**Abstract.** In the last decade, an effort has been made by the research community to find efficient ways to thwart side channel analysis (SCA) against physical implementations of cryptographic algorithms. A common countermeasure for implementations of block ciphers is Boolean masking which randomizes the variables to be protected by the bitwise addition of one or several random value(s). However, advanced techniques called *higher-order SCA* attacks exist that overcome such a countermeasure. These attacks are greatly favored by the very nature of Boolean masking. In this paper, we revisit the *affine masking* initially introduced by Von Willich in 2001 as an alternative to Boolean masking. We show how to apply it to AES at the cost of a small timing overhead compared to Boolean masking. We then conduct an in-depth analysis pinpointing the leakage reduction implied by affine masking. Our results clearly show that the proposed scheme provides an excellent performance-security trade-off to protect AES against higher-order SCA.

## 1 Introduction

*Side Channel Analysis* is a cryptanalytic technique that consists in analyzing the *side channel leakage* (e.g. the power consumption, the electromagnetic emanations) produced during the execution of a cryptographic algorithm embedded on a physical device. SCA exploits the fact that this leakage is statistically dependent on the intermediate variables that are processed. Some of these variables are *sensitive* in the sense that they are related to secret data, and recovering information on them therefore enables efficient key recovery attacks [13,2,10].

A very common countermeasure to protect implementations of block ciphers against SCA is to randomize the sensitive variables by masking techniques [3,12]. The principle is to add one or several random value(s) (called *mask(s)*) to every sensitive variable occurring during the computation. Masks and masked variables propagate throughout the cipher in such a way that every intermediate variable is independent of any sensitive variable. This strategy ensures that the

instantaneous leakage is independent of any sensitive variable, thus rendering SCA difficult to perform. The masking can be characterized by the number of random masks used per sensitive variable. A masking that involves  $d$  random masks is called a  $d^{\text{th}}$ -order masking. Such a masking can always be theoretically broken by a  $(d + 1)^{\text{th}}$ -order SCA, namely an SCA that targets  $d + 1$  intermediate variables at the same time [16,24,20]. However, the noise effects imply that the difficulty of carrying out a  $d^{\text{th}}$ -order SCA in practice increases exponentially with  $d$  [3]. The  $d^{\text{th}}$ -order SCA resistance (for a given  $d$ ) is thus a good security criterion for implementations of block ciphers. Unfortunately, only a few higher-order masking schemes exist and they are costly in timings [24,5,21,22].

Instead of looking for perfect security against  $d^{\text{th}}$ -order SCA, an alternative approach consists in looking for practical resistance to these attacks. It may for instance be observed that the efficiency of higher-order SCA is related to the way the masks are introduced to randomize sensitive variables. Merely all masking schemes proposed in the literature are based on *Boolean masking* where masks are introduced by exclusive-or (XOR). This masking enables securing implementations against first-order SCA quite efficiently, however it is especially vulnerable to higher-order SCA [16,18] due to the intrinsic physical properties of electronic devices.

A first work towards the direction of practical – instead of perfect – security against  $d^{\text{th}}$ -order SCA has been published by von Willich [27]. It argues that affine masking offers an improved SCA resistance compared to standard first-order masking schemes. However, implementation issues are not taken into account and the paper does not explain how to apply affine masking to usual block ciphers such as AES or DES. Moreover, von Willich defines the affine masking over the vector space  $\text{GF}(2)^n$ . When defined in such a way, it implies the generation of an invertible  $n \times n$  binary matrix, and  $n$  scalar products over  $\text{GF}(2)$  each time a sensitive variable must be masked. Those steps, and especially the scalar products, are very costly when applied in software. A natural idea to deal with this issue is to define the operations over the field  $\text{GF}(2^n)$  in place of the vector space  $\text{GF}(2)^n$ . The addition operation stays unchanged and the field multiplication is a particular case of the matrix product (the security analysis conducted in this paper shows that both operations offer similar SCA resistance). The idea of masking sensitive data with a multiplicative mask in a field structure was first proposed in [1] to protect an AES implementation. However it was shown in [11] that such a masking is insecure since, by nature, it fails in masking the zero value. A similar zero-value first-order flaw was subsequently exploited in [8] to break the linear masking proposed to protect DES in [12]. These works clearly show that letting the zero value unmasked renders a masking scheme insecure.

**Our contribution.** In this paper, we propose a practical application of affine masking to AES. Namely, we present an implementation of the block cipher such that every 8-bit intermediate result  $z \in \text{GF}(256)$  is manipulated under the form  $G(z) = r_1 \cdot z \oplus r_0$ , where  $(r_1, r_0) \in \text{GF}(2^n)^* \times \text{GF}(2^n)$  is a pair of random values generated before each new execution of the algorithm. Our scheme is very

efficient as it maintains the same compatibility as Boolean masking (which is a particular case of our scheme for  $r_1 = 1$ ) with the linear transformations of the algorithm. In the second part of the paper, we conduct an in-depth analysis which shows that the joint use of a multiplicative mask with a Boolean mask greatly improves the resistance of the scheme to higher-order SCA. As we argue, the multiplicative mask enables to complicate the relationship between the unmasked data and the leakage while the Boolean mask prevents the zero-value leakage. Our analysis pinpoints the leakage reduction resulting from affine masking as well as its improved higher-order SCA resistance.

*Length constraints do not permit us to give all proofs in details. They can be found in the extended version [7] of this paper.*

## 2 Securing AES with Affine Masking

The AES is an iterated block cipher algorithm. It is composed of several *rounds* that operate on a  $4 \times 4$  array of bytes denoted by  $\mathbf{s} = (s_{i,j})_{0 \leq i,j \leq 3}$  and termed the *state*. At the beginning of AES in encryption mode, the state is initialized with the plaintext.

Let us first briefly introduce the outlines of our method. Initially, both the state  $\mathbf{s}$  and the master key  $\mathbf{k} = (k_{i,j})_{0 \leq i,j \leq 3}$  are masked by applying a randomly generated affine transformation  $G$  to each  $s_{i,j}$  and  $k_{i,j}$ . Then, all the original transformations of the cipher are adapted in order to process on and to return affinely masked variables. Should the additive part of the mask cancel out within the computation, a temporary additive mask is introduced in order to avoid any potential zero-value first-order flaw. Eventually, the ciphertext  $(c_{i,j})_{0 \leq i,j \leq 3}$  is simply recovered by applying the inverse mapping  $G^{-1}$  to each coordinate of the final value of the masked state (which contains the values  $G(c_{i,j})$ ).

In the following section, we explain how the AES implementation can be adapted to securely operate on a state masked by an affine transformation  $G$ .

### 2.1 Affine Masking Applied to AES

A round of the AES is composed of the four following transformations whose description can be found in [7, Section 2.1]: *AddRoundKey*, *SubBytes*, *ShiftRows* and *MixColumns*. Each of them operates on the state  $\mathbf{s}$  and updates it. To distinguish the updated state from the state at input of the transformation, we denote it by  $\mathbf{s}' = (s'_{i,j})_{0 \leq i,j \leq 3}$ .

To secure the state manipulations thanks to the affine masking countermeasure every manipulation of  $\mathbf{s}$  is replaced by a manipulation of  $\mathbf{G}(\mathbf{s}) = (G(s_{i,j}))_{0 \leq i,j \leq 3}$ . In the following, we assume that  $G$  is defined with respect to a pair  $(r_1, r_0)$  of random elements of  $\text{GF}(256)^* \times \text{GF}(256)$  as:

$$G : x \in \text{GF}(256) \longmapsto r_1 \cdot x \oplus r_0 \in \text{GF}(256) .$$

In the sequel,  $G(x)$  shall be called the *G-representation* of  $x$  and the variables  $r_1$  and  $r_0$  shall be referred to as the *multiplicative mask* and the *additive mask* respectively.

Let us now explain how the four main AES primitives can be easily adapted to securely operate on a state masked by an affine transformation  $G$ . We shall denote by  $\mathbf{G}(\mathbf{s}) = (G(s_{i,j}))_{0 \leq i,j \leq 3}$  the masked state at the input of each transformation and by  $\mathbf{G}(\mathbf{s}') = (G(s'_{i,j}))_{0 \leq i,j \leq 3}$  the masked state at the output.

1. To securely compute the  $G$ -representation of the output of **AddRoundKey** from the  $G$ -representations of the input state and the round key, each byte  $G(s)$  of the state is XOR-ed with the corresponding round key byte  $G(k)$  as follows:

$$G(s') \leftarrow (((G(s) \oplus r) \oplus G(k)) \oplus r_0) \oplus r .$$

where  $r$  is randomly chosen in  $\text{GF}(256)$ . The method is essentially based on the following observation: each masked output byte  $G(s')$  can be computed as  $G(s') = G(s \oplus k) = G(s) \oplus G(k) \oplus r_0$ . A temporary random mask has to be introduced to ensure that the state bytes are always masked affinely and not only linearly.

2. To process the s-box transformations, we propose to use a new look-up table  $\tilde{\mathbf{S}}$  that is recomputed at each new AES execution from both  $G$  and  $\mathbf{S}$  such that for every  $x \in \text{GF}(256)$ , we have:

$$\tilde{\mathbf{S}}[G(x)] = G(\mathbf{S}[x]) . \tag{1}$$

It can be easily checked that processing  $\tilde{\mathbf{S}}$  on the  $G$ -representation of a byte  $s_{i,j}$  results in the  $G$ -representation of  $s'_{i,j} = \mathbf{S}[s_{i,j}]$ . Securing the **SubBytes** transformation with the affine masking thus simply consists in applying  $\tilde{\mathbf{S}}$  to each byte of the state:

$$G(s'_{i,j}) \leftarrow \tilde{\mathbf{S}}[G(s_{i,j})] .$$

3. Since we have  $\text{ShiftRows}(\mathbf{G}(\mathbf{s})) = \mathbf{G}(\text{ShiftRows}(\mathbf{s}))$  and since **ShiftRows** operates on each byte separately, it can be directly applied on  $\mathbf{G}(\mathbf{s})$  without introducing any flaw:

$$\mathbf{G}(\mathbf{s}') \leftarrow \text{ShiftRows}(\mathbf{G}(\mathbf{s})) .$$

4. Since each output byte of **MixColumns** can be expressed as a linear function of the bytes of the input state over  $\text{GF}(256)$ , it can be checked that we have:

$$\begin{aligned} \text{MixColumns}(G(s_{0,c}), G(s_{1,c}), G(s_{2,c}), G(s_{3,c})) \\ = (G(s'_{0,c}), G(s'_{1,c}), G(s'_{2,c}), G(s'_{3,c})) . \end{aligned}$$

This suggests to perform the following steps to securely process **MixColumns** on the  $G$ -representation of the state columns.

$$\left\{ \begin{array}{l} tmp \leftarrow r \oplus G(s_{0,c}) \oplus G(s_{1,c}) \oplus G(s_{2,c}) \oplus G(s_{3,c}) \\ G(s'_{0,c}) \leftarrow \text{xtimes}(G(s_{0,c}) \oplus r' \oplus G(s_{1,c})) \oplus tmp \oplus G(s_{0,c}) \oplus r \oplus \text{xtimes}(r') \\ G(s'_{1,c}) \leftarrow \text{xtimes}(G(s_{1,c}) \oplus r' \oplus G(s_{2,c})) \oplus tmp \oplus G(s_{1,c}) \oplus r \oplus \text{xtimes}(r') \\ G(s'_{2,c}) \leftarrow \text{xtimes}(G(s_{2,c}) \oplus r' \oplus G(s_{3,c})) \oplus tmp \oplus G(s_{2,c}) \oplus r \oplus \text{xtimes}(r') \\ G(s'_{3,c}) \leftarrow r \oplus G(s'_{0,c}) \oplus G(s'_{1,c}) \oplus G(s'_{2,c}) \oplus tmp \end{array} \right.$$

where `xtimes` denotes a look-up table for a multiplication by some constant in the field  $\text{GF}(256)$  (see [6] for more details). To ensure that the state bytes are always masked affinely and not only linearly, two temporary random masks  $r, r' \in \text{GF}(256)$  have to be introduced. Moreover, the operations above must be processed from left to right.

Finally, since the round key derivation is a composition of the previous transformations, it can be protected by the exact same methods as previously described.

## 2.2 Time-Memory Trade-Offs

Affine masking requires 32 computations of  $G$  in order to mask both the plaintext and the key, and eventually 16 computations of  $G^{-1}$  in order to unmask the ciphertext. Field multiplications and inversions involved in affine masking can be efficiently implemented with the well-known log/alog tables technique as long as conditional statements are avoided to thwart timing attacks (see Appendix A in [7] for an example of such an implementation).

Essentially, the processing of  $G(s_{i,j})$ ,  $G^{-1}(s_{i,j})$  and  $\tilde{S}(s_{i,j})$  may be conducted on-the-fly or may involve pre-computations. Both strategies have different impacts on time and storage costs.

The best time-memory trade-off consists in using two look-up tables for  $G$  and  $\tilde{S}$ , and in processing one field multiplication and one addition each time  $G^{-1}$  must be performed on a state element. The different steps of the look-up table generations of  $G$  and  $\tilde{S}$  are summarized in Algorithm 1.

---

---

### Algorithm 1

---

INPUT:  $r_0 \in \text{GF}(256)$ ,  $r_1 \in \text{GF}(256)^*$ , and the LUT  $S$  for the AES s-box

OUTPUT: The LUTs for  $G$  and  $\tilde{S}$

---

1. **for**  $i = 0$  **to** 255 **do**
  2.    $G[i] \leftarrow r_1 \cdot i \oplus r_0$
  3. **for**  $i = 0$  **to** 255 **do**
  4.    $\tilde{S}[G[i]] \leftarrow G[S[i]]$
  5. **return**  $(G, \tilde{S})$
- 

As  $G^{-1}$  is not stored as a look-up table, each byte  $\tilde{s}$  of the final output state has to be unmasked using  $s \leftarrow r_1^{-1} \cdot (\tilde{s} \oplus r_0)$ .

This way of implementing the affine masking requires the storage of 512 bytes for the look-up tables  $G$  and  $\tilde{S}$ . It also involves 256 multiplications in the field  $\text{GF}(256)$  and 256 XORs to generate  $G$ , while  $\tilde{S}$  is generated using look-ups only. The initial masking of the plaintext and the key only requires 32 table look-ups. Unmasking implies a total of 16 inversions and 16 multiplications in the field  $\text{GF}(256)$ .

As an alternative to the previous algorithm, two variants can be proposed.

1. **First variant.**  $\tilde{S}$ ,  $G$  and  $G^{-1}$  are pre-computed using three look-up tables in order to save on-the-fly computations. Masking both the plaintext and

the key involves 32 table look-ups and unmasking the ciphertext involves 16 table look-ups. This method requires the storage of  $3 \times 256$  bytes for these look-up tables. It also involves 256 multiplications in the field  $\text{GF}(256)$  to generate  $G$ .

2. **Second variant.** This variant involves a single look-up table for  $\tilde{S}$  and performs every other operation on-the-fly. It requires the storage of 256 bytes for this look-up table. It also involves  $2 \times 256$  multiplications in the field  $\text{GF}(256)$  to generate  $\tilde{S}$ , and 32 multiplications for the initial masking of the plaintext and the key. Unmasking implies a total of 16 inversions and 16 multiplications in the field  $\text{GF}(256)$ .

### 2.3 Implementation Results

In this section, we compare several AES implementations protected by affine masking, first-order Boolean masking and second-order Boolean masking. The codes are written in assembly language for an 8051-based 8-bit architecture. More details about these countermeasures can be found in the respective papers [15,21,24]. Table 1 lists the timing and memory performances of each implementation.

**Table 1.** Comparison of AES implementations

Method	Reference	Cycles	RAM (bytes)	ROM (bytes)
Unprotected Implementation				
No Masking	Na.	$2 \times 10^3$	32	1150
Provably Secure First-Order SCA Resistant Implementation				
First-Order Boolean Masking	[15]	$9 \times 10^3$	$256 + 35$	1744
Affine Masking (ref. implem.)	This paper	$29 \times 10^3$	$512 + 37$	2857
Affine Masking (1 <sup>st</sup> var.)	This paper	$28 \times 10^3$	$768 + 36$	2985
Affine Masking (2 <sup>nd</sup> var.)	This paper	$38 \times 10^3$	$256 + 37$	3252
Provably Secure Second-Order SCA Resistant Implementation				
Second-Order Boolean Masking	[24]	$594 \times 10^3$	$512 + 90$	2336
Second-Order Boolean Masking	[21]	$672 \times 10^3$	$256 + 86$	2215

Table 1 shows that the implementation of AES protected by affine masking is 3.2 to 4.2 times slower than the one protected by first-order Boolean masking, whereas the memory overhead is either +0% (2<sup>nd</sup> variant) or +100% (reference implementation) or +200% (3<sup>rd</sup> variant). When compared to the second-order Boolean masking proposed in [24] and [21], the affine masking of AES is 17.7 times faster with the third variant and 20.5 times faster with the first variant.

As every intermediate variable of the computation is affinely masked, we keep a perfect security with respect to first-order SCA. Moreover, as argued in the next section, we significantly increase the resistance of the implementation against higher-order SCA. In view of the implementation performances depicted in Table 1, this

rise in security has been obtained at the cost of a very small overhead when compared to the overhead of provably secure second-order Boolean masking.

### 3 Resistance to Higher-Order SCA

Affine masking is not inherently perfectly secure against higher-order SCA. It can for instance be checked that several pairs of intermediate variables of the scheme proposed in Sect. 2 depend on sensitive variables. We however argue in this section that affine masking is much more resistant than the widely-used Boolean masking. To highlight this statement, we quantify the information leakage reduction provided by affine masking and we study the efficiency of higher-order DPA [16,20] against it. For comparison purposes, we apply the same analysis to Boolean masking. We eventually give the results of several attack experiments in order to check the reliability of our theoretical analysis with respect to practical attack scenarios.

#### 3.1 Leakage of Affine Masking

In what follows, we shall consider that an intermediate variable  $U_i$  is associated with a leakage variable  $L_i$  representing the information leaking about  $U_i$  through side channel. We will assume that the leakage can be expressed as a deterministic *leakage function*  $\varphi$  of the intermediate variable  $U_i$  with an independent additive noise  $B_i$ . Namely, we will assume that the leakage variable  $L_i$  satisfies:

$$L_i = \varphi(U_i) + B_i . \quad (2)$$

In the following, we shall call  $d^{\text{th}}$ -order leakage a tuple of  $d$  leakage variables  $L_i$  corresponding to  $d$  different intermediate variables  $U_i$  that jointly depend on some sensitive variable. As already argued in Sect. 2, when an implementation is correctly protected by affine masking (*i.e.* when every sensitive variable is affinely masked), no first-order leakage of sensitive information occurs. This is a consequence of the action of the random additive mask  $R_0$ . However, as detailed hereafter, second-order and third-order information leakages do occur in the presence of affine masking.

**Second-order leakage.** To recover sensitive information when affine masking is applied, one must at least consider the joint leakage of two different intermediate variables  $U_1$  and  $U_2$  that share common masks. Those variables can thus be assumed to satisfy:

$$\begin{cases} U_1 = G(Z_1) = R_1 \cdot Z_1 \oplus R_0 \\ U_2 = G(Z_2) = R_1 \cdot Z_2 \oplus R_0 \end{cases} , \quad (3)$$

where  $R_1$  and  $R_0$  are random variables defined over  $\text{GF}(2^n)^*$  and over  $\text{GF}(2^n)$  respectively and where  $Z_1$  and  $Z_2$  are sensitive variables. A particular case is  $Z_2 = 0$  which amounts to target the pair  $(G(Z_1), R_0)$ .

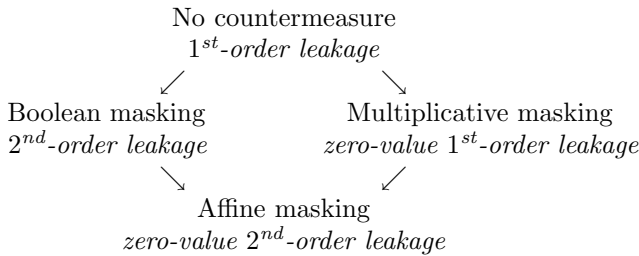

In the following, we shall assume that  $R_1$  and  $R_0$  are uniformly distributed over  $\text{GF}(2^n)^*$  and over  $\text{GF}(2^n)$  respectively and that they are mutually independent of the pair  $(Z_1, Z_2)$ , and of each other. After denoting by  $Z$  the sensitive variable  $Z_1 \oplus Z_2$ , we obtain the following lemma.

**Lemma 1.** *The pairs  $(U_1, U_2)$  and  $(G(Z), R_0)$  are identically distributed.*

Lemma 1 shows that the second-order leakage corresponding to a pair of sensitive variables  $(Z_1, Z_2)$  both affinely masked is equivalent to the the second-order leakage on a sensitive variable  $Z = Z_1 \oplus Z_2$  that is affinely masked and on the corresponding additive mask  $R_0$ . For this reason, in the following, we shall only consider a second-order leakage corresponding to a pair  $(G(Z), R_0)$ , with  $Z$  being possibly the sum of two sensitive variables. The analysis hereafter shall further make use of the following lemma.

**Lemma 2.** *The random pair  $((L_1, L_2)|Z = z)$  is identically distributed for every  $z \in \text{GF}(2^n)^*$  and the random pair  $((L_1, L_2)|Z = 0)$  has a distinct distribution.*

Lemma 2 shows that the second-order leakage  $(L_1, L_2)$  only reveals information about whether  $Z$  equals 0 or not (*i.e.* whether  $Z_1$  equals  $Z_2$  or not). Such a leakage can be thought as a *zero-value second-order leakage* analogously to the *zero-value first-order leakage* of multiplicative masking [1,11]. Intuitively, we have the following diagram where each arrow indicates an additional security level.

**Third-order leakage.** To get more information about  $Z$ , a natural idea is to exploit  $(L_1, L_2)$  together with the leakage  $L_3$  on the multiplicative mask  $U_3 = R_1$ . Indeed, while the pair  $(U_1, U_2)$  only reveals whether  $Z$  equals 0 or not, the triplet  $(U_1, U_2, U_3)$  does reveal the full value of  $Z$  by:

$$Z = U_3^{-1} \cdot (U_1 \oplus U_2) = R_1^{-1} \cdot (G(Z_1) \oplus G(Z_2)). \tag{4}$$

However, the information about the  $U_i$ 's that leak through the  $L_i$ 's does not enable a simple recovery as in (4). In fact, we expect that extracting information on  $Z$  through side channels is more difficult when affine masking is applied in place of Boolean masking. Indeed, when the mask is introduced by bitwise addition, then each bit of the mask acts on a single bit of the sensitive variable. In this case, every bit of the masked variable depends on a single bit of the mask. Since bits of processed variables usually contribute to the leakage independently, the information leaking about the mask and the information leaking about the masked variable can be efficiently combined to unmask the variable. This can be illustrated in the Hamming weight leakage model (where  $\varphi = \text{HW}$ ) by the important correlation between  $\text{HW}(Z)$  and either  $|\text{HW}(Z \oplus R_0) - \text{HW}(R_0)|$  or  $(\text{HW}(Z \oplus R_0) - n/2)(\text{HW}(R_0) - n/2)$  [16,20]. When a further mask is introduced

by multiplication in  $\text{GF}(2^n)^*$ , the additive mask still prevents from a zero-value first-order leakage (as for multiplicative masking [11]), and the new multiplicative mask ensures that every bit of the masked variable depends on every bit of both the sensitive variable and the multiplicative mask. In this case, it is legitimate to expect that the information leaked by side channel is much more difficult to exploit to recover information about  $Z$ . For instance, there is no evident way to combine  $\text{HW}(Z \cdot R_1)$  and  $\text{HW}(R_1)$  to construct a variable with high correlation with  $\text{HW}(Z)$ . In order to validate this intuition, we conduct in the next section an information theoretic evaluation of the leakages resulting from affine masking and different kinds of masking.

### 3.2 Information Theoretic Evaluation

In order to evaluate the information revealed by affine masking leakages (first-order and second-order) we follow the information theoretic approach suggested in [25]. Namely we compute the mutual information between the sensitive variable  $Z$  and either the pair of leakages  $(L_1, L_2)$  or the triplet of leakages  $(L_1, L_2, L_3)$ . For comparison purposes, we proceed similarly for Boolean masking and multiplicative masking. We list hereafter the leakages we consider and the underlying leaking variables:

- 2<sup>nd</sup>-order leakage of 1<sup>st</sup>-order Boolean masking:  $(Z \oplus R_0, R_0)$
- 3<sup>rd</sup>-order leakage of 2<sup>nd</sup>-order Boolean masking:  $(Z \oplus R_0 \oplus R'_0, R_0, R'_0)$
- 1<sup>st</sup>-order leakage of multiplicative masking:  $R_1 \cdot Z$
- 2<sup>nd</sup>-order leakage of multiplicative masking:  $(R_1 \cdot Z, R_1)$
- 2<sup>nd</sup>-order leakage of affine masking:  $(R_1 \cdot Z \oplus R_0, R_0)$
- 3<sup>rd</sup>-order leakage of affine masking:  $(R_1 \cdot Z \oplus R_0, R_0, R_1)$

The variables  $Z$ ,  $R_0$ ,  $R'_0$  and  $R_1$  are assumed to be uniformly distributed (over  $\text{GF}(256)$  for the former and over  $\text{GF}(256)^*$  for  $R_1$ ) and mutually independent. For each kind of leakage, we computed the mutual information between  $Z$  and the tuple of leakages in the Hamming weight model with Gaussian noise: the leakage  $L_i$  related to a variable  $U_i$  is distributed according to (2) with  $\varphi = \text{HW}$  and  $B_i \sim \mathcal{N}(0, \sigma^2)$  (the different  $B_i$ 's are also assumed to be mutually independent). In this context, the signal-to-noise *ratio* (SNR) of the leakage is defined as  $\text{Var}[\varphi(U_i)] / \text{Var}[B_i] = 2/\sigma^2$ . Fig. 1 shows the mutual information values obtained for each kind of leakage with respect to an increasing noise standard deviation over  $[0.1, 4.47]$  (*i.e.* a decreasing SNR over  $[\frac{1}{10}, 200]$ ). These results demonstrate the information leakage reduction implied by the use of affine masking. As expected, affine masking leaks less information than multiplicative masking and first-order Boolean masking for all SNRs. We further observe that affine masking leaks less information than second-order Boolean masking when  $\sigma$  is lower than 2.36, that is when the SNR is greater than 0.36. This first analysis allows us to conclude that affine masking is less leaky than 2<sup>nd</sup>-order Boolean masking when the amount of noise in the leakage is small. On the other hand, these results illustrate that a 2<sup>nd</sup>-order SCA security is asymptotically better than a 1<sup>st</sup>-order SCA security even if the masking relation is more complicated

**Fig. 1.** Mutual information ( $\log_{10}$ ) between the leakage and the sensitive variable over an increasing noise standard deviation

in the latter case. Similarly, we see that for a low noise amount, multiplicative masking is more resistant than 1<sup>st</sup>-order Boolean masking although it does not thwart 1<sup>st</sup>-order SCA while Boolean masking does.

Fig. 1 also confirms our intuition regarding the information provided by the leakage on the multiplicative mask. Observing the obtained mutual information for affine masking and for multiplicative masking, we note that the information gained from the leakage on the multiplicative mask is low. This phenomenon amplifies when  $\sigma$  increases and, beyond  $\sigma \approx 2$  the distance between the mutual information curves almost vanishes for both kinds of masking. This means that when the noise is sufficiently strong, the leakage on the multiplicative mask does not provide useful information anymore and only the zero-value leakage reveals sensitive information.

In this section, we have quantified the impact of affine masking on the reduction of the information leakage. We will now see to which extent this reduction also applies to the efficiency of side channel attacks on affine masking.

### 3.3 Higher-Order DPA Evaluation

Let us assume that  $Z$  depends on the plaintext and of a subkey  $k^*$ , and let us denote by  $Z(k)$  the hypothetic value of  $Z$  for a guess  $k$  on  $k^*$ . In a *higher-order DPA* (HO-DPA) [16,20], the attacker tests the guess  $k$  by estimating the correlation coefficient  $\rho [\hat{\varphi}(Z(k)), \mathcal{C}(\mathbf{L})]$ , where  $\mathcal{C}$  is a *combining function* that converts the multivariate leakage  $\mathbf{L}$  into a univariate signal and where  $\hat{\varphi}$  is a *prediction function* chosen such that  $\hat{\varphi}(Z)$  is as much as possible correlated to  $\mathcal{C}(\mathbf{L})$ . The guess  $k$  leading to the greatest correlation in absolute value is selected as key-candidate. In [14], the authors show that the number of traces required to mount a successful DPA attack is roughly quadratic in  $\rho^{-1}$  where  $\rho$  is the correlation coefficient  $\rho [\hat{\varphi}(Z), \mathcal{C}(\mathbf{L})]$  (that is the expected correlation for the

correct key guess). The latter can therefore be used as a metric for the efficiency of a (HO-)DPA attack.

The analysis conducted in [20] states that a good choice for  $\mathcal{C}$  is the *normalized product combining*:

$$\mathcal{C} : \mathbf{L} \mapsto \prod_i (L_i - \mathbb{E}[L_i]). \tag{5}$$

Although the effectiveness of the normalized product combining has been only studied in [20] in the context of Boolean masking, this combining function stays a natural choice against any kind of masking since  $\rho[\hat{\varphi}(Z(k)), \mathcal{C}(\mathbf{L})]$  is related to the *multivariate correlation*<sup>1</sup> between  $\hat{\varphi}(Z(k))$  and every coordinate of  $\mathbf{L}$  [26]. Besides, in the presence of (even little) noise in the side-channel leakage, the HO-DPA with normalized product combining is nowadays the most efficient unprofiled attack against Boolean masking in the literature (see for instance [20,26,22]). For those reasons, it is natural to study how efficient is a HO-DPA with normalized product combining against affine masking compared to Boolean masking.

In [20], it is also shown that the best choice for  $\hat{\varphi}$  given  $\mathcal{C}$  is:

$$\hat{\varphi} : z \mapsto \mathbb{E}[\mathcal{C}(\mathbf{L})|Z = z]. \tag{6}$$

As explained in [20], the attacker may not be able to evaluate  $\hat{\varphi}$  without knowing the exact distribution of  $\mathbf{L}$  given  $Z$  (as in a profiled attack scenario). In a security evaluation context, it however makes sense to assume that the attacker has this ability. As proved in [7, Appendix B], the optimal prediction function  $\hat{\varphi}$  computed according to (6) for the zero-value 2<sup>nd</sup>-order leakage of affine masking is an affine transformation of the dirac function  $\delta_0$  defined as<sup>2</sup>:

$$\delta_0(z) = \begin{cases} 1 & \text{if } z = 0, \\ 0 & \text{if } z \neq 0. \end{cases} \tag{7}$$

Therefore, we have  $\rho[\hat{\varphi}(Z(k)), \mathcal{C}(\mathbf{L})] = \pm \rho[\delta_0(Z(k)), \mathcal{C}(\mathbf{L})]$ , that is, the attack performs similarly with  $\hat{\varphi}$  and  $\delta_0$ .

*Remark 1.* Computing  $\rho[\delta_0(Z(k)), \mathcal{C}(\mathbf{L})]$  amounts to performing a zero-value DPA attack as in [11] but on the combined leakage  $\mathcal{C}(\mathbf{L})$ . After assuming that  $Z(k)$  is uniformly distributed over  $\text{GF}(2^n)$ , it can indeed be checked that the covariance between  $\delta_0(Z(k))$  and  $\mathcal{C}(\mathbf{L})$  (which is the discriminating element in the correlation) equals  $\frac{2^n-1}{2^n} \mathbb{E}[\mathcal{C}(\mathbf{L})|Z(k) \neq 0] - \frac{1}{2^n} \mathbb{E}[\mathcal{C}(\mathbf{L})|Z(k) = 0]$ .

When the leakage satisfies (2) with  $\varphi = \text{HW}$  and  $B_i \sim \mathcal{N}(0, \sigma^2)$  (*i.e.* when the Hamming weight leakage model with Gaussian noise is assumed), it is shown in

<sup>1</sup> What we call multivariate correlation here is the straightforward generalization of the correlation coefficient to more than two variables (see [26]).

<sup>2</sup> This is actually true whatever the leakage function and noise distribution as a direct consequence of Lemma 2.

[7, Appendix B] that the coefficient  $\rho_{\text{aff}}$  obtained for the zero-value second-order leakage of affine masking satisfies:

$$\rho_{\text{aff}} = \frac{n}{(4\sigma^2 + n)\sqrt{2^n - 1}}, \tag{8}$$

where  $n$  is the bit-size of  $Z$ .

We also computed the correlation coefficient corresponding to the 3<sup>rd</sup>-order leakage of affine masking. We did not obtain explicit formulae for this coefficient but we observed for several values of  $n$  and  $\sigma$  that it was always lower than  $\rho_{\text{aff}}$ . This suggests that HO-DPA with normalized product combining works better against the 2<sup>nd</sup>-order leakage of affine masking than against the 3<sup>rd</sup>-order one. From our analysis, we therefore concluded that  $\rho_{\text{aff}}$  not only quantifies the resistance of affine masking against 2<sup>nd</sup>-order DPA, but also that against HO-DPA in general.

Regarding Boolean masking, it has been shown in [23] that the correlation  $\rho_{\text{bool}}$  corresponding to HO-DPA with normalized product combining against  $d^{\text{th}}$ -order Boolean masking satisfies (in the Hamming weight model):

$$\rho_{\text{bool}} = (-1)^d \frac{\sqrt{n}}{(n + 4\sigma^2)^{\frac{d+1}{2}}}. \tag{9}$$

Let us denote by  $N_{\text{aff}}$  (resp.  $N_{\text{bool}}$ ) the number of leakage measurements for a successful attack on affine masking (resp. Boolean masking). Since, according to [14],  $N_{\text{aff}}$  and  $N_{\text{bool}}$  are respectively roughly quadratic in the values of the inverse of the correlation coefficients, the ratio  $\frac{N_{\text{aff}}}{N_{\text{bool}}}$  satisfies:

$$\frac{N_{\text{aff}}}{N_{\text{bool}}} \approx \left( \frac{\rho_{\text{bool}}}{\rho_{\text{aff}}} \right)^2 = \frac{2^n - 1}{n} \left( \frac{1}{n + 4\sigma^2} \right)^{1-d}. \tag{10}$$

Let  $\nu$  denote the value  $\frac{2^n - 1}{n} \left( \frac{1}{n + 4\sigma^2} \right)^{1-d}$ . In view of (10), affine masking is more resistant to HO-DPA than  $d^{\text{th}}$ -order Boolean masking if and only if  $\nu \geq 1$ . Comparing the resistance of Boolean masking and affine masking against HO-DPA thus amounts to study when  $\nu \geq 1$  is satisfied. Let us study this inequality with respect to  $d$ :

- When  $d = 1$ , we have  $\nu \geq 1$  for all  $n \geq 1$  whatever  $\sigma$ . We deduce that affine masking is more resistant to HO-DPA than first-order Boolean masking for all SNRs. Moreover, from (10), we expect that HO-DPA against first-order Boolean masking required around 32 times more leakage measurements than against affine masking whatever  $\sigma$ .
- For  $d = 2$ ,  $\nu \geq 1$  if and only if  $\sigma^2 \leq (2^n - n^2 - 1)/4n$ . This implies that for the case of AES where  $n = 8$ , affine masking is more resistant to HO-DPA than 2<sup>nd</sup>-order Boolean masking if  $\sigma \leq 2.44$ , which corresponds to a SNR greater than 0.335.
- For  $d \geq 3$ ,  $\nu$  is always smaller than 1 for every  $n \geq 1$ . Affine masking is hence less resistant to HO-DPA than 3<sup>rd</sup>-order Boolean masking for all SNRs.

**Fig. 2.** Correlation values with respect to  $\sigma$  (logarithmic scale)

Eventually Fig. 2 plots the correlation values  $\rho_{\text{bool}}$  for  $d \in \{1, 2, 3\}$ ,  $\rho_{\text{aff}}$  (2O-DPA against affine masking) as well as the correlation values obtained for the third-order DPA against affine masking. It illustrates the fact that the correlation corresponding to the 3<sup>rd</sup>-order leakage of affine masking is always lower than that corresponding to the 2<sup>nd</sup>-order leakage of affine masking. Moreover and as expected, it shows that the coefficient  $\rho_{\text{aff}}$  is always lower than  $\rho_{\text{bool}}$  for  $d = 1$ , always greater than  $\rho_{\text{bool}}$  for  $d = 3$ , and lower than  $\rho_{\text{bool}}$   $d = 2$  only when  $\sigma \leq 2.44$ .

### 3.4 Attack Experiments

In order to confront the theoretical analyses conducted in the previous sections to practice, we performed several attack experiments. In a first place, we applied several side-channel distinguishers to leakage measurements simulated in the Hamming weight model with Gaussian noise. We not only applied (HO)-DPA, but also two other kinds of attacks, namely (higher-order) *Mutual Information Analysis* (MIA) and *Template Attacks* (TA). We chose to test these three side-channel distinguishers against the different kinds of masking firstly because they are the most widely used in the literature, and secondly because they represent a brand spectrum of adversary capabilities. As already mentioned, HO-DPA with normalized product combining is the most efficient unprofiled attack against Boolean masking. On the other hand HO-MIA does not rely on a specific combining function, which is of interest for a fair comparison between Boolean and affine masking. Eventually, assuming that the adversary's templates are perfect, template attacks are the best possible attacks and hence they give the maximal security level reached by each kind of masking. Our methodology enabled us to observe how the different attacks perform against affine masking and to compare its resistance with that of the Boolean/multiplicative masking for different

SNRs. Afterward, we performed some attacks against real power consumption measurements of smart-card implementations in order to check our observations in a real-world context.

**Attack simulations.** The leakage measurements have been simulated as samples of the random variables  $L_i$  defined according to (2) with  $\varphi = \text{HW}$  and  $B_i \sim \mathcal{N}(0, \sigma^2)$  (the different  $B_i$ 's are also assumed independent). For all the attacks, the sensitive variable  $Z$  was chosen to be an AES s-box output of the form  $\mathbf{S}(X \oplus k^*)$  where  $X$  represents a varying plaintext byte and  $k^*$  represents the key byte to recover.

*Side-channel distinguishers.* We applied higher-order DPA such as described in Sect. 3.3 and we also applied higher-order MIA (HO-MIA) and template attacks. In a higher-order MIA [19,9], the correlation coefficient is replaced by the mutual information: the guess  $k$  is tested by estimating  $\mathbf{I}(\hat{\varphi}(Z(k)); \mathbf{L})$ . Since the mutual information is a multivariate operator, this approach does not involve a combining function. In a template attack [4,17], the attacker owns some *templates* of the leakage that he previously acquired during a profiling phase. More precisely, he has some estimations of the probability distributions  $(\ell, z) \mapsto \Pr[\mathbf{L} = \ell | Z = z]$ . Based on those estimations, the attacker tests a guess  $k$  by estimating the likelihood  $\Pr[k^* = k | \mathbf{L}, X]$ .

*Target variables.* Each attack was applied against the leakages of affine masking, multiplicative masking and Boolean masking. The target variables are those listed in Sect. 3.2 for  $Z$  being  $\mathbf{S}(X \oplus k^*)$ .

*Prediction functions.* For each (HO-)DPA, we chose  $\hat{\varphi}$  to be the optimal prediction function (6). As explained in Sect. 3.3, this leads us to select the dirac function  $\delta_0$  in the attacks against the zero-value 2<sup>nd</sup>-order leakage of affine masking (resp. the zero-value 1<sup>st</sup>-order leakage of multiplicative masking) and, according to [23], to select the Hamming weight function in the attacks against Boolean masking of any order.

For the (HO-)MIA attacks, we chose  $\hat{\varphi}$  such that it maximizes the mutual information  $\mathbf{I}(\hat{\varphi}(Z(k)); \mathbf{L})$  for  $k = k^*$  while ensuring discrimination (*i.e.* the mutual information must be lower for  $k \neq k^*$ ). As a direct consequence of Lemma 2, we chose  $\hat{\varphi} = \delta_0$  to attack the zero-value 2<sup>nd</sup>-order leakage. Naturally, we did the same choice for the zero-value 1<sup>st</sup>-order leakage of multiplicative masking. For the third-order MIA on affine masking (and second-order MIA on multiplicative masking),  $\hat{\varphi}$  was chosen to be the identity function since it maximizes  $\mathbf{I}(\hat{\varphi}(Z); \mathbf{L})$ . However, for the attack to succeed with such a choice, the target sensitive variable  $Z$  must be such that the function  $X \mapsto Z = f_{k^*}(X)$  (where  $X$  is the plaintext part involved in  $Z$ ) is not injective [10,19]. This constrained us to slightly modify the target variables for these attacks. Against affine masking, we targeted an affinely masked s-box output  $G(\mathbf{S}(X \oplus k^*))$  and an affinely masked plaintext byte  $G(X')$  (together with the multiplicative mask  $R_1$ ), which by Lemma 1 yields a non-injective function  $(X, X') \mapsto Z = \mathbf{S}(X \oplus k^*) \oplus X'$ . Against multiplicative

masking, we targeted the bitwise addition between two s-box outputs, which yields a non-injective function  $(X, X') \mapsto Z = S(X \oplus k^*) \oplus S(X' \oplus k^*)$ . Eventually, every HO-MIA against Boolean masking was performed with  $\hat{\varphi} = \text{HW}$  since the distribution of  $(\text{HW}(Z \oplus R_0), \text{HW}(R_0))$  only depends on  $\text{HW}(Z)$ , and therefore  $I(Z; (\text{HW}(Z \oplus R_0), \text{HW}(R_0))) = I(\text{HW}(Z); (\text{HW}(Z \oplus R_0), \text{HW}(R_0)))$  (the same argument holds for every masking order).

*Pdf estimation method.* For the (HO-)MIA attacks, we used the histogram estimation method with rule of [10] for the *bin-widths* selection.

*Leakage templates.* For the template attacks, the attacker's templates were assumed to be perfect. In our context, this means that the attacker is aware of  $\varphi = \text{HW}$  and  $B_i \sim \mathcal{N}(0, \sigma^2)$  for every  $i$ , and he uses this knowledge to evaluate the real probabilities  $\Pr[\mathbf{L}|Z]$ .

*Attack simulation results.* Each attack simulation was performed 100 times for various SNR values  $(+\infty, 1, 1/2, 1/5$  and  $1/10)$ , that is, for several noise standard deviation values  $(0, \sqrt{2}, 2, \sqrt{10}$  and  $2\sqrt{5})$ . Table 2 summarizes the number of leakage measurements required to observe a success rate of 90% in retrieving  $k^*$  for the different attacks.

The results presented in Table 2 show the significant gain of security induced by affine masking compared to multiplicative and first-order Boolean masking. Some more specific observations are reported hereafter.

- **Affine masking versus multiplicative masking.** In all scenarios, affine masking is more resistant than multiplicative masking. When the SNR decreases, the resistance of affine masking increases faster than that of multiplicative masking. This is a consequence of the fact that affine masking is perfectly secure against first-order attacks which is not the case of multiplicative masking.
- **Affine masking versus Boolean masking.** When compared to first-order Boolean masking, a successful HO-DPA requires between 30 and 40 more leakage measurements against affine masking. For low noises (*i.e.* high SNRs), HO-DPA is also less efficient against affine masking than against second-order masking. The tide is turned when noise increases, which corroborates that higher-order masking combined with noise provides good resistance to SCA [3]. These results validate the theoretical analysis done in Sect. 3.3, where it is expected that affine masking is around 32 times more resistant than first-order Boolean masking and more resistant than second-order Boolean masking only when the SNR is greater than 0.335. On the other hand, the results of template attacks confirm that affine masking is always more resistant than first-order Boolean masking, and that it is also more resistant than second-order Boolean masking for high SNRs. It is interesting to note the strong correlation between the information theoretic evaluation of Sect. 3.2 and the efficiency of template attacks. We see that template attacks are more efficient against second-order Boolean masking

**Table 2.** Number of leakage measurements for a 90% success rate

Attack \ SNR	$+\infty$	1	1/2	1/5	1/10
Unprofiled Attacks against Boolean Masking					
2O-DPA on 1O Boolean Masking	150	500	1500	6000	20 000
2O-MIA on 1O Boolean Masking	100	5000	15 000	50 000	160 000
3O-DPA on 2O Boolean Masking	1500	9000	35 000	280 000	$> 10^6$
3O-MIA on 2O Boolean Masking	160	160 000	650 000	$> 10^6$	$> 10^6$
Unprofiled Attacks against Multiplicative Masking					
1O-DPA on Multiplicative Masking	900	1500	2500	4000	7500
1O-MIA on Multiplicative Masking	700	2500	3500	5500	15000
2O-DPA on Multiplicative Masking	2500	7500	20 000	60 000	220 000
2O-MIA on Multiplicative Masking	4000	35 000	55 000	100 000	200 000
Unprofiled Attacks against Affine Masking					
2O-DPA on Affine Masking	6500	20 000	45 000	170 000	650 000
2O-MIA on Affine Masking	5500	100 000	600 000	$> 10^6$	$> 10^6$
3O-DPA on Affine Masking	$> 10^6$	$> 10^6$	$> 10^6$	$> 10^6$	$> 10^6$
3O-MIA on Affine Masking	100 000	$> 10^6$	$> 10^6$	$> 10^6$	$> 10^6$
Profiled Attacks					
2O-TA on Boolean Masking	20	500	1200	7000	20 000
3O-TA on 2O Boolean Masking	20	8000	35 000	300 000	$> 10^6$
1O-TA on Multiplicative Masking	500	1300	1900	4000	7000
2O-TA on Multiplicative Masking	60	900	1400	4000	8000
2O-TA on Affine Masking	1300	15 000	45 000	200 000	$> 10^6$
3O-TA on Affine Masking	260	15 000	35 000	200 000	$10^6$

than against affine masking when the SNR is greater than 1/2 (*i.e.*  $\sigma < 2$ ) which corresponds to the situation where the information leakage of affine masking is lower than that of second-order Boolean masking according to Fig. 1. This observation is in accordance with the argumentation of [25] that the mutual information metric is related to the efficiency of template attacks.

- **3<sup>rd</sup>-order attacks against affine masking.** It can be observed that targeting the multiplicative mask to mount a third-order attack against affine masking does not improve the efficiency of unprofiled attacks. On the contrary, they become clearly inefficient. This is quite natural for the third-order DPA using the product combining since unlike for an additive mask, such a combination is not suitable to remove a multiplicative mask. Therefore, the contribution of the third leakage to the combined leakage mainly acts as a noise, which renders the attack inefficient. For third-order MIA, the efficiency loss may result from the fact that precise estimations of 3-variate densities require significantly more samples than for bivariate densities which slows down the attack efficiency convergence. For template attacks, targeting the multiplicative mask improves the attack efficiency for high SNRs. However when the noise increases the efficiency of 2O-TA and 3O-TA against affine

masking become similar. Once again, this corroborates the information theoretic evaluation of Sect. 3.2 which shows that the information provided by the third-order leakage of affine masking get closer to that provided by the second-order leakage as the noise increases.

- **(HO-)MIA versus (HO-)DPA.** (HO-)MIA attacks are always less efficient than the corresponding (HO-)DPA. A possible explanation is that the measurements are simulated in the Hamming weight model which is a situation more favorable to DPA attacks than to MIA attacks. A second possible explanation is that the rule proposed in [10] for the bin-widths selection in the MIA is not suitable when targeting affine masking. This point is left for further research.

**Practical attacks.** In order to confirm our simulation results, we performed several attacks against software implementations of the AES s-box executed on a 8051 microcontroller. Results of these attacks are reported in [7, Figure 5] and corroborate quite well the attack simulations we performed for an SNR equal to  $1/2$  (which was approximately the observed SNR on the test device).

## 4 Conclusion

In this paper, we introduced affine masking as an alternative to the commonly used Boolean masking to protect implementations of block ciphers against side channel analysis. The principle is to mask each sensitive variable both additively and multiplicatively in order to complicate the masking relation and therefore achieve better higher-order resistance in practice. We described an affine masking scheme for AES and we provided some implementation results for our scheme. Moreover, we conducted an in-depth analysis which demonstrates that affine masking significantly improves the resistance to higher-order SCA compared to Boolean masking. This analysis together with our implementation tests clearly show that the proposed scheme provides a good performance-security trade-off compared to existing countermeasures.
