomineralisation, leading to smaller and therefore less valuable oysters (Fitzer et al. 2018). Indeed, these sorts of linkages are similar to those described above about how the condition of a prey fish stock may raise or lower the value of the predator stock. The 2008 System of National Accounts is clear that prices that come from markets include these 'general equilibrium' interactions (European Commission et al. 2009). Price- influencing interactions are also important for 'non- produced' natural asset valuation. Qualitative changes matter in physical accounts of resources and on the asset balance sheet.

Environmental processes, much like income distributions, are often not characterised adequately by a single number. Namibia is the only member country of the Ocean Panel to link environmental indicators such as sea surface temperature and plankton abundance explicitly with fisheries. The ocean transport sector influences regional ocean acidification (Hassellöv et al. 2013). However, for many countries the data for the transportation or commerce sector in supply-and-use (or input-output tables) are not disaggregated by transport mode. As a result, the share of commercial activity that occurs via maritime transportation is not available in the account. The link between ocean transport, regional ocean acidification and seafood product value (i.e. shellfish), is lost due to low data resolution. The greater the aggregation in the supply-and-use tables, the less useful they are for economic modelling and forecasting and the harder it is to link economic activity and biophysical changes in the ocean.

The ability to disaggregate monetary accounts, physical accounts and environmental indicators is important for characterising the overall state of the ocean economy. For some countries or sectors, maritime activity likely comprises such a large share of the sector that disaggregation is unnecessary. For example, mining and oil extraction in Norway is almost exclusively marine.

3.2.3 Satellite Accounts

Ten of the 14 countries have a tourism satellite account. In contrast, only two Ocean Panel countries, Portugal and Canada, have dedicated ocean satellite accounts. Only Portugal's is currently produced by the national statistics office. Portugal's efforts often are promoted as a national ocean accounting example, so it is useful to discuss them in a bit more detail.

Understanding what share of the tourism sector's contribution to the economy is due to ocean-related products and services depends, in part, on which ocean related product and service values are considered. Portugal's ocean account considers 65 different products and services across nine groups. The recreation, sports, culture and tourism group captures a range of activities including recreational and sport boating, cultural events related to the sea, coastal tourism (including state spending on advertising) and imputed rents from second homes on the coast.

Portugal creates a complete set of production, expenditure and income accounts and is able to produce a set of balanced national aggregates for the ocean economy. Portugal includes standard wage and employment data and household consumption information as part of the satellite account. Portugal includes non-produced assets on its national balance sheet, but these do not appear to include non-produced ocean assets.

Portugal's ocean account is one of the most advanced in the world, and is the model for many of the ocean accounting efforts underway. However, its headline numbers address Question 1, and it is less clear that additional effort has been made to address the other types of questions. Of the 65 sectors included, many are only tangentially related to the ocean. For example, shares of 'computer programming, consultancy and related services', 'legal and accounting services' and 'leather and related products' are included in the ocean account. These are industries that can be linked to the ocean but are hardly production from the ocean—Question 2. Using Portugal's 2013 numbers, we find that only 8% of the value added of 'sea products' seems to be clearly from the ocean, with another 34% possibly being from the ocean, as opposed to related industries. Linking industries to the ocean can mislead about the benefits from the ocean. For example, insurance is included in Portugal's ocean account. This is presumably insurance against ocean storms. It seems that, if anything, this is a cost of the ocean, not a benefit. This highlights the need to be clear about the question and enable disaggregation.

3.3 Country Implementation Globally

A growing number of countries are implementing national ocean accounting, with a focus on product accounts (Colgan 2016). Some individual countries or blocs of countries have further developed or expanded the frameworks for their own use. Eurostat's European System of Accounts 2010, for example, provided much of the methodological guidance for Portugal's Satellite Account of the Sea. However, for some countries interest or capability drives a wedge between framework and implementation. Other countries' capabilities and interest enable them to go beyond the international frameworks, providing experience, lessons-learned and guidance for future refinement of frameworks. These countries strive for backwards compatibility with internationally agreed frameworks, as in the case of China (Wang 2016). The guidance in international frameworks is seldom sufficient to address every scenario and provide complete production accounts for a nation's ocean economy, let alone asset balance sheets. In the case of asset balance sheets, it is likely that the lack of availability of guidance and data to create such balance sheets (which do not currently exist for any country's account of its marine economy) is a 'chicken or the egg' problem. Nevertheless, revision of internationally agreed frameworks is critical to avoid issues of interoperability of national accounts and the challenges of double counting (De Maio and Irwin 2016). Separation of physical and economic data also poses a challenge for balance sheets.

Consider the ocean accounting efforts of the United States, China, New Zealand, Portugal, the Netherlands and Australia. The National Oceanic and Atmospheric Administration's *Report on the U.S. Ocean and Great Lakes Economy* divides ocean productivity into six sectors: marine construction, offshore mineral extraction, tourism and recreation, living resources, ship and boat building, and marine transportation (NOAA 2019). Each of these sectors includes direct and indirect ocean production, where indirect contributions can be inferred using tools like input-output tables. Large gains are achievable using data already collected for national accounting or other national statistical purposes. The NOAA Economics: National Ocean Watch explorer represents a reorganisation of employment data from the U.S. Bureau of Labor Statistics that, coupled with imputed sectorial employment to GDP ratios, provides a first-order glimpse of contributions to the ocean economy by sector at the county (sub-state) level within the United States. Simultaneously, the U.S. Bureau of Labor Statistics reports wages in most marine sectors.

Canada divides ocean production into direct, indirect and induced ocean production (Fisheries and Oceans Canada n.d.-b). Direct and indirect production flows may depend on produced and/or non-produced assets.

China's Gross Ocean Product uses 12 major sectors to measure the gross value added of China's ocean economy.[14] Nearly half of this index is coastal tourism, just under 20% is transportation, and marine fisheries account for just under 15%.

New Zealand is a leader producing national balance sheets, but Stats NZ (2018) states, 'The SNA08 [2008 System of National Accounts] conceptually includes a wide range of natural resources beyond those included in New Zealand's accumulation accounts. The omitted natural resources need to be quantified and valued.' New Zealand focuses on land as a non-produced asset, like many other countries. However, New Zealand produces a satellite physical and monetary fish stock account, enabled by New Zealand's broad adoption of individual trade quotas (ITQs) for managing fisheries, which creates a market for the fish asset. Stats NZ claims this is an added benefit of ITQ management (Hammond 2005).

'Natural Capital Accounts for the North Sea: The Physical SEEA EEA Accounts', a pilot project in the Netherlands, represents an advancement towards paired physical and monetary asset accounts. Major headway in this project was achieved by defining boundaries with respect to economic and ecosystem activities and collating and repurposing existing data from Statistics Netherlands and external data sources. The conclusion of the pilot study was that it is feasible to pursue natural capital accounts for marine ecosystems and that it is possible to complete much of the work using extant data sources.

Determining which industries are and are not included in the ocean sector is not the challenge for the methodology employed in China, Canada, New Zealand and most all other countries that produce these aggregate measures, which define industries in a way that can be linked to the International Standard Industrial Classification of All Economic Activities (Wang 2016). However, some countries, such as the United States, attempt to partition at a scale of sub-classification schemes. It is clear that not all countries are making the same decisions, which is why within-country comparisons through time are more salient than cross-country comparisons. It is also clear that the aggregates do

[14] China's Gross Environmental Product index alters the production account boundaries, whereas the Gross Ocean Product is a conventional satellite account produced by China's Ministry of Natural Resources.

not provide sufficient information to evaluate questions of sustainability, but ideally measures of ocean production are comparable through time within a country.[15]

In practice, national ocean accounting remains a somewhat bespoke process. Reporting systems and frameworks have also been developed to either more easily use existing data sources at the country level, address areas of national interest or tackle unique country-specific accounting challenges.

3.4 Supporting Programs and Other Actors

Supporting programs and actors is a broad group of entities only connected by their interaction with at least two of the following: the ocean, countries and the formal internationally agreed frameworks for national accounting. Some groups exist to support their member countries and the suite of methodologies and other tools available to them (e.g. OECD, EU). Others have specialised agendas, such as the World Wildlife Foundation or the Great Barrier Reef Foundation. There are groups that aim to share information and expertise around national accounting among business and practitioners in a 'bottom-up' approach, such as the Capitals Coalition or the London Group on Environmental Accounting. There are finance organisations or country supporting partnerships aimed at developing technical capacity, such as the World Bank's Wealth Accounting and the Valuation of Ecosystem Services (WAVES), the UN Development Program's Biodiversity Finance Initiative (BIOFIN), the European Union's Mapping and Assessment of Ecosystems and Their Services and the partnership of the UN Development Programme, the Economics of Ecosystems and Biodiversity and the Convention on Biological Diversity (UNEP TEEB CBD).

These organisations can function as filters or mediators through which countries engage with central international accounting frameworks. Finance and capacity-building organisations like WAVES (https://www.wavespartnership.org/) facilitate development of institutional capacity. Regional supporting organisations like Partnerships in Environmental Management for the Seas of East Asia (PEMSEA) can provide management solutions and partnerships for promoting sustainability among groups of countries.

[15]Cross-country comparisons are challenging, as Jorgenson (2018) explains. Market exchange rates can be misleading, which leads the World Bank to produce purchasing power parity conversions. However, it is unclear how purchasing power parity can be developed when some goods or income-generating services are not market-based.

Many of these organisations solicit academics, other NGOs and outside consultants to produce fact-finding, momentum-building reports or both that address gaps or areas of interest in national accounting practices for the marine sector. Alongside these reports exist evaluations, methodologies and estimates produced in peer-reviewed academic literature. Below, we address a few of these reports and studies produced by noncountry organisations as they pertain to production accounts, balance sheets and income accounts. This is not an exhaustive survey, but it represents the use and misuse of national accounting for the ocean. We provide illustrations of three types of reports, though the categories are fluid: motivating reports, illustrative reports and policy reports. Decision-makers interested in the performance of the ocean or blue economy should

- make sure the results align with the question the decision-maker is asking;
- prefer a repeated series of reports or reports that document changes and enable disaggregation; and
- assess the agenda of the report's producer and if the claims align with the statistics and data used.

National statistics offices should pay attention to these reports to understand the information demands, especially demands that national statistics offices might be failing to satisfy. Jorgenson (2018) suggests this is a substantial problem once one moves beyond production questions.

3.4.1 Motivating Reports

Most people have seen at least one of the motivating reports. The thesis of these reports is that the ocean is important, the ocean provides opportunity or the ocean is valuable. These reports at times misuse national accounting because of the belief that GDP or some economic number implies importance. Others, like the UN working group, the World Bank and other stakeholders' high-resolution Blue Economy report, highlight the importance of ocean resources for least developed countries and small island developing states without promoting a single metric or calculating an aggregate value. The Blue Economy report characterises the 'blue economy' by assembling a diverse reference list of sectors and constructing a case for their importance. It advocates expanding the boundary of the ocean economy beyond fisheries to include the extraction of marine non-renewables, commerce and trade, and indirect contributions to economic activities. The report provides a framework for mapping *ocean-related* activities to sectors and then to major drivers of demand and growth in these sectors. The **headline policy recommendation of the Blue Economy report urges countries to accurately value the contribution of natural ocean capital to welfare to better guide policy decisions**

and trade-offs. This means focusing on net income and balance sheets, not GDP. Many countries have taken up this challenge.

Other motivating reports attempt to produce oneoff 'large number' monetary valuations of ocean environments to attract attention. For example, the 2015 World Wildlife Fund (WWF) report *Reviving the Ocean Economy* argues that 'the future of humanity depends on oceans' healthy living conditions', drawing attention to the crucial point that ocean biodiversity contributes to human well-being (WWF 2015). The report presents an indicator of the annual value generated from the global ocean economy or a 'Gross Marine Product' of ~US $2.5 trillion and a total ocean asset value of US $24 trillion.

Another example is the 2017 Deloitte report on the value of the *Great Barrier Reef, at What Price: The Economic, Social and Icon Value of the Great Barrier Reef*, which provides a headline indicator that the Great Barrier Reef contributes A$6.4 billion to Australian GDP.

These reports should be treated as little more than 'calls to action'. First, because they tend to be one-offs, they provide little useful information about trends, though some reports do look at changes over time. More critical is the risk of their undercutting the message that ocean products and assets are uniquely important, and sometimes irreplaceable. In *Reviving the Ocean Economy* and similar studies, one of the chief methods for computing the total value of gross marine product is rescaling the gross value added from the ocean economy available from G20 countries. Despite countries' use of different sectorial boundaries, it is clear that for most countries shipping, tourism and recreation, and other activities only tangentially related to the biological condition of the ocean contributed the most to the gross value added figures (NOAA 2019). Most of the asset value is transportation, coastal capital and other forms of produced capital. These are important, but do not speak directly to the importance of the biology or 'living conditions' of the ocean.

Assessing the sustainability of the ocean economy requires monitoring changes in the asset values or change in the balance sheet over time, coupled with assessment of the role of biodiversity in net national income, or development of a biological non-produced asset account tracked through time.

The numbers presented in the 2017 Deloitte report imply a gross value added of A$18,354 per square kilometre, given that the Great Barrier Reef covers approximately 350,000 square kilometres. This is almost equivalent to Australian agricultural GDP per square kilometre when dividing official statistics by the total agricultural land area (ABS 2018; Trading Economics n.d.). The report also provides an estimated asset value of A$56 billion, an asset value of A$1606/hectare, right around the median price of agriculture land in Australia (ABC 2018). This would make the value of the Great Barrier Reef equivalent to that of the tenth-largest Australian public company, right behind BHP Billiton. While not trivially small, these numbers are shockingly small in the context of something as unique and irreplaceable as the Great Barrier Reef. Of course, if asset management can be improved, then the value will be lower than expected under optimal or improved management (Fenichel and Abbott 2014).

3.4.2 Illustrative Reports

A second set of reports are illustrative reports. Good examples of these are the World Bank's *The Changing Wealth of Nations* and UN Environment's *Inclusive Wealth Reports* (Lange et al. 2018; Managi and Kumar 2018). These reports illustrate how comprehensive national balance sheets could be used to assess sustainability. However, they do not focus on ocean or blue assets. Moreover, the data used to produce these reports enter in a relatively aggregate form. National statistics offices should be able to do much better. Most academic studies fall into this category as well, where the goal is to illustrate methods rather than to provide regularly produced, definitive numbers.

3.4.3 Policy Reports

The third set are policy reports. These reports would ideally take ocean accounts as their starting point, but historically they have had to generate national-accounts-style data that were not readily available. A good example is *The Sunken Billions: The Economic Justification for Fisheries Reform*, jointly published in 2009 by the World Bank and FAO (Arnason et al. 2009). The report focuses on the contribution of wild marine fisheries to the global economy and the economic production lost due to overfishing and depleted stocks by comparing potential and realised economic benefits. The report models the world's fisheries as a single stock and uses global aggregate data to estimate the production deficit at around US $50 billion per year (in 2004$). This number is similar in magnitude to the 1992 FAO study *Marine Fisheries and the Law of the Sea: A Decade of Change*, which estimated the aggregate production deficit incurred by the world's fishing fleet at $22 billion (in 1989$). Adding in the capital cost, this early FAO report estimated the deficit at $54 billion per year. To put these numbers in context, the estimated gross revenues of the global marine fish harvest in 1989 were $70 billion. The methodology employed a single-stock model to estimate the deficit, leaving many questions open about the spatial heterogeneity of the operating deficit.

The follow-up, *Sunken Billions Revisited*, followed the same approach as its predecessor but delved further into the regional analysis to provide more disaggregated impacts and policy recommendations. This study found an $83 billion production deficit for the year 2012. ***Sunken Billions* is a benefit-cost analysis that highlights the potential gains of a policy change. This is not part of most national accounts.** However, robust national accounts would be a good starting point for this sort of analysis.

4 Guidance for a Path Forward

Developing national accounts to guide economic development for the ocean is critical but less daunting than it may seem. Many of the data already exist in national accounts, in government agencies or in scientific databases; the knowledge to build the connections exists, but it is dispersed throughout government, academia, business and NGOs. As we have seen, many countries already produce reports that are or are nearly marine GDP. These reports, however, make clear that GDP is about means, not about ends or sustainability. The ocean's biophysical assets are valuable. But marine GDP calculations do not and cannot measure this. Even as a measure of income, the dominance of shipping and coastal development in these sums could obscure the mostly unmeasured non-market income components. Academics and international organisations, such as the World Bank, do not have access to the fine-level data that most countries' statistics offices can access. Therefore, **country level statistics offices need to develop a sequence of accounts reflecting Fig. 8.1**, then partition out the ocean sections with reporting tools that enable adjustments to the ocean economy boundary. Changes in the country's ocean balance sheet are the country's 'ocean wealth index' for assessing the sustainability of blue development.

Experience implementing the System of Environmental Economic Accounting (United Nations et al. 2014) shows that even incomplete accounts can inform policy. For example, countries have started water accounts with available data on municipally supplied water. Subsequent revisions have added estimates of household, industrial and other use. Incomplete accounts highlight critical areas of data gaps and provide bounds useful for making policy decisions. It is likely that in the near future many more data sources will be available to populate ocean accounts. Indeed, this is a clear case of needing to plan for the data of the future rather than plan around existing data or the data of the past. With this in mind, we offer crosscutting Opportunities for Action for developing national ocean accounts.

4.1 Four Principles of Accounting for a Sustainable Ocean Economy

1. Ask multiple questions and expect multiple answers, especially questions about income and sustainability (balance sheets) in addition to production. This means that the impacts of policies and decisions about the ocean economy should be evaluated based on at least three indicators: income, production and ocean wealth.
2. Build on the existing structure of the System of National Accounts and System for Environmental-Economic Accounting so that ocean accounts are compatible with existing national accounts, and with international statistical standards.
3. Avoid an overreliance on GDP, which is not an indicator of either sustainability or the societal ends of economic activity. Do not use a hammer when you need a wrench.
4. Lead or contribute to collaboration efforts to improve national ocean accounting systems, including global partnerships to share best practices and build capacity. Such efforts will likely involve creating new integrated data management systems for ocean accounting and other purposes.

4.2 Crosscutting Opportunities for Action for Developing Credible Ocean Accounting

Eleven general crosscutting Opportunities for Action support the implementation of these principles, with additional detailed Opportunities for Action in the areas of physical measurement and valuation:

1. National statistical offices, in partnership with marine agencies, need to develop a complete sequence of national ocean accounts: product, income, balance sheets and supply-and-use tables. This should be achievable by 2025. It is important to aggregate these to a few key headline indicators (Fig. 8.1) and be able to disaggregate to examine specific sectors and constituencies nested within the ocean economy. The sequences of accounts provide a commonly agreed set of facts about the ocean and its relationship to human benefits. This is the starting point for ocean policy discussions.
2. Countries need to be able to track their own progress through time. Cross-country comparisons are of secondary importance and substantially more challenging to make.

3. Leadership needs to ask the right questions. National ocean accounts are only useful if national leaders use them to ask questions about the state of the ocean system and ocean economy. This needs to start now. Information on ocean income and changes in the ocean balance sheet, in addition to ocean GDP, needs to be considered in the decision-making process.[16] If asking for a hammer when you need a wrench is not helpful, worse is to then use the hammer to drive in the bolt. That aptly describes what is currently being done with GDP with respect to economic well-being and sustainability.
4. Avoid one-off accounts or reports. National ocean accounts increase in value the longer they are kept and the more frequently they are updated. The value of national ocean balance sheets may take years to fully materialise, but they would greatly enhance a country's ability to make decisions compatible with sustainable development.
5. The sequence of ocean accounts needs to be a structured compilation of consistent and comparable information concerning marine and coastal environments, social circumstances and economic activity. Standardisation enables a degree of third-party verification.
6. Ensure the compatibility of ocean accounting efforts with international statistical standards and approaches, mainly the System of National Accounts (SNA), the System of Environmental Economic Accounting (SEEA) and also other broadly accepted initiatives, such as those reviewed by Jorgenson (2018) (UN Stats n.d.-a; SEEA n.d.).
7. Ensure the compatibility of ocean accounting efforts with the 10 Fundamental Principles of Official Statistics endorsed by the UN General Assembly in January 2014. These principles were designed as a reference point to ensure that official statistics are fit- for-purpose given their critical role in policy decision- making in support of sustainable development and securing public trust in governance (UN Stats n.d.-b; UN-ESC 2013).
8. National governments should ensure that their national accountants, economic analysts and marine scientists participate in the workshops organised by the UN Statistical Division and associated organisations for developing ocean accounts. This helps to maintain standards and increase credibility. Furthermore, these international organisations need to evolve to provide a degree of third-party verification of accounts coupled with capacity-building assistance.
9. National statistics offices should use interactive dashboards (e.g. Fig. 8.3) for ocean account reporting. Ocean accounts need to address a variety of questions broader than Questions 1–6. Therefore, it is important that users have the ability to explore the data, aggregate and disaggregate sectors and groups of people, alter the account boundaries and access ethically acceptable disaggregation by digital means.
10. National leaders need to take the time to 'play with and explore' these dashboards to learn about the state of the ocean economy. This recommendation is intended to empower decision-makers. In the past, such dynamic structures were not feasible and would have required volumes of reports that no decision-maker had time to read. Old print media required statisticians to make decisions to generate 'hard copy'. This constraint is vanishing rapidly. New data-management and visualisation software is allowing these changes to be made through a user-friendly interface in real time, which allows the important political decisions to be shifted back to the policymakers and away from national statisticians and scientists. Corporations are already shifting to interactive dashboards for decision-making. National governments need to do so as well. This transition requires decisions by leaders to dedicate funds in national budgets for upgrades to national account reporting.
11. Governments need to invest in data architecture and engineering at levels surpassing global multinational companies. These investments are necessary to connect fine-scale data about the marine environment with detailed economic data into supply-and-use structures and other data structures for national accounting and forecasting the ocean economy. These investments should build on existing Earth observation programs when possible. Investment must also include investments in people. Hardware and software alone will not solve the problem.

4.2.1 Know the Condition of the Ocean

- National statistics offices need to work with marine scientists, agencies or organisations to identify marine data and audit their feasibility for use in national accounts.
- Direct digital pipelines need to be developed from marine agencies to national statistics offices without first aggregating. For example, fish stock assessment data should be matchable to valuation data. Surveys conducted by marine agencies, such as fishing log books, need to be accessible to national statistics offices. There are confidentiality issues with such data, but many national statistics offices already access micro-level tax data. Safeguards and appropriate regulatory frameworks for data privacy, anonymisation and use need to be put in place.
- National accountants and country scientists need to assemble physical account measurements to provide

[16] Some national statistics offices produced these or similar indicators in the past but stopped because they were not used.

easy-to-use data structures for prospective economic forecasts such as regional development analyses, general equilibrium models that include feedbacks with the environment (Kerry Smith 2012) and other forms of integrated assessment modelling (Kling et al. 2017). Decision-makers need to ask how non-market effects are treated in economic analyses.

- Not all data need to be produced locally. There is an increasing role for remotely sensed data. Various national governments are increasingly creating and using fine-scale global marine data sets derived from satellite-based sensors. Countries should consider using these data, but it would also be good for multiple nations or coalitions to produce and certify some of these products to reduce duplicate effort. This is not limited to geographic data but also includes physical, geo-chemical and biological data. Data should be assembled on a regular basis at reasonable time scales.

4.2.2 Use Valuation to Understand Economic Interconnections and Trade-Offs

Valuation is critical in order to enable analyses in comparable units and to analyse explicit or implicit trade-offs. Furthermore, valuation forces society to 'look in the mirror' and observe the trade-offs being made. Valuation is not without controversy. Part of the confusion is that valuation is often misused in an attempt to estimate a 'total value' where the thought experiment asks what society would be willing to pay to avoid losing the natural asset or ecosystem service completely. This is fundamentally different from the value added of a production process connected to the ocean, the additional economic well-being individuals experience with a change in the condition of the ocean or the expected change in net present value available given of an ocean natural asset under a specific management policy. These last three questions align with the types of questions one can query of national account data. National statistics offices should focus on these latter three questions, and decision-makers should interpret valuations as such.

- Heads of government need to start asking about changes in ocean balance sheets that contain produced and non-produced assets today. National statistics offices need to start producing these balance sheets. It is also important to accurately value produced marine capital. Some forms of produced marine capital, such as ships, are relatively easy to account for. There are market prices, but even some forms of marine produced capital are challenging, such as port infrastructure. For others it is important that national statistics agencies use methods to impute value (Hulten 2006) for produced and non-produced assets in general equilibrium systems (Carbone and Smith 2013; Fenichel et al. 2018). Including ocean non-produced natural assets on the balance sheet is important for two reasons:
  - The ocean's natural capital, non-produced assets, stores substantial wealth that is important for a sustainable ocean economy.
  - The valuation of produced ocean assets is influenced by the condition of ocean natural assets. Excluding natural assets runs the risk of mis-valuing produced ocean assets. For example, the value of fish-processing machinery may be influenced by a processor's ability to secure fish or the value of port infrastructure may depend on barrier islands and other natural protective features. Rouhi Rad et al. (2019) shows that the value of the locks in the Panama Canal, which transit close to 5% of global marine shipping, increases with the amount of water in the canal system during the dry season. Complementarity between natural and produced capital could be common.
- Heads of government and other policy leaders should encourage their national statistics offices (NSOs) to incorporate a broad definition of income to address ends because NSO heads are already engaging in these conversations. This should be in addition to a more restricted money income boundary to balance with produced means. The SNA's income boundary is governed by the production boundary (European Commission et al. 2009). This is a shortcoming, because 'measures of welfare are needed to appraise the outcomes of changes in economic policies and evaluate the results' (Jorgenson 2018). Irving Fisher (1906) defined income as services, and the ocean provides substantial services outside of the market economy. These services are also income.[17] Heads of state should start asking heads of NSOs about revisions to capture these sources of income.
- The international national accounting community should provide technical guidance for country-level statistics offices on welfare measures beyond the current income boundary. This guidance should adapt the vast literature on non-market valuation intended for benefit-cost analysis (e.g., Freeman 2003) and be developed to make use of available micro-data. An important issue related to research is that valuation for national accounting needs to focus on existing or agreed-to institutions, even when these are 'inefficient'. This means care must be taken not to use hypothetical changes in management to compute

[17] The SNA makes the argument for excluding non-market income because the information is not useful for monetary policy. However, national accounts are used for much more than monetary policy.

potential changes in value. It is unreasonable to assume 'optimal' management that is inconsistent with prevailing institutions (Fenichel and Hashida 2019). There is a need to map into actual situations existing valuation methods that focus on potential changes, and to develop benefits-transfer libraries (Boyle et al. 2010).

- The accounts should be used to track progress over time, provide data to evaluate past programs and provide the starting point to analysis of alternative ocean policies. Furthermore, aggregate income statistics need to be able to be disaggregated because income and consumption is where equity is reflected (Jorgenson 2018). There is a need to know what money and non-money income stems from the ocean and to whom.

5 Conclusion

When the Wright brothers took flight in 1903 there was no dashboard. As planes became more complex, gauges and indicators were added. Today, nobody would fly on a plane where the pilot only looked at the air speed. It is unfathomable that the joint economic- physical-biological system of the ocean economy is not at least as complex as an airplane. So how can we expect to develop a sustainable ocean economy, the 'blue economy', with a single indicator, ocean GDP?

The simple answer is we cannot. In this Blue Paper we have discussed **a system of national accounts with multiple indicators** and how they should be applied to the sustainable ocean economy. We have emphasised the need to develop the underlying data structures to anticipate unintended consequences of decisions that may increase production in the present at great cost to the opportunities afforded to future generations, or increase production to a select organised few at a cost to the great disorganised many. The opportunities for the ocean to spur production bring this challenge into focus. On the one hand, the OECD (2016) and others have raised the prospect of the ocean's spurring new means of production. On the other, there is great concern over the future of biophysical ocean processes, as highlighted in SDG 14 on 'Life under Water'. Without an accounting system capable of producing multiple, well-designed indicators it is unclear if these causes align, compete or simply coexist. Multiple indicators are needed, and the existing ***system*** of national accounts is a good place to start to look for them.

While terrestrial asset accounts capture the greatest fraction of the human population and manufactured capital, the sphere of influence that ocean assets have in governing global environmental systems (e.g. climate and weather) is unmatched. In addition to direct economic activities involving ocean resources, the ocean links the impacts of climate warming at the poles to critically important sources of food via ocean acidification, the resilience of infrastructure via sea level rise and many other facets of the global economy via interactions with atmospheric processes and weather events. Measuring the ocean economy in national accounts requires addressing the full suite of challenges of developing measures to determine if society is meeting the needs of current generations without compromising the ability of future generations to meet their needs. Using national accounts to measure 'ocean development' can be a model for using national accounts to measure 'sustainable development'.

Acknowledgements The authors are grateful for input from Jeffery Adkins and Christopher Lauer of the U.S. National Oceanic and Atmospheric Administration, Rebecca Blank of the University of Wisconsin, Ted Morgan of the U.S. Bureau of Economic Analysis, Jane Lubchenco of Oregon State University, the UN Statistics Environmental Economic Accounts Section, Alessandra Affieri and Bram Edens, Carl Obst, participants in the 2019 Glen Cove SEEA Conference and Charles Colgan. The paper's technical reviewers, Linwood Pendleton, Hugh Possingham, Michael Vardon and Rintaro Yamaguchi, as well as its arbiter, Adrien Vincent, all provided helpful technical comments. Highlights

- The ocean economy is currently at risk from multiple stressors, ranging from overextraction, direct habitat damage, pollution and climate change. Continuing with this 'business-as-usual' trajectory poses great risks to the health and integrity of the ocean and therefore to the world's population.
- Ocean finance can play a critical role in changing this trajectory and helping to achieve a sustainable ocean economy (SOE).
- However, current investments fall well below what is needed to transition to a SOE. In the last 10 years, less than 1% (US $13 billion) of the total value of the ocean has been invested in sustainable projects through philanthropy and official development assistance.
- Of the public and private sector investments already committed, a significant proportion are targeted at larger-scale economic activities that are often unsustainable and counter to the delivery of Sustainable Development Goal 14.
- To achieve a SOE, this sustainable finance gap needs to be closed. To close the gap, improved SOE policies, incentives, tools and approaches will need to be designed and established, knowledge and innovations proactively shared and capacities built to address environmental, social and economic risks, mobilise new forms of finance and redirect mainstream finance towards a SOE that empowers local people and supports responsible business and long-term societal goals.
- Several barriers are preventing the growth in financing of the SOE. Capacity constraints, data challenges, regulatory gaps and a lack of transparency all create a riskier enabling environment and negatively affect large-scale private sector finance. Most notably, complicated tenure and ownership and a lack of monitoring and enforcement increase the risk profile.

J. Lubchenco, P. M. Haugan (eds.), *The Blue Compendium*, https://doi.org/10.1007/978-3-031-16277-0_9

- Projects lack the appropriate deal size and risk-return ratios to match capital, making scaling and replication more complex than in familiar terrestrial sectors. There is a lack of familiarity with ocean-based project development and financing by both the business and finance sectors. Capacity gaps, particularly in developing countries, exist regarding how to access sustainable ocean finance.
- This paper finds that many potential actions can be taken by the private and public sectors to remove existing barriers and open the pipeline to investment in a SOE.
- The paper proposes priority opportunities for action to remove existing barriers and open the pipeline to investment into a sustainable ocean economy, including:
  - Adopt clear principles to redirect mainstream finance towards a SOE.
  - Create a supportive and inclusive enabling environment.
  - Proactively strengthen and scale up the pipeline of investible projects.
  - Explore new financing mechanisms and tools.
- Achieving a robust ocean finance supportive of a SOE requires that the public and private sectors create and better mobilise a full suite of financial tools and approaches, insurance, and fiscal and market incentives as well as strengthen key aspects of the enabling environment. These actions will support the transition to an ocean economy that is sustainable and inclusive by making the benefits it generates available to all, especially women, youth and marginalised communities.

1 Introduction

The ocean covers more than 70% of Earth's surface and plays a crucial role in providing ecosystem goods and services that sustain life and support the well-being of billions of people worldwide (Teh and Sumaila 2013; FAO 2018; Hoegh-Guldberg et al. 2019; IPBES (Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services) 2019). The ocean holds many economic opportunities, and many experts are recognising the need for a coordinated and sustainable approach to its use. Ocean finance can play a vital role in supporting sustainable development of the ocean economy by directing investments to sustainable development pathways that minimise ocean risks and maximise social equity, human well-being and environmental health.

The objective of this Blue Paper is to (1) inform about the inadequacy of the current financing of the sustainable ocean economy (SOE), (2) synthesise the barriers and challenges in financing the SOE and (3) propose concrete solutions to overcome these barriers.

Although a globally accepted definition of a SOE is still not agreed upon—with many organisations and entities providing varying definitions (see Appendix A)—refer to the SOE here as: 'development of the ocean economy in a way that balances the needs of people, planet and prosperity'. This is amplified by Winther et al. (2020) as ensuring 'long-term, sustainable use of ocean resources in ways that preserve the health and resilience of marine ecosystems and improve livelihoods and jobs, balancing protection and prosperity'. The size of the ocean economy is valued at an estimated 2.5% of global gross value added and is growing rapidly. In 2010, prior to the COVID-19 pandemic, the Organisation for Economic Co-operation and Development (OECD) projected that the estimated US $1.5 trillion in global gross value added of ocean industries—including fishing, shipping, offshore wind, maritime and coastal tourism and marine biotechnology—would increase to $3.0 trillion by 2030 (OECD 2016). Hoegh-Guldberg et al. (2015) concluded that if the ocean were a country, it would rank seventh in the world in terms of gross domestic product (GDP). This translates into significant contributions to national economies, generating millions of jobs in many countries. Note, however, that many valuations do not account for the ocean's full range of ecosystem goods and services, such as cultural and social values. In order to avoid undervaluation, ocean ecosystems must be valued as critical natural capital that underpins the vast public goods and ecosystem services they provide (Fenichel et al. 2020).

It is highly likely that COVID-19 will negatively impact this estimate (OECD n.d.), especially for the shipbuilding and tourism sectors of the ocean economy. However, the net effect of COVID-19 is not a given since governments worldwide are spending billions on short-term measures to prop up their economies in the face of the pandemic (Vivid Economics 2020).

The ocean economy is currently at risk from multiple stressors, ranging from overextraction, direct habitat damage, pollution and climate change (Hernández-Delgado 2015; Gaines et al. 2019; IPBES (Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services) 2019; IPCC (Intergovernmental Panel on Climate Change) 2019).

Continuing with this 'business-as-usual' trajectory poses great risks to the health and integrity of the ocean and therefore to the world's population, especially the future well-being of hundreds of millions of people in coastal and island communities. These risks undermine the 2030 Agenda for Sustainable Development and, in particular, the Sustainable Development Goals (SDGs) focused on 'life below water' (SDG 14) as well as others, including 'no poverty' (SDG 1), 'zero hunger' (SDG 2), 'decent work and economic growth' (SDG 8) and 'climate action' (SDG 13) (Wright et al. 2017). To change this trajectory, it is imperative to build ocean resilience and minimise ocean risks by restoring, protecting and effectively managing human use of and impacts to ocean ecosystems. Nevertheless, the bulk of investments in the ocean economy have been directed not at transitioning to a SOE but rather at large-scale infrastructure, energy, transport, commercial fisheries, aquaculture, biotechnology and tourism (Vivid Economics 2020).

The costs for not conserving and sustainably using the ocean are high. For instance, invasive species are estimated to cause $100 billion in economic damages to infrastructure, ecosystems and livelihoods each year (OECD 2017a). The total estimated cost of coastal protection, relocation of people and loss of land to sea level rise is projected to range from about $200 billion to $1 trillion annually by 2100, depending on the increase in sea level (0.5–1.0 m). Already, it appears that a 1-metre sea level rise is more than likely by the turn of the century (IPCC (Intergovernmental Panel on Climate Change) 2019). Noone et al. (2013) state that in the absence of proactive measures to mitigate climate change, the cost of damage to the ocean could be an additional $322 billion a year by 2050. The 2019 *IPCC Special Report on the Ocean and Cryosphere in a Changing Climate* (IPCC (Intergovernmental Panel on Climate Change) 2019) and Gaines et al. (2019) both report significant impacts of climate change on the ocean economy.

Despite the huge costs of inaction and the substantive investments in the ocean economy, current levels of investments in the 'sustainable' ocean economy are inadequate (Fig. 9.1). Although an estimated $8 billion from philanthropy and $5 billion from official development assistance (ODA) were invested during the last 10 years (de Vos and Hart 2020), this level is insufficient to drive the change needed to achieve a SOE. Most significantly, there is limited finance available to achieve the restoration, protection and sustainable management of the ocean—to ensure the building blocks for achieving a SOE are in place (Fig. 9.1). Evidence from the general conservation finance literature indicates that the ocean finance gap is most likely very high. Huwyler et al. (2014) estimated the gap in conservation finance across all major biomes at $300 billion globally, though the proportion of this relevant to the ocean has not been identified and the financing needs of the SOE extend significantly beyond conservation objectives. Furthermore, it has been estimated that to achieve the global need for conservation funding, investible cash flows from conservation projects need to be at least 20–30 times greater than they are today. Sumaila et al. (2017) report that currently about 0.002% of global GDP is invested in conserving and sustainably using biodiversity, and about 4 times the current level of investment is required to meet conservation needs. Although these estimates are for biodiversity in general, the available data suggest inadequate investments in ocean sustainability. We provide a detailed description of current funding gaps for marine protected areas (MPAs) in Appendix B.

Fig. 9.1 A major gap in ocean finance for supporting a sustainable ocean economy. Note: All figures are in US $. *ODA* official development assistance. Source: Authors. Designed by Patricia Tiffany Angkiriwang

The reasons for the low levels of sustainable financing and investment in SDG 14 and the SOE are manifold, and if addressed, they could result in real and sustained change in the way our ocean ecosystems are utilised and managed. These issues are discussed in this Blue Paper. Section 2 summarises the study method, Sect. 3 provides evidence of current challenges to financing and investing in a SOE, Sect. 4 discusses opportunities for actions that can be taken to overcome these challenges and Sect. 5 concludes.

2 Research Methodology

The methodology consists of reviewing the literature to identify what information is currently available on finance flows for the conservation and sustainable use of the ocean; understanding existing fiscal instruments and financing options, including insurance; and identifying opportunities for how these instruments for a SOE can be scaled up. Available data is compiled from various sources, and key data gaps are highlighted. Examples are used to illustrate good practice. We review and analyze the literature on the use of fiscal instruments to support ocean economic activities and governance. We specifically query the literature to help us understand the types of subsidies, fees and taxes currently applied to the ocean economic sector at different scales and ocean economic activity types, and we analyse how these can be re-designed and re-directed to make them support a SOE. We also review current practices of the insurance industry and ask pertinent questions, such as does insurance as currently practiced support the goal of promoting a SOE? What role could insurance have in accelerating the transition towards a new ocean economy? Finally, we review the literature on ocean risk and resilience in the context of the wider discussions about climate risks to identify how insurance products can best help to deliver ocean and coastal finance solutions. Since an important aim of this Blue Paper is to provide the most current information possible, we also rely on the expert knowledge of contributing authors about recent and ongoing initiatives to address current challenges and barriers to financing a SOE.

3 Current Barriers and Challenges to a SOE

Several root causes can explain the current low levels of sustainable financing and investment in a SOE (Fig. 9.2).

3.1 Inadequate Frameworks and Taxonomies

Current frameworks and taxonomies to guide which investments support a SOE—that is, 'blue' investments—do not adequately communicate with each other and are not yet being guided by universally adopted principles. This is necessary to establish a classification system of activities that are considered to comply with the principles of a SOE, thereby guiding investment decisions and development policy towards a SOE. Efforts towards common frameworks and taxonomies are under way (ADB (Asian Development Bank) 2020), with several notable examples outlined below.

3.1.1 The Sustainable Blue Economy Finance Principles

The European Commission, the World Wide Fund for Nature (WWF), the European Investment Bank and the Prince of Wales' International Sustainability Unit developed the Sustainable Blue Economy Finance Principles (WWF (World Wide Fund for Nature) 2018). Designed to build on and complement existing sets of principles for sustainable finance, such as the Equator Principles, these 14 principles aim to fill the current gaps associated with a SOE. If widely adopted, the principles could help to positively transform the way in which ocean ecosystems are used and managed.

3.1.2 The United Nations Environment Programme Finance Initiative

The United Nations Environment Programme (UNEP) recently launched the Sustainable Blue Economy Finance Initiative, a platform targeted at the finance, investment and insurance sectors (UNEP FI (United Nations Environment Programme Finance Initiative) n.d.). Adopting the Sustainable Blue Economy Finance Principles as a guiding framework provides practical information on SOE issues and will support the development of more granular guidance. UNEP works with financial institutions to incorporate environmental, social and governance (ESG) issues into their business principles and to integrate sustainability principles into financial market practices. This is done through frame-

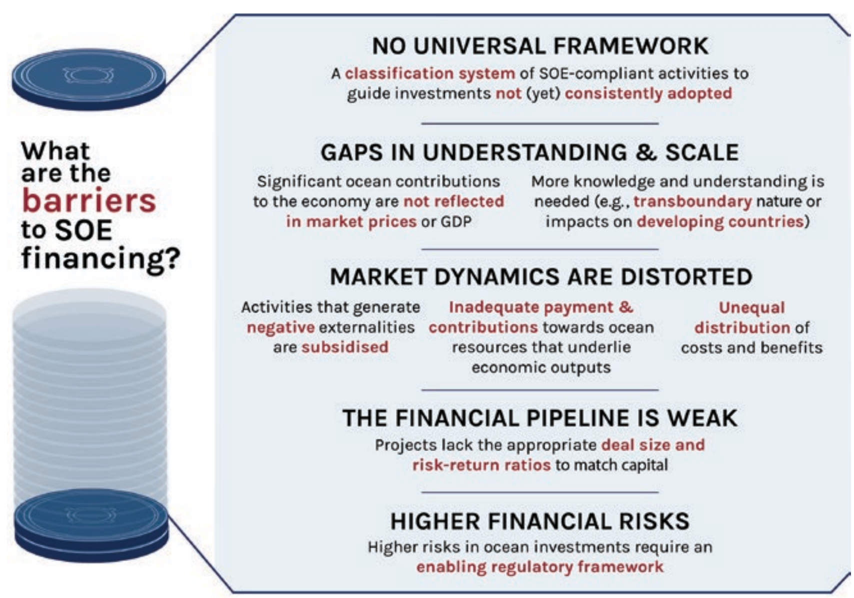

Fig. 9.2 Barriers to marshalling adequate funding for a SOE. *GDP* gross domestic product, *SOE* sustainable ocean economy. Source: Authors. Designed by Patricia Tiffany Angkiriwang

works such as the Principles for Sustainable Insurance (PSI), the Principles for Responsible Banking and the Principles for Responsible Investment. Other complementary sectoral principles include the Principles for Investment in Sustainable Wild-Caught Fisheries (EDF, Rare/Meloy Fund, and Encourage Capital 2018) and the Poseidon Principles (Poseidon Principles 2019) aimed at the shipping sector.

3.1.3 The European Union Taxonomy

The European Union (EU) taxonomy (European Commission 2020)—which includes a blue component—is the first to develop such a framework. It is likely that this taxonomy will significantly influence the creation of a common global taxonomy, which will be required to standardise decision-making across global markets and support the delivery of a SOE. Complementary frameworks are being developed by institutions such as multilateral development banks to guide the screening and selection of ocean investments by defining the sectors, segments and objectives that are allowable.

Notably, the Asian Development Bank (ADB) framework also stipulates rules to help reduce 'blue-washing' (ADB (Asian Development Bank) 2020).

To design guidance that is both ambitious and pragmatic, strong collaboration between a range of actors from the science, policy, non-governmental organisation (NGO) and finance communities will be critical.

3.2 Gaps and Mismatches in Information, Awareness, Capacity and Scale

3.2.1 Inadequate Information and Awareness

Information about the ocean and its economic, social and environmental value is missing or inadequate.

For appropriate and adequate finance to flow into the ocean economy, its overall contribution needs to be understood and measured more comprehensively than it is currently. Notably, humans derive multiple ecosystem services from the ocean whose values are generally not reflected in market prices and are therefore barely captured within the GDP. These include ecosystem services such as those linked to cultural values and benefits as well as natural hazard protection, carbon sequestration and climate mitigation and pollution buffering (OECD 2017a). The values of these services can be extremely high. For instance, Rogers et al. (2014) estimated the carbon sequestration value of marine life in the high seas to be 10 times the revenue generated by high seas fish catch.

3.2.2 Mismatched Capacity and Scale

Ocean finance systems do not yet have adequate capability to match the governance needs of a shared global ocean. Therefore, another prerequisite for finance to catalyse the transition to a SOE is the availability of comprehensive information about the shared and transboundary nature of the ocean. The ocean is ecologically and physically connected across the entire globe, and impacts to the ocean and marine ecosystem services in areas beyond national jurisdiction (ABNJ)—the high seas (Sala et al. 2013), for instance—can have large impacts on marine resources within exclusive economic zones, and vice versa (White and Costello 2014; Sumaila et al. 2015; Popova et al. 2019). Large pelagic stocks, for example, cross the boundaries of several countries, and financing schemes that take this into account are necessary for ensuring that the ocean economy is sustainable.

Given the large scales and complex connectivity of ocean systems, managing ocean resources requires regional and global initiatives. A cooperative approach for maritime security (including climate change and illegal activities), trade and investment, and transboundary ocean resource management (including consideration of ABNJ) are critical to achieving sustainable ocean/blue economy outcomes. While regional sustainable ocean strategies are being developed (Table 9.1), these initiatives need to cover ocean basins currently overlooked by working better together.

Ocean financing is needed that matches the scales of these large and complex ocean governance initiatives. The ongoing negotiations at the United Nations (UN) on the governance of ABNJ may result in new regimes for governing these areas and impact the kind of financing instruments that would be needed.

3.3 The Market Dynamics Are Distorted

3.3.1 Fiscal Policies Undermine a SOE

Ocean economic activities that generate negative externalities, such as fossil energy extraction, unsustainable fishing and aquaculture and non-green shipping (i.e., vessels that are not eco-friendly (Lee and Nam 2017)), receive subsidies.

Table 9.1 Examples of regional collaboration in sustainable ocean governance

Source: Authors

Fossil fuel support measures in the ocean economy are common and are in place in most countries (OECD 2019b). The International Monetary Fund estimates that 6.3% of global GDP ($4.7 trillion) was provided as fossil fuel subsidies in 2015 (Fig. 9.1), including uninternalized externalities (Coady et al. 2019). About $35 billion in subsidies is allocated to global marine fisheries alone each year, of which $22 billion is allotted to harmful subsidies (Sumaila et al. 2019). According to OECD estimates, governments spend on average an amount equal to 20% of the value of fisheries landings in support of the sector, amounting to $7 billion per year in the OECD region and reaching an estimated $35 billion worldwide. These harmful fisheries subsidies prop up fishing operations which would otherwise be unprofitable, thereby facilitating excessive fishing capacity which perpetuates the overexploitation of fisheries resources (Sumaila et al. 2019).

A large percentage of fisheries subsidies are currently allocated to large-scale industrial fishing fleets (Schuhbauer et al. 2017), which can make small-scale fishing fleets less economically viable (Schuhbauer and Sumaila 2016). Given the important food security, livelihoods and cultural roles that small-scale fisheries play worldwide (Österblom et al. 2020), public policies should not proactively disadvantage them if the aim is to meet the SDGs, especially SDGs 1–5 and 10 (‘no poverty’, ‘zero hunger’, ‘good health and well-being’, ‘quality education’, ‘gender equality’, and ‘reduced inequality’).

In particular, because relatively more women are small-scale than large-scale fishers (Harper et al. 2020), everything being equal, eliminating and/or redirecting harmful subsidies could improve gender equality by empowering female fishers. This is because most harmful fisheries subsidies go to large-scale fisheries, but women work proportionately more in small-scale fisheries (Harper et al. 2020). Certain subsidy policies, particularly those related to fuel use, also have the potential to disproportionately encourage large fishing operations to increase effort, thereby reducing the catches, food and livelihood opportunities available to small-scale fishers (Martini and Innes 2018).

Beneficiaries Do not Adequately Pay for Access or Management of Ocean Resources

Maritime countries are generating large economic outputs from the ocean economy, but the cost of ocean management is currently not being borne by those exploiting it, including direct harvesters and consumers. Consequently, there is underfunding of effective ocean governance and reviving and maintaining the health and integrity of ocean ecosystems required to sustain the ocean’s economic outputs. Although comprehensive economic outputs are not always fully measured and accounted for, or may not be considered at all (e.g., support for emerging sectors), current figures available indicate that in Australia, the ocean economy is valued at 4.3% of the GDP (AIMS (Australian Institute of Marine Science) 2018). In Mauritius, the ocean economy accounts for over 10% of GDP.

In China, the ocean economy accounts for nearly 10% of GDP and is rising steadily (EDB (Economic Development Board Mauritius) 2020). The fishing sector alone is worth 10% of the GDP in the Pacific Islands region, and this does not include all of the other ocean sectors. In East Asian countries, the ocean economy accounts for 15–20% of GDP (PEMSEA (Partnerships in Environmental Management for the Seas of East Asia) 2009). In the United States, the ocean economy is growing twice as fast as the U.S. economy as a whole (NOAA (National Oceanic and Atmospheric Administration) 2019). Despite the significance of the ocean economy to maritime countries and to the global economy, public investments to ensure that the ocean economy is sustainable are inadequate. For instance, Binet et al. (2015) estimated that Mediterranean countries were facing an annual financing gap of $776.4 million for effective management of marine protected areas in the Mediterranean (Appendix B).

The private sector also benefits from, as well as impacts, the ocean, but it generally does not contribute sufficiently to investments or initiatives that could improve the sustainability of the ocean economy.

Recognising the need to diversify funding sources and increase blending, the 2015 Financing for Development conference in Addis Ababa encouraged the use of different streams of funding to meet global challenges and the SDGs. ‘Turning billions into trillions’ requires mobilizing private finance alongside public capital to achieve sustainable outcomes. However, the scale of current financial flows is insufficient mainly because private finance is constrained by risk-return requirements (Appendix C), and the volume of public sector and philanthropic finance is inherently limited.

3.3.2 An Unequal Distribution of Costs and Benefits

Access to ocean finance is limited and not well understood by potential recipients, especially in developing countries. Österblom et al. (2020) found that ocean resources and sectors are ‘rarely equitably distributed’, and many of their benefits are captured by a few. At the same time, most of the costs from ocean- based economic activities, such as the environmental impacts from pollution, are borne by women, youth and marginalised communities. Women are particularly disadvantaged because they face inequity worldwide (Österblom et al. 2020). Further, the lack of enabling conditions in many developing countries means that access to finance is more limited to begin with, and it is not always fully understood by potential recipients.

The inequity identified by Österblom et al. (2020) results from the provision of subsidies to the fossil fuel sector to the tune of $4.7 trillion globally, or 6.3% of global GDP, in 2015

(Coady et al. 2019). Such subsidies to big business only serve to increase inequality, which ultimately leads to the unfair distribution of ocean economic values and benefits to small-scale actors, women and minority groups (Österblom et al. 2020).

Clearly, existing inequalities need to be solved so that the ocean economy can help reduce these inequities around the world. Österblom et al. (2020) make the important argument that promoting equity, both within and between countries, is integral to a SOE. Equitably allocating ocean finance to all groups in society (including women and minority groups) is a necessary, if not sufficient, condition for tackling inequality in the ocean economy. New innovative and inclusive investments that are fair and accessible to all members of society are needed.

The potential impacts of expanding the SOE in developing countries are not well captured. Economic inequality between nations has resulted in divergent progress in ocean activities, and this has affected millions of people worldwide who depend on the ocean for their livelihoods and culture. For example, seabed mining and fishing activities financed with capital from a range of countries affect the well-being of people in the developing world when they target, for instance, migratory fish stocks as well as stocks shared with developing countries (Jouffray et al. 2020). It is important that the impacts of these activities at all scales are studied and understood in order to provide the information base to ensure that finance, subsidies and insurance are designed to avoid supporting activities with negative impacts on people and nature.

The available data are too aggregated in existing national accounts and need to be disaggregated more, but this is not an easy task (Fenichel et al. 2020). The current effort by the UN System for Environmental Economic Accounting, which provides a standardised framework to account for environmental protection and management expenditure (and taxes or subsidies) in a manner that is interoperable, is a good effort that needs to be expanded to include ocean finance information more comprehensively (Fenichel et al. 2020). Similarly, the recently established Global Ocean Accounts Partnership has yet to include ocean financial flows in its framework for ocean accounting and capacity-building activities (UN ESCAP (United Nations Economic and Social Commission for Asia and the Pacific) n.d.).

3.4 The Investment Pipeline Is Weak

3.4.1 Limited Availability of High-Quality, Investible Projects

Although there is no shortage of investment capital available globally, the immediate lack of high-quality, investible projects that would contribute to a SOE is a substantial challenge (Koh et al. 2012; UN-OHRLLS (United Nations Office of the High Representative for the Least Developed Countries) 2013; PEMSEA 2015; Fritsch 2020). The majority of sustainable ocean interventions currently require grant capital and do not generate sufficient, if any, financial returns. For the minority of projects that do benefit the ocean and generate a financial return, many are (1) too small to be financially viable once the costs of due diligence are considered and/or (2) too high in the risk-return profile (see more on ocean risk in Sect. 3.5). This is exacerbated by the fact that many sustainable ocean interventions have low potential economic returns (see Appendix C). The good news, however, is that there is a growing number of ocean-focused start-up companies.[1]

3.5 High Risks Without an Enabling Regulatory Environment

3.5.1 Environmental Complexities, Untested Interventions, and Patchy Regulatory and Governance Frameworks

Historically, ocean economic sectors have operated under relatively more unpredictable conditions than those based on land due to the ocean's vast size, physical environment, and comparative lack of ownership and responsibility in the ocean. For instance, the fluid and interconnected nature of the sea means that pollutants and alien species can be carried across much greater distances than on land, thus creating unanticipated impacts in far-off places. Likewise, because water is less transparent than air, remote sensing technology is unable to penetrate deep down to the sea's surface, thereby making it a lot more difficult and expensive to understand what is occurring in the seabed and water column. To overcome the higher risk profile associated with the ocean environment and attract investments and new forms of finance, a number of challenging enabling conditions will need to be addressed. These include capacity constraints, data challenges and higher-risk operating and governance environments. In addition, structural challenges related to investment in the ocean make scale and replication more complex than in more familiar terrestrial sectors (notably, related to tenure and ownership, monitoring and enforcement). To attract large-scale investments, it is critical to find ways to de- risk the enabling environment associated with ocean- based sustainable development projects and activities. De-risking would help catalyse and catapult hundreds of promising sustainable ocean ventures that are already in development globally. The majority of these projects are still in their very early days, are small and are hampered by high risk levels that conventional venture capital investors are unwilling to take.

[1] For example, see Katapult Ocean (https://katapultocean.com/).

4 Opportunities for Action

Here, we suggest a number of ways and means by which the challenges and barriers identified can be removed through actions by governments, private entities and individuals.

4.1 Set Up and Implement New (Shared) Rules, Guardrails and Guidelines

To guide investment decisions and develop SOE policies, it is critical that effective guardrails and guidelines are in place and are widely adopted. An essential element of this emerging SOE finance ecosystem will also be the creation of ocean-based finance taxonomies, which, in effect, will create classification systems of those activities considered to comply with strong principles for a SOE. The definition of a SOE as the 'development of the ocean economy in a way that balances the needs of people, planet and prosperity' is a good working definition that could be adopted more widely in developing such guidelines. Ultimately, the goal should be to ensure that existing frameworks and guidelines bridge and speak to each other and identify commonalities and differences that exist between them. Finally, it is very important to make sure that the frameworks developed are actually implemented.

New standards and metrics need to be developed to encourage and support stronger transparency and consistent reporting across the SOE finance community. Adequate governance, tracking and monitoring of flows, as well as principles and policy frameworks, are needed to ensure that innovative financial mechanisms support the scaling up of blended finance and private funds that are effectively aligned with inclusive and sustainable development.

The Sustainable Blue Economy Finance Principles are a strong set of scientifically and economically sound principles, and wider adoption by private and public entities should be encouraged. The principles are very high level and, therefore, are relevant across many contexts. However, due to the high-level nature of the principles, more detailed guidance and common blue taxonomies are still needed. The EU taxonomy can provide an important first step in creating a common global taxonomy.

The Task Force on Climate-related Financial Disclosures (TCFD) is a private sector–led task force that provides a standardised disclosure framework so that carbon- related assets and climate risks can be better assessed and decisions better informed. Within an ocean context, the disclosure framework can help minimise unanticipated impacts arising from climate change, such as financial losses to coastal real estate and infrastructure resulting from sea level rise. With strong endorsement and leadership, in particular from central banks, uptake has already been high, with 1,068 supporters as of February 2020 and a market capitalization of over $12 trillion (TCFD (Task Force on Climate-related Financial Disclosures) 2020). Building on the success of the TCFD, dialogue is now ongoing around the potential to extend this approach to the risks associated with the loss of nature through a new Task Force for Nature-related Disclosures. These tools will need to align with science and the post-2020 framework on biodiversity.

4.2 Strengthen Knowledge, Data and Capacity in Ocean Health and Finance

This will allow decision-making processes and activities to adapt to new knowledge of the potential risks, cumulative impacts and opportunities associated with business activities. Moreover, information on the status of the natural asset being invested in is required for meeting rigorous criteria during a project's due diligence phase and throughout its life cycle. Consequently, strengthening knowledge is especially pertinent in developing countries, where data and information gaps are key challenges to attracting finance for investments, such as for fisheries reform (Holmes et al. 2014).

At the national level, investing in a coordinated research and development framework is a way to leverage funds and expertise to grow knowledge and human capital and to advance 'blue' technology for ocean sustainability. For instance, Australia's Blue Economy Cooperative Research Centre brings together government, public and private enterprises in the aquaculture and renewable energy sectors to develop sustainable offshore technologies to increase Australia's food and renewable energy production. A central focus is investment in higher education and research to increase knowledge and human capital to enable further engagement in a SOE.

SDG 17 on 'means of implementation' identifies targets and indicators that can be used to track financial flows for sustainable development. These are broad but nonetheless applicable to a SOE: (1) increasing domestic resource mobilisation, including through international support to developing countries to increase capacity for tax and revenue raising (17.1); (2) mobilising additional financial resources for developing countries from multiple sources (17.3); (3) assisting developing countries to attain long-term debt sustainability (17.4); and (4) achieving the target of 0.7% of gross national income to developing countries as ODA.

A recent tracking tool launched in 2019 by the Our Ocean conference, which also records monetary commitments to ocean conservation and sustainability, is beginning to fill this need (Our Ocean 2019). The OECD is developing estimates of financial support provided to the SOE, especially with respect to the role of ODA and blended finance in supporting sustainable ocean activities, and the finance flowing from the use of economic instruments (such as fees, taxes and charges). Finally, the philanthropic- and grant-funding tracker FundingtheOcean.org is seeking to shed greater light on the size of this source of finance.

Efforts should be made to more consistently and comprehensively monitor and report on finance for the conservation and sustainable use of the ocean, across both the public and private sectors. These efforts should involve better tracking and monitoring of financial flows for biodiversity, which cover finance for both terrestrial and ocean ecosystems (OECD 2019a). Countries should—individually and regionally—invest in data and analysis more generally. Government budgets need to be able to track spending on ocean-based sustainable development. Developing ocean data architecture at sufficient granularity will support adaptive management to assist with ocean health and social equity and will help private investors have sufficient information to make key investment decisions. It will also help local entrepreneurs and support good business plans and practices.

National ocean accounts are a major sub-component of the data infrastructure required. The integration of environmental and economic information through a sequence of ocean accounts is one means of improving the data situation highlighted here. For example, the time series of financial flows can be correlated with ecosystem changes within an integrated national accounting framework (Fenichel et al. 2020).

4.3 Strengthen the Enabling Environment, Increase Inclusivity and Correct Market Distortions

4.3.1 Strengthen the Enabling Environment

Effective and stable regulatory and policy environments will do a better job of attracting investment. To maintain and potentially increase the flow of economic benefits from the ocean economy, governments need to continuously provide a supportive enabling environment. Governments and multilateral agencies have critical roles to play, therefore, in creating attractive financing conditions by reforming policies and creating regulations that strengthen the sustainable management and governance of natural capital and facilitate and incentivise social enterprise and new forms of capital (UNDP (United Nations Development Programme) and GEF (Global Environment Facility) 2012; Morgan and GIIN (Global Impact Investing Network) 2014; Whisnant and Reyes 2015). This might include national policies that secure tenure and establish robust enforcement mechanisms in the fishing sector (FAO (Food and Agriculture Organization of the United Nations) 2013) or that support technology transfer and incentivise renewable energy (Thiele and Gerber 2017; IRENA (International Renewable Energy Agency) 2018). Ocean policymakers and managers should provide greater clarity regarding their policy objectives and approaches and maintain a high level of transparency and consultation with stakeholders at all levels.

Investing in improving and streamlining policies—such as those related to (1) transitioning shipping to become more green; (2) building renewal energy infrastructure; (3) nature-based solutions, such as the effective protection of habitats and ecosystems (e.g., coral reefs and mangroves) that provide essential ecosystem services (including coastal protection and carbon sequestration); (4) supporting multi-sectoral collaboration; and (5) the implementation of marine spatial planning to reduce user conflicts and ensure that cumulative impacts of activities do not exceed the carrying capacity of the ecosystem—would be an excellent way to improve the enabling environment.

4.3.2 Increase Inclusivity

Given the importance of small and medium enterprises (SMEs) to portfolio development, governments should also create conditions that provide access to financing, savings, micro-insurance and other services (Grace and van Anrroy 2019). Sovereign insurance products can also substantially improve the risk profile of projects.

Improved disaster and shock-related insurance, such as the Caribbean Catastrophe Risk Insurance Facility, is also critical to strengthen private investor confidence.

Other factors limiting ocean finance include the lack of intermediation capacity and transition capital.

Capacity building, training and tertiary education needs to support leaders, managers and local entrepreneurs who can speak both the language of finance and the language of ocean science. National and international organisations can build the capacities in support of sustainable ocean finance through information provision, training and networking.

Building the kind of information needed to attract investments into the ocean economy requires a significant increase in human capacity for acquiring, investing and aligning ocean finance in many developing maritime countries. Effective capacity building in the areas of ocean finance, insurance and the application of fiscal instruments—especially from the international community, such as multilateral organisations or bilateral aid—is urgently needed to support investment for a SOE.

4.3.3 Correct Market Distortions

A resilient ocean economy requires rigorous and comprehensive ocean governance, which is not cheap and therefore needs continuous funding. A greater proportion of ocean economic output needs to be allocated to multi-sector and multinational ocean governance strategies. In addition, market distortions need to be corrected through taxation, the pricing of services and the re-purposing of harmful subsidies to more sustainable and equitable uses.

The mechanisms by which countries could capture such revenue will vary according to the country context and include a combination of domestic taxes, levies, fines, fees and other mechanisms that monetize ocean benefits and ocean impacts. Once collected, these funds could be allocated, in a transparent way to multi-sector ocean governance strategies and marine spatial plans, including management of all significant threats and impacts to ocean health (Appendix D) as determined by the country.

Fiscal (e.g., subsidies, fees and taxes) and non-fiscal (e.g., tradable permits and social norms) incentives should also be deployed to ensure that the effects of negative externalities are eliminated while those of positive externalities are promoted. Environmentally or socially harmful subsidies could be diverted to support the move to renewable energy or related sectors such as sustainable aquaculture (Fig. 9.3).

Market-based incentives, such as certification, can increase the investment potential for projects by providing some assurances on sustainability throughout the supply chain and implementing more transparent monitoring approaches (Lubchenco et al. 2016). Governments again have a role to play in creating stronger incentives for certification, whilst the conservation and development sector will need to provide technical assistance. A key challenge for these products is their accessibility to developing countries. The costs of certification schemes, for instance, are usually high enough to make them out of reach for many developing countries. Also, the reporting requirements for these products may be too demanding for many countries, thereby limiting the ability to scale them up globally.

Environmental fiscal reform (i.e., taxation and pricing measures that can raise revenues while furthering environmental goals (OECD (Organisation for Economic Co-operation and Development) 2006)) provides an opportu-

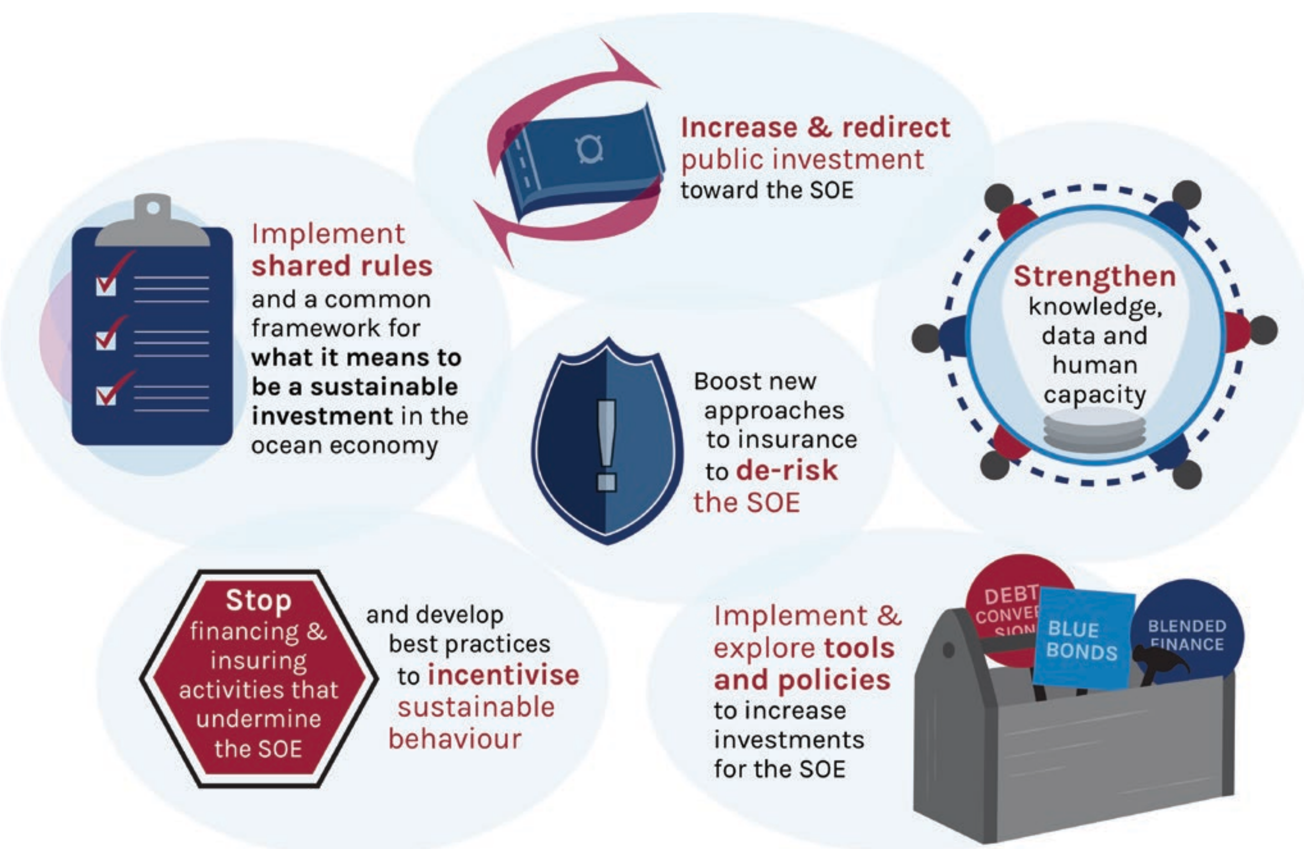

Fig. 9.3 Examples of opportunities for action by the private and public sectors in support of a SOE. *SOE* sustainable ocean economy. Source: Authors. Designed by Patricia Tiffany Angkiriwang

nity to align public and private incentives in the ocean economy. It is also a mechanism to share the wealth of ocean resources more broadly in society. The imposition of taxes, levies and fees on ocean economic activities, in combination with proper management measures—which may include assigning rights to or limiting access appropriately to these resources—can generate revenues to help bring about a SOE.

Auctions for access to ocean resources can help measure their value and generate funds to use for sustainable management and for the benefits of communities at large. The vessel day scheme of the Parties to the Nauru Agreement provides an example whereby vessel days are pooled and then auctioned to distant fishing nations. This ensures that the owners receive the full value of these ocean resources from users. Auctions need to consider community, customary and indigenous rights—for example, by reserving quotas for indigenous or local fishing communities or by establishing license banks and funding mechanisms for community fishing associations (Sumaila 2010).

Existing funds can also be used more wisely. Redirecting harmful subsidies to beneficial uses is an opportunity to catalyse a SOE and improve gender and other equalities (Österblom et al. 2020). For example, international negotiations and mandates, such as the Asia-Pacific Economic Cooperation, the Group of Twenty, SDG 14.6, the World Trade Organization negotiations and the Group of Seven, have called repeatedly to phase out inefficient fuel subsidies and distortive support measures (OECD 2018). This momentum for reform can be channeled into better policies for a SOE.

4.4 Stimulate the Pipeline of Investible Sustainable Projects

Some recent studies estimate the potential economic benefits of transition investments (e.g., WWF (World Wildlife Fund) 2019) and find that the return on investments can be high (Sumaila et al. 2012; Costello et al. 2016; World Bank 2017; Waldron et al. 2020). This opens the opportunity for finance to capture future economic gains in exchange for helping to pay for and smooth the transition. It is unlikely that a single financial transaction or institution will be responsible for bringing a green shipping business or fishery all the way through the policy reform process to environmental and economic sustainability. Yet a variety of mechanisms can blend early stage grant funding and concessional finance from philanthropic organisations and development finance institutions with later-stage capital from the private sector (EDF (Environmental Defense Fund) and Nicholas Institute for Environmental Policy Solutions 2018).

Investments into these kinds of SOE tools and approaches should be considered to be an essential part of any business or nation's risk-reduction and resilience-building plan. In particular, large-scale sustainable—and, more importantly, natural—ocean and coastal infrastructure spending must become a priority to address climate adaptation and build the resilience of the ocean to cumulative impacts. The Energy Sector Management Assistance Program, funded by the World Bank and the governments of World Bank Group members, helps low- and middle-income countries develop environmentally sustainable energy solutions, including offshore wind energy. Importantly, it does this by focusing on addressing poverty and knowledge-creation needs. The private sector can also play a key role in delivering sustainable coastal infrastructure at a local scale. For example, Swimsol, a company based in Europe, set up the first floating solar panels in the Maldives. It achieves a 3–8% rate of return from its investment by engaging in a long-term power purchasing agreement with its clients (either hotels or utilities). Both parties benefit from this agreement because Swimsol's solar power is 10–50% cheaper than its clients' current power generation costs, which are based on diesel generators.[2]

Efforts to deliver debt, equity and grants to key initiatives—including finance for the implementation of the high seas or ABNJ agreements currently being developed by the UN, the next phase of delivery on SDG 14 and the Decade of Ocean Science for Sustainable Development—would be achieved through the broad adoption of a common implementation framework and guidance that aligns with the Sustainable Blue Economy Finance Principles. In this regard, the Ocean Financing Initiative spearheaded by the ADB supports Asia-Pacific countries in developing bankable investments needed to meet SDG 14.

International institutions, such as the Intergovernmental Oceanographic Commission of the United Nations Educational, Scientific and Cultural Organization; the Food and Agriculture Organization of the United Nations; the United Nations Development Programme; UNEP; the OECD; and the United Nations Economic Commission for Africa, as well as international NGOs and others, also have a role in clearly communicating ocean challenges to their respective sectors (IOC-UNESCO (Intergovernmental Oceanographic Commission of the United Nations Educational, Scientific and Cultural Organization), IMO (International Maritime Organization), FAO (Food and Agriculture Organization of the United Nations), and UNDP (United Nations Development Programme) 2011).

By doing so, the impacts of a changing ocean on food, human health, development and the environment are highlighted and can be used to deliver funding strategies. Such dialogues will also present a good opportunity to develop an understanding with the finance community on the scale and

[2]Based on personal communication from D. Schmitz of Swimsol.

urgency of the issues that need to be tackled, of the importance of building in flexibility in investment time horizons, and of including a diverse stakeholder group (from decision-makers to the wider community) in governance and equity ownership.

In addition to addressing specific inequalities related to ocean governance and developed versus developing countries (e.g., capping carbon limits for developed countries; improving fisheries access regimes), developed countries should financially support developing maritime countries with sustainable ocean management. Individual projects and regulations that address specific components of ocean governance are important and necessary, but there is a larger picture of whole-domain ocean governance that requires significant financial capital. In addition, for SMEs beset with problems associated with economies of scale and high transaction costs, business technology and innovation incubators are needed.

4.5 Explore New Financing Mechanisms and Tools

New innovative financing vehicles can be created and launched by the private sector alone or in partnership with public entities in developed and developing countries alike. In fact, the latter can leapfrog to innovative financial instruments in support of a SOE, climate change mitigation and adaptation, and the environment in general. Two recent examples are described in Box 9.1.

Box 9.1. Innovative Financial Instruments

Example 1: Ghana launches funds to attain Sustainable Development Goals (SDGs). On 1 August 2019, Ghana introduced two funds with the objective of attracting finance to the country's effort to achieve the SDGs of the United Nations. The funds known as the SDG Green Fund and the SDG Delivery Fund will be mobilised and managed by the private sector, with government support—a kind of public-private partnership arrangement. The SDG Green Fund is geared towards the provision of clean and renewable energy ('Think Ocean') for use by industry, whereas the SDG Delivery Fund will draw finance to fund climate-smart activities. The funds are expected to raise billions of Ghanaian cedis (US $1 = 5.40 cedis) from voluntary contributions and corporate social responsibility initiatives from the private sector to support the country's efforts towards achieving the SDGs.

Example 2: The Development Bank of Southern Africa establishes a 2-billion-rand (US $142.86 million) Climate Finance Facility (CFF). The CFF will be available to infrastructure projects and businesses that mitigate or adapt to climate change. The finance facility raises capital from both private sector commercial banks and other development finance institutions. It co-funds projects by offering credit-enhancing products in the form of subordinated funding and/or tenor extension. The CFF provides risk mitigation where new technology is involved or the project and businesses are still in a developmental phase. This initiative applies the green bank concept. Green banks have been established in the developed world, but South Africa is probably the first to establish it in the developing world. The goal of these banks is to support the Paris Agreement and the SDGs. A similar example is the Seychelles blue bond. This blended finance combines a World Bank–guaranteed Global Environmental Facility concessionary loan and private investment to support a transition to sustainable fisheries and is implemented through the independent Seychelles Conservation and Climate Adaptation Trust and the national Development Bank of Seychelles.

New financing tools and access to capital markets are needed to act as a positive incentive for sustainable, inclusive and climate-resilient ocean activities.

Innovative mechanisms that bring new forms of finance into the system and are more accessible to communities in developing countries, particularly women, youth and marginalised communities, will need to be created while reducing the overexploitation of ocean resources. These tools can also facilitate effective management and governance while promoting the security of the ocean space in a context of increased access to new ocean resources. In the Caribbean, programs are currently being developed to provide small-scale fishers with micro-insurance policies to protect them from extreme weather risks and to provide governments with parametric policies that would help with the recovery of fisheries after an event with a severity that surpassed an agreed-upon threshold point (McConney et al. 2015).

In Madagascar, a partnership between a commercial seafood exporter and a local research institute produces juvenile sea cucumbers for locally managed sea cucumber aquaculture farms, thereby enabling locals to earn income while reducing exploitation of wild stocks. It is expected that these schemes will also indirectly strengthen conservation and fisheries management.

A noteworthy financial mechanism developed and implemented by Impact Investment Exchange (IIX) and the IIX Foundation USA, known as the IIX Sustainability Bonds (ISBs), explicitly targets the inclusion of women in economic activities. These bonds are debt securities that effectively mobilise large-scale private sector capital by pooling together a basket of high-impact entities (underlying borrowers) into a single structure. These instruments are then sold to impact investors and are paid back over time by the underlying borrowers, with a reasonable rate of interest. These ISBs can be listed on a social stock exchange to add an additional layer of transparency for both financial and impact performance.

Green/blue/climate bonds have to meet investment criteria and accountability requirements (e.g., Green Bond Principles; ESG criteria; and investment principles for sustainable fisheries) and certification to qualify for such labels and ensure the integrity of markets in the investment community. The Climate Bonds Initiative has put in place a number of sector criteria, including for marine energy and water utilities.[3] Other relevant initiatives include the Blue Natural Capital Positive Impacts Framework and the technical guideline for blue bonds (Roth et al. 2019).[4] Innovative financial instruments (e.g., green/blue bonds) are increasingly attractive and can generate new capital for sustainable ocean economic activities built on a healthy and well- managed ocean resource base (Hudson and Glemarec 2012; Miller et al. 2016; Thiele and Gerber 2017; Iyer et al. 2018; Walsh 2018; Jouffray et al. 2019).

Under a debt conversion program, also known as debt restructuring and formerly known as debt-for-nature swaps, negotiations take place whereby a portion of the debt owed to creditors is restructured and converted into agreed-upon initiatives that address, for instance, marine conservation and climate change. The debtors are then obligated to execute the initiatives. As an example, the government of Seychelles entered into a debt conversion program with the Paris Club, with the assistance of The Nature Conservancy (TNC). One of the conditions linked to the debt conversion was the development of the Seychelles Marine Spatial Plan. A new act was also passed to create the Seychelles Conservation and Climate Adaptation Trust, which provides a well-governed funding mechanism for the long-term financing of activities related to the stewardship of Seychelles' ocean resources and blue economy. We suggest that additional debt conversions be designed and implemented to support developing countries to implement ocean governance priorities. This will only be possible with full government commitment due to the comprehensive negotiations and related obligations.

Having the right kind of investment structure is critical to the success of innovative finance mechanisms. Trust funds and endowments, in particular, have a strong track record in assuring long-term funding sources for conservation and development projects (de Vos and Hart 2020). Ultimately, the most appropriate financing mechanism depends on many factors, including scale and debt/equity mix. It will be important to showcase the ability of these mechanisms in achieving beneficial financial, social and environmental returns (Bladon et al. 2014; Baumann et al. 2017; Fitzgerald et al. 2020).

Along with having the right model, a trusted project entity is needed to manage and distribute the funds across aggregated projects, reducing the overall project risk and transaction costs, especially when projects are small scale (Bladon et al. 2014). Local business communities can achieve this by acting collectively in networks and forming cooperatives (Lubchenco et al. 2016) that can substantially lower transaction costs, identified as a key priority for investments into fisheries (WWF (World Wildlife Fund) 2019). However, unless cooperatives have strong governance in place, they may not be suitable for large investment structures.

Although micro-finance continues to be important to many communities in the global south and east, innovative sustainable finance mechanisms should also play an important role in attracting and sustaining new forms of finance. These may include tried-and-tested models, such as payments for ecosystem services, debt- for-nature or adaptation swaps, new SOE investment funds or emerging MPA-financing models. Seychelles' innovative and blended financing mechanism has provided an important model at a national scale and has shown that developed countries have a strong role to play in supporting debt conversions that enable maritime developing countries to effectively invest in a SOE. The green finance space, which considers wider terrestrial sustainable finance challenges, has had a head start on sustainable ocean finance and may offer a wealth of experience, examples and best practices to adapt and apply to finance for the SOE.

For instance, blended finance can offer substantial opportunities to improve investor confidence by providing up-front low-interest or grant-based investments to strengthen the enabling environment—such as strengthening the governance and regulatory environment and restoring the resource base—towards reducing the risk profile and improving investor confidence. This might include investing in (1) improved fisheries policies as well as monitoring control and surveillance at sea, including ABNJ, to reduce illegal, unreported and unregulated (IUU) fishing and strengthen sustainable management of fisheries; (2) the effective protection of habitats and ecosystems, such as coral reefs, sea grass and man-

[3]For more information about the Climate Bonds Initiative, see https://www.climatebonds.net.

[4]To learn more about the Blue Natural Capital Positive Impacts Framework, see https://bluenaturalcapital.org.

groves that provide essential ecosystem services, including coastal protection and carbon sequestration; (3) technology and capacity for implementation of marine spatial planning to reduce user conflicts and ensure that the cumulative impacts of activities do not exceed the carrying capacity of the ecosystem; and (4) setting up investible entities that can substantially lower transaction costs and aggregate sustainable projects in a way that they become more investible. Larger projects can be structured as blue bonds and blended finance, whereas smaller projects may be more suitable for other forms of impact investing or other incremental investment approaches. The OECD's *Principles on Blended Finance* provides an important reference in this context (OECD 2017b).[5]

4.6 Stop Insuring Non-compliance and Develop Best Practices to Incentivise Sustainable Behaviour

The understanding and design of policies to deal with the negative effects of externalities is fundamental to achieving a SOE. This is because externalities underlie many aspects of our unsustainable behaviour. Whilst the SOE finance ecosystem develops, immediate action should be taken to avoid financing practices that support illegal and significantly harmful activities in the SOE, such as illegal fishing (Sumaila et al. 2020; Widjaja et al. 2020) and pollution (Jambeck et al. 2020), and work towards incentivising positive behaviour at both macro and micro levels.

Such activities pose risks to the ocean and have significant costs to people, the private sector (e.g., insurance companies) and governments. In 2017, an industry-wide statement against IUU fishing was launched, confirming the commitment of insurers, brokers and agents to not knowingly insure or facilitate the insuring of IUU fishing vessels (Miller et al. 2018). Economic instruments such as subsidies and taxes are cost-effective mechanisms that can help eliminate the effects of negative externalities while promoting positive externalities (Milazzo 1998; Akerlof and Kranton 2000; Ellickson 2001; Kübler 2001; Clark et al. 2005; Sumaila and Pauly 2007; Sumaila et al. 2010).

Institutional investors can use their influence to promote transparency and best practices in seafood and other ocean sectors, such as those implemented by the Fisheries Transparency Initiative (FiTi). Supply chain traceability is fundamental to the ability of any investor to exercise due diligence. The arguably low traceability in many marine seafood supply chains currently impedes this capacity of corporate investors to steer investments towards more sustainable practices. Yet catch documentation and certification schemes offer mechanisms to enhance traceability. To ensure scrutiny of corporate behaviour, investors should demand that companies show demonstrable efforts at achieving full-chain traceability, and that they fully declare their product mix and sourcing (including area and supplier). Furthermore, investors should insist on the systematic disclosure of metrics such as biomass produced, amount of antibiotics used and percentage of eco-certified products.

Corporate debt also provides a powerful source of influence for banks to promote sustainability in all ocean sectors. Although the literature on bank lending and environmental sustainability remains limited (Coulson and Monks 1999; Thompson and Cowton 2004; Jouffray et al. 2019), a recent review of the plausible power of banks in setting a sustainability agenda suggests that covenants are a key mechanism to examine further (Jouffray et al. 2019). By regulating the actions of the borrower, covenants can be important mechanisms through which banks can incentivise and steer companies towards implementing improved sustainability measures. Unlike blue or green loans, which are earmarked to finance a specific project, sustainability-linked covenants can be used for general corporate purposes. Providers of corporate debt should develop loan covenants based on the best available practices. Whereas such covenants will require tailoring to fit specific sectors, initiatives such as the Principles for Investment in Sustainable Wild-Caught Fisheries (EDF, Rare/Meloy Fund, and Encourage Capital 2018) and the Ocean Disclosure Project can serve as valuable baselines to be further developed.[6]

A good example of how to overcome these challenges is the introduction of special green investment funds in the Netherlands that are exempt from income tax, thus allowing investors in green projects to contract loans at reduced interest rates (usually around 2% less than commercial rates). Some of the approved funds include investments that aim to improve ocean sustainability by encouraging green shipping or incentivising cruise ships to use electric energy. These Dutch green funds have attracted more investment than can be utilised in the available schemes (Mountford and Keppler 1999), which is a very good sign for the future prospects of such initiatives.

4.7 Boost New Approaches to Insurance

The insurance industry has the potential to play three important roles: as risk managers, risk carriers, and investors. As risk managers and carriers who rely on research, modelling

[5] For an overview of some other instruments and how they enable investment, please consult *The Ocean Finance Handbook* (de Vos and Hart 2020).

[6] For more information about the Ocean Disclosure Project, see www.oceandisclosureproject.org.

and data analysis, insurers can recommend more sustainable practices to their clients and the communities they service. Insurers are also major institutional investors, and in this role, they can elect to support only those clients or projects that contribute to a SOE and to divest from those that do not. There is also an opportunity for all levels of government—local, national and international—to work with the insurance industry to promote the development of a SOE. At the local level, this could involve making improvements in risk modelling; at the national and international levels, policy and regulatory frameworks could be reshaped to incentivise responsible and sustainable maritime industry practices (Carr 2018; Laffoley and Baxter 2018; Niehörster and Murnane 2018).

Insurance can also be a source of finance that can be used both to leverage private investments such as blended finance and/or directly invest in the conservation and sustainable use of the ocean.

Mechanisms to address local externalities can be designed and implemented by a single country, but it is much more challenging to address global externalities.

In June 2019, the first-ever insurance policy on natural infrastructure was put in place on a portion of the Mesoamerican Reef in the Mexican Caribbean. Created through an initiative led by TNC, this policy secures funding to repair damages to the reef following a hurricane, preventing long-term damage and enhancing protection of the onshore community. Studies have been completed that estimate the monetary values of the protection offered by coastal habitats, and these findings justify the development of the Mesoamerican Reef policy and the future creation of insurance policies elsewhere, which TNC hopes to pursue.

Insurance companies could design novel products that proactively seek commercial opportunities. For example, TNC, Swiss Re and several partners have developed a coral reef insurance mechanism in Quintana Roo, Mexico, to provide finance to build the resilience of coral reefs to storm damage and to fund restoration activities in the event of a large storm event (Iyer et al. 2018) (Fig. 9.4).

There appears to be great potential for the creation of additional insurance products and services that can contribute to the creation of a SOE. The insurance industry could become a leader in tackling the issue of marine plastic pollution (Lau et al. 2020), for example. Insurers could provide insurance statistics to show the extent to which plastic debris enters the ocean from at-sea sources and its economic impact. Similar to what has been done on the topic of IUU fishing, insurance industry guidelines and other strategies for influencing reduced plastic marine pollution from at-sea sources, seabed mining and biotechnology investment could be developed.

The Pacific Ocean Finance Program is funding the analysis and development of novel ocean insurance products for the Pacific Islands region in partnership with Willis Towers Watson (Wharton and Young Forthcoming). Three draft concepts for the potential application of parametric insurance to support ocean health are in development, including (1) parametric cyclone insurance for a segment of the Great Sea Reef in Fiji to incentivise preparedness and finance rapid response and early recovery after major cyclone shock events, (2)

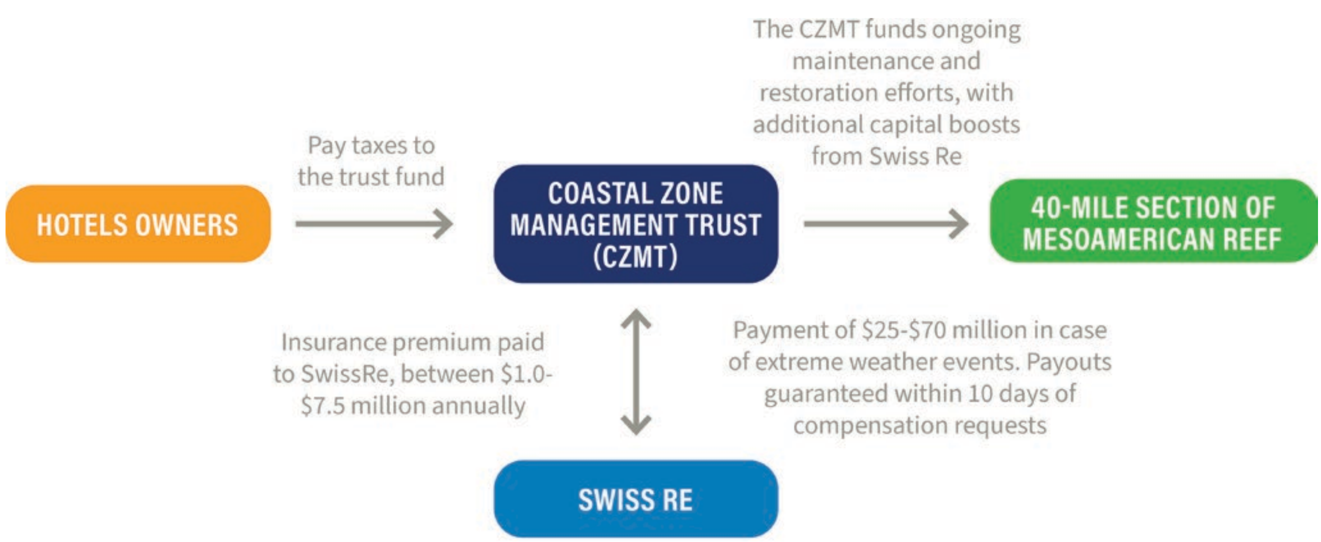

Fig. 9.4 Simplified conceptual diagram of coral reef insurance for the Mesoamerican reef. Note: All figures are in US $. Source: Iyer et al. (2018)

parametric insurance for marine thermal shock events using a sea surface temperature index to help mitigate the economic consequences of tourism revenue decline due to sudden natural asset degradation in Palau and (3) livelihood protection as a social benefit through parametric insurance to support fishers' resilience and incentivise improved fisheries management in Vanuatu.

In addition, the ADB, the Global Environment Facility, and TNC are collaborating on developing natural capital insurance products for coral reefs in Asia and the Pacific Islands. Another relevant initiative is the Ocean Risk and Resilience Action Alliance, launched at the UN Secretary-General's Climate Action Summit in 2019, which is designed to help drive the development of innovative finance products to regenerate coastal natural capital and build resilience in the world's most exposed and vulnerable regions and communities.

The marine insurance sector has already begun implementing strategies to manage and reduce ocean- related risks. The development of this statement was facilitated by the environmental non-profit organisation Oceana and UNEP's PSI initiative. To date, more than 30 insurers, insurance market bodies and key stakeholders, spread across five continents, have signed and supported this statement, including some of the world's largest companies. Working again with the PSI Secretariat and with contributions from industry stakeholders, Oceana developed risk management guidelines that were launched in February 2019 (Miller et al. 2018). These guidelines help insurers avoid contracts associated with IUU fishing and improve transparency and accountability within the global fishing sector. The FiTi and other transparency programs can help guide and support appropriate investment in the ocean economy.

Looking to the future, insurers can also follow guidance issued by the PSI to determine how they can best contribute to a SOE and manage ESG risks. Together with the support of industry contributors, the PSI Secretariat recently developed a draft guide for managing ESG risks in the non-life insurance business (UNEP FI and PSI (Principles for Sustainable Insurance) 2019). The guide contains heatmaps indicating areas of potential elevated risk within various economic sectors and lines of insurance, and it also provides a list of standards and technical guidelines that are available to help insurers identify, assess and mitigate risks.

5 Conclusions

A healthy ocean that supports a SOE requires a range of interventions to improve governance, science and management; finance is an important enabler of a SOE and the major driver behind all ocean-based commercial activities. The best ocean policies and practices can be undone by inadequate financing and by economic externalities that undermine conservation and sustainable use.

This Blue Paper provides an evaluation of how economic instruments and finance mechanisms can be applied to realise a SOE. To turn ocean sustainability challenges into opportunities, the public and private sectors need to create and better mobilise a full suite of financial tools and approaches, insurance, and fiscal and market incentives. Additionally, they need to strengthen key aspects of the enabling environment to support the transition to an ocean economy that is sustainable and inclusive; this can be accomplished by making the benefits the SOE generates available to all, especially women, youth and marginalised communities.

The most significant action will be to influence future mainstream finance. By providing clear principles, guiding frameworks and metrics, and by proactively avoiding the financing of known illegal and harmful activities, trillions of dollars of ocean finance could be redirected towards sustainable development pathways, creating long-term and positive systemic change.

If our suggestion to allocate a higher proportion of ocean GDP to attaining a SOE is followed by half of the world's maritime countries, that alone could generate the seed money needed to incentivise the kind of public and private investments needed to ensure a SOE. The big message from this contribution is that a significant increase in sustainable ocean finance will be required to ensure a SOE that benefits all, including a broad section of society and businesses.

Acknowledgements The authors thank the paper's technical reviewers, Chip Cunliffe, Klaas de Vos, Justin Mundy and Kelly Wachowicz; its arbiters, Mari Elka Pangestu and Adrien Vincent; as well as the Expert Group co-chairs, who all provided helpful technical comments. The authors also thank World Resources Institute for providing support as the Ocean Panel Secretariat.

Although numerous colleagues were very generous with their time and input, this report reflects the views of the authors alone and does not necessarily reflect the views of the organisations or their countries of employment. Finally, we thank Patricia Tiffany Angkiriwang for the design of Figs. 9.1, 9.2, and 9.3. The authors thank Lauri Scherer for copyediting and Romain Warnault for design.

About the Authors

U. Rashid Sumaila is Professor and Canada Research Chair in Interdisciplinary Oceans and Fisheries Economics at the Institute for the Oceans and Fisheries and the School of Public Policy and Global Affairs at the University of British Columbia.

Melissa Walsh is a Blue Finance Specialist with the Asian Development Bank and also a principal at Marine Conservation Finance Consulting.

Kelly Hoareau is the Director of the James Michel Blue Economy Research Institute at the University of Seychelles.

Anthony Cox is the Deputy Director of the Environment Directorate of the OECD.

Patrízia Abdallah is Professor and Acting Director of the Institute of Economy, Administration and Accounting at the Federal University of Rio Grande in Brazil.

Wisdom Akpalu is Associate Professor of Economics and the Dean of the School of Research and Graduate Studies at the Ghana Institute of Management and Public Administration.

Zuzy Anna is the Executive Director of the Center for Sustainable Development Goals Studies at Universitas Padjadjaran in Bandung, Indonesia.

Dominique Benzaken is a Senior Policy Expert and PhD candidate on the sustainable blue economy, ocean governance and islands with the Australian National Centre for Ocean Resources and Security.

Beatrice Crona is Executive Director of the Global Economic Dynamics and the Biosphere Programme at the Royal Swedish Academy of Sciences as well as Associate Professor and Deputy Science Director at the Stockholm Resilience Centre.

Timothy Fitzgerald is Senior Director of Oceans Climate Strategies at the Environmental Defense Fund.

Louise Heaps is the Global Lead on the sustainable blue economy for WWF and is based at WWF-UK.

Katia Karousakis is an environmental economist at the OECD.

Glenn-Marie Lange is a Senior Environmental Economist with the Environment and Natural Resources Global Practice and Chief Technical Adviser at the World Bank.

Amanda Leland is Executive Vice President of the Environmental Defense Fund and oversees programs including climate, energy, health, ecosystems, and oceans.

Dana Miller is a Senior Policy Advisor for Oceana in Europe.

Karen Sack is currently President and Chief Executive Officer of Ocean Unite. She was formerly the Senior Director for International Oceans at Pew Charitable Trusts, where she helped initiate the Global Ocean Commission.

Durreen Shahnaz is the founder and Chief Executive Officer of Impact Investment Exchange in the United States.

Louise Teh is a Research Associate in Interdisciplinary Oceans and Fisheries Economics at the Institute for the Oceans and Fisheries and the School of Public Policy and Global Affairs at the University of British Columbia.

Torsten Thiele is a Visiting Fellow at the Institute of Global Affairs at the London School of Economics and Political Science, where he leads on blue finance, and a Senior Research Associate at the Institute for Advanced Sustainability Studies in Potsdam.

Niels Vestergaard is Professor and Head of the Department of Sociology, Environmental and Business Economics at the University of Southern Denmark.

Nobuyuki Yagi is Professor at the University of Tokyo and Member of the Science Council of Japan.

Junjie Zhang is an Associate Professor of Environmental Economics at Duke Kunshan University and in the Nicholas School of the Environment at Duke University.

Appendix A: Definitions of Sustainable Ocean Economy and Blue Economy

Asian development bank	The environmental, social and economic sustainability of sectors that impact and/or derive economic activity from the ocean
Center for the Blue Economy	It uses three related but distinct meanings: (1) the overall contribution of the ocean to economies, (2) the need to address the environmental and ecological sustainability of the oceans, and (3) the ocean economy as a growth opportunity for both developed and developing countries
Economist Intelligence Unit (2015 adapted working definition)	A sustainable ocean economy emerges when economic activity is in balance with the long-term capacity of ocean ecosystems to support this activity and remain resilient and healthy
Organisation for Economic Co-operation and Development	The ocean economy can be defined as the sum of the economic activities of ocean-based industries as well as the assets, goods and services of marine ecosystems
United Nations Development Program	Protecting and restoring ocean resources while increasing the economic activity derived from the ocean
World Bank	The sustainable use of ocean resources for economic growth, improved livelihoods and jobs while preserving the health of the ocean ecosystem
World Wide Fund for Nature	A sustainable blue economy is one which provides social and economic benefits for current and future generations; restores, protects and maintains diverse, productive and resilient ecosystems; and is based on clean technologies, renewable energy and circular material flows

Appendix B: The MPA Financing Gap

Binet et al. (2015) assessed financing needs and gaps for MPAs in the Mediterranean and found that the 14 countries studied funded their MPA systems to the tune of nearly \$60.5 million per year. The authors also found that the financing needs for effective management of these MPAs was much higher, resulting in a financing gap (available funds minus financial needs) of \$776.4 million per year. Data reported in Sumaila et al. (2019) reveals that the total cost of establishing and maintaining MPAs in 2018 worldwide was $2.3 billion. It is known that not all of the currently declared MPA area of 7.3% of the ocean surface is adequately protected. In fact, only 2.3% is currently 'highly' or 'fully protected', and most of the remaining 5% is not protected at all (Sala et al. 2018). Hence, to get to 10% of highly or fully protected areas from the current 2.3%, $7.7 billion is needed globally. Clearly, and as suggested by Laffoley et al. (2020), adequate, comprehensive and effective funding mechanisms will need to be put in place to deliver the actions required for integrated ocean management in support of a SOE.

Although the costs of establishing and running MPAs (which should be more appropriately seen as investments) are high, there are numerous benefits for implementing MPAs. Effectively managed and located MPAs reduce fishing pressure and increase habitat protection and ecosystem resilience (Costello 2014). This can lead to ecological benefits such as an increase in the abundance, diversity, size and biomass of fish and invertebrate species (McClanahan et al. 2007; Russ et al. 2008; Lester et al. 2009). MPAs may also help marine organisms, ecosystems and societies adapt to climate change by protecting habitats from harm and degradation, thereby reducing the effects of climate change. For example, intact coastal ecosystems can reduce the risks arising from more frequent and severe storms and flooding (Roberts et al. 2017). The ecological benefits from MPAs can translate into economic benefits. For instance, fisheries benefits can arise from the spillover of fish biomass from inside the MPA to fished areas outside the MPA (Russ et al. 2004; Goñi et al. 2008). Well-implemented MPAs can also benefit the tourism and recreation sectors (Ballantine 2014) and provide ecosystem goods and services (e.g., coastal protection from coral reefs, mangroves and sea grass) (Davis et al. 2019). These studies show the insurance, market and non-market values of protecting a significant portion of the ocean portfolio and highlight the fact that establishing MPAs not only support social equity and ocean health but also make economic sense.

Appendix C: The Types and Sources of Capital for Financing a SOE

Several capital types are currently available that can be used to either finance a SOE or serve as the basis for developing new innovative ones that can better serve the ocean economy. A broad categorisation of capital types is provided by de Vos and Hart (2020). The deployment of these different types of capital by investors depends on the expected returns from the investment, which, in turn, depend on the risk-return equation faced by investors (Table 9.2).

Table 9.2 Capital types and their use depending on expected returns

Capital type	Description	Expected return (market or below market, including <0 return)
Impact only • Corporate social responsibility investment • Public grants • Philanthropic grants • Public financing • Official development assistance	This is usually long term but small-scale in comparison to larger types of commercial finance	Below-market return
Debt • Loans • Bonds	This is a low-risk, low-reward type of cap- ital. Debt providers do not have the same level of influence over an investment as equity investors	Market return
Equity • Public equity • Equity investment	Equity is based on taking an ownership stake in an investment; some types of equity (e.g., venture capital) are high risk, high reward	Greater-than-market return
Blended finance	This combines official development assistance with other private or public resources in order to 'leverage' additional funds from other actors	Below-market return

Note: See de Vos and Hart (2020) for more details and examples

Some of the needed investments in a SOE are likely to generate competitive expected **market returns** and should be better promoted/simplified for private investors. Other investments should expect positive but **below-market returns**. In this case, the blending of private and public capital can still deliver adequate returns to investors, such as impact funds. Other investments are 'pure costs' and need socially beneficial subsidies (i.e., those that help society eliminate negative externalities or reinforce positive ones), public investments and philanthropy (grants) to work (Table 9.2).

Appendix D: Threats to the Ocean Economy

The following environmental and social impacts have the potential to undermine the sustainability of the ocean economy.

Environmental Impacts

Fishing and Capture of Marine Life

Overfishing, whaling and shark finning; habitat destruction from fishing gear and practices; ghost fishing; discards, bycatch and entanglement

Marine Pollution

Plastics, mercury and other heavy metals; garbage; and land-based pollution, including nutrients and agri-chemicals, directly harm marine organisms and ecosystems (e.g., ingestion of plastics, algal blooms, eutrophication)

Climate Change

Ocean warming; ocean acidification, sea level rise, more frequent events, hypoxia and dead zones; melting ice caps

Marine Mining, Offshore Oil and Gas

Biodiversity and habitat loss; oil spills

Fish Farming

Escapees; overuse of antibiotics; excessive use of fishmeal and oil

Coastal and Marine Tourism

Habitat destruction and damage from the construction and operation of tourism infrastructure; impact of tours and activities on habitat and biodiversity; wastewater and garbage pollution from tourists

Coastal Development

Habitat destruction and damage from the construction and operation of coastal infrastructure; impact of coastal cities on habitat and biodiversity; wastewater and garbage pollution from coastal populations

Ports and Shipping

Habitat damage; ship groundings; anchor damage; the dumping of rubbish; invasive species from ballast water; oily waste

Social Impacts

Ocean Grabbing/Blue-Washing

Delineation of ocean space that marginalises certain groups, resulting in loss of livelihoods, and compromises food security; hasty planning and limited resources can impact integrated ocean management.

Perverse Economic Incentives

Fisheries and other sectoral subsidies that harm marine ecosystems while favouring industrial scale operators, compromise food security and put small-scale operators and women at a disadvantage.

Global Markets

The pursuit to service global markets can jeopardise locals' access to ocean resources, compromising food security and livelihoods; gains generated in distant markets also rarely trickle down to local producers.

Highlights

- Evidence suggests that ocean biodiversity at all levels is being lost as a result of the direct and indirect impacts of human pressures. The main drivers of biodiversity loss are overexploitation and human pressures in coastal environments (development, habitat loss, pollution, disturbance). Increasingly, climate change and ocean acidification are and will be drivers of biodiversity loss especially in sensitive coastal ecosystems.
- Despite advances in understanding the distribution of species and habitats in the ocean, many aspects of marine biodiversity remain poorly understood. As a result, changes in marine biodiversity are difficult to ascertain and there is a critical need to establish current baselines and trends through survey and monitoring activities.
- There needs to be a concerted effort to increase funding and capacity for marine biodiversity research, especially in developing countries which are rich in biodiversity. There also needs to be an increase in collaboration across scientific disciplines and other data users and measures to make data collection and analysis interoperable and repeatable to ensure that we can enjoy the benefits of ecosystem services which underpin the blue economy whilst ensuring that biodiversity is conserved. These efforts should be focused on the already established international networks for biodiversity monitoring that include the Biology and Ecosystems Panel of the Global Ocean Observing System (GOOS Bio-Eco), the Group on Earth Observation Biodiversity Observation Network (GEO BON), the Marine Biodiversity Observation Network (MBON), and global data integrators such as the Ocean Biogeographic Information System (OBIS) of the International Oceanographic Data and Information Exchange (IODE) programme of the Intergovernmental Oceanographic Commission of the United Nations Educational, Scientific and Cultural Organization (UNESCO-IOC) and the Ocean Data Viewer of the United Nations Environment Programme's World Conservation Monitoring Centre (UNEP-WCMC).
- There has been a significant apparent increase in the coverage of marine protected areas (MPAs). However, most MPAs are only lightly to minimally protected, with many lacking even management plans and very few classified as fully protected. Maximum environmental and societal benefits accrue only when 30–40% of key marine ecosystems are represented in fully or highly protected and implemented MPAs. We estimate that only 3% of the key habitats explored in this study lie in fully protected MPAs, and for some habitats, no countries have placed them in fully protected MPAs. Hence, opportunities abound to strengthen protection in existing MPAs and create new highly to fully protected MPAs, paying close attention to positive enabling conditions, good design principles and adequate enforcement and funding.
- It is critical to establish a legal framework for the conservation of biodiversity in the whole ocean, including areas beyond national jurisdiction. For this reason, reaching a strong agreement for the new international legally binding instrument on the conservation and sustainable use of biological diversity of areas beyond national jurisdiction (BBNJ) is essential.
- The ability of wealthier countries to implement conservation measures within their exclusive economic zones (EEZs) is higher and might need to compensate for less wealthy countries with higher biodiversity and higher pressures. Achieving the 30–40% target in fully or highly protected areas, especially in developing countries, will be greatly enhanced by capacity building, financial support and development of alternate economically viable options for employment.
- Marine ecosystems often exhibit tipping points where pressures lead to a major regime shift that results in an alternative and less productive state. Recognising such tipping points and incorporating them as reference points in fisheries management can greatly improve marine species conservation as well as the functioning and resilience of marine ecosystems.
- Accelerated and expanded reform of fisheries management practices are required if the food and nutritional needs of a growing human population are to be met with-

out permanent and long-lasting biodiversity loss resulting in the erosion of ecosystem services. It is especially important that these reforms include greatly improved monitoring of catch and bycatch in fisheries; the elimination of illegal practices in industrial fisheries through improved enforcement; a reduction in the fishing capacity where it is contributing to overfishing and/or damage to biodiversity whilst ensuring that basic needs for food, nutrition and livelihoods are met in coastal communities; and better incorporation of biodiversity considerations into all levels of fisheries management and the fishing industry. There must be better collaboration with the environmental sector for government departments and also with intergovernmental and non-governmental organisations.

1 Overview

Marine habitats are extremely valuable in many ways (e.g., economically, culturally or for subsistence) and provide many necessary services for humans (Costanza et al. 1997, 2014). Despite their importance, coastal and oceanic habitats are increasingly threatened by fishing, climate change, oil and gas exploration, pollution and coastal development (Jackson et al. 2001; Halpern et al. 2008, 2019; Heery et al. 2017; Harris 2020). Habitat degradation and loss from these threats are not uniformly distributed and are cumulative with poorly understood interactions between pressures (Halpern et al. 2008). Despite the enormous impacts humans have had on marine ecosystems in the global ocean over the past 50 years, they tend to appear not as the complete extinction of individual species (Dulvy et al. 2003) but rather as changes in ecosystem composition and in the relative abundance and ecological status of individual species, along with more regional or local extirpations (Worm and Tittensor 2011). A species need not become globally extinct to radically alter the composition of the ecosystem ('ecological extinction'), disappear from the local environment ('local extinction') or become commercially non-viable ('commercial extinction'). Biodiversity loss is a globally significant symptom of unsustainable exploitation of Earth's natural environment and a major threat to the ecosystem services on which we, and future generations, depend.

The ocean's natural capacity to provide ecosystem services such as food, coastal protection and carbon sequestration are being eroded as a result of the above changes (Cheung et al. 2010, 2013; Barange et al. 2014; Spalding et al. 2014; Arias-Ortiz et al. 2018). Over 500 million people worldwide live in the coastal zone and are afforded protection by ecosystems such as coral reefs, mangroves forests, seagrass beds and kelp forests. In the case of coral reefs, the reduction in damage to terrestrial assets conferred through coastal protection is estimated at US $4 billion annually (Beck et al. 2018). For the top five countries that benefit from reef protection, this is the equivalent benefit of $400 million annually in mitigated damage to society (Beck et al. 2018). Without reefs, the economic impact of flooding would more than double, with the area of land affected increasing by 69% and people affected by 81% (Beck et al. 2018). The loss of this critical ecosystem, which is estimated to result in a 1–10% reduction of its former range under the most optimistic future scenarios (IPCC 2018), is a looming crisis of vast ecological and social dimensions.

In response to habitat degradation, losses in biodiversity and associated impacts, there has been an international effort towards conserving marine ecosystems. The Strategic Plan for Biodiversity 2011–2020 from the Convention on Biological Diversity (CBD) has resulted in an accelerated effort to increase the protection of marine areas. Specifically, Aichi Biodiversity Target 11 calls for the conservation by 2020 of 'at least 10% of coastal and marine areas, especially areas of particular importance for biodiversity and ecosystem services … through effectively and equitably managed, ecologically representative and well-connected systems of protected areas and other effective area-based conservation measures'. A body of scientific literature suggests that the Aichi Biodiversity Target should be a first step. More ambitious targets of ocean protection (e.g., 30%), have been proposed and discussed in the scientific literature for many years (Gell and Roberts 2003; Balmford et al. 2004). Recent meta-analyses indicate that maximum environmental and societal benefits do not accrue until 30–40% of representative marine ecosystems are protected (Gell and Roberts 2003; Gaines et al. 2010; O'Leary et al. 2016; Sala et al. 2018a). This call for an enhanced scope for protection was endorsed by Resolution 50 of the International Union for the Conservation of Nature (IUCN) at the World Conservation Congress in 2016 'to designate and implement at least 30% of each marine habitat in a network of highly protected MPAs and other effective area-based conservation measures, with the ultimate aim of creating a fully sustainable ocean'. This call included specific reference to implementing protected areas in the exclusive economic zone (EEZ) of countries and in areas beyond national jurisdiction (ABNJ) (IUCN 2016).

Spatial conservation measures such as marine protected areas (MPAs) are one way of addressing these problems and have become the most recognised area-based marine conservation measure worldwide. An abundance of evidence suggests that if they are well designed, enforced and financed, fully protected MPAs can provide an abundance of benefits, including increases in biodiversity, size and abundance of previously targeted species (Halpern 2003; Lester and Halpern 2008; Lester et al. 2009; Edgar et al. 2014; Sala and Giakoumi 2017); enhanced spillover of juveniles and adults to adjacent fished areas (Halpern et al. 2010; Di Lorenzo et al. 2016); and restoration of ecological interactions within the protected area (Micheli et al. 2004; Mumby et al. 2007). More recent studies report additional benefits, including enhanced resilience to environmental and climate changes (Mumby and Harborne 2010; Micheli et al. 2012; Roberts et al. 2017; Bates et al. 2019). It is important to note here that biodiversity may benefit even further if more than 30–40% of representative habitats are protected by networks of MPAs. However, because of trade-offs between ocean conservation and uses such as fisheries, placing 30–40% of habitats in highly or fully protected MPAs is viewed as the optimal balance between protection of biodiversity and ecosystem service provision (Gaines et al. 2010). Also, to attain a representative coverage of 30% of marine habitats in fully or highly protected MPAs, a larger area may be required than 30% of the ocean to attain representativeness (O'Leary et al. 2018; see Jones et al. 2020 for an assessment based on species ranges lying within MPAs). Other effective area-based marine conservation measures (OECMs), such as locally managed marine areas, territorial use rights for fishing programs (TURFs), fisheries restricted areas, particularly sensitive sea areas, and areas of particular environmental interest, among others, have proven successful in conserving important areas for biodiversity and ecosystem services that include food security and poverty alleviation, such as in Northern Mozambique (Diz et al. 2018). The IUCN has created guidelines to recognise and report OECMs (IUCN-WCPA 2019) to incentivise robust long-term conservation and management of biodiversity. OECMs are an important but complementary tool to supplement an existing MPA network; however, they are not necessarily (or generally) mandated with a biodiversity conservation objective (Tittensor et al. 2019).

Therefore, this Blue Paper focuses on MPAs because they are supported by an important body of peer-reviewed literature indicating their effectiveness as fisheries management and conservation tools. Furthermore, MPAs can protect biodiversity but can also restore ecosystem structure, function and potentially services (Cheng et al. 2019) that mitigate and promote adaptation to climate change (Mumby and Harborne 2010; Micheli et al. 2012; Roberts et al. 2017). Therefore, implementing MPAs preserves habitats and their biodiversity and allows the maintenance of valuable ecosystem services (Costanza et al. 2014). We can roughly divide MPAs into no-take areas (where no fishing is allowed) and multiuse areas. Although, in some cases, the latter category does generate some benefits, in others, MPAs fail to reach their conservation objectives completely (Agardy et al. 2011). Scientific evidence is now accumulating in favour of fully protected MPAs (also known as marine reserves), which are dubbed most effective in environmental management (McClanahan et al. 2008; Edgar et al. 2014; MacNeil et al. 2015; Sala and Giakoumi 2017). Fully protected marine reserves, besides prohibiting fishing activities, also remove or minimise other human pressures that enable species to maintain or recover their abundance, biomass and diversity (Lester et al. 2009). It is notable, however, that MPAs are often not well designed, enforced or financed (Gill et al. 2017; Dureuil et al. 2018), which impacts their effectiveness, and there is particular concern for regions of high marine biodiversity, such as the marine biodiversity hot spot in Southeast Asia, where many species are reduced and destructive exploitation is expanding largely unchecked even within MPAs.

The High Level Panel for a Sustainable Ocean Economy has a vision of a productive and protected ocean, which will play a major role in achieving the Sustainable Development Goals (SDGs). Continued loss of marine biodiversity will undermine our ability to achieve a number of the SDGs, especially SDG 14 (to conserve and sustainably use the ocean), but also other goals (e.g., SDG 2, hunger and food security; SDG 9, resilient infrastructure). This Blue Paper addresses the topic of critical habitats and marine biodiversity with the following specific aims:

- Synthesise knowledge presenting the most recent inventory of marine habitats and biodiversity in the global ocean.
- Provide a brief overview of the impacts of habitat degradation and biodiversity loss in reducing ecosystem services.
- Review evidence of how biodiversity relates to ecosystem function and exploitation/degradation tipping points.
- Identify the range of measures undertaken by governments and industrial sectors to monitor, protect and address loss of marine biodiversity and their effectiveness.
- Determine opportunities for action to improve the sustainability of blue economic activities with respect to maintaining, and, where possible, restoring, the ocean's habitats and biodiversity.

We use the Convention on Biological Diversity's definition of biodiversity as the variability among living organisms, including diversity within species, between species and of ecosystems. The topics of marine biodiversity and ecosystem integrity are complicated by a lack of data, which pervades almost all aspects of our understanding of its distribution and trends. By necessity, therefore, we have been driven to examine specific aspects of the topic, such as well-studied groups of organisms or habitats as well as particular case studies.

This underlines the need for more scientific work on many aspects of ocean biodiversity, from variation within species and connectivity of populations to processes at the level of habitats and entire ecosystems, the sum of which underpin the functioning of Earth.

2 An Inventory of Marine Habitats and Biodiversity

2.1 Species

Globally, it is estimated that only 10–25% of marine species have been described (Mora et al. 2011; Appeltans et al. 2012), and some of the least known groups are likely to have thousands to over a hundred thousand undescribed species (e.g., Isopoda, Gastropoda, Tanaidacea). The geographic distributions of even fewer species are known (Gagné et al. 2020). Genomic approaches, coupled with large-scale sampling of the upper layers of the ocean (e.g., the Tara expedition), have also revealed tens of thousands of uncharacterised microbes, including eukaryotes, prokaryotes and viruses (de Vargas et al. 2015; Sunagawa et al. 2015). However, it is estimated that about half of the major taxonomic groupings (e.g., Vertebrata) have identified more than 50% of their known species already, and with the current rate of description of new species (average of 2000 new species described per year), those groups might have all their species described by the end of the century (Appeltans et al. 2012).

Knowledge of marine biodiversity varies markedly across regional, national and, more importantly, trophic levels (Costello et al. 2010). Data from the Census of Marine Life (CoML) programme is available in the ever-growing Ocean Biogeographic Information System (OBIS)[1] of the Intergovernmental Oceanographic Commission (IOC) of the United Nations Educational, Scientific and Cultural Organization (UNESCO). The CoML data suggest that, in relative terms, China, Australia and Europe have the best knowledge base of marine species with the tropical western Atlantic, tropical eastern Pacific and Canadian Arctic regions being poorly studied (Costello et al. 2010). Ecosystems that are particularly poorly known include the deep sea, coral reefs, icecovered areas and chemosynthetic habitats (Costello et al. 2010). Knowledge of the identity and distribution of commercially exploited taxa is greater than that of non-extracted taxa, and larger organisms tend to be better known than smaller organisms (Fautin et al. 2010; Worm and Tittensor 2018). Currently, only a handful of species are considered to have enough independent records that describe their full geographic distribution (about 50,000 species; Gagné et al. 2020). Emblematic (mammals, corals or fish) and exploited species (fish and invertebrates) are among the most well-documented spatially. Other patterns of biodiversity, including intraspecific genetic variation and habitat diversity, are also not well described (Fautin et al. 2010; Blasiak et al. 2020), with some exceptions. The Global Ocean Biodiversity Initiative (GOBI), which uses CoML and OBIS as primary sources of data, has participated in the CBD effort to identify ecologically and biologically significant areas (EBSAs) in the ocean.[2] These areas can be characterised by high biological diversity, but they also include a number of other criteria, including unique or rare species or communities; importance for the life history stages of marine species; importance for threatened or endangered species or habitats; vulnerability, fragility or slow recovery; biological productivity; and naturalness (CBD 2009). Geographic areas with the best knowledge of marine biodiversity do not match well with areas of highest diversity, reflecting both historical and present-day scientific capacity for taxonomy. Historically, highly sampled regions are often located in the Northen Hemisphere in the coastal regions around developed countries. It is crucial to account for such sampling bias when examining the distribution of biodiversity (Tittensor et al. 2010; Gagné et al. 2020). The common approaches to provide an unbiased picture of marine biodiversity consist of (1) removing species with not enough records to describe their full distribution and (2) applying statistical methodologies on known species records to correct for bias. The main hot spots of marine biodiversity have been recognized in the Indo-Pacific Coral Triangle and a lower peak in the Caribbean (Briggs 2007; Worm and Tittensor 2018; see Box 10.1). A general decline in biodiversity from the tropics to the polar latitudes has also been hypothesised, although there is debate on whether some taxa show more bimodal patterns (Thorson 1952, 1957; Fischer 1960; Stehli et al. 1967, 1972; Clarke and Crame 1997; Williamson 1997; Roy et al. 1998; Tittensor et al. 2010; Edgar et al. 2017; Worm and Tittensor 2018; Box 10.1). Hypothesised explanations include speciation and extinction rates over geological timescales as correlated with latitude (Crame and Clarke 1997; Jablonski et al. 2006, 2013) and ecological drivers such as habitat area, land versus ocean area by latitude, sea surface temperature (Worm and Tittensor 2018), and intrinsic biological traits such as larval development mode and interspecies interactions (Roy et al. 1998; Pappalardo and Fernández 2014; Edgar et al. 2017).

Box 10.1 Estimating Global Patterns of Biodiversity

Using the biodiversity data found in Reygondeau (2019) and Gagné et al. (2020), the authors developed a standardised database drawing on online websites with records of the global distribution of marine species with sufficient records to have a robust distribution. Specifically, the database was populated with species data for which at least 10 spatially informed occurrences were available. Occurrence data originated from the Ocean Biogeographic Information System (OBIS);[a] Intergovernmental Oceanographic Commission (IOC) of the United Nations Educational, Scientific and Cultural Organization (UNESCO);[b] the Global Biodiversity Information Facility (GBIF);[c] Fishbase;[d] the Coastal and Oceanic Plankton Ecology Production and Observation Database (COPEPOD);[e] the Jellyfish Database Initiative;[f] and the International Union for the Conservation of Nature (IUCN).[g] The full filtering methodology can be found in Gagné et al. (2020).

From the initial data set (more than one billion entries), we removed records (1) with spatial location as "not assigned" (NA) or null values, (2) not identified to species level and (3) replicated among databases (i.e., records with the same species name, coordinates, and sampling details). The remaining records (731,329,129 records; more than 101,000 species) were assigned full taxonomic information using the Taxize library4 in R Studio. We also used this procedure to update all species' synonyms to valid names, as officially recognised by the Integrated Taxonomic Information System (ITIS)[h] and the World Register of Marine Species (WoRMS).[i] Next, we explored the relationship between the number of independent records (independent in time and area of sampling) and latitudinal range and thermal range for species with well-known global coverage and ecology (number of observations greater than 2000; 1196 species). For each known species, we randomly selected n records (number of observations from 1 to 1000) within the global pool, and for each selected number of records (n = 1 to 1000 records), we computed the species' latitudinal range and thermal range. The procedure was replicated 1000 times. We then confronted the simulated latitudinal range and thermal range (1000 simulations) to values obtained using all the information gathered on the species. We computed an interval of confidence of known range by quantifying the difference between the 1st and the 99th percentile of observed latitude coordinates and thermal value, and we assumed that the acceptable number of records to capture the latitudinal and thermal range was obtained when more than 950 randomly selected records were included within the confidence interval determined from the global pool of records. The median number of points found to capture the latitudinal range was 33 ± 4 records and 41 ± 3 records for thermal range. All species with less than 41 independent records were removed from further analysis.

Thus, the final data set on which all analyses presented in this study are based comprises up-to-date taxonomic information and filtered occurrences for 41,625 species, for a total of 51,459,235 records representing 17% of all accepted marine and non-fossil species.

The distribution of biodiversity in the global ocean has been described for numerous taxa, particularly in recent years as more observations have been synthesised into large-scale patterns (Tittensor et al. 2010; Reygondeau 2019). While there is consistency across many groups, it is important to bear in mind that there remains a significant taxonomic bias in our understanding.

There are some groups that we know well (typically those species in which we have a keen commercial interest or which are charismatic, such as vertebrates, or those which form biogenic habitats such as corals and seagrasses), but there are many for which we have very limited information (numerous invertebrate groups, most deep-sea taxa, and much of the microbial biosphere). In Box 10.1 we present a new analysis of the global pattern of marine biodiversity which is aimed at reducing bias from the issue of uneven sampling of species from different parts of the ocean.

At a global scale, the biodiversity distribution estimated from our study appears to be relatively consistent with other studies, resolutions and analyses (Fig. 10.1; Tittensor et al. 2010; Asch et al. 2018; Reygondeau 2019). The pattern across multiple taxa is primarily tropical to subtropical peaks

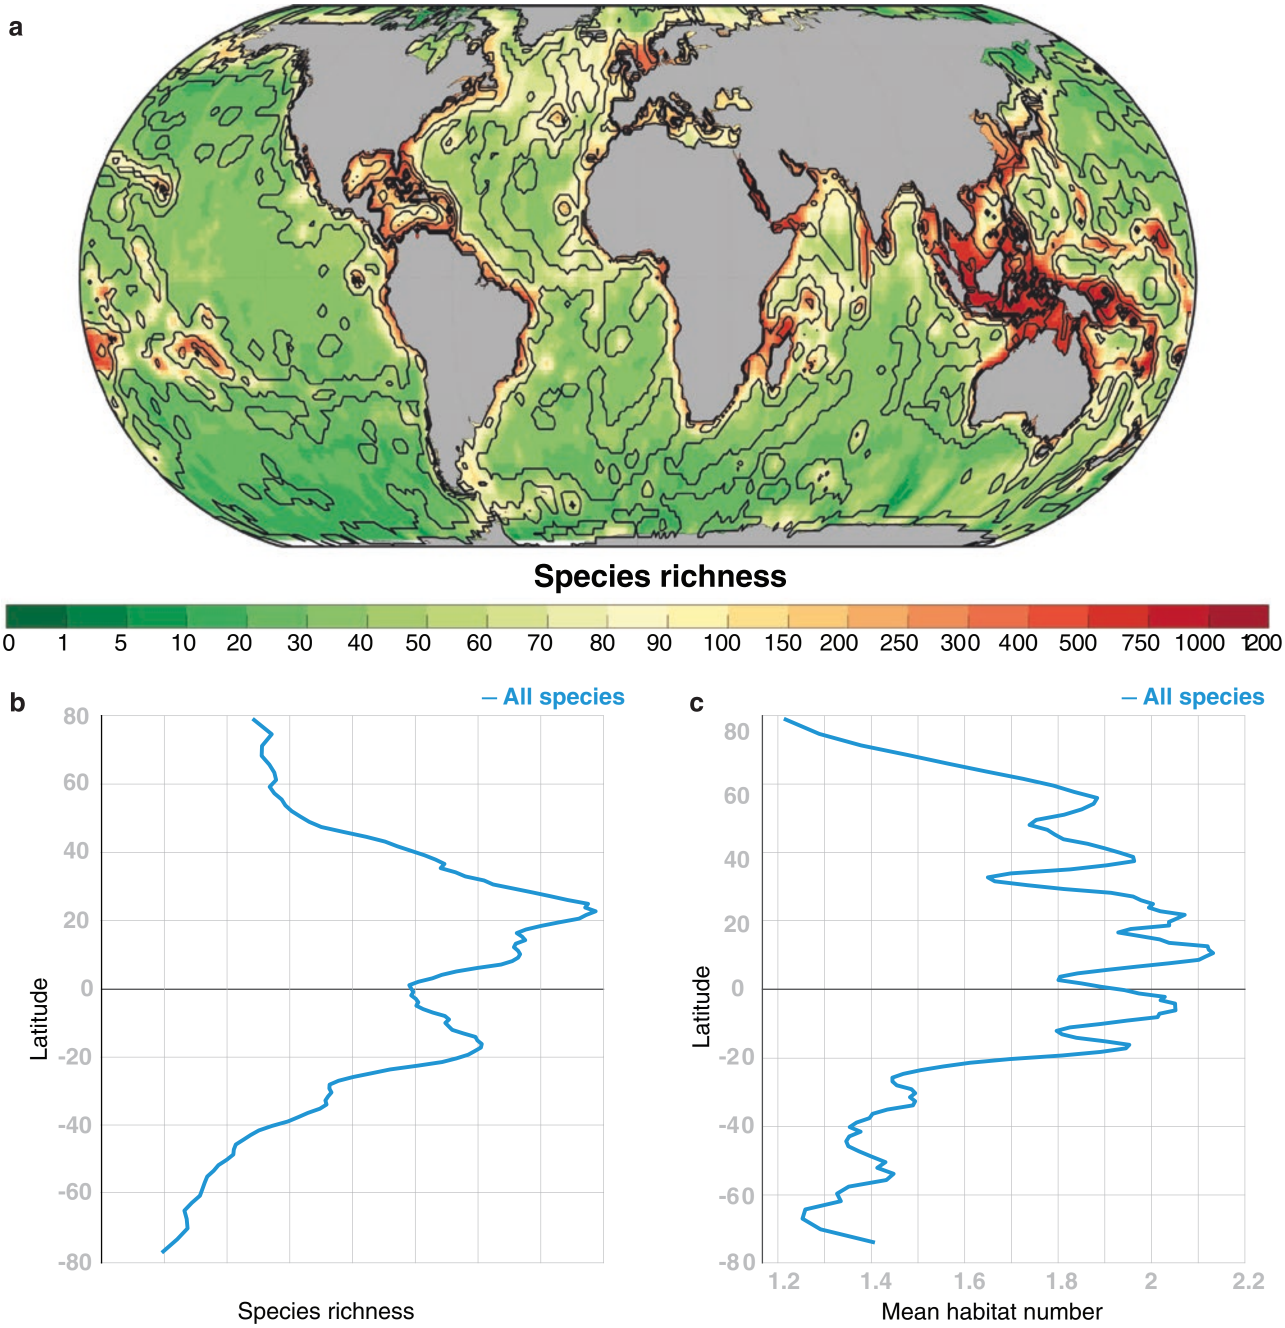

Fig. 10.1 Global patterns of biodiversity and habitat richness. *Notes: Map of species richness* (**a**) *is on a 100 × 100 km equal-area grid with a superimposed contour map of the number of habitats per geographical cell (see Sect. 2.2). Latitudinal gradient of species richness* (**b**) *is of all marine species.* (**c**) *Plot of the average number of habitats versus latitude). (Source: Authors)*

in species biodiversity, particularly for coastal species; but there are steep longitudinal gradients in diversity, with an increase from both east and west towards Southeast Asia, and from east to west in the tropical Atlantic. The Indo-Pacific Coral Triangle, central and western Indian Ocean, Red Sea, South West Pacific Islands (i.e., the Bismarck Archipelago, the Great Sea Reef of Fiji, New Caledonia, New Guinea, the Solomon Islands, Vanuatu) and Southeast Asia show the highest levels of species richness as indicated in previous studies (e.g., Selig et al. 2014). The Caribbean also has a relatively high species richness, but not as high as the aforementioned areas and parts of the northeast Atlantic, such as the North Sea, are as diverse. This latter result may reflect the high number of species records in the northeast

Atlantic, introducing some bias into the overall picture of the distribution of species richness given the exclusion of species with less than 41 samples. Also, small areas, such as tropical or subtropical islands, which are characterized by a high species diversity may be unresolved because of the spatial resolution of this analysis (as for Selig et al. 2014). Individual taxonomic groups and different parts of the ocean (coastal, pelagic, deep sea) can show differing distributions. Taxa that follow the general pattern, albeit with some variation in relative intensity of hot spots, include reef-building corals, coastal fishes, shallow-water ophiuroids (brittle stars), cone snails, mangroves, coastal cephalopods, lobsters and gastropods. Seagrasses have a more temperate-skewed distribution of richness, perhaps reflecting their improved ability to tolerate cold water, relative to reef-building corals and mangroves.

Macroalgae (seaweeds such as kelp) are less well-known in terms of distribution at the species level, but at the genus level again appear to peak at more temperate or subtropical latitudes (Gaines and Lubchenco 1982; Kerswell 2006; Short et al. 2007; Tittensor et al. 2010; Keith et al. 2014; Worm and Tittensor 2018). Coastal sharks show a similar pattern to other coastal fishes, but their distribution is more centered around temperate latitudes (Lucifora et al. 2011). Deviations from the general patterns described include coastal marine mammals, whose endothermy has enabled them to develop a metabolic advantage in colder waters (Pompa et al. 2011; Grady et al. 2019). Pinnipeds (seals, sea-lions and walrus) show an inverse pattern with peak species diversity in subpolar and polar environments (Tittensor et al. 2010; Pompa et al. 2011).

Biodiversity in the open ocean shows a generally bimodal pattern (Chaudhary et al. 2016), with pelagic zooplankton such as foraminifera, copepods and euphausiids, open ocean fishes such as tuna and billfishes, pelagic sharks, and cetaceans all showing a mid-latitudinal peak in species richness, generally between latitudes 30 and 40° (Tittensor et al. 2010). Some differences between these taxa are apparent, including cetaceans being widely distributed in terms of richness peaks across latitudinal bands, whereas pelagic shark hot spots tend to skew towards the coast. Marine bacteria and phytoplankton diversity patterns remain much less well-known at a global scale, though modelling has predicted an intermediate latitude peak in phytoplankton, and there may be a similar gradient in bacteria, though more data and analyses are needed to confirm this for both groups (Worm and Tittensor 2018). Pelagic cephalopods are undersampled, but they appear to show a similar intermediate latitudinal peak, albeit only in the Northern Hemisphere (Tittensor et al. 2010). Pelagic seabirds (such as albatross and petrels) show a mid-latitude peak, but only in the Southern Hemisphere (Davies et al. 2010).

Deep-sea biodiversity is far less known, and whilst regional patterns have been described for multiple groups (Rex and Etter 2010), global patterns are far less well understood at the species level (though model predictions of habitat suitability are available at higher taxonomic levels for other taxa, such as cold-water corals; Tittensor et al. 2009). A global pattern has been described only for the ophiuroids (brittle-stars), which, as mentioned above, show a relatively typical shallowwater pattern of a peak in diversity at low latitudes on the continental shelf and slope, but they have a markedly different distribution in deep waters (more than 2000 m; Woolley et al. 2016). Deep-water ophiuroids show maximum richness at temperate latitudes (between latitudes 30 and 50°), with diversity higher in regions closer to continental margins where particulate organic material export from the surface, used as a food source by most deepsea organisms, is higher. The deep sea is an extremely food-limited, lightless environment, with relatively shallow gradients of temperature over large distances horizontally, and these environmental factors may shape different patterns, though more information is needed to ascertain whether these patterns hold across multiple taxonomic groups.

Biodiversity metrics, other than species richness, that have been assessed at a global scale are few. The global distribution of functional richness in fishes appears similar to species richness, but evenness shows an opposite pattern (increasing with latitude), and functional diversity appears highest in the tropical eastern Pacific (Stuart-Smith et al. 2013). The fish food web is globally connected and suggests a higher vulnerability to species extinctions in the open ocean compared to coastal areas (Albouy et al. 2019).

In summary, known patterns (based on a biased sample of taxonomic groups) indicate that species biodiversity appears to peak in the tropical Indo-Pacific, with a secondary peak in the Caribbean, and a general tropical or subtropical peak in richness. Coastal species tend to match this pattern more closely than oceanic species, which tend to show bimodal peaks at intermediate latitudes; yet whilst deep-sea taxa remain poorly known, one group (brittle stars) shows a markedly different distribution with temperate peaks close to continental margins and in areas of high food export from the surface ocean.

2.2 Habitats

Using previously published spatial data sets (Table 10.1), we synthesised information at the global level to produce patterns of habitat diversity (see Fig. 10.2). Because of their ecological and socio-economic importance, and the relative availability of information, we focused on the following marine habitats ordered from their distance to the coast: estuaries, mangroves, saltmarshes, seagrasses, coral reefs, kelp

Table 10.1 Spatially referenced habitat data for coastal and oceanic ecosystems included in the habitat diversity analysis

Habitat	Time span	Data type	Source

forests, shelf valley and canyons, cold-water corals (deep sea corals), seamounts and guyots, trenches, hydrothermal vents and ridges (Table 10.1).

The global habitat diversity index was based on the 12 habitats in Table 10.1. First, these habitats were converted into binary rasters at a 1-km resolution and projected into the World Robinson projection. A constant raster was created at a resolution of 1000 km by 1000 km. Next, these rasters were imported into R Studio. The packages 'raster', 'sp', 'rgdal', and 'tidyverse' were used to work with the data. Within each cell of the constant raster, the number of 1 km pixels that contained a habitat were summed. Each of the cells of the constant raster was then viewed as a community, and the Shannon Index of diversity was used to calculate a diversity value for each cell using the number of cells of each habitat as species counts. These values were then transformed into a raster and were uploaded into ArcGIS Pro 2.4 to create Fig. 10.2.

Coastal areas had a much higher diversity, because of the occurrence of 6 of the 12 habitats considered. The other 6 habitats occur in deeper waters, where many areas remain understudied. Although our technological capability is increasing through efforts like the global Seabed 2030 mapping project,[3] there are still large gaps in our understanding of deepwater habitat distribution (Rogers et al. 2015). Hence, although the data considered (Table 10.1) are the current best-available representation of the extent of global habitats, the progressive use of improved large-scale mapping technologies will improve our knowledge of global habitat diversity patterns.

Based on the habitat diversity analysis, the Indo-Pacific Coral Triangle, the eastern seaboard of Australia and the Caribbean are hot spots for habitat diversity (Fig. 10.2), a

[3]Information about the Seabed 2030 project can be found at https://seabed2030.gebco.net/

pattern which is similar to that for species diversity (Fig. 10.1). The distribution of these data skews to the right, with fewer areas with higher diversity. The United States, Australia and Indonesia have the highest area of analysed habitats with an average of 6.94%, 5.81% and 5.05% of the global total, respectively. Unsurprisingly, there is a strong and significant correlation with EEZ area, explaining 63% of the variation. Russia, which also has a very large EEZ, does not seem to follow this trend—probably because much of its coastline lies at polar latitudes.

3 Biodiversity Loss

3.1 Evaluating the Loss of Species

The dominant pressures on the ocean are direct exploitation by fisheries, followed by land and sea use change (Costello et al. 2010; IPBES 2019). These pressures were identified by the Global Assessment Report on Biodiversity and Ecosystem Services of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) and by previous studies. Of the three other main drivers considered, invasive species, climate change and pollution are growing in importance. Climate change impacts arise from ocean warming, acidification, deoxygenation, changes in currents and circulation, and sea level rise (IPCC 2019). Temperature rise is correlated with global shifts in distribution, generally away from the tropics but influenced by regional and local oceanography (Cheung et al. 2009; Burrows et al. 2011, 2014; Poloczanska et al. 2013, 2016; Humphries et al. 2015; Molinos et al. 2016). This is driving the large-scale alteration of marine communities at middle to high latitudes (e.g., the Atlantification of the Barents Sea; Fossheim et al. 2015; Oziel et al. 2017; Vihtakari et al. 2018) and may be exacerbated by geographic patterns of thermal tolerance in marine species (Stuart-Smith et al. 2015). Deoxygenation of the ocean has already caused a shift in the vertical and horizontal distribution of pelagic species such as marlins and squid (Stramma et al. 2012; Stewart et al. 2013; reviewed in Breitburg et al. 2018). Climate change is also a significant driver of ecosystem damage, including on coral reefs (Hoegh-Guldberg et al. 2007; Gattuso et al. 2015; Hughes et al. 2018a) and seagrass beds (Thomson et al. 2015; Arias-Ortiz et al. 2018).

To evaluate such impacts on biodiversity, we analysed the IUCN Red List for 12 marine invertebrate and vertebrate taxa. This list comprises analyses of the current status of populations of species with respect to extinction risk, and it considers population decline, negative changes in range (e.g., range of occupancy and/or levels of fragmentation of populations), and whether populations of a species are very small (IUCN 2017). For marine invertebrates and vertebrates, data were extracted from the IUCN online Summary Statistics.[4]

To reduce bias, the assessment was restricted to taxa with more than 10 species assessed. Whilst these taxa represent a relatively small proportion of those living in marine environments, they are the best studied to date; therefore, they present a good (if taxonomically biased) data set on which to assess the threat of extinction and its causes across a range of marine ecosystems (Webb and Mindel 2015). Only around 3% of the roughly 240,000 described marine species have been assessed for the Red List (Sullivan et al. 2019).

3.2 Invertebrates

There are 3081 marine invertebrate species in seven classes across four phyla that have had some representative assessment on the IUCN Red List (see Fig. 10.3 and Table 10.2). The numbers reflect the extremely low level of assessment of marine invertebrates, a total of 2.6% of species across these four phyla, from as low as 0.5% for Arthropoda to 7.5% for Cnidaria (Table 10.2). Furthermore, these samples are biased: 839 species of hard corals (order Scleractinia) and 16 fire corals (genus *Millepora*) make up 97% of the cnidarians assessed, all from a single assessment (Carpenter et al. 2008), and the 686 Cephalopoda species represent 44% of all marine Mollusca assessed but likely less than 1% of all marine Mollusca. By their nature, Red List assessments tend to focus on relatively well-described taxa for both marine and terrestrial species (Webb and Mindel 2015).

With these caveats and the challenge of data deficiency, the proportion of species threatened ranges from a lower bound of 11% to an upper bound of 46%. The most speciose invertebrate classes (Anthozoa, Gastropoda, Malacostraca) as well as the Cephalopoda show the lowest levels of threat. The criteria used for assessment are indicative of marine species characteristics: of the 326 species listed in one of the three ‘threatened’ categories (vulnerable, endangered, and critically endangered), over 75% (254) are listed on the basis of estimated population decline (Criterion A, for the past, present and/or future), 14% were listed on the basis of small range and decline (Criterion B), and 7% were listed for their very small population size or range (Criterion D). Only 5 species were listed under more than one criterion.

3.3 Vertebrates

Compared to invertebrates, marine vertebrates are relatively well represented in the IUCN Red List (Fig. 10.3). Reptiles, birds and mammals have been fully assessed, and among

[4]See IUCN Red List, https://www.iucnredlist.org/search

Fig. 10.3 IUCN Red List threat categories for marine species. *Note: These taxa have more than 10 species assessed. Data deficient (DD) species are depicted between the threatened categories (CR critically endangered, EN endangered, VU vulnerable) and non-threatened categories (NT not-threatened, LC least concern). EX extinct in the wild. Numbers on the right of the bars represent the total number of species assessed per taxon group. (Source: Authors)*

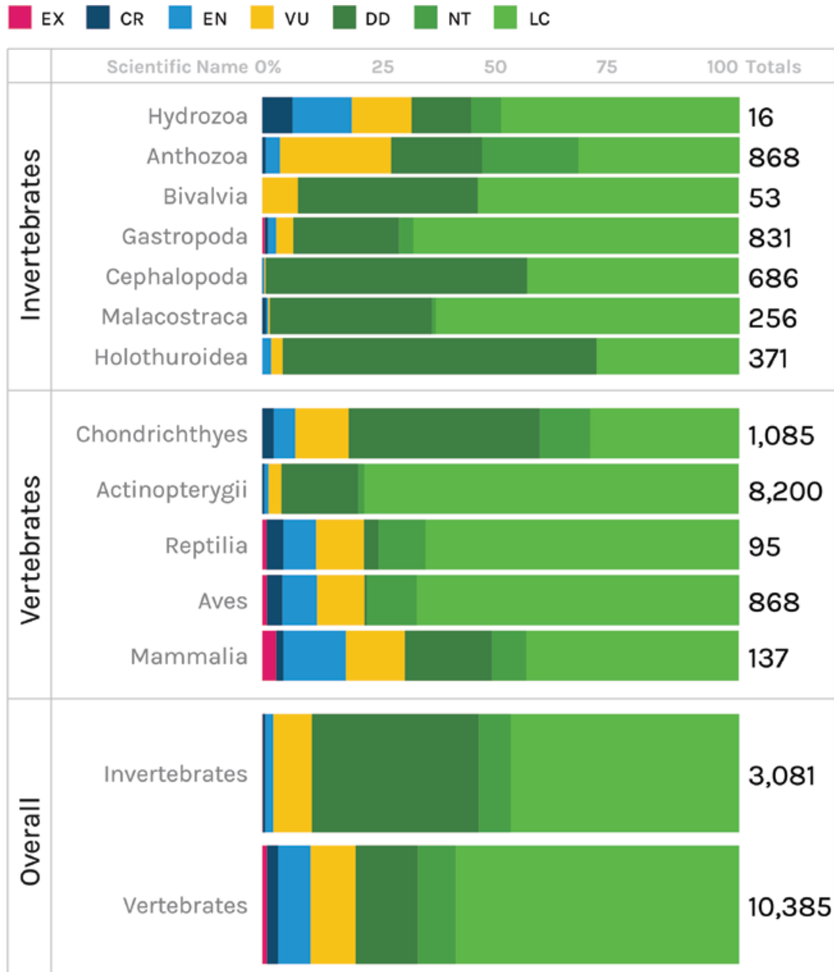

Table 10.2 Proportion of invertebrate species assessed on the IUCN Red List compared to the total number of species currently described on the World Register of Marine Species

Phylum	Number of species described	Number of species assessed	% Assessed
Arthropoda	56,479	266	0.5
Cnidaria	11,744	884	7.5
Echinodermata	4408	372	5.0
Mollusca	48,275	1570	3.3
TOTAL	120,906	3092	2.6

Source: WoRMS (n.d.)

marine fishes, of the approximately 18,000 described to date, just over 50% have been assessed (9285 species of sharks, rays and bony fish). Of these, there are 8200 marine actinopterygians, from 30 different orders, for which at least 10 species have been assessed. The two fish classes included in this analysis make up 79% of all assessed marine vertebrates and compose 70% of marine vertebrates listed as threatened. However, the actinopterygians have the lowest overall proportion of threatened species (4%) compared to other marine vertebrate taxa (20–30%). The chondrichthyan extinction risk at this taxonomic level of analysis is substantially higher than for most other vertebrates, and only about one-third of species are considered safe (Dulvy et al. 2014). We note that all species of marine turtles are currently threatened with extinction.

The actinopterygians are less well understood than marine reptiles, birds and mammals, and, as a result, have by far the highest proportion (and number) of species listed as 'data deficient' (DD; see Fig. 10.3); some of these DD species may also be threatened but the lack of data prohibits this assessment from being made.

This situation highlights the poor overall understanding we have of many fish species, even some that are heavily exploited, such as many deepwater and coral reef fishes; examples include the deepwater orange roughy (*Hoplostethus atlanticus*), coral reef groupers and snappers (Epinephelidae and Lutjanidae), coastal and estuarine groups such as croakers (Sciaenidae), and cold-water wolf-fishes (*Anarhichas*). The documentation of these species should be a priority from the perspective of population (status, distribution and trends) and use (i.e., fisheries catches). However, for all taxa there is also a need to collect data on less well-understood aspects of impacts on populations, such as from unintentional catch/

bycatch or through destruction of key life history areas such as spawning or nursery grounds. Such data are collected for some fisheries but by no means all, and data are often aggregated at higher taxonomic levels that render them useless for species-level assessments.

3.4 Drivers of Species Decline

We analysed the identified drivers of extinction risk for species listed as critically endangered, endangered or vulnerable for the 12 groups in Fig. 10.3. This was achieved by looking at each threatened species in the IUCN Red List and recording the drivers of extinction risk. Whilst many of the IUCN drivers of biodiversity decline are relatively straightforward to interpret, the category 'biological resource use' requires some explanation. This refers to the effects that harvesting activities have on the extinction risk, including those caused by targeted catch and bycatch for commercial and artisanal fisheries, the aquarium trade, marine curio trade, shell collecting and traditional medicine. We also note a controversy that began in the 1990s regarding the use of the IUCN extinction threat categories for commercially fished species (Rice and Legacè 2007). The main policy instruments used for fisheries management such as the United Nations Convention on the Law of the Sea (UNCLOS), the United Nations Fish Stocks Agreement and the Code of Conduct for Responsible Fishing (CCRF) by the Food and Agricultural Organization of the United Nations (FAO) all highlight biomass at maximum sustainable yield (B_{msy}) as a target for sustainable fisheries management. Under a sustainable management regime, it is possible to reduce a stock size to below levels which would trigger categorising a species or stock as threatened with extinction under the IUCN Red List criterion of decline in population size while other fisheries management reference points indicate the stock can still be exploited (Rice and Legacè 2007).

Whilst this has been a subject of debate (see Rice and Legacè 2007), more recent studies have demonstrated that conservation metrics as assessed by Red List criteria align well with fisheries assessments of stock status (e.g., Davies and Baum 2012; Fernandes et al. 2017). Thus, it can be concluded that threat categories identified through the Red List criteria do not exaggerate extinction or extirpation risk and occurrences of disagreement between the two approaches are rare (Davies and Baum 2012; Fernandes et al. 2017). The IUCN has specifically identified this issue in the guidelines for applying extinction risk criteria (IUCN 2017).

For invertebrates, the most significant threat for mobile taxa was biological resource use (Fig. 10.4), including overexploitation of populations through directed fishing (Holothuroidea), bycatch (Cephalopoda) or for shell collecting (Gastropoda). For sessile taxa, Anthozoa and Hydrozoa, drivers of extinction risk are evenly distributed amongst multiple drivers, reflecting a range of anthropogenic stressors in coastal ecosystems. The assessed Gastropoda are also predominantly coastal, and this is reflected in the broader range of drivers of extinction risk in this taxon. Other contributing factors to extinction risk included small geographic range (e.g., cone shells; Peters et al. 2013), life history factors (e.g., Cephalopoda, Holothuroidea; Bruckner et al. 2003; Collins and Villanueva 2006) and high commercial value (e.g., Holothuroidea; Purcell et al. 2014). We also note that the first assessment of threat from deep-sea mining has just occurred, with the first of 14 hydrothermal vent invertebrates (a snail) being listed as 'endangered' (Sigwart et al. 2019). This assessment was on the basis of the small geographic range and number of populations of this species, an attribute shared by other vent-endemic taxa. Deep-sea mining is currently controversial, and regulations for environmental management of this activity are still being formulated by the International Seabed Authority (ISA) of the United Nations. Whether these measures will be sufficient to protect vent-endemic species with small ranges from the effects of exploitation of seabed massive sulphides remains to be seen (Durden et al. 2018; Washburn et al. 2019).

Across the marine vertebrate taxa assessed (except birds), the major driver of extinction risk is resource use, including by both small- and large-scale fisheries and both targeted and incidental catch (Fig. 10.4). This is in general agreement with the key messages of the IPBES Global Assessment Report (2019). In particular, larger species at higher trophic levels have been heavily reduced by exploitation whether as high-value target species or because they are taken incidentally as bycatch, and many have shown a sharp decline (Christensen et al. 2014; Suazo et al. 2014; Fernandes et al. 2017). However, the full impacts of incidental catch are little understood for smaller fish species and many invertebrates, because catch data poorly documents them at the species level. Despite little evidence that overexploitation or bycatch have caused global extinctions, local extinctions and commercial extinctions (in which a species is reduced to a level at which it is no longer commercially viable) are much more common (Dulvy et al. 2003). In addition, overexploitation has dramatically reduced the abundance of numerous species worldwide, both large and small (McCauley et al. 2015), caused large range contractions (Worm and Tittensor 2011) and impacted body mass (Ward and Myers 2005). At the ecosystem level, overexploitation has triggered trophic cascades (Worm and Myers 2003; Frank et al. 2005; Daskalov et al. 2007), reduced total community biomass (Ward and Myers 2005) and degraded habitat structure (Thrush and Dayton 2002; Clark et al. 2016). Within species, it has also affected

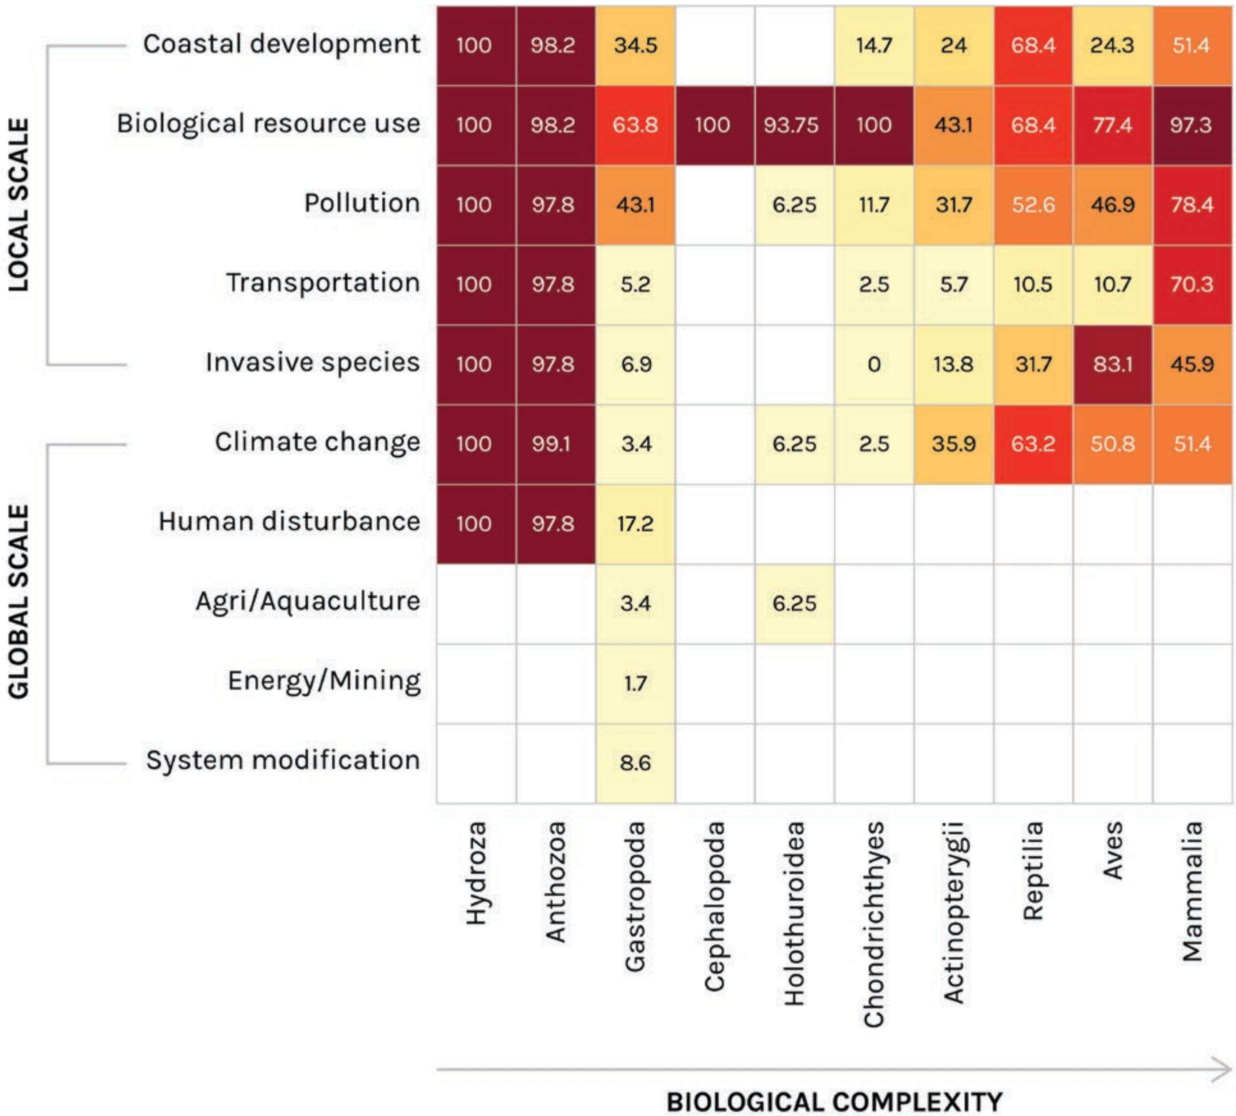

Fig. 10.4 The proportion of the threatened species of each taxon affected by different drivers of extinction risk. *Note: The percentage is reported within each cell. Threatened species out of those assessed for each taxon were: 5 out of 16 Hydrozoa; 226 out of 868 Anthozoa; 58 out of 831 Gastropoda; 5 out of 52 Cephalopoda; 16 out of 371 Holothuroidea; 197 out of 1085 Chondrichthyes; 334 out of 8200 Actinopterygii; 19 out of 95 Reptilia; 177 out of 868 Aves; 37 out of 137 Mammalia. Note that drivers are drawn from the IUCN (2019) Red List. Several drivers are often listed for an individual species. (Source: IUCN Red List)*

genetic diversity and induced evolutionary effects (Pinsky and Palumbi 2014; Heino et al. 2015; Kuparinen and Festa-Bianchet 2017), both of which can potentially reduce the capacity of populations to adapt to threats such as climate change (Blasiak et al. 2020).

A growing number of species are part of high-value consumer markets. As with the Holothuroidea (Purcell et al. 2014), greater rarity pushes their value even higher, which means that they continue to be sourced even if they become more difficult to procure (Courchamp et al. 2006; Sadovy de Mitcheson et al. 2018). Examples of this include shark fins and fish swim bladders, exotic pet species and a range of animals highly valued as luxury food, traditional medicines or ornamentals.

Box 10.2 Fish Spawning Aggregations as Key Biodiversity Areas

To illustrate the importance of key biodiversity areas (KBAs), we selected fish spawning aggregations to contextualise the term "site" in the KBAs,a a seascape unit that (1) can be delimited on maps, (2) encompasses the important habitat used by the species of conservation concern and (3) can actually or potentially be managed as a single unit for conservation. Fish spawning aggregation 'timing' is also part of the context of KBAs. Unlike the conspicuous and betterunderstood breeding colonies of birds and mammals, or the well-known turtle nesting beaches, spawning aggregations of fish are relatively less well-known. But like bird colonies and turtle nesting beaches, they can remain consistent from year to year in time and space and are often appealing targets for fishing because catchability can be particularly high.

Many medium- to large-sized demersal and benthopelagic species in the global ocean form temporary aggregations solely for the purpose of reproduction; these gatherings are the only occasions known for locating a mate and spawning. In the case of tropical groupers (Fig. 10.5a, b) and snappers, many aggregations are highly predictable both spatially and temporally; typically, they form for a week or two over several consecutive months each year. Among temperate species, of the top 25 fishes by weight supplying global fisheries,b many undergo regular spawning migrations, aggregate to spawn for short or extended periods in small or extensive areas, and are exploited at these times. Examples range from Alaska (walleye) pollock (*Theragra chalcogramma*), Atlantic cod (*Gadus morhua*) and Atlantic mackerel (*Scomber scombrus*) to largehead hairtail (*Trichiurus lepturus*) and European pilchard (*Sardina pilchardus*).

Overfishing of spawning aggregations, or of migrations towards these, was a major factor in several fishes declining to threatened status, including the Nassau grouper (*Epinephelus striatus*), the totoaba croaker (*Totoaba macdonaldi*) and the 74 sparid, *Polysteganus undulatus* and other species, none of which were effectively managed prior to declines. Aggregation fishing is likewise implicated for certain populations of orange roughy (*Hoplostethus atlanticus*) (Fig. 10.5c), barred sand bass (*Paralabrax nebulifer*) and large yellow croaker (*Larimichthyes crocea*).[c] Spatial concentration from spawning was also identified by fuzzy logic as an intrinsic extinction vulnerability factor in marine fishes.[d] A global assessment of the known status of 948 spawning aggregations (mainly reef fishes) shows that 26% are decreasing (as determined by reduced catches or underwater visual census counts), 13.5% are unchanged and 3–4%, each, are either increasing or have disappeared entirely; the remaining 53% are of unknown status (Fig. 10.6). These aggregations occur in the global ocean, in over 50 countries, in almost 50 families and in more than 300 fish species.

As productivity hot spots that support a massive proportion of fish biomass, spawning aggregations are key components of the marine ecosystem. Because they are particularly vulnerable to fishing—yet are important to fisheries—they need more conservation and management attention than they have attracted to date, especially from spatial and/or seasonal protective measures.[e] Although conventional management controls may be used for aggregating species—such as minimum sizes, fishing effort or gear controls—and assessments consider maximum sustainable yield or recruitment overfishing, the spawning aggregations themselves are not often explicitly the focus of management, partly because they are so appealing to target. Their management, for example, is not included as a criterion in the Marine Stewardship Council fishery assessment Principle 1, except in relation to habitat protection or access to spawning grounds. However, given issues such as hyperstability and possible depensatory effects at low population levels associated with assessing and managing exploited aggregating species, a specific focus on protecting spawning fish deserves higher priority and special management consideration, especially for species forming large aggregations.[f] On the other hand, well-managed spawning aggregations can support valuable fisheries and contribute to food security as well as conserving biodiversity.

Loss or compromise of key biodiversity areas (such as key egg-laying, nesting, pupping or mating grounds) can quickly reduce populations (see Box 10.2). The finding that biological resource use is the number-one driver of species decline, both in this study and in the IPBES Global Assessment Report (2019), suggests that Aichi Biodiversity Target 6[5] of the Strategic Plan for Biodiversity 2011–2020 has not been attained across the fisheries sector. This is a surprise considering the reported stabilisation and rebuilding of many fish stocks resulting from improved management practices in recent decades (Fernandes and Cook 2013; Hilborn and Ovando 2014; Fernandes et al. 2017; Hilborn et al. 2020). Findings of stabilisation of fisheries are also in contrast to observations that the overall trend, globally, is one of increased overfishing (Pauly and Zeller 2016; FAO 2018). One explanation of the global trends of fisheries declines is the massive increase in the size of the global fishing fleet from 1950 to the present (2015 figures) from 1.7 to 3.7 million vessels (Rousseau et al. 2019). As a result of improving technology (e.g., vessel power) over this period, fishing effort has increased almost exponentially, and catch per unit effort (CPUE) has declined exponentially (Rousseau et al. 2019). The catches from artisanal fishing fleets are often not reported in official government figures, and yet globally the total power levels of these fishing fleets are comparable to those of industrial fishing fleets; they are also less well managed (see below; Rousseau et al. 2019). Asian fishing fleets, in particular, have increased dramatically in both numbers of vessels and fishing power (Rousseau et al. 2019).

Fishing fleets in Europe and North America were reduced in the 2010s, and evidence suggests that it is in these regions CPUEs have stabilised and the decline has also decreased in Oceania as a result of improved fisheries management (Rousseau et al. 2019). Despite a continued increase in overfishing and the decline in CPUEs, global fishing fleets have continued to increase in size and power (Rousseau et al. 2019). If past trends continue, a million more motorized vessels could appear in global marine fisheries in the coming decades.

Both small-scale fisheries and those undertaken by developing states are performing worse than those of developed

[5]By 2020 all fish and invertebrate stocks and aquatic plants are managed and harvested sustainably, legally and applying ecosystem-based approaches, so that (i) overfishing is avoided, (ii) recovery plans and measures are in place for all depleted species, (iii) fisheries have no significant adverse impact on threatened species and vulnerable ecosystems, and (iv) the impacts of fisheries on stocks, species and ecosystems are within safe biological limits.

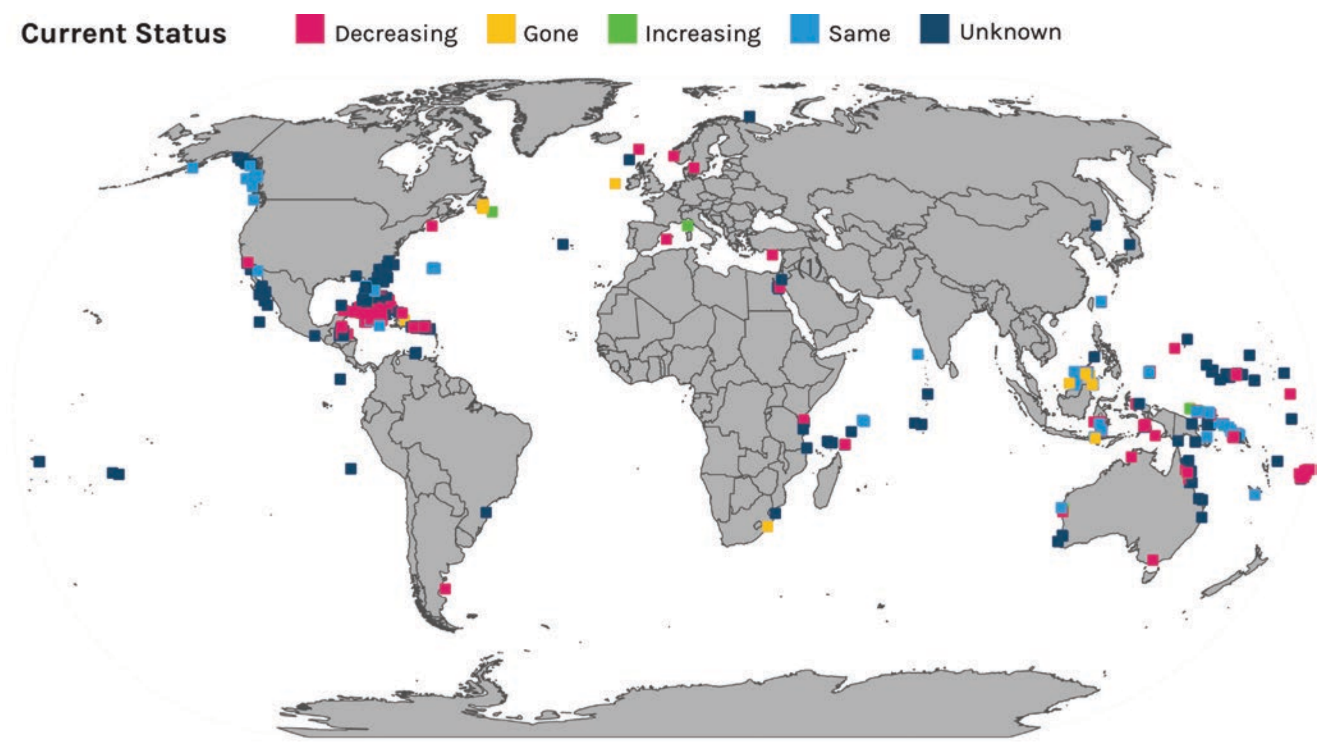

Fig. 10.6 Proportion of invertebrate species assessed on the IUCN Red List compared to the total number of species currently described on the World Register of Marine Species. *Note: A total of 948 documented spawning aggregations are shown. The database is weighted towards tropical reef fish species and underrepresents non-reef and temperate or polar regions.* (*Source: Science and Conservation of Fish Aggregations (database),* https://www.SCRFA.org. *Accessed 14 July 2019*)

states (Hilborn and Ovando 2014; Ye and Gutierrez 2017). A conservative estimate that 23% of global fish catch comes from unassessed fisheries indicates that the lack of data gathering is a significant barrier to sustainable management of target and non- target (bycatch) species (Costello et al. 2012; Gilman et al. 2014; Rousseau et al. 2019). Unassessed fisheries perform poorly in terms of sustainable management compared to those which are subject to scientific stock assessment (Hilborn and Ovando 2014). A large proportion (though not all) of the unassessed fisheries are small, mostly coastal and often artisanal, and many of them are located in the developing world. The costs of scientific fisheries assessments are high and therefore may be uneconomical for implementation in small fisheries, particularly for developing coastal states. In such cases, methods for data-poor fisheries assessment—which rely on broader life history characteristics and/or catch trends, including catch-per-unit-effort estimates—may be a more cost-effective and practical means of management (Hilborn and Ovando 2014), although less reliable (Edgar et al. 2019). Ecosystem-based fisheries management may also be appropriate for small-scale, multispecies fisheries but there is a challenge between the need for complex data with that of practical implementation (Hilborn and Ovando 2014).

Studies that have found standards of fisheries management to be generally poor amongst coastal states with many fisheries exhibiting overcapacity, capacity-enhancing subsidies, problems with foreign access agreements and issues around the transparency of management and decision-making, show that such problems are worse within developing states (Mora et al. 2009; Pitcher et al. 2009). This emphasises the lack of capacity to manage fisheries in these countries (Pitcher et al. 2009; Hilborn and Ovando 2014; Ye and Gutierrez 2017). This situation is magnified because developed countries either import fish from other regions of the world or establish fisheries partnership agreements, effectively externalising their costs for fisheries management (Ye and Gutierrez 2017). As with smallscale fisheries, investment in management methods that are appropriate for developing countries are needed to establish more even standards for global fisheries sustainability. However, this may need reciprocal arrangements between developed and developing countries, especially where the former benefit from the fisheries resources of the latter, to enhance fisheries management capacity through finance, training and technology transfer (Ye and Gutierrez 2017). Seafood trading mechanisms that promote sustainability may also be useful for addressing the management of fisheries in developing countries. Carrot-and-stick approaches may be useful as well, such as marketbased measures (e.g., certification or eco-labelling) which promote sustainable fishing or impose import restrictions on overfished stocks (Ye and Gutierrez 2017).

We also point out that overfishing is by no means restricted to developing states, and a cursory examination of the literature indicates that even in the waters of regions such as Europe, a significant number of stocks are in decline or are overfished, especially smaller stocks (Fernandes et al. 2017). Studies of fisheries sustainability also often neglect to acknowledge that even modern fish stock assessment methods have levels of uncertainty associated with them and relatively few use, or are validated by, fisheries independent data (Edgar et al. 2019). Improvements in catch efficiency in fleets may also be difficult to represent in stock assessments (Edgar et al. 2019). An increasing issue is also that stock assessments are often based on historical assessments when current climate change means that the environment is changing rapidly and such data may not reflect alterations in stock dynamics or distribution (Edgar et al. 2019). Stock assessments also concentrate on management of single species or stocks, ignoring interspecies interactions (e.g., with predators and prey) and other aspects of ecosystem structure, function and health (Edgar et al. 2019).

There have been increasing measures to incorporate biodiversity considerations into fisheries management (Garcia 2010; Rice and Ridgeway 2010; Friedman et al. 2018). These measures can be seen as part of a broader shift in societal views on the use of natural resources from one of straightforward economic exploitation to one of sustainable development whereby the use of ecosystem goods and services must be traded off against the resilience of the environment (Garcia 2010; Friedman et al. 2018). These concepts were introduced into the arena of resource management following World War II, but they were significantly strengthened through the adoption of the World Conservation Strategy in the 1980s, the outcomes of the United Nations Conference on Environment and Development and the Brundtland Commission (1983–87), culminating in the CBD which entered into force in 1993 (Friedman et al. 2018). UNCLOS and the subsequent 1995 Fish Stocks Agreement both included specific provisions with respect to sustainability of both target fish stocks and the wider ecosystem. At this point, states began to incorporate increasing measures to address sustainability and to decrease the environmental impact of fishing. These measures have been reviewed on a regular basis through the United Nations General Assembly, and biodiversity considerations have been gradually mainstreamed in fisheries management through a variety of voluntary agreements and measures by the FAO (e.g., the CCRF; international plans of action to reduce fishing impacts on sharks, seabirds and turtles; see Friedman et al. 2018 for a more comprehensive list). Likewise, the fisheries management and environmental sectors have increased their collaboration to improve the environmental performance of fisheries (Friedman et al. 2018). However, given the impact on extinction risk in marine species (this study and the IPBES Global Assessment Report 2019), there is clearly a long way to go in improving the environmental sustainability of marine capture fisheries. It is also notable that reducing overfishing would in itself reduce impacts on threatened species affected by bycatch (e.g., mammals, seabirds and turtles; Burgess et al. 2018).

Uneven implementation at the global level is also an issue with measures to conserve biodiversity from the destructive effects of fishing. For example, the Convention for the Conservation of Antarctic Marine Living Resources (CCAMLR), which manages fisheries in the Southern Ocean, has worked with the nongovernmental organisation (NGO) Birdlife International to massively reduce interactions (often fatal) of albatrosses and petrels with longline fishing in the region by 67,000 per annum (Friedman et al. 2018). However, at present it is estimated that seabird bycatch in longline fisheries globally range from an average of 160,000 to an upper range of 320,000 per annum and is a major driver of the decline of albatrosses and petrels (Anderson et al. 2011; Dias et al. 2019). Technical measures for longline fishing, including setting lines at night, are known to decrease bycatch and have been successful at reducing this source of mortality in albatrosses and petrels in areas of the Southern Ocean such as South Georgia (Anderson et al. 2011; Phillips et al. 2016). Yet recent analysis of the behaviour of pelagic longline fishing vessels in the southern Atlantic, Indian and Pacific Oceans indicate that less than 5% of vessels may be complying with requirements south of latitude 25° south by setting in the daytime (Winnard et al. 2018). We point out that obtaining data on fisheries bycatch is problematic for many fisheries, especially on the high seas and where observer coverage is low and reporting mechanisms are weak (Anderson et al. 2011; Gilman et al. 2014; Phillips et al. 2016), while the impact of purse-seine fisheries, such as for forage fish, have not been properly evaluated.

Another example of uneven implementation of actions to conserve biodiversity has been in the uptake of the FAO's International Guidelines for the Management of Deep-Sea Fisheries in the High Seas (FAO 2008). These guidelines were established to protect vulnerable marine ecosystems (VMEs), such as deep-sea cold-water coral reefs and seamounts, from the impacts of bottom trawling as well as to improve the management of low-productivity deepwater fisheries. The guidelines have resulted in significant actions to protect biodiversity by regional fisheries management organisations (RFMOs) or agreements through the use of spatial conservation measures, gear restrictions and encounter rules, which require a vessel to move away from an area where VMEs are encountered and to report the encounter (Rogers and Gianni 2010; Wright et al. 2015; Bell et al.

2019). There have also been efforts to implement biodiversity conservation measures using RFMOs and Regional Seas Agreements to implement biodiversity conservation measures (Friedman et al. 2018).

A good example is the action by the North-East Atlantic Fisheries Commission (NEAFC) and the Oslo Paris (OSPAR) Commission to initiate MPAs in areas beyond national jurisdiction, such as the Mid-Atlantic Ridge (Wright et al. 2015). The collaboration between the NEAFC and the Oslo Paris (OSPAR) Commission was formalised first through a memorandum of understanding (NEAFC/OSPAR 2008) and then through a collective arrangement (NEAFC/OSPAR 2014). However, implementation of the FAO guidelines has progressed much more slowly and unevenly with other RFMOs and agreements (Rogers and Gianni 2010; Wright et al. 2015) with some showing poor progress even to the present (Bell et al. 2019). In some cases, this seems to be linked to a lack of capacity and financial support to achieve a better performance of fisheries in areas beyond national jurisdiction in terms of sustainability of stocks and protection of biodiversity (Bell et al. 2019).

For birds, the major threats are invasive species for breeding colonies and unintentional bycatch at sea, with the latter being solely responsible for many species becoming threatened (Paleczny et al. 2015; Dias et al. 2019). For mammals, it is notable that transportation corridors are a major threat given the increasing impacts of ship strikes on cetacean populations (Ritter and Panigada 2019). Climate change and extreme weather are also significant threats for four of the five vertebrate groups assessed. Additional threats include coastal activities such as residential and commercial development and pollution.

Box 10.3 The Global Risk to Marine Biodiversity

In order to estimate the patterns of global risk to biodiversity, we overlaid spatial data on human impacts from Halpern et al. (2008) onto the data on species diversity used to generate Fig. 10.1. Human impact index data were regridded on a 110-by-110-km equal area grid and overlaid with the species richness data (Fig. 10.7a). The relationship between species richness and the corresponding human impact index was assessed by computing the centroid of the relationship in a log-log dimension (Fig. 10.7b). Based on the position of the geographical cell, we established four categories: high richness and high impact in red, low richness and high impact in violet, high richness and low impact in green and, finally, low richness and low impact in blue. Then the Euclidean distance among each geographical cell to the centroid of each category was computed, and the shades of colour in Fig. 10.7b represent these distance intervals.

The multitude of impacts from human society on the ocean have been summarised at a global level, showing alteration of all marine ecosystems.[a] The examination of the relationship between biodiversity[b] and anthropogenic pressures[c] (Fig. 10.7a, b), reveal four different scenarios:

1. Regions where the level of biodiversity and human impact are very high include the Indo-Pacific Coral Triangle; Southeast Asia, including the seas off Thailand, China and Korea; northern Australia; the western Indian Ocean; the Mediterranean; the coasts of northern Europe (North Sea); and some western Pacific Islands. Although this analysis specifically aimed to reduce sampling bias, the levels of sampling for species from different regions of the ocean vary dramatically. Therefore, it is likely that sampling bias has resulted in some areas being classified as having a high biodiversity as a result of intense sampling rather than in having a high inherent species richness; the North Sea is the most obvious example. Some areas have been identified as high impact with a high diversity in other studies (e.g., Indo-Pacific Coral Triangle, northern Australia, some of the western Pacific Islands, areas of the Indian Ocean).[d] In some cases, they are also in locations where there is a rapid increase in human pressures (e.g., Australia and parts of the Indo-Pacific Coral Triangle).[e] The explanation for some areas of the ocean having high levels of diversity and impact vary. In some cases, there is a high coastal population and/or high levels of direct (e.g., fisheries) and indirect (e.g., pollution) exploitation of coastal and offshore marine ecosystems. These waters include those of both developed and developing coastal states.
2. Areas where human pressures and biodiversity are moderately high include the central Indian Ocean and Caribbean, the eastern seaboard of the United States and Canada, and the western coast of the United States as well as northern Brazil. Some of these areas have been identified as high impact with a high diversity in other studies (i.e., the Caribbean and parts of the Indian Ocean).[f] The recent rapid increase in human pressures has also been observed for the coast of Brazil.[g]
3. Areas of high biodiversity and low human pressure include some of the islands in the western and central tropical Pacific, parts of Hawaii, the Galapagos Islands, the Seychelles and areas of the open ocean, Russian Arctic and Alaska. Some regions with a high diversity and a low level of human threat include those in which

significant fully or highly protected MPAs have been established and have reduced pressures as well as being relatively remote (e.g., Kiribati and the Galapagos Islands).

4. We note that there is also a lack of areas which have a lower diversity which are highly impacted (i.e., points in the lower right quadrant of Fig. 10.7b). This may be explained by relatively low observed impacts in polar and open ocean ecosystems, regions with a lower diversity than the tropics and coastal ecosystems. Lack of data on human impacts may be a factor here.

In conclusion, more than half of the ocean is considered to be heavily perturbed by human activities; this includes more than half of the hot spots of marine species richness.

[g] Halpern et al. (2019)

Climate change, especially increasing temperature and habitat impacts, is predicted to become an increasing threat to many invertebrate and vertebrate species (IPCC 2019), but there are uncertainties in terms of projections. The upper thermal tolerance limits for shallow tropical reef-building corals have been exceeded in multiple global stress events from 1998 to 2017 (Hughes et al. 2018a; Stuart-Smith et al. 2015), resulting in large-scale coral loss, local and regional scale shifts in species composition and ultimately reef function. This impacts ecosystem function and the provisioning of ecosystem services (Hughes et al. 2017), and as waters warm, such thermal limits will be more frequently exceeded. There is already evidence that reproductive synchrony in broadcast-spawning corals is breaking down (Shlesinger and Loya 2019), and in fish species, spawning times could be radically affected; these are often temperature-associated changes, and they may impact reproductive success (Asch and Erisman 2018). Some fish appear to go deeper, tracking cooler waters in warming seas, illustrating the rapid responses of marine life to ocean warming (Burrows et al. 2019). It is also stressed here again that the taxa assessed for the IUCN Red List are a biased sample often focusing on those which are heavily exploited (e.g., the Holothuroidea for the invertebrates). Many groups of organisms, especially poorly known invertebrates, are likely to be significantly impacted by climate change either directly as their environmental tolerances are exceeded or indirectly as their habitat is destroyed. The overall impacts of climate change on marine biodiversity is therefore likely to be currently underestimated.

Particularly in the coastal zone, development and pollution, which are often connected, have been the other major drivers of species declines. As with the lack of information on small-scale fisheries, it is notable that the monitoring of biodiversity within the waters of coastal states is weak despite it being a requirement in several of the conventions and agreements reviewed in this report. An indicator of this is the number of species categorised as DD in Red List assessments (see Fig. 10.3). There is overwhelming evidence from a broad range of taxa that loss of habitats formed by foundation species, including corals, mangrove forests, seagrass beds, saltmarshes and kelp forests, continues unabated in many regions of the world (see Sect. 3.5), despite specific agreements or conventions which are aimed at conserving such ecosystems (e.g., the Ramsar Convention on Wetlands).

In summary, biodiversity impacts in the ocean have generally manifested as population declines, habitat degradation and loss, and ecosystem-level changes rather than as global extinctions. Although overexploitation has been the primary driver of loss to date for many groups, it is notable that habitat destruction through coastal development and pollution are major contributors to species being added to the Red List's threatened categories. Climate change impacts are expected to grow in the future.

Although few marine extinctions have been observed (Dulvy et al. 2003), in the best-assessed groups of marine species around 11–46% are judged to be at risk of extinction, a range that spans the proportion of threatened terrestrial species in well-assessed groups (20–25%; Webb and Mindel 2015) with individual groups falling above and below this range. Global extinctions in the marine environment are relatively rarely documented (Dulvy et al. 2003; McCauley et al. 2015), and trends in the species richness of local communities can be relatively flat, though with turnover in species composition (Dornelas et al. 2014). OBIS currently holds over 50 million occurrence records of 125,000 marine species; about half of the total number of marine species described to date according to the World Register of Marine Species (WoRMS). Given this, extinction rates in marine species may be higher than previously estimated because they have simply not been documented.

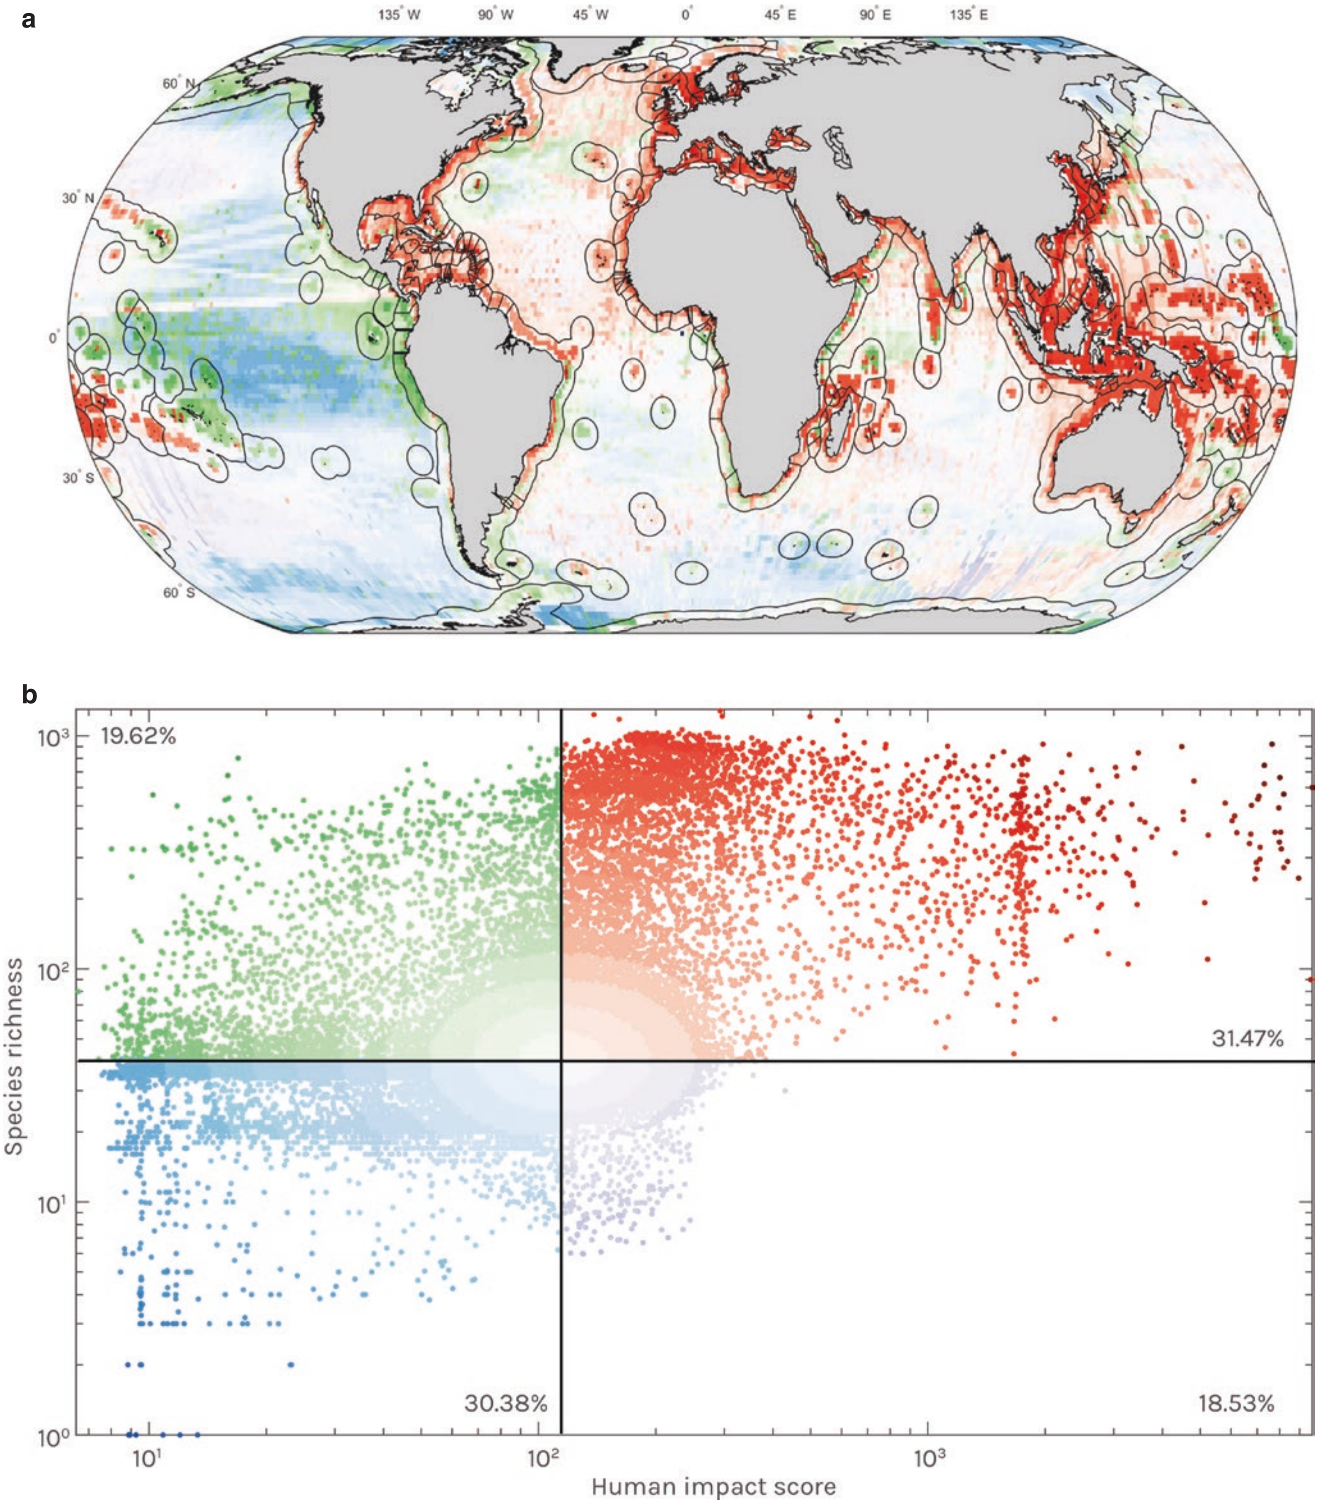

Fig. 10.7 Marine biodiversity in relation to human impacts. *Note: Map* (**a**) *and scatter plot* (**b**) *of the relationship between marine biodiversity and the human impact score. Each quadrant has been computed based on the centroid of the relation in a log-log dimension. Colour shades are computed as the Euclideian distance of the geographical pixel from the centroid of the relation. (Sources: Based on Halpern et al.* 2008 *and Reygondeau* 2019*)*

3.5 Habitat Degradation and Its Drivers

The IPBES Global Assessment Report (2019) summarised key threats to the ocean. Overall, 66% of the ocean is experiencing increasing cumulative impacts (Halpern et al. 2015). The area of ocean still classified as 'wilderness', characterised by having a low impact across a range of anthropogenic stressors, is as low as 13% (Jones et al. 2018), and the area with no discernible human footprint is down to 3% (Halpern et al. 2015). Seagrass meadows decreased in extent by over 10% per decade from 1970 to 2000, the global cover of mangroves has declined about 40% (Thomas et al. 2017) and that of saltmarshes by an estimated 60% (Gedan et al. 2009). Regionally, kelp forests have also shown significant declines in distribution, such as in the Great Southern Reef area of Australia, where they are associated with a high level of endemism (species restricted to a specific geographic location) (Bennett et al. 2016). However, kelp forests are highly dynamic ecosystems, and globally the picture is more complicated; whereas in some areas no trends are apparent, in others, kelp forests are extending their range (Krumhansl et al. 2016).

The role of coral reefs as a flagship ecosystem is characterised by their high biodiversity (Fisher et al. 2015) and their benefits to people (Wilkinson et al. 2016; IPBES 2019). Coral reefs have lost half of their live coral cover since the 1870s, and losses have accelerated over the last two to three decades as a result of the direct effects of climate change (Wilkinson et al. 2016; IPCC 2019) and the indirect effects of other drivers, such as predator outbreaks or disease epidemics, some of which are exacerbated by climate change (Wilkinson et al. 2016; IPBES 2019, BG 4, 5).

Projections for coral reef loss—even at the most optimistic climate change scenarios—are dire: corals could be reduced to 10–30% of their former abundance at warming of 1.5°C, and they could be reduced to only 1% at 2 °C (IPCC 2018). Estimates of coral loss generally conflate loss of cover with loss of reefs. Most reefs will endure, but coral cover on them will decline.

Marine habitats have experienced significant reductions in area in the past century. Coastal reclamation and land-use change, together with pollution and, more recently, climate change, have led to the vast loss of many valuable coastal habitats, estimated at an average of 30–50% (Pandolfi et al. 2003; Polidoro et al. 2010; Waycott et al. 2009; Barbier 2017; Duarte et al. 2020). The first large-scale loss of coastal habitats was documented in China more than a millennium ago and in Europe around the 14th century, when seawalls were built to prevent tidal inundations and to transform saltmarshes into agricultural land (Loke et al. 2019). Such coastal development sprawls throughout much of the world, leading to significant saltmarsh losses in Europe, the United States, Canada and Asia. In China, for instance, more than 60% of the coastline is now artificial (Liu et al. 2018). Land reclamation and conversion to aquaculture ponds and rice paddies has led to much of the observed mangrove loss (Richards and Friess 2016).

Eutrophication and physical impacts, such as dredging, are responsible for much of global seagrass losses (Waycott et al. 2009). It is important to note that as well as causing the loss of ecosystems such as mangroves and saltmarshes, coastal engineering can also prevent such ecosystems from adapting to climate change by preventing the landward migration of such habitats as sea level rises which is known as transgression (Hughes 2004; Alongi 2015; Lovelock et al. 2015).

The first losses of coral reefs were driven by siltation derived from the deforestation of tropical watersheds, overfishing and reduced water quality from sewage and excess nutrient inputs from agricultural land (Pandolfi et al. 2003; MacNeil et al. 2019; Williams et al. 2019). Recent global bleaching events, driven by El Niño warming events exacerbated by anthropogenic ocean warming (Hughes et al. 2017, 2018a, b; Claar et al. 2018; Lough et al. 2018), have now emerged as a major driver of present, and future, coral loss. Under such a multiplicity of detrimental anthropogenic stressors, coral reefs have a tendency to convert to alternative stable states, such as dominance by fleshy algae or cyanobacterial mats (Ford et al. 2018a). This can be associated not only with loss of positive ecosystem services, such as coastal protection or fisheries, but also the potential for negative impacts on coastal human communities (e.g., an elevated risk of ciguatera or ciguatera-like diseases; Ford et al. 2018a).

Upwelling regions, where most of the fisheries for forage fish are located, have also been degraded by overfishing. This results in food chain alterations and the risk of trophic structure breakdown, particularly when small pelagic fish—which are the link between primary producers and the secondary consumers in the typical wasp-waist trophic structure—are removed from the food web (Cury et al. 2000). Such examples have already been observed affecting top predators and lower trophic levels (Velarde et al. 2015a, b).

Overfishing of small pelagic or forage fish results in increased population fluctuations (Cisneros-Mata et al. 1996; Hsieh et al. 2006) and reduces their resilience to natural environmental periodic changes such as the El Niño Southern Oscillation and the Pacific Decadal Oscillation, rendering these forage fish populations more vulnerable to these natural variations, risking their final collapse. Furthermore, more than one million square kilometres (km^2) of the seabed are subject to bottom trawling each year (about 14% of the total trawlable area of 7.8 million km^2 which lies shallower than 1000 m depth; Amoroso et al. 2018). This degrades seabed communities through physical impact, affecting biodiversity and ecosystem function (Thrush and Dayton 2002; Pusceddu et al. 2014; Ashford et al. 2018) and significantly alters ecosystem processes such as sedimentation at large scales (Puig et al. 2012; Pusceddu et al. 2014). Deep-sea ecosystems can be especially vulnerable to the effects of fishing. Seafloor ecosystems are fragile and have low resilience (Clark et al. 2016; Rogers 2018) and the targeting of deep-sea fish species and the effects of bycatch have been observed to rapidly overexploit stocks (Norse et al. 2012; Victorero et al. 2018). The deep sea is increasingly contaminated with litter (Pham et al. 2014; Woodall et al. 2015) and in the near future, it will experience increased temperatures, stratification, decreased oxygen concentrations, and ocean acidification (Rogers 2015; Sweetman et al. 2017). The increasing demand for raw metals and minerals, coupled with the depletion of terrestrial resources, is making deep-sea mining more attractive economically (Petersen et al. 2016; Miller et al. 2018). The impacts of this industry are likely to be extremely severe (Niner et al. 2018).

3.6 Reducing the Provisioning of Ecosystem Services

Biodiversity plays a significant role in ecosystem functioning, which underpins nature's contribution to people (NCP). The concept of NCP is elaborated in the IPBES Global Assessment Report (2019), as the positive and negative contributions of living nature to people's lives. Here, we focus specifically on positive ecosystem services, 'the benefits people obtain from ecosystems' (MA 2005), a subset of NCP. This is because we focus on the potential negative consequences of biodiversity loss in the ocean, and the positive provisioning of ecosystem services has been widely discussed in the context of the marine environment. The benefits of ecosystem services include provisioning services; the production of goods and materials such as food, raw materials and pharmaceuticals; regulatory services; the control of climate, atmosphere and other aspects of the environment that maintain the Earth system; supporting services; those that enable the provision of direct and indirect ecosystem services to humankind; and cultural services, including recreation, tourism, inspiration for art, culture, spiritual experience and cognitive development (de Groot et al. 2012; Costanza et al. 2014; Barbier 2017).

There have been various attempts to estimate a monetary value for marine ecosystem services (Costanza et al. 1997, 2014; WWF 2015; Martin et al. 2016), demonstrating that conservation of species and ecosystems is economically advantageous (Costanza et al. 2014). Specific examples include the use of natural ecosystems for coastal defence (Narayan et al. 2017; Hooper et al. 2019) and for sustainable fisheries management (Costello et al. 2016, 2019; World Bank 2017). Valuations for ecosystem services have been developed for land-based systems where the 'value' of natural capital (abiotic and biotic elements of nature) can easily be estimated from the areas of different types of habitat. Such valuation methods run into difficulties when applied to marine ecosystems, which are three-dimensional; contain many mobile elements, both spatially and temporally; are highly connected and often data-poor (Hooper et al. 2019). Ecosystem services are also provided at different scales—from the individual to human society as a whole (Pendleton et al. 2016; Small et al. 2017)—and, as such, are often public goods or the product of common assets that lead to problems with simplistic systems of monetisation (Costanza et al. 2014). Also, whilst ecosystem services are generally positive, nature can also generate negative impacts on people depending on spatial, temporal, social and cultural contexts (IPBES 2019). This is particularly complicated by the fact that many ecosystem services are strongly linked; thus, enhancing provisioning services, for example, can have a negative impact on regulating services (Raudsepp-Hearne et al. 2010). This can be assessed through analysis of bundles of ecosystem services and the trade-offs between them (Raudsepp-Hearne et al. 2010). The cost-benefit analysis approach inherent in the monetary valuation of ecosystem services can be useful in some contexts, but a more comprehensive methodology is required to establish a value for ecosystem services that takes into account more than just instrumental values (Colyvan et al. 2010; Hooper et al. 2019). One way of counteracting some of the difficulties in valuing ecosystem services can be the development of a risk register, which identifies those ecosystems and their services in danger of loss (Mace et al. 2015).

The relationship between Biodiversity and Ecosystem Functioning (the BEF curve), and thus the provisioning of ecosystem services, is not well understood but is generally observed to be positive (Hector and Bagchi 2007; Harrison et al. 2014; Lefcheck et al. 2015), including in marine ecosystems (Stachowicz et al. 2007; Danovaro et al. 2008; Gamfeldt et al. 2014; Duffy et al. 2016). The shape of the BEF curve has major implications for the impacts of biodiversity loss on ecosystem functioning and service provision and can be saturating, linear or accelerating (Fig. 10.8). These studies provide some scientific understanding of the mechanisms that may underlie the degradation of ecosystem services when biodiversity is lost, including biomass production, resilience to disturbance and biological invasions (Stachowicz et al. 2007; Duffy et al. 2016).

The impacts of biodiversity loss on ecosystem services are multi-faceted. Regional changes in biodiversity have been shown to affect fisheries and other services and generate risks, including harmful algal blooms, oxygen depletion, coastal flooding, and species invasions (Worm et al. 2006).

High biodiversity may also result in greater resistance to climate change impacts, potentially mitigating the effects on fishery yields (Duffy et al. 2016). On coral reefs, ecosystem

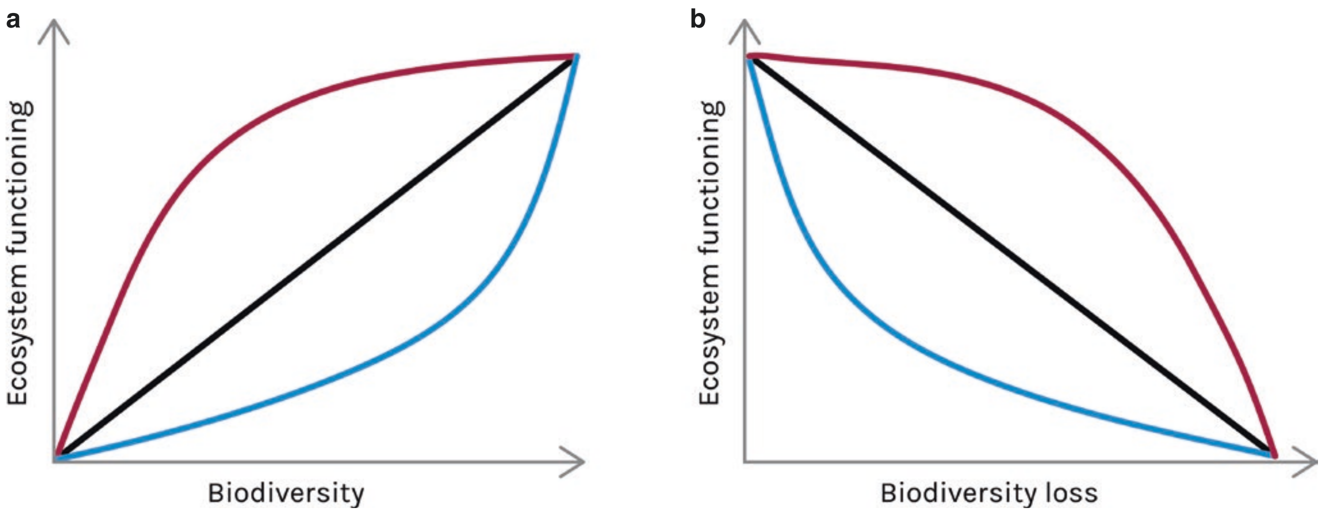

Fig. 10.8 Three types of positive biodiversity-ecosystem functioning relationships. *Notes:* (**a**) *Ecosystem functioning relationships: saturating (red), linear (black), and accelerating (blue).* (**b**) *Relationship between biodiversity loss and the three types of biodiversity-ecosystem functioning relationships. (Source: Modified from Naeem 2002; Strong et al. 2015)*

functioing has been suggested to scale with biodiversity, with human population density impacting both biodiversity and ecosystem functioning (Mora et al. 2018). The loss of coastal habitats renders coastlines more vulnerable to flood risks from sea level rise (Guannel et al. 2016) and cyclones (Barbier 2017; Hochard et al. 2019). In the case of coral reefs, the reduction in damage to terrestrial assets conferred through coastal protection is estimated at $4 billion annually (Beck et al. 2018). For the top five countries that benefit from reef protection (Indonesia, Philippines, Malaysia, Mexico, Cuba), this is the equivalent benefit of $400 million annually in mitigated damage (Beck et al. 2018). Annual expected damage from flooding would double, and costs from frequent storms would triple without coral reefs (Beck et al. 2018). The global loss of coral reefs has been estimated to have an economic impact of more than $10 trillion per annum (Costanza et al. 2014). Coastal habitats are important habitats and nursery sites for many species, so their losses result in reductions in fisheries and coastal food production (Aburto-Oropeza et al. 2008; Barbier 2017; Robinson et al. 2019; Unsworth et al. 2019), and they increase threats to species with a fragile conservation status.

Seagrasses, saltmarshes and mangroves are the three internationally recognised blue carbon habitats that actively sequester and store organic carbon from the environment (Nellemann et al. 2009; Duarte et al. 2013a, b). Mangroves are able to sequester more organic carbon on average than seagrasses and slightly more than saltmarshes (Mcleod et al. 2011). However, seagrasses have an area of around 180,000 km^2 globally, more than twice the area of mangroves, highlighting their importance as a significant carbon sink in comparison to mangroves. However, some of the carbon that is stored in these marine macrophytes has an allochthonous source from other habitats. Kelp beds and other macroalgae communities (Wernberg and Filbee-Dexter 2019) are only recently being considered important in blue carbon storage (Trevathan-Tackett et al. 2015; Krause-Jensen and Duarte 2016; Krause-Jensen et al. 2018). This may not only be through the existence of natural kelp and macroalgal communities but also through kelp aquaculture, where a significant amount of carbon is sequestered prior to harvesting (Duarte et al. 2017). Therefore, it is critical to focus on filling the gaps in knowledge of the extent, distribution and role of macroalgae in a global context, for both climate mitigation and adaptation, and as providers of crucial ecosystem goods and services.

Projected reductions in overall marine biomass associated with climate change may further impact ecosystem services such as fishery yields (Lotze et al. 2019). Any impact on fishery yields may have knock-on effects on food security. It is possible that some countries are likely to face a 'double jeopardy' of impacts on both agricultural and fisheries sectors as a result of climate change (Blanchard et al. 2017).

4 Thresholds and Tipping Points

There are ecological thresholds and other reference points that—if exceeded through the alteration of marine habitats, the exploitation of living marine resources or other human impacts on marine ecosystems—could result in negative and irreversible changes to ecosystems and the broader services they provide (Rockström et al. 2009; Lenton 2013).

The ecosystem approach to management of marine resources aims to preserve the integrity and resilience of marine ecosystems by reconciling conservation and exploitation (Pikitch et al. 2004). Under heavy fishing and climate pressures, many ecosystems are facing severe and abrupt regime shifts. This results in alternate ecosystem states that are most often less productive for fisheries, more prone to booms and busts, weakly reversible and thus less manageable (Pine et al. 2009; Estes et al. 2011, Travis et al. 2014). In this context, a major challenge for research and management is understanding evolving species interactions while identifying critical thresholds and tipping points involved in the disruption of marine ecosystems.

4.1 Changes in Marine Ecosystems

Climate patterns have long been recognised as responsible for regime shifts in both pelagic and benthic marine ecosystems. Empirical evidence has accumulated to indicate that shifts in species composition are initiated by large environmental changes, such as in the California Current (Hooff and Peterson 2006), the Gulf of Alaska (McGowan et al. 1998), the northern Pacific (Hare and Mantua 2000), the northern Atlantic (Aebischer et al. 1990) or the Humboldt Current (Chavez et al. 2003). Likewise, regime shifts between tropical coral reefs and algal-dominated reefs have been reported in response to thermal anomalies associated with El Niño events (Hughes et al. 2007; Diaz-Pulido et al. 2009), now compounded with anthropogenic ocean warming (Graham et al. 2015).

Long-term ocean warming and acidification—as well as extreme events that are becoming more frequent, more intense and longer lasting—alter the structure of ecosystems and cause mortality and community reconfiguration. This is particularly noticeable for sessile organisms that are impacted by discrete, prolonged, anomalous warm-water events known as marine heat waves (Hobday et al. 2018). The widespread bleaching and mortality of reef-building corals (e.g., in the Great Barrier Reef, the Caribbean Sea and the Gulf of Mexico), seagrass meadows and kelp forests have been strongly affected by localised, extreme warming of the ocean (Smale et al. 2019). The density and diversity of corals on reefs are declining, leading to vastly reduced habitat complexity, loss of biodiversity and domination by macroalgae that form stable communities relatively resistant to a return to coral domination (Wilson et al. 2006; Hoegh-Guldberg et al. 2007).

Climate change reinforces the frequency and strength of ecosystem shifts by affecting the distribution of marine life. Geographical shifts in marine species, from plankton and fishes to mammals and seabirds, occur as the result of ocean warming and have changed the distribution by hundreds of kilometres or more since the 1950s (Poloczanska et al. 2013, 2016; IPCC 2019). Ocean warming and heat waves also cause a poleward expansion of corals, leading to a phase shift from kelps to corals in South West Australia, facilitated by the poleward expansion of tropical herbivorous fish that prevent kelp from reestablishing (Wernberg et al. 2016). A poleward shift in species distributions is the most commonly observed pattern; it leads to changes in community structure, resulting in cascading impacts on ecosystem structure (IPCC 2019). The tropics may be particularly sensitive to this phenomenon as well as the transition zone between tropical and temperate communities, where the rate and magnitude of change will be highest. However, in the Humboldt upwelling system off the coast of Chile, most fish species do not show expansion of their southern endpoint because of a weak warming trend, reinforcing the hypothesis that temperature is a major determinant of species range dynamics (Rivadeneira and Fernandez 2005).

A global decrease in abundance and biodiversity of marine species driven by ocean warming is projected to diminish the catch potential for global fisheries in the 21st century (Britten et al. 2017; IPCC 2019). Global rates of biomass production as well as standing stocks are projected to decrease in ocean ecosystems at all depths, from the surface to the deep seafloor. The large-scale redistribution of global fish and invertebrate species biomass is expected to occur by 2055, with an average increase of 30–70% in high-latitude regions and a drop of up to 40% in the tropics under climate change scenarios (Cheung et al. 2010).

These changes in distribution are already affecting the species composition of catches. Fisheries are catching an ever-increasing percentage of warm-water marine species, a phenomenon identified as the ‘tropicalisation’ of the world catch (Cheung et al. 2013). Displacement of tropical herbivorous fish to temperate habitats also drives a similar tropicalisation of benthic habitats (Vergés et al. 2014; Wernberg et al. 2016). Using an ensemble of multiple climate and ecosystem models, it is projected that even without considering fishing impacts, mean global marine animal biomass will decrease by 5% (±4% standard deviation) under low emissions and 17% (±11% standard deviation) under high emissions by 2100, with an average 5% decline for every 1 °C of warming (Lotze et al. 2019).

In ecosystems stressed by overexploitation and climate change, cascading effects that have promoted regime shifts have been thoroughly documented in diverse marine ecosystems, ranging from upwelling systems to coral reefs. In the upwelling system of Namibia, following the collapse of the forage fish during the 1970s, namely sardines (*Sardinops sagax*) and anchovies (*Engraulis encrasicolus*), the ecosystem became dominated by two species of very low caloric value: the bearded goby (*Sufflogobius bibarbatus*) and a jellyfish (Cnidaria, Medusozoa). The latter reached a biomass estimated at more than 40 million tonnes during the 1980s and 12 million tonnes during the

2000s. As a consequence, the predators of these forage fish, the African penguin (*Spheniscus demersus*) and the Cape gannet (*Morus capensis*), suffered a lack of adequate prey and declined by 77% and 94%, respectively. Juvenile penguin survival was found to be approximately 50% lower than in proximate areas that were not food depleted, revealing the extent and effect of marine ecological traps. Cape hake (*Merluccius capensis*) and deepwater hake (*Merluccius paradoxus*) catches declined from 295,000 tonnes in 1972 to 150,000 tonnes since 1990, and the production of Cape fur seal (*Arctocephalus pusillus*) pups was strongly affected (Roux et al. 2013; Sherley et al. 2017).

In the Gulf of California, elegant terns (*Thalasseus elegans*) experience low or failed breeding and nesting distribution changes during years of positive sea surface temperature anomalies associated with increased sardine fishing effort by the local industrial fleet (Velarde et al. 2015b). In the Black Sea ecosystem, intense fishing of large predators and eutrophication of the ecosystem resulted in an outburst of an invasive comb jelly, *Mnemiopsis leidyi*, in a system-wide trophic cascade (Daskalov et al. 2007). Likewise, Wanless et al. (2005) observed that the major reproductive failure of birds in the North Sea during the 1990s was caused by a change in the dominant trophic pathway, which forced the birds to feed on sprats rather than sand eels, with the latter constituting higher-energy feed. A comprehensive fishery-independent data set of North Pacific seabird tissues was recently used to inform pelagic ecosystem trends over thirteen decades (from the 1890s to the 2010s), revealing a long-term shift from higher trophic level prey to lower trophic level prey, from fishes to squids (Gagné et al. 2018).

Most Caribbean reefs experienced a rapid shift from coral to algal dominance during the 1980s. The regime shift was initiated by a decline in the abundance of herbivorous fish caused by overexploitation. The role of herbivory was replaced by the urchin *Diadema antillarum*, but populations of this animal were severely depleted by a disease epidemic. Macroalgae proliferated over the reefs, thereby reducing reef coral recruitment.

Key interactions among four major tropical taxa—coral, macroalgae, fish and urchins—have created a self-perpetuating process that locked reef ecosystems into an alternative, nearly coral-free state (Travis et al. 2014), sometimes together with increased nutrients, to cause and perpetuate regime shifts cascading down to microbial components (Bozec et al. 2016; Haas et al. 2016; Zaneveld et al. 2016). Similarly, in the Humboldt upwelling system, the influence of overfishing of carnivores has favoured the increase in the biomass of herbivores, which subsequently changed the structure of kelp forests (Pérez-Matus et al. 2017).

4.2 Quantifying Tipping Points

The above examples illustrate the need to quantify connectivity in food webs, particularly the strength of predator-prey interactions in order to identify thresholds that push marine ecosystems past their tipping points.

Small pelagic fish exert a major control on the trophic dynamics of upwelling ecosystems and constitute mid-trophic level, 'wasp-waist' populations (Cury et al. 2000; Bakun 2006). These small- and medium-sized pelagic species are the primary food source of many marine mammals, larger fishes and seabirds, transferring energy from plankton to larger predators. They also are grazers/predators in marine ecosystems, feeding upon phytoplankton, zooplankton, and, in some cases, the early life stages of their predators. Using 72 ecosystem models, a global meta-analysis quantified the required forage fish biomass to sustain all fish predators in marine ecosystems, including marine mammals (Pikitch et al. 2012). A minimum precautionary biomass of 40% of forage fish is required to sustain predators.

The cascading effect of the overexploitation of forage fish is particularly detrimental to seabirds. The global and substantial overlap and competition between small pelagic fisheries and seabirds represents 48% of all marine areas, notably in the Southern Ocean, Asian shelves, Mediterranean Sea, Norwegian Sea, and California coast (Grémillet et al. 2018). Behind all of the diversity and complexity of the world's marine ecosystems and the multitude of adverse drivers in bird declines, a striking pattern relating seabird breeding success and their fish prey abundance was found for 14 bird species within the Atlantic, Pacific, and Southern Oceans (Cury et al. 2011). A threshold in prey (fish and krill, termed forage fish) abundance, equivalent to one-third of the maximum prey biomass, was found below which there is the occurrence of consistently reduced and more variable seabird breeding success. This threshold is also equivalent to the long-term average prey abundance and constitutes an evolutionary stable strategy for marine birds. This empirically derived guiding principle embraces the ecosystem approach to management aimed at sustaining the integrity of predator-prey interactions and marine food webs. In well-documented ecosystems, this universal threshold can be revisited and sometimes adapted according to specific ecological and environmental constraints, such as the quality of food or the existence of specific reproductive habitats that are accessible to birds (Guillemette et al. 2018).

Coral bleaching events resulting from global warming and ocean acidification will compromise carbonate accretion, with corals becoming increasingly rare on reef systems (Hoegh-Guldberg et al. 2007). Consequently, policies that result in atmospheric levels of carbon dioxide above 500 parts per million, appear extremely risky for the future of coral reefs and should be strongly avoided. Moreover, near-future increases in local sea temperature of as little as 0.5°C will result in the protective mechanism of coral reefs being lost, which may increase the rate of degradation of local coral reefs (Ainsworth et al. 2016). The loss of ecological resilience occurs because coral cover increases more slowly after disturbances but also when competitive interactions with macroalgae become more frequent and longer in duration. To reduce those interactions, coral reefs require higher levels of grazing to exhibit recovery trajectories (i.e., about 40% of the reef being grazed; Hoegh-Guldberg et al. 2007). Maintaining resilient coral reefs similarly requires harvest limitations and maintaining the minimum biomass of grazing fish species playing a key role, such as parrotfish (with a harvest limitation of less than 10% of virgin fishable biomass combined, with an enforceable size restriction of more than 30 cm) (Bozec et al. 2016).

4.3 Fisheries Management Perspective

With climate change and overexploitation, ecosystems are more vulnerable to changes that previously could be absorbed and may suddenly shift from desired to less desired states in their capacity to generate ecosystem services (Folke et al. 2004). Recovering ecosystems that have experienced regime shifts and have moved past their tipping points appears very difficult, to almost impossible (Haas et al. 2016), so that adaptive practices work only poorly or not at all (IPCC 2019).

For sustainable exploitation and conservation, it is crucial to fully appreciate the fact that ecosystems have tipping points, identify the potential thresholds, and implement them into management (Suding and Hobbs 2009; Travis et al. 2014). In a global change context, multiple and confounding factors influence the state of marine ecosystems. Reliable detection and attribution appear to be fundamental to our understanding of ecosystem changes (IPCC 2019), however, the confident attribution of tipping points in ecosystem dynamics remains challenging. Overexploitation and climate change can promote tipping points and can potentially act in synergy within ecosystems, increasing the risk of irreversible changes. Marine conservation and adaptive management approaches must consider long-term persistent warming and acidification as well as consequent discrete extreme events that are pivotal in shaping ecosystems. The limitation of CO_2 emissions appears to be a strong constraint in the preservation of marine ecosystems, despite the difficulty in reaching the Paris Agreement targets. However, the growing threat of abrupt and irreversible climate change must compel political and economic action on carbon emissions (Lenton et al. 2019).

Fisheries management will have to consider the structuring role of key species, such as small pelagics in upwelling systems or herbivorous fishes in coral reef ecosystems. To avoid regime shifts, the ecosystem approach would greatly benefit from the integration of readily available limit reference points, defined by predator-prey interactions between species, into fisheries management strategies. Examples of such ecosystem-based management approaches which go beyond the traditional single-species stock assessment are plentiful. For example, the CCAMLR has the principle embodied in its articles to ensure that target stocks and their dependent and related species are all maintained at productive levels (Constable 2011). This has steered the management of krill fisheries in the Southern Ocean to ensure that stocks are fished sustainably but also that the predators of this keystone species are supplied with ample prey (Constable 2011). Similar approaches are used to manage finfish in the Antarctic (Constable 2011). Other successes of the CCAMLR ecosystem approach include technical measures to prevent the mortality of albatrosses and petrels in longline fisheries for Patagonian and Antarctic toothfish (*Dissostichus eliginoides* and *Dissostichus mawsoni*; Friedman et al. 2018). Many fisheries, including those in the CCAMLR, employ observer programmes to estimate the bycatch of endangered species or non-target species which may be vulnerable to fishing mortality and to alter fishing practices to reduce such impacts should they be detected (see Gilman et al. 2017). Integration of such ecosystem-based indicators will help to sustain desired ecosystem states while protecting marine species.

5 Monitoring

Humans and climate change continue to impact the marine world and its resources. Thus, when evaluating policy and management approaches, it is vital to be guided by indicators that can capture the status, trends and drivers of ocean health (Block et al. 2011; Miloslavich et al. 2018b; Cubaynes et al. 2019). The main indicators used in marine conservation planning relate to habitat extent, species diversity and extinction risk. Nevertheless, quantifying habitat extent and its associated diversity is difficult because of the high technical and logistical requirements as well as funding constraints; therefore, results are limited in statistical power and often fail to provide the required spatial- temporal dimension (Palmer et al. 2002).

5.1 How Can We Effectively Monitor and Manage Biodiversity and Enjoy the Benefits of a Sustainable Blue Economy in a Changing World?

Ocean monitoring and surveillance have been identified as components of the blue economy needed to respond to ocean health challenges (EIU 2015). The Framework for Ocean Observing (Lindstrom et al. 2012; Tanhua et al. 2019) provided key concepts based on the delivery of a multidisciplinary system, focused on the use of Essential Ocean Variables (EOVs). EOVs act as the common focus for observations to generate data and information products based on the scientific and social requirements. Biological EOVs, which are highly focused on understanding biodiversity trends, were identified based on their relevance to address such social and scientific requirements and their feasibility for global measurement in terms of cost, available technologies and human capabilities (Miloslavich et al. 2018a). The sustained observation of these EOVs will serve as the foundation for implementing management and policy based on science to promote a healthy and sustainable ocean, from local to regional to global scales. These biological EOVs also support the global climate observing system as plankton communities and some coastal ecosystems (e.g., coral reefs, seagrass beds, and mangrove forests) are considered to be essential climate variables (WMO 2016). Planning is currently underway for the internationally coordinated and global networks that measure these biological EOVs. Such planning includes (1) identifying existing data sets for each EOV at all geographical scales; (2) reviewing technological monitoring approaches and standard operating procedures along with the capacity needed to use them; and (3) recommending approaches for data and metadata consolidation in findable, accessible, interoperable and reusable (FAIR) systems. Building the system required to achieve the sustainability of marine diversity and ecosystems, which is critical for the blue economy, will require governance, broad communication and establishing partnerships. It will also require the development of new technologies and of human capacity. Investing in people and their institutions, particularly for developing countries, is required to build infrastructure and long-term support networks with enhanced access to data, tools and technologies. Additionally, collaborations that combine multiple knowledges, including indigenous knowledge, can provide an important role in understanding species distribution (Skroblin et al. 2019) and may play an increasing role in enhancing our capacity to have a more holistic understanding of ecology (Ens et al. 2015).

This can be facilitated by international initiatives, but it will require the long-term engagement of national institutions and local communities as well as funding, including major contributions from philanthropists and the private sector if it is to be sustained (Bax et al. 2018; Miloslavich et al. 2018b).

5.2 What Are the Technological Tools for Biodiversity Monitoring?

The methods for monitoring marine biodiversity are quite extensive and specific to the taxonomic group, type of ecosystem and/or spatial scale of the monitoring effort. Some of the persistent technical challenges of marine biodiversity monitoring include the need for clearly defined and standardised best practices and interoperable observation technologies. Data are collected through a combination of remote sensing and in situ observations (see Canonico et al. 2019 for a recent review). Remote sensing allows for observations at broad, global scales repeatedly, with a resolution highly dependent on the sensor. It provides information on functional phytoplankton groups and on the cover and distribution of some coastal habitats, such as coral reefs, seagrass beds, mangroves and macroalgae, and some structured habitats such as floating macroalgae (e.g., *Sargassum*). In situ observations include a variety of methods, from simple visual survey and/or sample collection to the use of sensors, instruments, and platforms. At the most basic level these observations rely on survey and/or sampling either on shore or in shallow water using scuba divers. Large-scale application of such methods can be used to tackle global questions about spatial differences in coastal marine communities or for monitoring over time if protocols are standardised (e.g., the Natural Geography in Shore Areas, or NAGISA, sampling protocol used in the CoML; Iken and Konar 2003; Cruz-Motta et al. 2010). Some of the most-used newer technologies include acoustic monitoring, which supports biomass and abundance estimates among other parameters; animal telemetry for animal movement in combination with environmental descriptions; 'omic' approaches to report on biodiversity across scales and taxa; and video/photo imagery from automated underwater vehicles (AUVs), remotely operated vehicles (ROVs), submersibles and divers. These technologies are already generating big data, which will require the use of artificial intelligence and machine learning processes, improved (real-time) quality control and enhanced data capabilities (Edgar et al. 2016). In the next decade, it will be critical to develop technologies that enable increasingly automated real-time biological observations.

In this context, satellite based remote sensing is frequently proposed as a cost-effective tool to lower the costs of obtaining spatially and temporally relevant information and monitoring changes (Mumby et al. 1999, 2004; Green et al. 2000). As technology continues to advance, improving the resolution and accuracy of satellite imagery, our knowledge of the distribution of habitats is improving. Although there has been a progression in monitoring a number of coastal habitats (Mumby et al. 2004; Giri et al. 2011), remote sensing has certainly not reached its full potential (Andréfouët 2008) because of technical limitations and difficulties classifying habitats (Zoffoli et al. 2014). Often there is a need to supplement this with existing field data and/or expert knowledge to obtain a more complete picture (Andréfouët 2008). Moreover, only the shallower component of subtidal critical habitats, such as seagrass meadows and algal stands, can be resolved by even the most advanced remote sensing technologies (e.g., hyperspectral satellite imaging; Wicaksono et al. 2019). Likewise, important habitats, such as deep-sea corals, are beyond the reach of existing or future airborne remote sensing technologies. The mapping of seabed topography at a relatively coarse scale can be undertaken using satellite gravity mapping (e.g., for seamounts; Yesson et al. 2011).

Habitats at shelf depths and in the deep sea were traditionally mapped by using plumb lines which had a wad of tallow in a cavity at the bottom of the plummet (the weight at the end of the line). The tallow would pick up fragments of whatever was on the seabed and a notation of the seabed type was added to nautical charts, providing a navigational aid for mariners.

As modern oceanographic science developed in the 19th century, habitat mapping was undertaken by trawling, dredging or other forms of seabed sampling. A significant advancement in seabed mapping was the development of single-beam sonar. Using this technology, Bruce Heezen and Marie Tharp constructed the first global topography maps of the seafloor. In the present day, the main tool of habitat mapping in coastal and deep waters is multibeam acoustic survey (Harris and Baker 2012; Lamarche et al. 2016). These sophisticated sounders not only accurately measure the depth of the seafloor but also give information on the hardness of substrata through the strength of acoustic return as well as seafloor microtopography (roughness) and volume heterogeneity, which relates to sediment grain size and composition (Harris and Baker 2012; Lamarche et al. 2016). This information can be used to identify seafloor texture, whether it is made of rock or sediment, for example, and can be used to classify habitat (Lamarche et al. 2016). Coupled with the use of seabed sampling using surface deployed gear (e.g., trawls or cores) and/or image-based surveying using towed cameras, ROVs, AUVs or submersibles for groundtruthing, these methods can provide accurate maps of seabed habitats (Harris and Baker 2012; Lamarche et al. 2016). An issue with this approach is that it is time consuming and expensive, and coverage tends to be restricted to areas targeted for specific study for scientific or industrial purposes. The global Seabed 2030 mapping project is currently collecting multibeam data to produce a more comprehensive map of seafloor topography than previously available.

Although it will certainly allow the identification of larger-scale geomorphological structures such as seamounts, canyons and plains, the extent this will be used in mapping of finer-scale habitats is unclear. An alternative technology to multibeam bathymetry is side-scan sonar. This produces a photograph-like sonar image of the seabed and can be particularly useful in imaging small objects and finer-scale structures on the seabed (e.g., sand waves; Lamarche et al. 2016). This technology is cheaper than multibeam systems but has a poor georeferencing capability, and backscatter calibration is usually not possible (Lamarche et al. 2016). A relatively new technology now being carried by AUVs is synthetic aperture sonar which provides very high resolution imagery but at a longer range than side-scan sonar (Hansen 2011). AUVs with hyperspectral imaging capabilities are now being developed to extend remote sensing capabilities to deeper waters for high-resolution habitat identification (Bongiorno et al. 2018; Foglini et al. 2019).

Many marine habitats and areas of the world still remain under-studied at larger scales, such as rocky reefs, algae beds, and large areas of the deep ocean for which there are no publicly available global distribution maps at present (Rogers et al. 2015). For the habitats where spatially referenced and processed information are available, often data sets relate to one point in time with very little indication of changes through time (Halpern et al. 2015). This limits their utility in understanding how, where and when the natural world is changing. As new technology is made available, such as the Google Earth Engine platform (Gorelick et al. 2017; Traganos et al. 2018; Nijland et al. 2019),[6] and barriers for information sharing are removed, there is a great opportunity to increase our capacity to understand, monitor and develop evidence-based policies and management plans to protect marine ecosystems.

Satellite remote sensing has had a significant impact on assessing the levels of fishing effort in the global ocean. Access to fisheries data is often denied for reasons of commercial confidentiality, but in a world where fisheries are sustainably managed, it is not necessary to hide what is taken or conceal the location, whether in national waters or in ABNJ. Satellite surveillance is increasingly useful as a means of spotting problems such as illegal fishing and transhipments; it is also a useful way to assess patterns of fishing even in the remotest parts of the ocean (Eigaard et al. 2017; Amoroso et al. 2018; Boerder et al. 2018; Elvidge et al. 2018; Ford et al. 2018b, c; Kroodsma et al. 2018;

[6]For more information about the Google Earth engine, see https://earthengine.google.com/

Longépé et al. 2018; Rowlands et al. 2019). The development of online platforms such as the Global Fishing Watch has exposed the industry to societal oversight where previously it did not exist, especially in waters far from the coast.[7]

The new model of fisheries surveillance has been taken up by several coastal states, such as Chile, Indonesia and Panama. These countries have now committed to making the tracking data of vessels carrying their flags available to public scrutiny. Such data can only improve the sustainability of fishing; it will not only identify where and when fishing is taking place but also provide insight into the enforcement of MPAs (Rowlands et al. 2019) and destructive fishing practices (Winnard et al. 2018).

5.3 Overseeing the Monitoring of Biodiversity

At the intergovernmental level, two major organisations provide a governance framework for marine biodiversity observations.

The first, the IOC of UNESCO, through the Global Ocean Observing System (GOOS), has led the implementation of the Framework for Ocean Observing (Lindstrom et al. 2012) with the goal of serving users across climate, operational services and ocean health (Tanhua et al. 2019). GOOS is also co-sponsored by the World Meteorological Organization, the United Nations Environment Program, and the International Science Council. Within GOOS, marine biodiversity observations are coordinated by the Biology and Ecosystems Panel, or GOOS BioEco (Miloslavich et al. 2018a). GOOS also provides governance at the regional level through the GOOS Regional Alliances, examples of which are the Integrated Marine Observing System (IMOS) of Australia, the Integrated Ocean Observing System (IOOS) of the United States and the European Global Ocean Observing System (EuroGOOS) in Europe. Through expert panels, regional alliances, the Observations Coordination Group, and affiliated projects, GOOS supports a broad observing community, from individual scientists and research organisations to governments, UN agencies, and international programmes.

The second major organisation is the Marine Biodiversity Observation Network (MBON) framed in the Group on Earth Observations Biodiversity Observation Network (GEO BON), which facilitates the coordination between individual monitoring programmes and existing networks (Muller-Karger et al. 2018). Both MBON and GOOS BioEco share common goals and encourage the use of best practices for marine biodiversity monitoring, the contribution of data to open access data systems and provide a framework for data management, communication and applications (Canonico et al. 2019).

Based on these shared goals, these organisations have signed an agreement together with OBIS, which operates under the IOC's International Oceanographic Data and Information Exchange (IODE) programme, to work together to advance sustained, globally consistent observations of marine biodiversity with the commitment to open access and data sharing, implementing best practices and international standards and enhancing global capacity (Miloslavich et al. 2018a). Having this overarching governance in place is a major step; however, much work still needs to be done. To achieve the required level of coordination and communication across all networks, programmes and countries, the organisations need to ensure the interoperability of the data and that the data contributes to the development of indicators to address policy and management requirements. Specifically related to governance in coastal zones, an assessment carried out by the Economist Intelligence Unit across 20 countries found that the Coastal Governance Index is uneven, with developed countries doing relatively well but still requiring work. Other important factors that contribute to better coastal policies include participatory inclusion in decision-making and accountability, the level of economic development, having the capacity required for the implementation of policies, and having marine spatial planning policies (EIU 2015).

With the proper training and quality control, citizen science can be used both as a way of communication and as a way for data collection on a broad range of scales. An excellent success story of citizen science is the Reef Life Survey (RLS) programme.[8] The RLS was established in Australia in 2008 to collect data on the biodiversity of benthic and fish communities on rocky and coral reefs through trained volunteer scuba divers (Stuart-Smith et al. 2017). Since its establishment, it has expanded globally to more than 3000 sites in nearly 50 countries, providing invaluable data for ecosystem management and conservation (Stuart-Smith et al. 2018). Furthermore, the Biodiversity Indicators Partnership, which promotes the development and delivery of biodiversity indicators to measure progress on Aichi Biodiversity Targets and SDGs, has recently accepted two of the RLS indicators (the 'Large Reef Fish Indicator' and the 'Reef Fish Thermal Index') to inform Aichi Biodiversity Targets 6, 10 and 11 and also SDG 14.2 (RLS 2019).

6 Gaps and Challenges in Habitat Protection

6.1 How Much of Key Marine Habitats Are Protected?

To understand how MPAs are currently distributed across the key habitats considered (Table 10.1), the March 2020 version of the World Database of Protected Areas (UNEP-WCMC and IUCN 2020) was used to calculate the extension of all the coastal protected areas and MPAs (hereafter collectively referred to as MPAs), or the number of reported locations of each habitat, inside of an MPA within EEZs. We considered three scenarios for the analyses: (1) all areas designated as MPAs without distinction, (2) only MPAs reporting a management plan and (3) only fully protected MPAs (labelled in the database as 'no-take zones').

We estimate that 12% of the habitats considered in this study lie within an MPA. However, when we considered only the MPAs with management plans, only 6% of the habitats are included, and just 3% are in fully protected MPAs at a global level. An example of how these three scenarios overlap is provided by kelps, where more than 40% of the world extent of these habitats are recorded as protected within all forms of MPAs (Fig. 10.9a). However, kelp protection decreases to only 24% under MPAs with management plans and only 1% in fully protected MPAs (Fig. 10.9a).

The deeper habitats show a similar trend, with the habitat with most of its area protected being cold-water corals. They have 24% lying within MPAs, which drops when only managed and fully protected MPAs are considered to 14% and 4%, respectively.

It is important to consider that coastal habitats have arguably received historically higher levels of human pressures

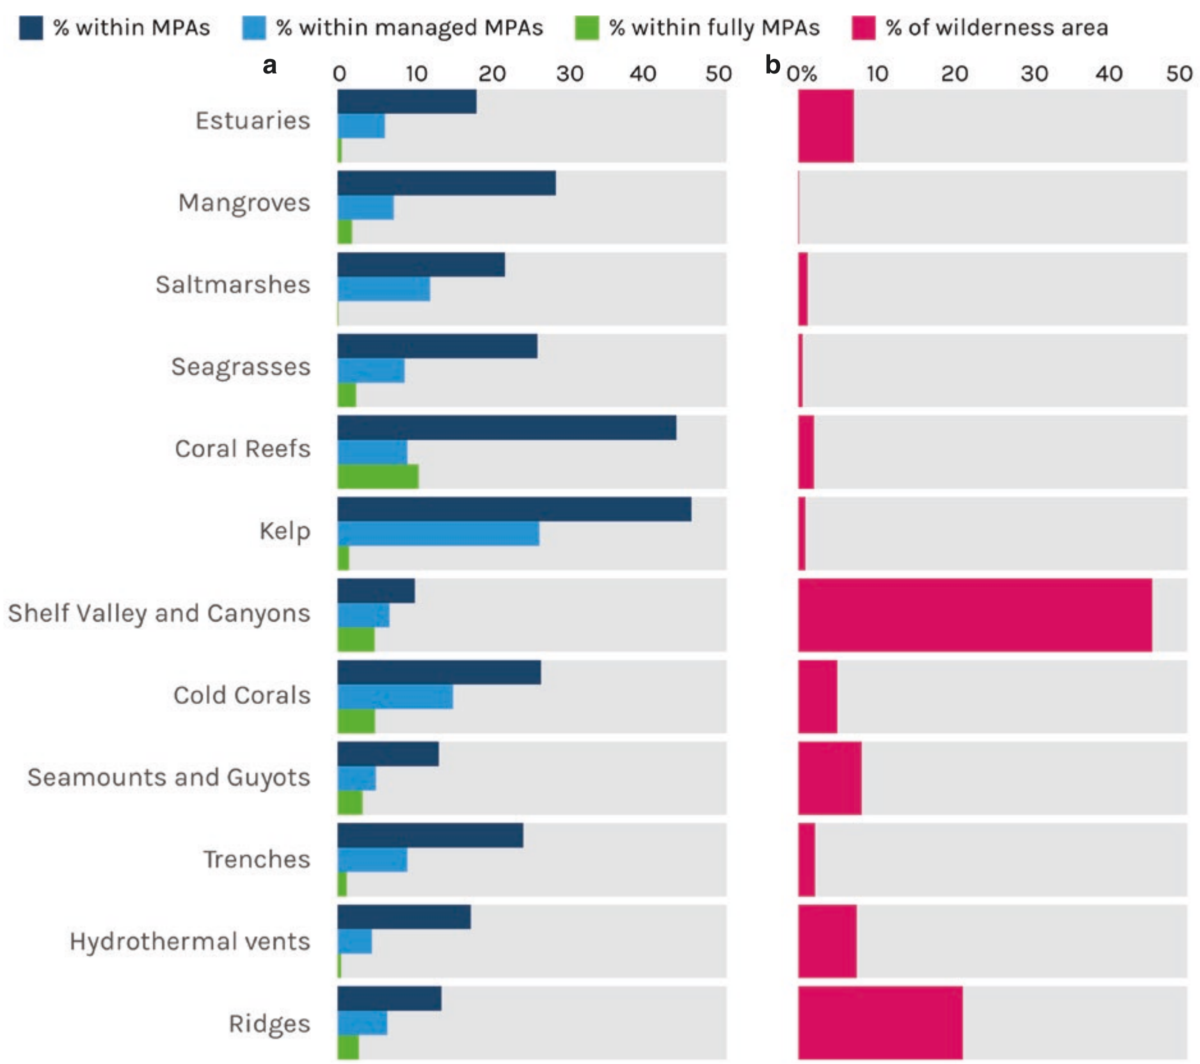

Fig. 10.9 Current conservation efforts for key selected habitats. *Notes: Habitats on the x-axis are ordered according to their distance to the coast, as a proxy for their average depth.* (**a**) *The bars represent the percentage of the habitat within MPAs, within MPAs with a management plan, and fully protected MPAs.* (**b**) *The percentage of wilderness inside the habitat area. (Source: Authors)*

compared to oceanic habitats. Evidence of the destruction of coastal habitats (see Sect. 3.5, Habitat Degradation and Its Drivers), which has already severely reduced their original distributional area, should be taken into account when considering the percentage of the current habitat extent in MPAs.

Estuaries and saltmarshes are the coastal habitats with the lowest proportion in fully protected MPAs (Fig. 10.9a) despite their importance in habitat provision for a wide range of species and ecosystem services (e.g., carbon sequestration, nutrient cycling, coastal protection; Barbier 2017).

The area of the selected habitats lying within designated MPAs declines moving from the coast to offshore (Fig. 10.9a). However, this pattern is much less obvious for MPAs with management plans and non-existent for fully protected MPAs (Fig. 10.9a). This suggests that both coastal and offshore habitats are equally poorly represented within fully protected MPAs. The offshore habitats had on average a higher proportion in marine wilderness (based on the area estimated by Jones et al. 2018); most likely the result of decreased accessibility (Fig. 10.9b). At present the global coverage of MPAs is 7.43%, with 17.22% of national waters designated as MPAs, but this figure falls to 1.18% in ABNJ (UNEP-WCMC and IUCN 2020; accessed on 30 March 2020). The discrepancy between the coverage of MPAs in EEZs and ABNJ results from the lack of a coherent international legal framework for the establishment of marine protected areas on the high seas, putting at risk largely unknown biodiversity (O'Leary et al. 2012; Rogers et al. 2015). International efforts towards protecting habitats such as seamounts in ABNJ have been made in regional or sub-regional organisations such as RFMOs (e.g., New England seamounts protected from bottom trawling by the Northwest Atlantic Fisheries Organization), and the ongoing negotiations to manage marine biological diversity in ABNJ, which are aimed at establishing a new legal framework for protection of biodiversity in international waters and on the seafloor.

Additionally, the existence of a habitat inside of an area designated as an MPA does not mean it is protected. As can be seen from the above analyses, many MPAs lack a management plan, and even where such plans exist, MPA objectives and management might not involve the habitat, and permitted activities may even be destructive and/or poorly enforced (e.g., trawling in MPAs; Dureuil et al. 2018). In many meta-analyses of MPA effectiveness, there are benefits to conservation even where protection is partial (i.e., MPAs where not all activities are banned; e.g., Lester and Halpern 2008; Sciberras et al. 2013; Gill et al. 2017; Sala and Giakoumi 2017). Our analyses suggest that despite the apparent progress reported in MPA designation (UNEP-WCMC and IUCN 2020), reaching the Aichi Biodiversity Target 11 of having 10% of representative habitats of our oceans being well protected is still a remote target, as has been found in other studies (Klein et al. 2015; Jenkins and Van Houten 2016; Sala et al. 2018a; Jones et al. 2020). Key shortfalls and key features that can hinder and enhance MPA effectiveness, respectively, have been recognised in current literature (Edgar et al. 2014; Gill et al. 2017). In particular, the NEOLI features identified the most important characteristics of an MPA: being No-take (i.e., fully protected), well Enforced, Old (more than 10 years), Large (more than 100 km^2) and Isolated. The main issue is that MPAs that fulfill some or all of these features, are not common globally (Edgar et al. 2014; Sala et al. 2018a). Although, most existing MPAs could improve in some of the NEOLI features by increasing the no-take area, fostering compliance and enforcement, and extending the boundaries to isolate key habitats to protect, these features are difficult to achieve. Our analyses indicate that to reach international goals and markedly increase the conservation benefits of the global MPA network, it is important to improve existing MPAs while also creating new ones.

6.2 Protection Gaps in EEZs

Humans are exerting pressures on marine habitats throughout the world, often leading to significant damage to them as well as loss of associated biodiversity (Halpern et al. 2015). To understand this on a global scale, we calculated the average biodiversity value for each EEZ, using biodiversity data from Reygondeau and Dunn (2018), and found the sum of ecological and social factors that decrease the health of the ocean. This analysis reveals that countries that have higher biodiversity also experience higher pressure (p-value <0.001, $R^2 = 0.165$; see Fig. 10.7). One might expect that countries with high gross domestic product (GDP) would be capable of protecting a larger fraction of their EEZ. Although we found a significant relationship, GDP explains very little of the variation in the area of MPAs that are implemented in the national waters of each country (p-value <0.001, $t = 0.11$; see Fig. 10.10a). We would expect that countries with higher investment capacities (i.e., GDP) would show a higher relative area of MPA coverage, especially because EEZs and GDP tend to be related. Furthermore, although there are considerable conservation efforts and investments—reflected in MPA coverage—biodiversity and the relative MPA area to each country's EEZ are not correlated (p-value >0.05; see Fig. 10.10b). These results indicate that areas with high biodiversity should be prioritised for protection not only for their biodiversity per se but also to create resilience from the high pressures they experience.

However, representative biodiversity from all regions must be included in a global network of fully or highly protected MPAs, and this must be complemented by sustainable management of all human activities in the ocean (see below; Margules and Pressey 2000). The lack of correlation between

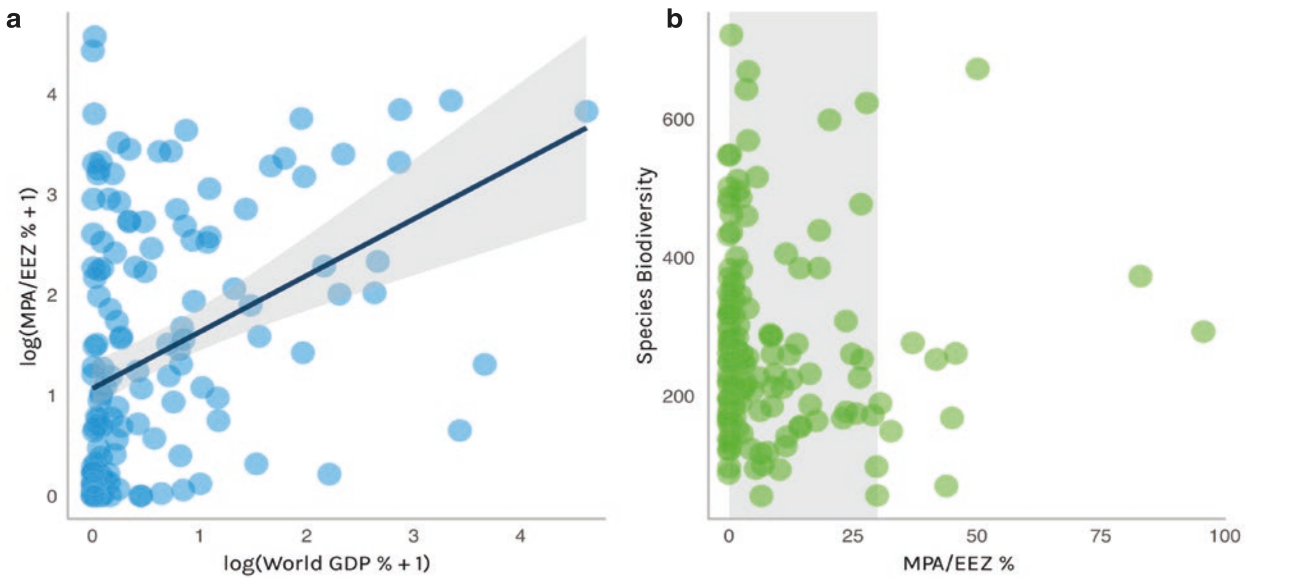

Fig. 10.10 Relationships between biodiversity, GDP and MPA extent. *Notes: Panel* (**a**) *shows the gross domestic product (GDP) that a country has relative to the world and the amount of their exclusive economic zone (EEZ) that is covered by marine protected areas (MPAs). Panel* (**b**) *reveals that the relative size of a country's MPAs are not correlated with their biodiversity. The grey region in Panel* (**b**) *represents the countries with less than 30% of their EEZ with MPA coverage. (Source: Authors)*

the biodiversity within an MPA and the amount of the EEZ that is protected by a coastal state suggests that biodiversity-rich countries do not develop more MPAs than biodiversity-poor countries.

Further, Kuempel et al. (2019) found that MPAs with the strictest protection were 6.3 times more likely to be found in low-threat ecoregions, indicating that countries focus conservation efforts in the least threatened areas as opposed to areas with high threats to biodiversity. Additionally, areas with lower biodiversity can still be highly productive and valuable in terms of ecosystem services provision to coastal states as well as in ABNJ.

Even when considering the best-case scenario, using all the MPAs reported and assuming that these have at least some benefit to protect habitats, it is possible to see that between 45% and 90% of countries are protecting less than 30% of habitat extent (Table 10.3). The numbers worsen, in area terms, when the two other scenarios are considered, with at best 23.3% of countries with 30% or more of a habitat lying within a managed MPA (saltmarsh) and 4.2% in fully protected MPAs (hydrothermal vents; Table 10.3).

For saltmarshes and estuaries, no countries include 30% of the area of habitat in fully protected MPAs (Table 10.3). Indeed, if we break down the conservation effort for each country for the category of all MPAs, there is a large gap where some countries are committing more effort whereas others are not performing as well. Here, we propose to measure the proportional conservation efforts amongst countries by using measures of central tendency, the mean and the median percentage of habitat protected globally, as an alternative to absolute measures of habitat area. The overall protection effort is 'fair' when the mean and median percentage of habitat protected globally coincide to form a normal distribution of the conservation efforts (Fig. 10.11). The mean and the median percentages are reported as blue and red circles, respectively, which show that for most habitats there is a wide gap between area present and area protected. This indicates that current global conservation efforts are inadequate. Most countries are protecting very little (less than 1%) of the habitats they could protect, and conservation efforts are unevenly distributed. If MPAs with management plans are considered, for some habitats the 'effort gap' metric is even worse (e.g., saltmarshes, kelps and coral reefs; Table 10.3). In other cases, the effort gap appears to decrease, but this is mainly because the amount of habitat in managed MPAs is so small compared to all MPAs. A very small amount of habitat lies within fully protected MPAs, rendering the effort gap metric very small as all states are equally performing badly. Through this effort gap metric, we see that for fair habitat conservation globally, countries need to cooperate to reach international goals, thereby compensating for the effort gap either by increasing their MPAs and/or aiding conservation programmes in less wealthy countries or regions. The effort gap highlights how even if some countries are contributing towards achieving a 'total conservation target', the majority of countries are under-performing.

This proportional conservation approach could also be applied to properly measure the effort each country should give to the protection of the high seas. This approach can be useful in a context where the use of ABNJ is emerging and

Table 10.3 Summary of the habitat protection target proposed

Habitat	Percentage of countries below 30%	Percentage of area below 30%	Mean percentage effort	Median percentage effort	Effort gap
Saltmarshes	51.2	87.9	41.0	28.1	12.9
	(76.7/100)	(92.0/100)	(21.1/0.5)	(1.8/0)	(19.3)
Kelps	45.3	37.2	36.3	37.7	−1.4
	(77.4/98.1)	(52.6/100)	(17.0/2.88)	(1.0/0)	(16)
Coral Reefs	61.6	44.5	30.7	17.5	13.2
	(86.6/97.3)	(91.7/95.8)	(22.3/1.1)	(0/0)	(22.3)
Hydrothermal vents	64.6	62.6	29.5	0.0	29.5
	(85.4/95.8)	(94.1/99.3)	(13.9/3.2)	(0/0)	(13.9)
Mangroves	59.1	59.2	29.3	19.9	9.4
	(86.0/98.9	(92.3/97.3)	(9.3/1.1)	(0/0)	(9.3)
Seagrasses	70.3	58.6	24.4	6.68	17.7
	(89.0/99.2)	(86.6/98.5)	(9.0/0.8)	(0/0)	(9)
Estuaries	72.8	76.2	20.2	5.7	14.5
	(88.8/100)	(94.8/100)	(8.5/0.1)	(0/0)	(8.5)
Cold Corals	76.6	77.5	18.7	0.0	18.7
	(91.2/98.5)	(87.3/99.8)	(7.98/1.5)	(0/0)	(7.98)
Trenches	80.4	74.8	18.3	0.0	18.3
	(93.5/97.8)	(91.4/100)	(6.59/2.34)	(0/0)	(6.59)
Ridges	82.0	73.1	16.4	0.0	16.
	(92.6/98.4)	(89.6/97.8)	(7.77/2.26)	(0/0)	(7.77)
Seamounts and guyots	81.4	59.1	14.4	0.0	14.4
	(92.0/96.5)	(84.7/86.6)	(6.3/2.5)	(0/0)	(6.3)
Shelf Valley and Canyons	90.6	97.1	11.1	0.1	11.0
	(95/98.9)	(98.0/99.9)	(5.3/1.0)	(0/0)	(5.3)

Notes: For each habitat, the percentage of countries that have granted less than 30% protection is shown ('Percentage of Countries below 30%') for all MPAs and then, in parentheses, the figure for managed MPAs/fully protected MPAs that is below 30% protection. The 'Mean' and 'Median Percentage Effort' refers to the percentage of habitat countries protect on average. The differences between these two values is reported as the 'Effort Gap', representing the percentage by which countries below the threshold should ideally increase their protection to make a fair contribution to conservation. We did not calculate this for fully protected MPAs as the amount of habitat lying within this category of protected area is so low that the effort for all countries is equally very poor
Source: Authors

presents serious governance challenges (Merrie et al. 2014). For example, each country should deploy a conservation effort relative to its use of ABNJ across all sectors (e.g., fishing, shipping). ABNJ are a special case of global commons management. In these areas, establishing and enforcing conservation measures will require new financing mechanisms, such as a levy on the use of the resources and/or by establishing an international trust fund under the new legally binding instrument for the conservation and sustainable use of biological diversity of ABNJ. It is important that ABNJ are managed fairly by a proportional conservation measure rather than international goals with total conservation targets, which might disproportionately favour some countries over others and imperil the health of the high seas.

Whilst we have emphasised the use of MPAs in biodiversity protection mainly because their implementation can be quantified and analysed spatially to some extent, MPAs are not the only management measure that can conserve biodiversity (Duarte et al. 2020). It has been argued that the ocean can be compared to a frontier system, both to within EEZs and in ABNJ, where there is open access to resources, larger and less differentiated jurisdictions than on land and fewer laws that constrain human activity (Norse 2005). This situation has led to a free, open access scramble for resources. This has resulted in increasingly unsustainable levels of exploitation of marine living and other resources and the impacts on biodiversity that have been documented here and in other studies (Norse 2005). Marine reserves by themselves do not necessarily reduce overfishing, competition amongst fishers or the growth of global fishing fleets, and they may even increase competition amongst fishers by reducing areas available to fish, possibly even displacing fishing effort to areas where levels of fishing have been low or nonexistent (Kaiser 2005; Norse 2005; Agardy et al. 2011; FAO 2011; Hilborn 2018).

Marine reserves also provide little protection from threats such as long-range pollutants (e.g., many persistent organic pollutants; Agardy et al. 2011) or invasive species (e.g., Burfeind et al. 2013). The connectivity of populations of marine species and between habitats also means that even if fully protected MPAs are designed to ensure maximum con-

Fig. 10.11 Current conservation efforts for key selected habitats. *Notes: Best-case scenario, using all the MPAs reported. Habitats on the x-axis are ordered according to their distance to the coast, as a proxy for their average depth. Black circles represent countries hosting one of the key habitats. The y-axis represents the percentage of area that each country is protecting of that habitat within its exclusive economic zone (EEZ). Most of the countries are below the 30% target (white line), which has been identified as a threshold to ensure the maintenance of the ecosystem services of a habitat. The blue circles represent the mean percentage of all the countries' protection efforts for that habitat, whereas the red circles are the median percentage of all the countries' protection efforts. (Source: Authors)*

servation effectiveness, other measures are required outside of reserves to ensure success (e.g., Lipcius et al. 2005; Gaines et al. 2010). This concern applies also and increasingly to climate change and ocean acidification. It is therefore important that all areas of the ocean are managed, including global measures to improve the sustainability of fisheries and aquaculture (Costello et al. 2019; Widjaja et al. 2020; Duarte et al. 2020), as well as of industries extracting non-living resources. As such, it will be important to implement zoning or marine spatial planning to include all areas of EEZs and ABNJ to reduce competition between ocean uses (e.g., Norse 2005) and to reduce the occurrence of pollution from all sources (Duarte et al. 2020) as well as opportunities for alien species to invade non-native ecosystems (Molnar et al. 2008). Reducing and mitigating greenhouse gas emissions to hold global temperature increases to 1.5oC or below is also a priority (IPCC 2019; Duarte et al. 2020) in which the ocean has a role to play (Hoegh-Guldberg et al. 2019).

7 International Conventions and Agreements

We have identified 23 international conventions and agreements that relate to protection of the marine environment and biodiversity (Table 10.4). It is important to consider that these conventions and agreements are not exhaustive in terms of the binding obligations on states. Below the level of international conventions and agreements are regional and sub-regional conventions and agreements (e.g., for RFMOs) as well as voluntary actions such as the CCRF (for a list of examples, see Friedman et al. 2018). Also, decisions under the governance framework of such conventions and agreements, as well as by their implementing agencies, put further binding obligations on states. Added to this is national legislation which provides a complex and interacting web of marine legislation (for an example based on Europe, see Boyes and Elliott 2014). Therefore, the absence of a 'yes' in Table 10.4 does not necessarily mean that a signatory state is not obliged to conform to the activity in the column.

Table 10.4 Characteristics of the International conventions and agreements to protect marine biodiversity and environments

Convention/Agreement	A	B	C	D	E	F	G	H	I	J	K
1. IWC	Yes	Yes		Yes		Yes					
2.Convention on fishing	Yes									Yes	
3. Convention on high seas oil casualties								Yes		Yes	
4. Ramsar	Yes	Yes	Yes	Yes		Yes				Yes	Yes
5. Dumping convention						Yes		Yes		Yes	Yes
6.Heritage Convention			Yes	Yes						Yes	Yes
7. CITES	Yes	Yes				Yes				Yes	
8. Marine pollution (not oil)								Yes		Yes	
9. Marpol						Yes		Yes		Yes	
10. CMS	Yes	Yes	Yes	Yes		Yes				Yes	
11. UNCLOS	Yes	Yes	Yes			Yes	Yes	Yes	Yes	Yes	Yes
12. Basel						Yes		Yes		Yes	Yes
13. CBD	Yes	Yes	Yes	Yes		Yes	Yes		Yes	Yes	Yes
14. High seas fisheries compliance	Yes									Yes	Yes
15. Part XI UNCLOS							Yes			Yes	Yes
16. Straddling stocks agreement	Yes	Yes			Yes	Yes		Yes		Yes	Yes
17. Protocol marine pollution					Yes	Yes	Yes	Yes		Yes	Yes
18. Cartegena							Yes		Yes	Yes	Yes
19. Stockholm						Yes	Yes	Yes		Yes	Yes
20. Antifouling					Yes	Yes	Yes	Yes		Yes	
21. Ballast						Yes	Yes		Yes	Yes	Yes
22. Port state measures	Yes									Yes	Yes
23. Nagoya	Yes	Yes	Yes							Yes	Yes

A. Sustainable management of living resources; B. Sustainable management of unexploited species; C. Habitat management or protection; D. Implement protected areas; E. Precautionary principle; F. Monitoring of species, habitats or environment; G. Environmental impact assessment; H. Prevention of environmental pollution; I. Biosecurity; J. Encourage or impel international cooperation; K. Capacity building

Notes: a. Where trade in that species may impact on an endangered species. The conventions and agreements are as follows: (1) International Whaling Convention (1946); (2) Convention on Fishing and Conservation of the Living Resources of the High Seas (1958); (3) International Convention Relating to Intervention on the High Seas in Cases of Oil Pollution Casualties (1969); (4) Convention on Wetlands of International Importance Especially as Waterfowl Habitat (Ramsar; 1971); (5) Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter (1972); (6) Convention Concerning the Protection of the World Cultural and Natural Heritage (1972); (7) Convention on International Trade in Endangered Species of Wild Flora and Fauna (CITES; 1973); (8) Protocol Relating to Intervention on the High Seas in Cases of Marine Pollution by Substances Other than Oil (1973); (9) Protocol of 1978 Relating to the International Convention for the Prevention of Pollution from Ships, 1973, (Marpol); (10) Convention on the Conservation of Migratory Species of Wild Animals (CMS or Bonn Convention; 1979); (11) United Nations Convention on the Law of the Sea (UNCLOS; 1982); (12) Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and Their Disposal (1989); (13) Convention on Biological Diversity (CBD; 1992); (14) Agreement to Promote Compliance with International Conservation and Management Measures by Fishing Vessels on the High Seas (1993); (15) Agreement Relating to the Implementation of Part XI of the United Nations Convention on the Law of the Sea of 10 December 1982 (1994); (16) Agreement for the Implementation of the Provisions of the United Nations Convention on the Law of the Sea of 10 December 1982 Relating to the Conservation and Management of Straddling Fish Stocks and Highly Migratory Fish Stocks (1995); (17) Protocol to the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter, 1972 (1996); (18) Cartegena Protocol on Biosafety to the Convention on Biological Diversity (2000); (19) Stockholm Convention on Persistent Organic Pollutants (2001); (20) International Convention on the Control of Harmful Anti-Fouling Systems on Ships (2001); (21) International Convention for the Control and Management of Ships' Ballast Water and Sediments (2004); (22) Agreement on Port State Measures to Prevent, Deter and Eliminate Illegal, Unreported and Unregulated Fishing (2009); (23) Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from Their Utilization to the Convention on Biodiversity (2010)

Notwithstanding this, Table 10.4 provides an overview at the highest level of what what ocean management measures states have enacted to protect marine biodiversity.

The 23 international treaties to protect the marine environment and conserve marine biodiversity were analysed using clustering and were found to fall into in three hierarchal groups (Fig. 10.12a): those that aim to protect biodiversity, those dedicated to fisheries and regulation of anthropogenic activities (navigation, ballast waters, etc.) and those regulating pollution.

Beginning more than 60 years ago, the International Whaling Convention (1946) was aimed at the sustainable management of whaling but also concerns protected areas specifically targeted at whale conservation. Almost all the international treaties since then have required cooperation between countries; capacity building; monitoring of species, habitat or the environment; and the management of living resources (Fig. 10.12b). In the last three decades, they have evolved to include a wider range of considerations, including prevention of pollution, conservation of non-commercial species and habitats and biosecurity (Fig. 10.12c). However, many of these treaties focused on specific sectors (e.g., pollution or fisheries management; see Fig. 10.12a) with some specifically dealing with a narrow range of issues (e.g., the Cartagena Protocol relating to biosecurity of organisms modified through biotechnology). Of the 23 conventions, 11 represent the sustainable management of living resources in the ocean and 10 pertain to preventing damage to the marine environment by pollution. It is notable that only 8 conventions and agreements deal with managing or conserving species which are not fished commercially, and only 6 protect marine habitats. Five of the conventions or agreements specifically require the implementation of MPAs.

7.1 Fisheries Governance, Sustainability and Impacts on Biodiversity

On the face of it, the range of international and sub- international conventions and agreements would appear to adequately manage the marine environment and biodiversity. However, as outlined in Sect. 3 of this report, marine species and habitats are in decline, and this amounts to a loss in the provisioning of ecosystem services. For fisheries, this has a significant impact in economic terms; for example, the Sunken Billions report suggests that lost revenue resulting from overfishing amounted to $83 billion in 2012 (World Bank 2017).

Improved management and judicious conservation of wild fisheries would lead to increased biomass in the ocean, higher profits for fishers and greater food provision (40% more production in the future than under business as usual and 20% more than now; Costello et al. 2019; see also World Bank 2017).

No fewer than 11 conventions and agreements deal with the sustainable management of living resources, and all but 3 of them also cover non-target species (Table 10.4). This does not include the large number of regional and sub-regional agreements and additional binding measures that states are committed to for fisheries (Friedman et al. 2018). As already indicated in Sect. 6 the problem in fisheries management is one of uneven implementation of measures to increase sustainability of catches of target species and to prevent harm to biodiversity. There are many aspects of fisheries management where this unevenness of implementation is apparent. For example, compliance to the FAO's CCRF, one of the primary pillars in placing biodiversity measures in fisheries management (Friedman et al. 2018), is better in developed countries than in developing ones, but for most it falls far short of 'good' (Pitcher et al. 2009). Likewise, RFMOs have been widely criticized for their performance both in terms of managing target fish stocks on the high seas and also bycatch (Cullis-Suzuki and Pauly 2010; Polacheck 2012; Gilman and Kingma 2013; Gjerde et al. 2013; Gilman et al. 2014; Clark et al. 2015; Leroy and Morin 2018; Pentz et al. 2018). Since 2006, the United Nations General Assembly has called for the development of performance reviews (PRs) for RFMOs (Haas et al. 2019). By 2016, all RFMOs which had entered into force by 2012 had undergone PRs, and some have been reviewed twice (Haas et al. 2019). There is evidence that these reviews have led to improvements, particularly in the areas of compliance and enforcement, conservation and management and international cooperation (Haas et al. 2019). Decision-making and dispute settlement and financial and administrative issues were areas where lower improvement scores were obtained (Haas et al. 2019). Other recent reviews of RFMO performance reveal a more mixed picture of improvement (Gjerde et al. 2013; Gilman et al. 2014; Pons et al. 2018).

An analysis of the drivers of management effectiveness in tuna RFMOs identified that those with a greater number of member countries, a greater economic dependency on the fisheries, a lower mean GDP, a greater number of fishing vessels and a higher proportion of small vessels had lower levels of research, management and enforcement (e.g., the Indian Ocean Tuna Commission; Pons et al. 2018). There are multiple issues within RFMOs, but those most pertinent to biodiversity conservation include the fact that fisheries management has paid insufficient attention to the environmental management of a broader range of natural assets (Gilman et al. 2014; Hooper et al. 2019). In the analysis on tuna RFMOs by Pons et al. (2018), it was noted that scores

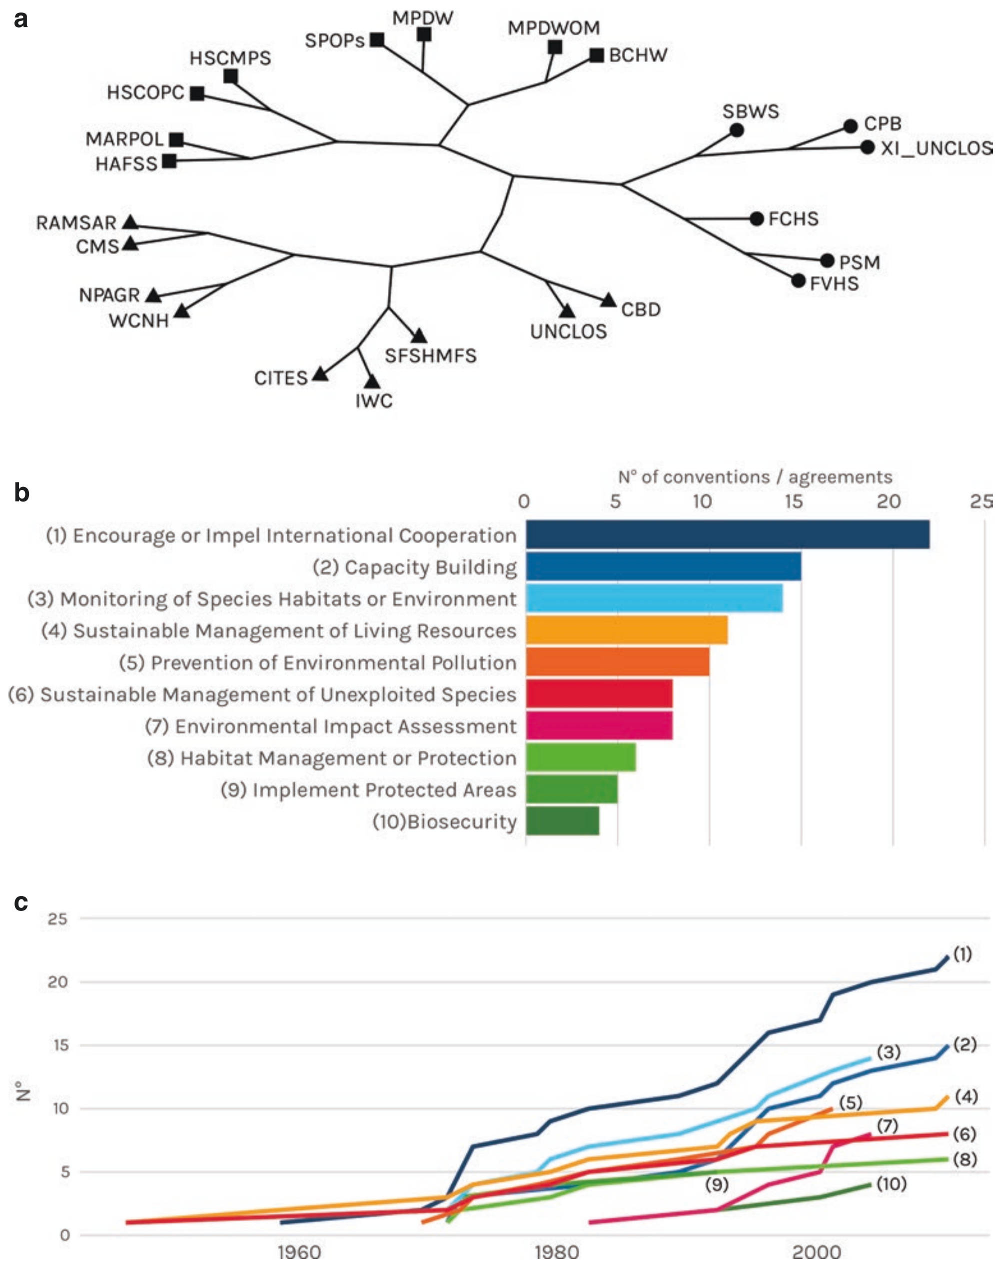

Fig. 10.12 Analysis of 23 International treaties to protect the marine environment and conserve marine biodiversity. *Notes: Panel* (**a**) *shows Ward's hierarchical clustering with Euclidean distance of international conventions/agreements according to their mission topics; the convention acronyms are as follows: BCHW basel convention on the control of transboundary movements of hazardous wastes and their disposal, CBD convention on biological diversity, CITES convention on International trade in endangered species of wild flora and fauna, CMS convention on the conservation of migratory species of wild animals (or Bonn), CPB cartegena protocol on biosafety to the convention on biological diversity, FCHS convention on fishing and conservation of the living resources of the high seas, FVHS agreement to promote compliance with international conservation and management measures by fishing vessels on the high seas, HAFSS International convention on the control of harmful antifouling systems on ships, HSCMPS protocol relating to intervention on the high seas in cases of marine pollution by substances other than oil, HSCOPC International convention relating to intervention on the high seas in cases of oil pollution casualties, IWC International Whaling Commission, Marpol protocol of 1978 relating to the International convention for the prevention of pollution from ships, MPDW protocol to the convention on the prevention of marine pollution by dumping of wastes and other matter, MPDWOM convention on the prevention of marine pollution by dumping of wastes and other matter, Ramsar convention on wetlands of international importance especially as waterfowl habitat, SFSHMFS agreement for the implementation of the provisions of the United Nations convention on the law of the sea of 10 December 1982 relating to the conservation and management of straddling fish stocks and highly migratory fish stocks, SPOPs Stockholm convention on persistent organic pollutants, UNCLOS United Nations Convention on the Law of the Sea, WCNH convention concerning the protection of the world cultural and natural heritage, XI_UNCLOS agreement relating to the implementation of Part XI of the United Nations Convention on the Law of the Sea of 10 December 1982. Panel* (**b**) *shows the number of conventions/agreements associated towards a main goal as listed in Table 10.4; Panel* (**c**) *shows how the number of each conventions/agreements changed over time for each main goal. (Source: Authors)*

for fisheries management in general were low and, in particular, for discarding and bycatch measures. This was attributed to a lack of severe consequences for exceeding bycatch quotas, with the result that non-target species such as marlins and sharks scored low for all management dimensions (Pons et al. 2018). Application of the precautionary principle can be useful in such cases, but this has been included in few international agreements or conventions (Table 10.4), although its use in RFMOs is spreading (de Bruyn et al. 2013).

Illegal, unregulated and unreported (IUU) fisheries contribute significantly to the overexploitation of fish stocks as well as impacts on biodiversity. They are a particular problem for commercial species, which acquire a high value because of their increasing scarcity. Examples of such species include several croakers, giant clams and red corals (Zhang and Wu 2017). These IUU vessels do not adopt fishing practices to avoid bycatch or other forms of environmental damage (Petrossian et al. 2018). A very sad example of this is the imminent extinction of the vaquita (*Phocoena sinus*), a porpoise found in the Sea of Cortez. The vaquita is suffering high mortality as bycatch in illegal gill nets set for the totoaba (*Totoaba macdonaldi*), a croaker whose swim bladder is prized in Chinese medicine and which is also endangered with extinction (Jaramillo-Legorreta et al. 2019).

What is less recognised is the role of state-corporate crime in marine fisheries (Standing 2015). This is an issue in developing coastal states where fisheries access agreements are used to allow foreign fishing vessels into their waters. There is ample evidence that the licensing coastal states and the vessels' flag states often ignore overfishing, corruption and the significant losses to the livelihoods and incomes of local small-scale fisher folk (e.g., Belhabib et al. 2015; Standing 2015; Zhang and Wu 2017). States can use their political and economic power to impose such agreements on countries, even where there is awareness of the likely outcome in terms of overfishing and negative societal impact (Standing 2015; Zhang and Wu 2017). There is also a significant role in such activities by business elites and global investment companies (Standing 2015). This is further exacerbated when political issues arise, such as in the disputed waters of the South China Sea (Zhang and Wu 2017).

Whilst fisheries impacts are not the only drivers of loss of species and habitats in the ocean, they illustrate the barriers to tackling the biodiversity crisis. Setting specific targets as policy objectives and then ensuring that their progress is monitored and reported on is crucial. Despite the objectives of increasing MPAs under the CBD (and other conventions and agreements), it was the adoption of Aichi Biodiversity Target 11 that has spurred the international community to reach a specific goal of 10% of coastal and marine areas, which are in ecologically representative and well-connected protected areas or other forms of spatial conservation management.

Likewise, SDG 14 has reinforced Aichi Biodiversity Target 11 by also calling for the protection of 10% of coastal and marine areas (SDG 14.5); the elimination of overfishing, IUU fishing, and destructive fishing practices (SDG 14.4); and the prohibition of fishing subsidies which enhance overcapacity and overfishing and which contribute to IUU fishing (SDG 14.6).[9] These targets also come with indicators against which progress can be monitored. By setting such clear goals and guidelines for reporting progress, coastal and flag states can better manage their ecosystems (Lidström and Johnson 2019).

Along with the clear setting of targets for achieving standards of fisheries sustainability, biodiversity and environmental protection, high seas fisheries management organisations should be operating to clear international standards and a system of monitoring progress to achieve such standards should also be put in place. Further improvement in the sustainability of fisheries can also be achieved by using innovative technologies to improve the monitoring of fishing activities and catches (Kroodsma et al. 2018; Bradley et al. 2019) as well reducing bycatch (Avery et al. 2017) and other environmental impacts of large- and small-scale fisheries. Implementing these measures will require adequate funding and increased capacity, especially amongst developing coastal states (Friedman et al. 2018).

A significant improvement in fisheries management would also be attained through the adoption of several voluntary codes and guidelines as clear international standards for management of fisheries (e.g., the FAO's CCRF, 1995, and Voluntary Guidelines for Flag State Performance, 2014), but again, without mechanisms for monitoring and reporting such standards will be slow in improving performance.

The implementation of new conventions and agreements should also be more rapid, and we note that the Agreement on Port State Measures to Prevent, Deter and Eliminate Illegal, Unreported and Unregulated Fishing 2009) to date only has 61 parties. A new implementing agreement for UNCLOS, known as the biodiversity beyond national jurisdiction (BBNJ) agreement, currently under negotiation, represents a step forward in putting in place a framework for spatial conservation and other measures to protect biodiversity in ABNJ. The text of this agreement contains strong provisions for monitoring and reporting on progress in implementation as well as the establishment for international standards through the operation of a Scientific and Technical Committee and a decision body (e.g., a Conference of Parties

[9] For more information on SDG 14, see https://sustainabledevelopment.un.org/sdg14

in collaboration with existing agreements and implementing agencies). It also includes the precautionary principle and significant improvements in transparency and the involvement of civil society in aspects of decision-making, particularly in processes related to environmental impact assessment. The inclusion of provisions for capacity building and technology transfer among states in the BBNJ agreement may also be extremely important not just for improving the capacity of developing states to monitor and manage biodiversity in ABNJ but also within their own coastal waters.

8 Opportunities for Action

The IPBES Global Assessment Report identifies that biodiversity is declining faster than at any other time in human history, and rates of species extinction are likely tens to hundreds of times higher than any time in the last ten million years (IPBES 2019). Despite the data limitations, we have presented evidence in this paper that marine ecosystems, like their terrestrial and freshwater counterparts, are suffering from severe habitat degradation, species population reductions and ecosystem impacts at multiple levels, with significant consequences to society through loss of ecosystem services provision which is the cause of direct economic losses, impacts on livelihoods and ultimately on human health and security.

Although these findings present a gloomy prospect for the future there are notable successes in reversing the decline of marine species through strong management and conservation measures (Duarte et al. 2020). The most notable of these is the recovery of populations of the great whales following the moratorium of whaling imposed by the IWC (Duarte et al. 2020). As related in the present report, reduction of fishing fleet capacity, coupled with modern fisheries management approaches and strong monitoring, control and enforcement has led to the stabilisation and recovery of fish stocks in the waters of Europe, the United States and elsewhere (Fernandes et al. 2013, 2017; Hilborn and Ovando 2014; Rousseau et al. 2019; Hilborn et al. 2020). Some habitats have also showed some recovery from past losses, an example being the recovery in seagrass beds in northern Europe (de los Santos et al. 2019).

This recovery was attributed to management actions including those reducing coastal pollution, measures to prevent anchoring and trawling in seagrass beds, as well as natural recovery (de los Santos et al. 2019). There are also examples of habitat restoration leading to local rehabilitation of habitats such as mangrove forests in the Mekong Delta (Duarte et al. 2020). Duarte et al. (2020) suggest that strong management action could lead to substantial recovery of abundance of species and structure, function of communities with increased provision of ecosystem services by 2050. Given the evidence for strong recovery of species and some recovery of specific habitats over decadal timescales we believe that such optimism is justified. However, recovery will only take place at large scales following strong and coordinated management action. Based on this evidence and our analysis of drivers of biodiversity loss, we find these opportunities for urgent action at local to international levels.

There are opportunities to improve monitoring, increase efficiency in MPAs, and achieve sustainable ecosystem-based fisheries management. Some specific actions/ deliverables for these high-level policy decisions include no net loss of habitat; establishing a blue bond market for investing in marine environmental sustainability; marine spatial planning to identify (on a regional basis) best options to increase no-take areas, including in the vicinity of offshore renewable energy projects; moving intensive aquaculture operations offshore, where feasible; and planning conservation responses to future coastline inundations (e.g., determining where the new sea grass meadows and mangroves will exist with sea level rise). Bringing the entire ocean under sustainable management is also a critical element in reducing open access and overexploitation of resources which has led to declines in marine species and ecosystems (Norse 2005).

8.1 Technology for Mapping

Technological advancements in remote sensing, including satellites, lidar, unmanned aerial vehicles, AUVs, and the computational ability to process such multidimensional big data in the past few decades has drastically expanded our capacity to understand the world. With increasing spatial and temporal resolution of the data captured, there is a large opportunity to further enhance our understanding of the status and trends in marine habitats and ecosystems, the drivers of change and the impacts of degradation on their contribution to people and, thus, improved visualisation and maps to support the decision-making process. The advancements in the field of artificial intelligence have also paved the way for the application of data mining and natural language processing into biodiversity and ecosystem studies. Therefore, marine scientists have the unique opportunity to extract knowledge from historical and unstructured sources (e.g., text, images, audio), store complex information in machine-readable formats and connect with expert systems to set up knowledge bases—all areas of marine science that have yet to be well explored. For effective management, governments need to know where, what, why, and how much of an activity is sustainable because anthropogenic impacts expand into deeper and deeper waters (Baker and Harris 2020).

However, there are challenges to overcome with regard to harnessing the above-mentioned technological advancements into global marine studies. Utilising the technological advancements into a thematic discipline requires multidisciplinary experts, dialogue and knowledge exchange across disciplines as well as basic scientific programming skills and knowledge of machine-readable data and metadata formats. The lack of interoperable web services and a catalogue for referencing remote sensing products and geospatial data sets limits the smooth communication of needs from a thematic discipline to the technology developers.

There is an opportunity for NGOs, industry, researchers, and government institutions to collaborate to increase the application of current advancements in technological capacity. To accomplish this cross-disciplinary discussion, there needs to be an exchange of knowledge, and scientists need to be trained to make their analysis and work interoperable. Streamlined services are also needed to support the production of standard essential variables and indicators in the field, including a catalogue of key data sets, which would integrate a wide variety of primary data, and standardised processing services (i.e., web rest services), which would improve access and maintain frequently used data resources.

We envision that by 2030 a catalogue of marine habitats, including those that we currently have limited information on, such as kelp forests and rocky reefs, will have their EOVs monitored spatially and temporally, and variation and distribution changes within them will be automatically generated over time and publicly accessible. We support the development of a comprehensive ocean observing system which has been identified as a priority for the United Nations Decade of Ocean Science for Sustainable Development and GOOS. With this information accessible, organisations can effectively monitor the global distributions of economically important marine habitats, such as coral reefs, mangroves and seagrasses. On a local level, governments should collaborate with industry and NGOs to effectively map drivers of habitat degradation and ground truth the data produced from the global habitat mapping efforts. Such mapping and monitoring of marine ecosystems has been among recommendations for improved management of marine biodiversity for almost 30 years (Norse 1993).

To be able to develop the collaborations and technological capacity to make this vision a reality, we suggest the following high-priority opportunities for action:

- The present intergovernmental organisations (e.g., UNESCO-IOC), biodiversity monitoring networks (GOOS BioEco, GEO BON/MBON), databases (e.g., OBIS) and philanthropic efforts involved in gathering and making ocean data available for management purposes (e.g., Google Earth Engine; Ocean Data Foundation)[10] require a coordinated approach to face the challenge of comprehensive and global monitoring of biodiversity. These organisations, under the leadership of UNESCO-IOC, in partnership with national ocean biodiversity monitoring networks (e.g., IMOS, IOOS, EuroGOOS) and the CBD, should— through workshops or other means—create maps of both habitat extent and environmental drivers to identify conflicts and gaps in knowledge, including in the distribution of marine habitats, technological limitations and solutions with explicit goals and institutions/organisations assigned to meeting the goals. These efforts should include multidisciplinary scientists, including, but not limited to, marine, artificial intelligence and data experts.
- The Decade of Ocean Science for Sustainable Development provides an ideal jump-off point for such a coordinated approach to ocean biodiversity monitoring, especially as it recognises the importance of producing actionable data but will also produce significant new data sets on species and habitat distribution in the ocean.
- By 2025 this should culminate in collaborative research platforms where global habitat maps and EOVs can be compiled based on interoperable data sources, be visualised and be made publicly available in a way that facilitates ecosystem-based management of human activities in the ocean whilst enabling biodiversity conservation.
- By 2028, integration of novel technological developments with quality-control standards increase temporal resolution of habitat maps and drivers so that quality annual maps of habitat extent and impacts are made available.
- Throughout 2020–30, knowledge bases and technology transfer between governments is promoted to equip all countries with the tools necessary to sustainably manage and map the ocean. Capacity-building efforts are targeted at providing all countries with the expertise to access and act upon biodiversity data for meeting international targets and ocean management needs.

- By accomplishing these goals, we believe there will be numerous additional benefits past increasing our understanding of the planet, including improved environmental and biodiversity monitoring plans, technological advancements, the training of new generations of scientists from diverse backgrounds and increased collaboration between stakeholders.

8.2 Addressing the Biodiversity Data Gap

There is a pressing need for a greater coordinated effort to gather information on marine biodiversity and extinction risk, from baselines of diversity and ecosystems to the long-term monitoring of population genetics, species, habitats and

[10] Information about the Ocean Data Foundation can be found on its website, https://www.oceandata.earth/

ecosystems. Again, despite recommendations to develop such coordinated knowledge gathering on marine biodiversity, as well as improving the capacity to do so by all nations nearly 30 years ago (Norse 1993), this has not happened to date. The IUCN Red List shows that although there are a good range of assessments for marine vertebrates (fish, seabirds, marine mammals), extinction risk assessments on marine invertebrates are restricted to a few scattered groups.

There is now an opportunity for states, intergovernmental organisations, foundations and other philanthropic organisations to invest in the infrastructure, including human resources, to meet their international commitments (e.g., under the CBD) to establish baselines of biodiversity and long-term monitoring of the status of species and habitats both within their EEZs and in ABNJ, especially where their flagged vessels are or will be undertaking activities such as fishing or other extractive activities. Such an effort should focus on the already established networks for biodiversity monitoring, including GOOS BioEco and the marine component of GEO BON, MBON.

The first has developed a framework and a globally coordinated strategy for monitoring biodiversity change using biological EOVs which are complemented by the EBVs coordinated by the latter. Data repositories already exist to receive such information (e.g., OBIS; Navarro et al. 2017). GOOS BioEco is facilitating the establishment of coordinated networks to implement monitoring of these essential variables. These will be established in collaboration with MBON and will include oceanographic research centres, government institutions and universities, and natural history museums. These networks should also build on existing efforts, such as the Global Coral Reef Monitoring Network.

By establishing such networks, states will be able to establish a baseline of marine biodiversity in their waters and in ABNJ, allowing the subsequent monitoring of changes in biodiversity through time. This will enable the continual assessment of the success of measures to reduce biodiversity loss by states and allow them to actively manage their activities to mitigate or reverse biodiversity loss. For developing states, assistance in capacity building will be required. Associated benefits from such an effort will include

- maintenance or enhancement of marine ecosystem services provision (e.g., fisheries, coastal protection, tourism);
- identification of marine genetic resources (Blasiak et al. 2020);
- the training of a new generation of marine scientists;
- increased opportunities for citizen science and education; and
- increased effectiveness of investment in biodiversity conservation through specific targeting of interventions.

At present, there are no alternative measures to achieve such a goal, and without it, undocumented biodiversity loss will continue in the face of pressures arising from poverty, the increasing human population and the drive for economic development. We envision a pathway to improved biodiversity monitoring to include the following milestones:

- The identification or establishment of national centres for marine biodiversity monitoring and developed capacity in taxonomy and field ecology, including training in new taxonomic tools such as environmental DNA (eDNA) and other emerging technologies, to undertake baseline assessments and long-term monitoring.
- A baseline biodiversity inventory and the establishment of key monitoring sites as part of the GOOS BioEco networks or of an existing MBON and expanding geographic coverage through the establishment of new MBON sites/regions (2023–25).
- The coordination of biodiversity monitoring activities at a regional basis implementing best practices to exchange knowledge, deliver FAIR and open-access data and share resources where appropriate (2020–25).
- The establishment of a marine biodiversity programme that feeds into national policies and management actions to mitigate biodiversity loss as well as into regional organisations, such as RFMOs, to manage activities in a way as to protect and conserve biodiversity. Biodiversity management becomes embedded into national institutions and legislation and into regional bodies (2025–30+).

There are a range of habitats formed by foundation species that are overwhelmingly important to biodiversity because they are connected to ecosystem functions over a wider geographic area than their immediate occurrence. These include, most notably, coral reefs, mangrove forests, seagrass beds, saltmarshes, kelp forests and other coastal ecosystems. In ABNJ, these are probably strongly represented within EBSAs and may include habitats such as seamounts.

We recommend that coastal states and regional ocean management organisations should adopt a policy of zero net loss for such ecosystems. Because the costs of habitat restoration are often much higher than conservation (Friess et al. 2019), such a policy should prioritise avoidance of activities which lead to significant damage in the first place.

We believe that by establishing or further developing a national MBON coordinated at a regional level, including ABNJ, it could—if used to support effective management and conservation—help to improve and secure economic and other societal gains from the provisioning of ecosystem services. Additional benefits from developing marine genetic resources (Blasiak et al. 2020) and improving environmental awareness and education within society are difficult to estimate but would certainly be positive.

8.3 Citizen Science and Education Programmes

Citizen science provides a great opportunity to increase public participation in science, overcome significant barriers to the scientific process and improve natural resource management (Theobald et al. 2015; McKinley et al. 2017). Citizen science and environmental education programmes are also scientific projects that can produce reliable information in which members of the public directly engage in research to answer particular questions (Parrish et al. 2018; McKinley et al. 2017). Biodiversity-related projects have been shown to span greater geographic and temporal ranges than conventional academic research, engaging millions of volunteers and generating up to $2.5 billion in kind annually (Theobald et al. 2015). There are many goals and benefits for citizen science, spanning publishing results in peer-reviewed journals, education, community empowerment and personal fulfilment (Parrish et al. 2018).

Despite many long-term citizen science projects creating robust data sets,[11] many academic researchers still show a bias against citizen science (Bonney et al. 2014). Theobald et al. (2015) found that only about 12% of projects out of 388 provide data to scientific publications. Therefore, methods of quality assurance (actions taken to ensure the quality of measurements taken) and quality control (post hoc actions to ensure the quality of results) are pivotal to many projects where the primary goal is science generation and should continue to be developed (Bonney et al. 2014; McKinley et al. 2017). A participant's time and success in mastering a task is a function of the complexity of the task (Sauermann and Franzoni 2015), which supports that projects should be simply designed at scale, and projects at smaller scales, with higher complexity, can be more involved (Parrish et al. 2018).

Citizen science programmes can also generate significant social outcomes, including increasing science education, engagement in policy and collaboration. As such, they represent the following opportunities for action:

- Governments increase general science education in line with SDG 4 to 'Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all' (2020–25).
- Citizen science programmes coordinate and organise to ensure that the wealth of information gathered is accessible, usable, known to decision-makers and connected with networks of biodiversity monitoring, including GOOS BioEco and the marine component of GEO BON, MBON, starting in 2023.
- Industry and governments that benefit from this information provide increased funding for the development of community-based programmes in developing countries to increase exposure to science and raise a new generation of scientists by 2025.
- Academia generates best practices and resources to increase the amount citizen science can be used to generate robust data and science, thus removing the bias against this information by 2030.

By accomplishing the previous recommendations, we see a future defined by increased scientific literacy around the world, improved efficiency of moving conservation science into conservation action, and higher awareness and knowledge of the planet around us.

8.4 Well-Enforced, Green-Listed, Fully Protected Marine Reserves

There is strong evidence that the implementation of well-enforced, fully protected MPAs that include 30–40% of key marine habitats will conserve biodiversity, enhance biomass and abundance of marine life as well as improve the resilience of marine ecosystems (Roberts et al. 2001; Lester and Halpern 2008; Gaines et al. 2010; Sciberras et al. 2013; Edgar et al. 2014; Mellin et al. 2016; Sala and Giakoumi 2017). These MPAs can also benefit fisheries (Roberts et al. 2001; Gaines et al. 2010; Di Franco et al. 2016; Ban et al. 2017), provide coastal protection (Roberts et al. 2017) and improve the resilience of ecosystems against the impacts of climate change (Mellin et al. 2016; Roberts et al. 2017). However, poor capacity for the enforcement of MPAs (Gill et al. 2017) and poverty alleviation—specifically, the generation of jobs (Cinner et al. 2009; Gurney et al. 2014)—can undermine MPA objectives. Additionally, the social impacts of protected areas are poorly understood largely because MPA evaluations have tended to focus on one or very few outcomes, and few have had the requisite data to assess causal effects (Gurney et al. 2014). Opportunities over the next two years (e.g., the BBNJ agreement and the CBD Conference of Parties in 2021) offer the chance to adopt a new target beyond the 10% of marine protection and to accelerate the slow progress made to date. Whatever targets for biodiversity protection are set, they must represent the full range of marine ecosystems and species. The aims should include no net loss of important habitats which structure marine ecosystems, such as coral reefs, mangrove forests, seagrass beds, saltmarshes and others.

Experts, conservation practitioners, philanthropic organisations and representatives from government should come together convened by the IUCN, the United Nations Environment Programme (UNEP) and the CBD to establish

[11] See eBird (https://ebird.org/home), COASST (https://coasst.org/) and Zooniverse (https://www.zooniverse.org/)

the best strategy for increasing and improving existing MPAs on the basis of the approach we have outlined in this paper for coastal states.

Strategies tailored for each group of countries—and ultimately each individual country—can be developed, and international assistance, including economic, capacity building and technical advice, can be targeted to effectively achieve global, regional and national targets. For ABNJ, a different approach can target areas of conservation importance whilst balancing these with economic need. The framework developed by O'Leary et al. (2018), with input from the CBD EBSA process, offers a practical approach to achieve this. We envision the pathway as follows:

- The MPA targets are established internationally, at the CBD's Conference of Parties or (for the ocean) at the United Nations Ocean Conference in 2021.
- An implementation conference is initiated to identify specific targets at global, regional and national levels to protect representative marine ecosystems and the best strategic approaches and practical measures to achieve these targets. The conference should be convened by the IUCN, UNEP and the CBD, with attendance from experts and governmental, intergovernmental and non-governmental organisations as well as potential funders (Global Environment Facility, government-funding agencies, private philanthropists and foundations). The target year for the conference is 2022.
- By 2022, a large campaign and economic support should be in place to involve communities and stakeholders to implement community-based MPAs (Pollnac et al. 2001; Aburto-Oropeza et al. 2011). By 2023, a global map to implement community- based MPAs should be generated by states. In the Philippines, where government policy, international aid, universities and NGOs have invested a great effort to implement community-based MPAs, there are over 400 of these management areas. Although only 25% of them are effective in the protection of the resources, clear common factors have been described as the path to successful community-based MPAs: (1) relatively small communities, (2) community census statistics to prioritise targeted interventions, (3) overfishing challenges, (4) movement to alternative income projects, (5) increased level of community participation in decision-making, (6) strong local leadership, (7) receiving scientific and MPA-implementing advice and (8) closely working with local or municipal governments (Pollnac et al. 2001; Crawford et al. 2006; Rossiter and Levine 2014). These small but successful examples of community- based MPAs have proven that not only is it possible to recover marine biodiversity in a short time period (one decade), but they are also producing significant economic benefits for local communities. Cabo Pulmo National Park in Mexico is considered a success according to both biological and social measures: the MPA has seen significant recovery of biomass (Aburto-Oropeza et al. 2011) and demonstrable community engagement and participation, along with extensive socio-political support (and media attention) at the local, national and international levels. Cabo Pulmo has achieved a kind of symbolic power in the world of marine conservation (Anderson 2019), and it has influenced the transition of a governance system into a new, adaptive tourism model (Langle-Flores et al. 2017). There is a need for scaling up community-based MPAs to increase the social and ecological benefits for coastal areas. Evaluating approaches has demonstrated that 'opportunistic approaches' and 'donor-assisted approaches' do not create the necessary outcomes requested by global conservation targets. Rather, a systematic conservation planning approach of community-based MPAs can improve ecological and social outcomes, particularly if this planning incorporates equity for stakeholders (Kockel et al. 2019).
- The implementation conference should lay out a clear road to attaining established targets, with appropriate milestones (2023–30). We suggest that a single agency be tasked with measuring progress towards milestones and the final targets (e.g., UNEP- WCMC). Reports should be produced for the CBD's Conferences of Parties in 2024, 2026 and 2028 prior to 2030. Reporting should also extend to other relevant meetings (e.g., the Our Ocean and United Nations Ocean Conferences).

Balmford et al. (2004) estimated the costs of running a global MPA network covering 20–30% of the ocean at \$5–\$19 billion per annum. However, the potential gain in direct enhancement of fisheries and tourism and the avoided costs in environmental damage through reduction/mitigation of coastal inundation is likely to dwarf these costs. This is without accounting for other ecosystem services, such as CO_2 sequestration, nutrient cycling, waste remediation, protection of marine genetic resources and cultural services, which represent a value in the trillions of dollars overall (Costanza et al. 2014).

Furthermore, we point to the already estimated erosion in the value of marine ecosystem services as a result of the erosion of habitats which amount to a loss of more than \$10 trillion per annum in just over a decade between 1997 and 2011. Much of this loss was focused on coastal ecosystems, with coral reefs losing nearly half their value as a result of the loss of this habitat (Costanza et al. 2014).

8.5 Ecosystem-Based Fisheries Management

There is an extreme urgency to eliminate IUU fishing and accelerate the reform of fisheries management to reflect modern ecosystem-based concepts where biodiversity is managed sustainably alongside target stocks. Both the IPBES Global Assessment Report (IPBES 2019) and our own analyses indicate that overfishing, illegal fishing and destructive fishing practices are the prime drivers of biodiversity loss in the ocean. Whilst much progress has been made in sustainable ecosystem-based fisheries management (Hilborn and Ovando 2014; Friedman et al. 2018; Hilborn et al. 2020), progress remains fragmented. The fishing power of the global fishing fleet is continuing to grow and underlies overfishing in much of the global ocean (Rousseau et al. 2019). We have identified clear barriers to accelerating progress in fisheries sustainability and increasing consideration of biodiversity conservation in fisheries. These barriers include a lack of capacity and funding, whether being associated with institutions or developing states, and overwhelming pressure in some parts of the world to exploit living marine resources exacerbated by growing industrial and small-scale fishing fleets. There is also evidence that in some states, elements of the fishing industry and financial institutions are complicit in allowing overfishing and illegal fishing to continue (Standing 2015; Zhang and Wu 2017). This is not only immensely damaging to biodiversity but also leads to massive economic losses (Costello et al. 2016; World Bank 2017) and the loss of livelihoods and impacts food security (Sumaila et al. 2013; Standing 2015; Freduah et al. 2017). In the face of climate change impacts, overfishing will exacerbate these problems (Badjeck et al. 2010). If biodiversity loss in the ocean is to be halted or reversed, this elephant in the room cannot be ignored.

The reform of fisheries management practices and of the institutions charged with their management is already under way (Friedman et al. 2018). This reform process must be accelerated and driven through the adoption of appropriate targets by the competent authorities. The most important of these reforms include the following:

- Good data underlies all fisheries management both in the context of target species, bycatch species and the environmental impact of fishing. Given the development of modern technologies, from remote sensing to mobile computing and phones, there is an opportunity to greatly improve the monitoring of catches of target and bycatch species in all industrial fisheries. Given the importance of small-scale fisheries in terms of global fishing power, special measures to include these in fisheries catch statistics as well as fisheries management (including co- management/community management arrangements) is critical. Such measures will also allow an assessment of the nutritional and economic benefits of small-scale fisheries at the national level so they are accounted for in decisions on fisheries policy.
- Uniformly adopting modern principles of ecosystem-based fisheries management and the precautionary principle for all fisheries management as expressed in the UN conventions and agreements, the FAO's CCRF and other FAO guidelines and codes.
- Eliminating IUU fishing and other illegal practices in fishing through improved monitoring, control and enforcement. It is especially important that measures to eliminate IUU fishing are adopted rapidly by all fishing and port states.
- Stabilising, and then reducing, fishing pressure should be a priority in regions where growth in fishing capacity continues, undermining efforts to sustainably manage fisheries pressure and to conserve biodiversity. It is critical to ensure that measures to reduce fishing capacity protect the basic needs for food, nutrition and livelihoods in coastal communities, particularly in developing countries.

We also note the opportunities for other important reforms in fisheries management:

- Develop and fund infrastructure and human capacity to enable sustainable management of biodiversity as well as target fish stocks.
- Reform decision-making processes and adopt greater transparency by fisheries management organisations to speed up progress in eliminating overfishing.
- Make all fisheries data public, including data on vessel tracking, catch and bycatch within 12 months of collection.
- Specify measures to address issues of overfishing by developing states and in small-scale fisheries, including investment in data-poor stock assessment methods and the use of reciprocal mechanisms to enhance institutional, management and governance capacity in developing states through finance, training and technology transfer.
- Establish community-based fisheries management to assist in increasing the biological and socio-economic sustainability of fisheries.
- Continue efforts to merge and coordinate the objectives of the fisheries and environmental sectors at all levels of fisheries management (international to local).
- Develop a set of investment standards for the investment in fisheries, and especially infrastructure such as vessels, so only sustainable fisheries/fishing operations are financed.
- Initiate a formal regular review of RFMOs, ensuring they are meeting new standards of fisheries management; the

following areas specifically require attention: (1) updating conventions and agreements to implement modern standards of ecosystem-based fisheries management, including specific provisions for the conservation and protection of biodiversity; (2) further convergence between fisheries and environmental sector governance structures to integrate biodiversity considerations into fisheries management; (3) implementing mechanisms to ensure the rapid and accurate reporting of catches of target and bycatch species; (4) more rigorous target-based efforts to ensure rapid implementation of rules and recommendations; (5) a transformation of transparency for both fisheries-related data and decision-making processes; (6) reforming decision- making structures to prevent 'opt-out' or lowest- common-denominator regulations within fisheries management organisations; and (7) greater clarity on participatory rights, such as allocation of catch levels or fishing effort (Gjerde et al. 2013; Friedman et al. 2018).

- Develop a set of minimum standards for fisheries partnership agreements to ensure (1) sustainable fishing; (2) fair and equitable financial benefits for parties; (3) clear financial structures and reporting arrangements to ensure licence fees or other financial benefits flow to society; (4) adequate arrangements for monitoring, control, surveillance and enforcement of fisheries; and (5) formal structures for dispute resolution amongst partners with arbitration by an impartial third party.

Aichi Biodiversity Target 6 and SDG 14 embody specific targets for fisheries sustainability, and the measures above will clearly help to attain these goals. The SDGs are set for 2030 (with some interim targets due in 2020), but the CBD post-2020 biodiversity framework also provides a timetable for achievement of these goals and an opportunity to finally achieve the objectives of Aichi Biodiversity Target 6. We view the next decade, therefore, as critical in accelerating reforms of fisheries and biodiversity objectives to protect marine living resources.

By adopting these reforms, overfishing and IUU fishing will be eliminated, and fish stocks and associated ecosystems should be able to rebuild. The financial benefits of this just in fisheries revenue alone has been estimated at $83 billion per annum (World Bank 2017). Broader benefits will include increasing fish catches (Costello et al. 2016) and securing both livelihoods and food supplies as well as increasing their resilience to climate change impacts for the future. Given that destructive fishing impacts, such as bycatch, are the main drivers of biodiversity loss for a number of marine species, the benefits of reducing extinction risk and restoring ecosystem function and services provision will be enormous. This will also increase ecosystem resilience against climate change and other impacts.

9 Limitations of the Paper and Conclusions

As identified in several parts of this study, a lack of FAIR and open data on marine biodiversity is problematic when trying to identify patterns of species and habitat diversity as well as changes in these parameters over time. For example, in the IUCN Red List data, many species are classified as DD, and many groups of invertebrates have not been assessed at all. Without this information, it is very difficult to estimate the current state of, and trends in, marine biodiversity in the ocean.

There are significant gaps in our analyses because comparable global data sets were not available for many coastal habitats, including rocky reefs. Within the available data sets, there are many gaps and sampling biases, leading to higher diversity values in areas which likely do not correspond to species or habitat diversity. Likewise, particularly for deep-sea and offshore parts of the ocean, only large-scale oceanic habitats that can be identified through physical features (e.g., seamounts) could be identified, and the water column, the largest ecosystem on Earth, was largely neglected in this study. A trend analysis for the marine habitats examined here was not possible with the current publicly available data but should be pursued in future efforts as outlined in Sect. 8.

Despite these gaps, we have sufficient information to understand the broad state of marine species and habitat diversity to generate effective management responses. However, to reduce habitat loss and degradation, we need an increase in multi-decadal monitoring because it is essential to be able to understand, prevent future damage and monitor potential recoveries of marine ecosystems (Bayraktarov et al. 2016; Gangloff et al. 2016). Monitoring will establish baselines so that we can quantify changes in habitat extent and impacts from anthropogenic activities and use this information effectively to manage our natural resources.

A lack of adequate funding and capacity—particularly in developing countries but also in the organisations charged with sustainably managing economic activities in the ocean—is repeatedly highlighted in this study. Urgent measures are required to build capacity, transfer technology and build the global financial supporting structures so the blue economy can grow in a sustainable fashion that neither depletes marine species or habitats nor undermines the ecosystem services on which humankind relies. Current biodiversity loss in the ocean is at least partially due to a lack of equitability in states' ability to monitor biodiversity and manage activities within their EEZs and ABNJ.

The current crisis of biodiversity loss in the ocean may require developing and implementing further international agreements and national measures to protect habitats and species. A new legally binding instrument under UNCLOS to conserve and sustainably use marine biodiversity of areas beyond national jurisdiction (the BBNJ agreement) is currently being negotiated and should become an important legal framework for the conservation of 50% of Earth's surface area. In addition, new protocols could be developed as part of existing conventions, specifically the CBD, the World Heritage Convention and the Convention on Migratory Species, among others. Such protocols should include provisions that human activities should not result in the long-term or permanent loss of biodiversity in the ocean, with clear mandates for monitoring their effectiveness. They should also lay out renewed commitments for implementing biodiversity protection measures as well as monitoring and data-gathering activities which are already embodied in existing conventions and agreements. These new protocols should apply to all sectors operating in the ocean and should include the broad family of UN specialized agencies, including the FAO and associated RFMOs, the International Maritime Organization and the ISA.

The fisheries reforms described in this Blue Paper would likely cost millions to tens of millions of dollars on a state-by-state basis; yet in economic returns from fisheries alone, there is the potential for billions of dollars in return. Not undertaking these reforms will lead inevitably to commercial and/or local to wide-scale extinction of both exploited and non-target species, undermining ecosystem resilience and service provision. By extending this to the broader values to society and to the restoration of biodiversity and ecosystem services, reforms could be transformative.

The speed of the decline of marine species and habitats means that the opportunities for action we have identified should be taken up with urgency. Such an international effort, spanning all sectors involved in the blue economy as well as the implementing organisations involved in their management, may require a coordinated effort on the scale of that currently addressing climate change. A large-scale global plan of action for ocean biodiversity conservation may be required to expedite these opportunities with the speed required.

Acknowledgements The paper's technical reviewers, Miriam Fernandez Bergia, Stuart Kininmonth and Boris Worm, as well as its arbiter, Martin Stuchtey, all provided helpful technical comments.

The authors also thank the World Resources Institute for providing support as the Ocean Panel Secretariat.

While our colleagues were very generous with their time and input, this report reflects the views of the authors alone. Jorge Assis was supported by the Foundation for Science and Technology (Portugal) through the projects UIDB/04326/2020, BIODIVERSA/004/2015 and the transitional norm—DL57/2016/CP1361/CT0035.

The authors thank LSF Editorial for copyediting and Rosie Ettenheim for design.

About the Authors

Lead Authors

Alex D. Rogers is the Science Director of REV Ocean, a not-for-profit working for a healthier ocean. He is also a Visiting Professor of the Department of Zoology, University of Oxford, a Researcher of the Oxford Martin School and a Senior Research Fellow of Somerville College, University of Oxford. Prof. Rogers has a background in marine ecology, systematics and molecular ecology.

Octavio Aburto-Oropeza is an Associate Professor at Scripps Institution of Oceanography (SIO), a professional photographer associate with the International League of Conservation Photographers and a National Geographic Explorer. His research and photographs have focused on marine reserves and commercially exploited marine species and their fisheries in Latin America and the United States.

Contributors

Ward Appeltans is the marine biodiversity focal point of UNESCO- IOC and since 2012 is the head of the secretariat of OBIS. Before joining UNESCO-IOC he managed WoRMS and was a project leader at the data centre of the Flanders Marine Institute and was involved in several European marine biodiversity projects.

Jorge Assis is a research fellow at the Centre of Marine Sciences and lecturer at the University of Algarve. He has a background in marine ecology and data science and currently focuses his research in addressing the potential consequences of global climate changes (past, ongoing and future) to marine biodiversity.

Lisa T. Ballance is Director of Oregon State University's Marine Mammal Institute, Endowed Chair for Marine Mammal Research and a former marine ecologist with the National Oceanic and Atmospheric Administration (NOAA). Her research focuses on ecology and conservation biology of cetaceans and seabirds, largely in the Pacific and Southern Oceans far from shore.

Philippe Cury is senior scientist at IRD (Institut de Recherche pour le Développement; French National Research Institute for Sustainable Development) and the IRD representative for Europe in Brussels at CLORA (Club des Organismes de Recherche Associés). He is the President of the Scientific Council of the Monaco Institute of Oceanography and one of the two scientific Directors of Euromarine Consortium (www.euromarinenetwork.eu). His research focuses on sustainable management of marine resources in an ecosystem perspective.

Carlos M. Duarte is Professor of Marine Science and Tarek Ahmed Juffali Research Chair in Red Sea Ecology at King Abdullah University of Science and Technology (KAUST), and Professor at the Arctic Research Center, Aarhus University, Denmark. His research addresses marine ecology, conservation and the impacts and responses to human pressures for ecosystems ranging from polar to tropical and from coastal to the deep sea. He is a member of the Expert Group supporting the HLP commissioning this series of Blue Papers.

Fabio Favoretto is a Marine Ecologist at the Universidad Autónoma de Baja California Sur in La Paz, Mexico. He has a background in benthic ecology and currently works on remote sensing applications in coastal environments.

Joy Kumagai is a Research Associate at SIO. Her research focuses on the impacts of anthropogenic activities on ecosystem services and marine biodiversity. Her background is in marine biology and applying Geographical Information Systems to answer research questions.

Catherine Lovelock is a Professor at the School of Biological Sciences at the University of Queensland, Australia. She has investigated the physiology and ecology of mangroves and other coastal plant communities over their global distribution, focusing on climate change and its impacts as well as the role of coastal wetlands in climate change adaptation and mitigation.

Patricia Miloslavich is the Executive Director of the Scientific Committee on Oceanic Research (SCOR), an international NGO to help address interdisciplinary science questions related to the ocean. She is a retired professor from the Universidad Simón Bolívar in Venezuela. Her background is in marine biology, biodiversity and global ocean biological observations.

Aidi Niamir is a scientist at the Data and Modelling Centre of the Senckenberg Biodiversity and Climate Research Institute in Germany. His research and services mainly focus on spatiotemporal models, application of earth observation in biodiversity and ecosystem studies and open geo-information tools to support science-policy interactions. He is a lead author of the IPBES Global Assessment Report on Biodiversity and Ecosystem Services and the head of the IPBES technical support unit on data.

David Obura is a Director of CORDIO (Coastal Oceans Research and Development in the Indian Ocean) East Africa, a Kenyan research organisation focused on coral reefs of the Western Indian Ocean. From a foundation in coral reef resilience, he increasingly works to integrate conservation and development in ways that will be necessary for a sustainable future for coastal systems. He works with a number of global working groups, including the Earth Commission and GOOS BioEco, and chairs the IUCN Coral Specialist Group.

Bethan C. O'Leary is a Research Associate at the University of York and a Senior Research Fellow at the University of Salford. Her research focuses on sustainable management of marine resources, particularly through marine protected areas, and the integration of scientific research with applied environmental management and policy.

Gabriel Reygondeau is a research associate in the Changing Ocean Research Unit at the University of British Columbia and in the Department of Ecology and Evolution at Yale University. He is an oceanographer, ecologist and biogeographer who explores the relationship between climate, biodiversity and human activities.

Callum Roberts is Professor of Marine Conservation at the University of York. His research focuses on threats to marine ecosystems and species and on finding the means to protect them. His team helped design the world's first network of high seas protected areas and provided the scientific underpinning for a new ocean protection target—30% by 2030—which is gaining widespread international support.

Yvonne Sadovy was a Professor at the School of Biological Sciences of the University of Hong Kong for over 25 years after directing the government fishery lab in Puerto Rico. She founded and co-chairs the IUCN Groupers & Wrasses Specialist Group and co-founded and directs Science and Conservation of Fish Aggregations. Her specialty is reef fishes and fisheries, their conservation and management

Tracey T. Sutton is Professor in the Halmos College of Natural Sciences and Oceanography at Nova Southeastern University (Dania Beach, Florida) and Assistant Chair of the Department of Marine and Environmental Sciences. His research entails oceanic ecosystem structure, food web dynamics, organismal ecology, biogeography, fish taxonomy, and deep ocean stewardship, with emphasis on human impacts. He is a member of the Expert Panel for the first and second United Nations World Ocean Assessments.

Derek P. Tittensor is the Jarislowsky Chair in Marine Ecosystem Forecasting at the Department of Biology, Dalhousie University, Canada. He is a marine ecologist with a research focus on biodiversity and human impacts on marine ecosystems. He is also coordinator of the Fisheries and Marine Ecosystem Model Intercomparison Project (Fish-MIP).

Enriqueta Velarde is Senior Researcher/Professor at the Institute of Marine Sciences and Fisheries at the Universidad Veracruzana in Mexico and has 42 years of experience in research projects related to seabird ecology. Main areas of interest include generating a long-term time series of biological and ecological seabird parameters providing information to support demographic, trophic and fisheries predictive models; marine protected area planning as well as genetic and life history research of endangered species in natural protected areas. Other work areas focus on ethno-ornithology, indigenous knowledge and citizen science.
