Abstract. Clustering Web services that groups together services with similar functionalities helps improve both the accuracy and efficiency of the Web service search engines. An important limitation of existing Web service clustering approaches is that they solely focus on utilizing WSDL (Web Service Description Language) documents. There has been a recent trend of using user-contributed tagging data to improve the performance of service clustering. Nonetheless, these approaches fail to completely leverage the information carried by the tagging data and hence only trivially improve the clustering performance. In this paper, we propose a novel approach that seamlessly integrates tagging data and WSDL documents through augmented Latent Dirichlet Allocation (LDA). We also develop three strategies to preprocess tagging data before being integrated into the LDA framework for clustering. Comprehensive experiments based on real data and the implementation of a Web service search engine demonstrate the effectiveness of the proposed LDA-based service clustering approach.

1 Introduction

The explosive growth of Web services poses key challenges for Web service discovery. Existing service discovery approaches rely on either UDDI (Universal Description Discovery and Integration) or Web service search engines to locate matching services. As many service providers choose to publish their Web services through their own websites instead of using public registries, the number of Web services in public UDDI registries decreases significantly. A recent study shows that more than 53% of the UDDI business registry registered services are invalid, whereas 92% of Web services cached by Web service search engines are valid and active [1]. Therefore, using search engines to search and discover Web services becomes more common and effective than UDDI service registries [17].

Existing Web service searching engines primarily focus on keyword-based matching on names, input/output parameters, and bindings defined in the Web service description file [1]. In this case, if a service description does not match

S. Basu et al. (Eds.): ICSOC 2013, LNCS 8274, pp. 162–176, 2013.

the query term, it won't be discovered even though the service may provide the user desired functionality. As it is difficult for a casual user to choose keywords that match the terms in a service description, keyword-based search usually suffers from low recall, where services containing synonyms or concepts at a higher (or lower) level of abstraction will not be discovered. As an example, a service named "Mobile Messaging Service" may not be returned for the query term "SMS" submitted by a user even though they describe the same concept. To handle this issue, service clustering has been recently exploited to improve the search quality [19,20]. By clustering Web services together, services in the same cluster are expected to provide similar functionalities so that they can be discovered together as a group. However, existing service clustering algorithms mainly rely on the WSDL descriptions of services, which usually contain very limited terms, some of which are even not proper words. Hence, these algorithms may lead to low clustering quality, which will negatively affect the accuracy of service discovery.

Recently, some real-world Web service search engines, such as Seekda!, have allowed users to manually annotate Web services using tags. Tags provide meaningful descriptions of objects and allow users to organize and index their contents. Tagging data has been proved to be very useful in many domains such as multimedia, information retrieval, data mining, and so on. Figure 1 shows two examples of Web service tags in Seekda! service search engine. Meteorology WS in Fig. 1(a) is a weather forecasting Web service, which has two tags, weather and waether. However, there is no word weather in its service name or WSDL document. Thus, it is hard for this service to be clustered into the weather cluster. Further, this service will be hard to be retrieved without utilizing the tag information, if the query term is weather. Besides, the tag waether is also useful as some users may make a mistake in the typing process and use waether as the query term. As a service provider, one may have different naming convention and prefer to use *Meteorology* instead of weather in the generated WSDL file, as shown in Fig. 1(a). On the other hand, service users are likely to use the same tag to annotate services with similar functionality. Therefore, leveraging the tagging information along with the WSDL can help improve the quality of service clustering.

Fig. 1. Example of Web Service Tags

In this paper, we propose to augment the Latent Dirichlet Allocation (LDA) model [3,13], referred to as WT-LDA, to seamlessly integrate WSDL documents and service tags for service clustering. LDA has been demonstrated to be an effective tool in topic modeling and document clustering in the text domain. Specifically, WT-LDA models each service as a distribution of a set of topics and functionally similar services are expected to be represented by a similar distribution of topics. Service tags are also used to determine the topics of the services. We assess the effectiveness of the proposed WT-LDA via real-world Web services collected from Seekda!. Preliminary experimental results reveal that the performance of WT-LDA is affected by Web service with few tags or many meaningless tags. To tackle this issue, we propose three strategies to preprocess service tags before being used by WT-LDA. The experiment results in Section 5 demonstrate that our tag preprocessing strategies help improve the performance of WT-LDA. The major contributions of this paper can be summarized as follows:

- 1. We propose a novel Web service clustering approach WT-LDA based on a probabilistic graphic model (i.e., LDA), in which both the WSDL documents and service tags are effectively utilized.
- 2. We propose three tag preprocessing strategies to improve the performance of WT-LDA.
- 3. We crawl 15,968 real Web services to evaluate the performance of WT-LDA and three tag preprocessing strategies.

The rest of this paper is organized as follows. Section 2 gives an overview of the related work on Web service discovery and clustering. Section 3 details the proposed WT-LDA, while Section 4 presents the tag preprocessing strategies that help improve the performance of WT-LDA. Section 5 shows the experimental results and Section 6 concludes the paper.

2 Related Work

With the wide adoption of service computing and cloud computing, Web service discovery becomes a popular research topic that attracts significant attention. Recently, Web service clustering [8,10,21] has been demonstrated as an effective tool to boost the performance of Web service discovery. Most service clustering algorithms rely on the computation of similarity between services, which can be (1) semantic based and (2) non-semantic based. Ontology is utilized to compute the semantic similarity between Web services in many studies [2,6,11,15]. Specifically, Cristina et al. [11] propose to use an ant-based method to cluster Web services based on semantic similarity. Sun et al. [15] propose to adopt Petri net as the modeling language for the specification of a service process model, and cluster services based on functional similarity and process similarity. In this paper, we focus on the clustering of non-semantic Web services as most services are described using the WSDL standard, which focuses on the syntactic description of services.

Several approaches have been developed for the calculation of similarity between non-semantic Web services [7,16]. Liu et al. propose to extract 4 features, i.e., content, context, host name, and service name, from the WSDL document to cluster Web services [16]. They take the process of clustering as the preprocessor to discovery, aiming to building a search engine that crawls and clusters non-semantic Web services. Khalid et al. also propose to extract features from WSDL documents to cluster Web services [7]. Different from the work in [16], a set of different features, including content, types, messages, ports, and service name are extracted from the WSDL documents. SVD based and matrix factorization based approaches are adopted to achieve the co-clustering of services and operations in [19,20]. Co-clustering exploits the duality relationship between services and operations to achieve better clustering quality than one-side clustering.

Despite WSDL-based clustering being widely adopted, the clustering performance is rather limited as only WSDL documents are employed. With the development of Web service community, more and more tags are annotated to Web services by users. These tags can be employed to enhance the accuracy of service discovery. However, limited work has exploited tagging data for service discovery. In our preliminary work [4,5,18], we investigated the benefits of utilizing both WSDL documents and tagging data to cluster Web services. The findings motivate our present study. In this paper, we improve the performance of Web service clustering by introducing a novel LDA based approach to explore the knowledge behind WSDL & tags and by proposing three tag preprocessing strategies to improve the performance of service clustering.

3 WT-LDA Based Service Clustering

In this section, we first describe the proposed architecture for Web service discovery framework in Section 3.1, and then introduce data preprocessing component and the probabilistic graphic model of WT-LDA in Section 3.2 and Section 3.3, respectively.

3.1 Web Service Discovery Framework

Figure 2 shows the proposed architecture for Web service discovery framework, which consists of two major components: data preprocessing and service discovery. In the first component, both WSDL documents and tags of Web services are crawled from the Internet, which will be used for service clustering. Specifically, we use the meaningful words in WSDL documents as the feature words to construct a probabilistic graphic model, i.e., WT-LDA. After we extract feature words and tags from Web services, the WT-LDA is used to cluster Web services. Since data preprocessing and service clustering are conducted offline, the efficiency of service discovery can be guaranteed. Hence, the focus will be placed on accuracy. In the second component, clustered result of WT-LDA will be used to improve the search result of a Web service search engine. When a query term is sent to the Web service search engine, it can return a more accurate search result by leveraging the clustered result.

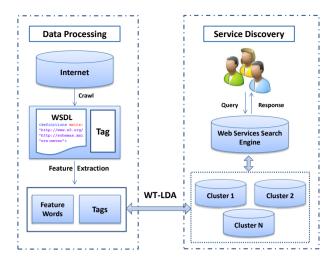

Fig. 2. Framework for Web service Discovery

3.2 Data Preprocessing

As discussed above, we extract the meaningful words from WSDL documents as the feature words, then jointly model these feature words and tags for the purpose of clustering of Web services. In this part, we describe the details in data preprocessing component.

- 1. **Building an original vector**. In this step, we perform tokenization over the entire WSDL document to produce the original content vector.
- 2. **Suffix Stripping**. Words with a common stem will usually have the same meaning, for example, *connect*, *connected*, *connecting*, *connection*, and *connections* all have the same stem *connect* [16]. We strip the suffix of all these words that have the same stem by using the Porter stemmer [12]. After the step of suffix stripping, a new content vector is produced.
- 3. **Pruning**. In this step, we remove two kinds of words from the content vector. The first kind is XML tags, such as s:element, s:complexType, and wsdl:operation, which are not meaningful for the comparison of content vectors. Content words are typically nouns, verbs or adjectives, and are often contrasted with function words which have little or no contribution to the meanings of texts. Therefore, the second kind of word to be removed is function word. Church $et\ al.$ state that the function words could be distinguished from content words using a Poisson distribution to model word occurrence in documents [9]. Typically, a way to decide whether a word w in the content vector is a function word is by computing the degree of overestimation of the observed document frequency of the word w, denoted by n_w using Poisson distribution. The overestimation factor can be calculated as follows.

$$\Lambda_w = \frac{\hat{n_w}}{n_w},\tag{1}$$

where $\hat{n_w}$ is the estimated document frequency of the word w. Specifically, the word with higher value of Λ_w has higher possibility to be a content word. In this paper, we set a threshold Λ_T for Λ_w , and take the words which have Λ_w higher than threshold as content words. The value of threshold Λ_T is set as follows:

$$\Lambda_T = \begin{cases} avg[\Lambda] & \text{if}(avg[\Lambda] > 1); \\ 1 & \text{otherwise} \end{cases}$$
(2)

where $avg[\Lambda]$ is the average value of the observed document frequency of all words considered. After the process of pruning, we can obtain a new content vector, in which both XML tags and function words are removed.

4. **Refining**. Words with very high occurrence frequencies are likely to be too general to discriminate between Web services. After the step of pruning, we implement a step of refining, in which words with too general meanings are removed. Clustering based approaches were adopted to handle this problem in some related work [7,16].

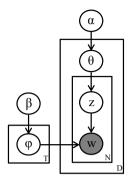

After the above four steps, we obtain the meaningful words in a WSDL document.

3.3 WT-LDA

The proposed WT-LDA model extends Latent Dirichlet Allocation and takes both the content of WSDL documents and the user-contributed tagging data into consideration. WT-LDA can find short description of members of a collection that enable efficient processing of large collections of WSDL documents while preserving the essential statistical relationship that are useful for Web services clustering. Main advantages of the proposed WT-LDA model are listed below:

- 1. It provides a generative probabilistic graphic model of WSDL documents and a probabilistic view to extract latent variables from WSDL documents which can significantly improve the clustering result of Web services
- It measures the word co-occurrence from heterogeneous service description in WSDL documents, infer the topic distribution of each WSDL document and the result topic vectors can contribute to Web services clustering.
- 3. It takes tagging data of WSDL documents into consideration while unique tag has its own distribution of topics. Tags with similar meaning or function have similar distribution of topics. Thus the content of WSDL documents as well as tagging data can contribute to the clustering of Web services.

In the model of WT-LDA, tag related to one document is chosen uniformly at random for each word in that document. Each tag has its own distinct contribution to the topic distribution of the documents. Thus, the topic distribution corresponding to each tag of Web service is drawn from Dirichlet hyper-parameter α . The word distribution specific to each topic is drawn from the Dirichlet hyper-parameter β . Then, a topic is drawn from the topic distribution according to the chosen tag in the document, and the word is generated from that chosen topic.

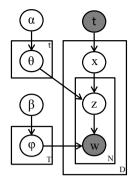

Fig. 3. Probabilistic graphical models of LDA and WT-LDA: the nodes denote random variables, while the edges indicate conditional dependencies. The shaded nodes are observed variables (words); the unshaded nodes are latent variables (topics). The outer rectangles, or "plates", indicate repeated samples.

WT-LDA is a generative model of user-contributed tagging data and words in the WSDL documents. The generative process can be described as follows:

- 1. Draw T multinomial ϕ_z from a Dirichlet prior β , one for each topic z
- 2. For each tag t_d in document d, draw a multinomial θ_{t_d} from a Dirichlet prior α
- 3. For each word w_{di} in document d:
 - (a) Draw a tag x_{di} uniformly from tags t_d in document d;
 - (b) Draw a topic z_{di} from multinomial $\theta_{x_{di}}$;
 - (c) Draw a word w_{di} from multinomial $\phi_{z_{di}}$;

The probabilistic graphical model corresponding to WT-LDA is shown in Fig. 3. As a Web service clustering model, each topic is associated with a distribution ϕ over words, drawn independently from a Dirichlet prior β . x indicates the tag responsible for a given word, chosen from t_d , and each tag has a distribution θ over topics generated from a Dirichlet prior α . The topic distribution of tags and the word distribution of topics is combined to generate a topic z_{di} , then a word w_{di} is drawn from the chosen topic.

As shown in the above process, the posterior distribution of topics depends on the information from both content of the WSDL documents and the tags. WT-LDA parameterization is given as follows:

$$\begin{array}{lll} \theta_{x}|\alpha & \sim & \mathrm{Dirichlet}(\alpha) \\ \phi_{z}|\beta & \sim & \mathrm{Dirichlet}(\beta) \\ x_{di}|t_{d} & \sim & \mathrm{Uniform}(t_{d}) \\ z_{di}|\theta_{x_{di}} & \sim & \mathrm{Multinomial}(\theta_{x_{di}}) \\ w_{di}|\phi_{z_{di}} & \sim & \mathrm{Multinomial}(\phi_{z_{di}}) \end{array}$$

We employ Gibbs sampling as a common means of statistical inference to infer WT-LDA. Note that Gibbs sampling provides a simple and effective method to estimate the latent variables under Dirichlet priors and observed variables given by the content of the WSDL documents and the user-contributed tagging data of corresponding documents. There are four latent variables in WT-LDA model: the word distribution of topic ϕ_z , the topic distribution of tag θ_x , the tag assignment x_{di} of each word, and the topic assignment z_{di} of each word. Gibbs sampling construct a Markov chain that calculate the conditional distribution $P(z_{di} = j, x_{di} = k | w_i = m, z_{-di}, x_{-di}, t_d)$ where z_{-di} represents the topic assignments for all tokens except w_{di} , the conditional probability is shown below:

$$P(z_{di} = j, x_{di} = k | w_i = m, \mathbf{z}_{-di}, \mathbf{x}_{-di}, \mathbf{t}_d) \propto \frac{m_{x_{di}z_{di}} + \alpha_{z_{di}}}{\sum_{v=1}^{V} (m_{x_{di}v} + \alpha_v)} * \frac{n_{z_{di}w_{di}} + \beta_{w_{di}}}{\sum_{v=1}^{V} (n_{z_{di}v} + \beta_v)}$$
(3)

where n_{zw} is the number of tokens of word w are assigned to topic z, m_{xz} represent the number of tokens in tag x are assigned to topic z.

In Gibbs Sampling, we sample z_{di} and x_{di} by fixing z_{-di} and x_{-di} . The other two latent variables: the word distribution of topic ϕ and the topic distribution of tag θ are estimated from samples by:

$$\theta_{xz} = \frac{m_{x_{di}z_{di}} + \alpha_{z_{di}}}{\sum_{v=1}^{V} (m_{x_{di}v} + \alpha_v)}, \phi_{zw} = \frac{n_{z_{di}w_{di}} + \beta_{w_{di}}}{\sum_{v=1}^{V} (n_{z_{di}v} + \beta_v)}$$
(4)

For document d, we sum over all the θ_x where $x \in t_d$ to compute the topic distribution of document d. Therefore, we can cluster web service by θ and get the detail information of each cluster by ϕ .

4 Tag Preprocessing Strategies

Some inherent properties of Web service tagging data, e.g., uneven tag distribution and noisy tags, impact the reliability of tagging data. In this section, we introduce three tag preprocessing strategies to make the tagging data more reliable and suitable for the proposed WT-LDA model to further improve the service clustering accuracy.

4.1 Tag Recommendation

Through our observation, some Web services, especially those newly deployed ones, do not have tags. In this case, we have to assign some initial tags from the textual features of the services first by using approaches such as TF-IDF, and then use a tag recommendation approach to improve the quality of the tagging data. For the Web services with few user-contributed tags, tag recommendation approaches could be directly employed. Typically, an initial set of tags \mathcal{I}_s associated with a Web service s is provided to the recommendation method,

which outputs a set of related tags C_s , where $I_s \cap C_s = \emptyset$. Tag co-occurrence is a commonly used method for tag recommendation.

Figure 4 shows an example of tag co-occurrence based recommendation framework, in which it first generates candidate tags based on original tags by using tag co-occurrence, and then obtains the recommended tags by using some tag ranking strategies, e..g, Sum and Vote [14]. Due to the space limitation, we do not give the details of tag recommendation. In this paper, tag co-occurrence and Vote ranking strategy are employed for recommendation.

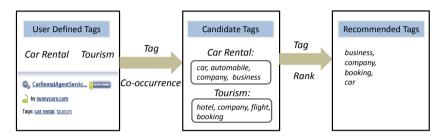

Fig. 4. An Example of Framework for Web Service Tag Recommendation

4.2 High-Frequency Tags

In order to cluster Web services into the exact cluster they belong to, we expect tags of Web services provide accurate information of distinct property between different clusters and common property shared among the Web services in same cluster. As a result, we believe high-frequency tag, which means the unique tag of one Web service that occurs with a high frequency among all tags of the Web service, as an important evidence for Web service clustering.

4.3 Tag Preprocessing Strategies

Based on the above analysis, we present three tag preprocessing strategies to improve the performance of WT-LDA

- 1. **Original tags**. In this strategy, only the original user-contributed tags are provided for *WT-LDA* based Web service clustering.
- 2. **Original tags** + **Recommended tags**. In this strategy, we mix original tags with recommended tags generated by the proposed approach in Section 4.1.
- 3. **High-frequency tag**. In this strategy, we select the high-frequency tag of each Web service for clustering.

5 Experiments

In this section, we first compare the performance of different Web service clustering approaches and then study the performances of tag preprocessing strategies.

WSDL Document	185
Word	62,941
Token	1481
Tag	888
Recommended Tag	799

Table 1. Experimental Data Description

5.1 Experiment Setup

To evaluate the performance of Web service clustering approaches and tag preprocessing strategies, we crawl 15,968 real Web services from the Web service search engine Seekda!. For each Web service, we get the data of service name, WSDL document, tags, and the name of service provider. We publicize the crawled dataset via http://www.zjujason.com. Further, to implement the overall process of service discovery, we build a Web service search engine *Titan*, which could be accessed via http://ccnt.zju.edu.cn:8080.

As the manual creation of ground truth is an expensive process, we randomly select 185 Web services from the dataset we crawled to evaluate the performance of Web service clustering. We perform a manual classification of these 185 Web services to serve as the ground truth for the clustering approaches. Specifically, we distinguish the following categories: "Weather", "Stock", "SMS", "Finance", "Tourism", and "University". There are 28 Web services in "Weather" category, 21 Web services in "Stock" category, 37 Web services in "SMS" category, 21 Web services in "Finance" category, 31 Web services in "Tourism" category, 27 Web services in "University" category. 20 Web services are randomly selected from other categories as noise in our experiment. Limited by space, we don't show the detailed information of these Web services. The experimental data description is given in Table 1.

All experiments are implemented with JDK 1.7.0-10, Eclipse 3.6.0. They are conducted on a Dell OptiPlex 390 machine with an 3.10 GHZ Intel Core I3 CPU and 2GB RAM, running Windows 7.

5.2 Evaluation Metric

To evaluate the performance of Web service clustering, we introduce two metrics: Precision and Recall, which are widely adopted in the information retrieval community.

$$Precision_{c_i} = \frac{succ(c_i)}{succ(c_i) + mispl(c_i)}$$
 (5)

$$Recall_{c_i} = \frac{succ(c_i) + mispi(c_i)}{succ(c_i) + missed(c_i)},$$
(6)

where $succ(c_i)$ is the number of services successfully placed into cluster c_i , $mispl(c_i)$ is the number of services that are incorrectly placed into cluster c_i ,

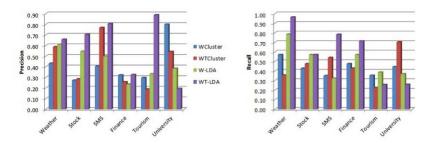

Fig. 5. Performance Comparison of Four Web Service Clustering Approaches

and $missed(c_i)$ is the number of services that should be placed into c_i but are placed into another cluster.

5.3 Performance of Web Service Clustering

In this section, we compare the performance of four Web service clustering approaches, including two state-of-the-art clustering approaches and two versions of the proposed WT-LDA approach. The details of these algorithms are given below:

- 1. **WCluster**. In this approach, Web services are clustered according to the semantic WSDL-level similarity between Web services. This approach has been adopted in some related works [4,7,16].
- 2. **WTCluster**. In this approach, both WSDL documents and the tagging data are employed to cluster the Web services according to the composite semantic similarity [4].
- 3. **W-LDA**. In this approach, we extract feature words from WSDL documents and cluster Web service without any additional information using traditional LDA approach.
- 4. **WT-LDA**. In this approach, we utilized both feature words from WSDL documents and the user-contributed tagging data, then cluster Web services using WT-LDA approach proposed in Section 3.

Figure 5 shows the performance comparison of above 4 Web service clustering approaches. Empirically, we set $\alpha=0.01$, $\beta=0.01$ and run Gibbs-sampling for 1000 iterations in the proposed WT-LDA approach. It can be discovered that the proposed WT-LDA outperforms the other three approaches in most cases in terms of precision and recall, respectively. Further, it can be found the addition of tagging data improves the performance of service clustering, as WT-LDA outperforms W-LDA, and WTCluster outperforms WCluster in most cases.

Table 2 shows the average precision and recall values of the above four service clustering approaches. It can also be found that the proposed WT-LDA has the best performance in terms of average precision and average recall. Further, we can also find that WTCluster outperforms WCluster, and WT-LDA outperforms

Clustering Approach	Precision	Recall
WCluster	0.4219	0.4378
WTCluster	0.4387	0.4553
W-LDA	0.4350	0.5017
WT - LDA	0.5966	0.5919

Table 2. Average Precision and Recall of Four Web Service Clustering Approaches

Fig. 6. Word Distribution of Two Clusters: the left cluster is about weather forecast, while the right cluster is about stock

W-LDA. As we discussed above, the user-contributed tagging data of Web services contains a lot of information, such as service function, location, and other semantical information. Utilizing these information improves the performance of Web service clustering.

Figure 6 shows the word distribution of two clusters, for each of which we pick words with top ten probability in each cluster and the size of word in Fig. 6 is corresponding to its probability. After observing the services in each cluster, we find the services in the first cluster are most about weather forecast, which matches the word distribution in the left figure. And the services in the second cluster are most about stock, which also matches the word distribution in the right figure. Thus, the proposed WT-LDA is quite effective. Compared with traditional unsupervised clustering approach, one additional advantage of WT-LDA is that user could directly know the main functionality of services in one cluster, instead of observing all services in the cluster.

5.4 Evaluation of Tag Preprocessing Strategies

In this section, we compare the performance of the proposed three tag preprocessing strategies with the one without tagging data. The four clustering approaches for comparison are detailed as follows:

- No Tag. In this approach, Web services are clustered according to word features from WSDL documents. We cluster Web services using the traditional LDA approach.
- 2. *Original Tag*. In this approach, we utilize both the WSDL documents and the original tags, and cluster the Web services using the proposed WT-LDA.

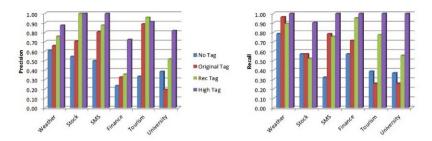

Fig. 7. Performance Comparison of Tag Preprocessing Strategies

Table 3. Average Precision and Recall of Four Tag Strategies

Clustering Approach	Precision	Recall
No Tag	0.4350	0.5017
Original Tag	0.5966	0.5919
Rec Tag	0.7442	0.7426
High Tag	0.8882	0.9841

- 3. **Rec Tag.** In this approach, we utilize the WSDL documents, the original tags, and the recommended tags. Then we cluster the Web services using the proposed WT-LDA.
- 4. *High Tag*. In this approach, we utilize both the WSDL documents and the high-frequency tags, and cluster the Web services using WT-LDA.

Figure 7 shows the performance comparison of the above four approaches. It can be found that the *High Tag* approach outperforms the other three ones in most cases in terms of precision and recall, respectively. This is because the high-frequency tags are helpful for distinguishing services, while the addition of low-frequency tags has a negative effect. From Fig. 7, it can also be found that the *Rec Tag* approach outperforms *Original Tag* approach in most cases, which means the recommended relevant tags improves the performance of service clustering.

Table 3 shows the average precision and recall values of the above four clustering approaches. It can be found that the *High Tag* has the best performance in terms of both average precision and recall, while the performance of *No Tag* is the worst. This can be easily understood because *No Tag* does not utilize tagging data, which contains a lot of meaningful information. Similarly, it can be observed that *Rec Tag* outperforms *Original Tag*. Therefore, it can be found that the *High Tag* strategy is the best strategy for *WT-LDA* clustering.

6 Conclusion

In this paper, we propose a probabilistic graphical model based approach, referred to as WT-LDA, which explores the knowledge behind WSDL documents

and user-contributed tagging data to cluster Web services. Three tag preprocessing strategies are also developed to improve the service clustering performance. Extensive experiments conducted over real Web services demonstrate the effectiveness of the proposed WT-LDA approach and tag preprocessing strategies.

In our future work, we plan to use an online version of WT-LDA to improve the efficiency of Web service clustering, which allows the algorithm to scale to a massive number of services and service tags contributed by a large number of users.
