■ Introduction

Magnetic resonance imaging (MRI) is currently performed with scanners operating at field strengths ranging from 0.02 to 4.0 T [1–5]. Multiple manufacturers now supply open design MRI systems that operate predominately at field strengths below 0.5 T. Issues regarding field strength remain controversial and largely unresolved. This includes diagnostic yield, imaging sequences, manufacturer variation, diagnostic accuracy, adequacy of image quality, cost effectiveness, and safety [6–16]. In spite of these unresolved issues clinical MR units operating at 0.5 T or below may make up as much as 80% of the systems in

use in developed countries, and more than 2000 of these lower field strength systems are operational in the United States. At least six manufacturers offer an array of clinical MR systems below 0.6 T, with the sales of open design systems rapidly increasing. Brain imaging on high-field strength magnets in general provides higher resolution, but such systems are more costly to site, operate, and maintain. Open design low-field strength systems tend to demonstrate higher contrast with slightly less resolution; however, costs for siting, operation, and maintenance are significantly lower. In addition, patient tolerance is often superior to that seen in a high-field environment. Technical factors can be critical at both

high and low field; however, lower field strength systems tend to be more heavily criticized [10].

■ High-Contrast Versus High-Resolution MRI

As field strength changes in MR, there is a direct effect on relaxation times [17–19]. A shortening of T1 occurs as the field strength decreases,

Fig. 1. T2-weighted open-design, low-field MRI demonstrating marked abnormal signal intensity in the left medial temporal lobe. High-field MR interpreted as normal. (Image from a 0.64-T Toshiba open MR system)

Fig. 2. FLAIR sequence (TR 5500, TE 104, TI 1550) demonstrating “black CSF” and abnormal hyperintensity in the left temporal lobe on this heavily T2-weighted sequence. (Image from a GE 0.2-T open-design magnet)

and there is thus an improvement in signal-to-noise per unit time at lower fields. This results in improved lesion contrast [19].

When interpreting brain images at lower field strengths it is important to remember that as the field strength decreases, contrast increases. In general, a high-field-strength scanner provides higher resolution. This implies that if there is a detectable difference in tissue contrast, the higher-field-strength magnet demonstrates smaller regions of difference, and the images are clearer. However, when there is no difference in contrast, regardless of size, the lesion is not apparent. The use of MR contrast agents is based in part on this principle. When lesion contrast is not evident on routine MR and not enhanced by contrast, the lesion goes undetected. Since lower field strength improves contrast on MR, there is the possibility of detecting lesions with low-field MR that go undetected by either high-field MR or contrast-enhanced high-field MR. An example is the report of the longitudinal relaxation rate, $1/T_1$ values of mobile water protons at lower field strengths for distinguishing between pituitary tumor types [20]. Figure 1 also illustrates this point in a case of herpes simplex encephalitis detected by T2 imaging at low field (0.06 T) but undetected by T2 at 1.5 T. Imaging sequences such as fluid-attenuated inversion recovery (FLAIR) may eliminate this low-field advantage in many cases (Fig. 2).

■ Technical Factors

In brain imaging at lower field strengths the more open designed magnet frequently allows imaging of patients who are unable to tolerate the older “long-bore” design. Although “short-bore” systems are becoming more widely available, in all probability the most open design will continue to be preferred by many patients. The availability of an open magnet often dictates that the patient being scanned is either younger or more difficult. However, as a direct result of this open design these more difficult patients frequently require less sedation. It is common practice in open MRI to reserve sedation for only those patients who are unable to follow instructions, regardless of age. Successful imaging of children as young as 3 years of age has routinely been accomplished on open systems by having the parent or other family member accompany the patient in the scan room. This individual can stand or sit next to the patient, if necessary, and simply holding the patient’s hand in some instances is sufficient to al-

low for satisfactory completion of the scan. It is also possible to keep younger children quiet in the magnet for extended periods of time by having a parent or sibling actually lie next to the child in the scanner. This can also serve as an effective adjunct to sedation for children who are reluctant to cooperate even when having received a full dose of sedative.

In general, imaging of the brain involves the use of T1-, T2-, and intermediate-weighted sequences. Image quality can be significantly enhanced for the T1 weighted sequences by using a gradient echo technique rather than a spin echo sequence. As with all gradient echo sequences, motion can be a significant degrading factor in image quality, and if patient motion is severe, a spin echo sequence can be substituted. At field

strengths in the range of 0.06 T a typical gradient echo sequence can be substituted. At field strengths in the range of 0.06 T a typical gradient echo sequence would include a TR of 68, TE of 24, and FA of 60 or a similar configuration for adequate image quality. At 0.23 T excellent image quality can be obtained on an open MR system using TR of 30, TE of 10, and FA of 35. A detailed summary of manufacturer supplied brain protocols successfully used in open systems of varying field strengths is included in Tables 1–3.

As with high-field imaging, standard T2 and proton density (intermediate) weighted sequences are usually obtained on lower field strength imaging systems. The value of these techniques in imaging of the brain is well established, and for a rapid screen T2-weighted sequences may be suffi-

Fig. 3. T1 (TR 68, TE 24, FA 60) open-design, low-field MRI examination demonstrating acute SAH as markedly high signal intensity. (Image obtained on a 0.64-T Toshiba open MR system)

cient to exclude significant pathology. However, an additional advantage of lower field strength systems is the ability to detect changes that may go undetected at higher field (see Fig. 1, above). Another example is in the area of acute subarachnoid hemorrhage (SAH) where T1-, T2-, and proton density weighted imaging may be negative at high field but obvious on T1 weighted low-field images (Fig. 3). Therefore in general it is advantageous to perform at least both T1- and T2-weighted sequences on all patients referred for a brain evaluation.

Fluid-Attenuated Inversion Recovery

The advent of fluid-attenuated inversion recovery (FLAIR) imaging has drastically altered the evaluation of the brain by MR, and has given the brain imager yet another advantage in the diagnosis of cerebral pathology. FLAIR sequences produce heavily T2-weighted and cerebrospinal fluid (CSF) nulled images of the brain on MR. This novel method of imaging was first described by the group from Hammersmith Hospital in the United Kingdom and demonstrates dramatic changes on MRI that may otherwise go undetected [1-3, 8, 21]. By reducing the signal from CSF and enhancing the T2 weighting FLAIR sequences provide a unique opportunity to evaluate brain pathology (see Fig. 2). Clinical applications of FLAIR have been demonstrated in disease processes including SAH, cerebral infarction, brain trauma, cerebral neoplasms, inflammatory conditions, and most notably demyelinating diseases [1, 5-7, 21].

The routine use of FLAIR is recommended for all brain evaluations regardless of field strength, but, again, lower field strength scanners may prove to be advantageous in this regard. Higher field strength systems tend to demonstrate significant and often severe artifacts on FLAIR sequences. The artifacts that result from CSF or vascular flow and pulsation on high-field FLAIR images are less of a problem at lower field, and in some cases at low field can be virtually eliminated (Fig. 4).

One of the most significant limitations of FLAIR imaging has been the presence of signifi-

Fig. 4. a A 1.5-T FLAIR image (TR 8243, TE 112, TI 1600) demonstrating a right posterior cerebral artery infarction. Note the artifact in the prepointine cistern identified as high signal. (Image from a 0.23-T Picker open MR system) **b** A 0.23-T FLAIR image (TR 4752, TE 120, TI 1600) de-

monstrating the right posterior artery infarction seen in **a**, but without the prepointine flow artifact that is prominent on high-field MR. (Image from a 0.23-T Picker open MR system)

cant artifacts that are particularly related to CSF motion. These are often encountered in the region of the lateral ventricles, foramen of Monroe, third ventricle, cerebral aqueduct, and fourth ventricle. These artifacts at high-field can be particularly problematic when attempting to evaluate cerebral pathology adjacent to regions of the brain that are contiguous with or adjacent to pulsatile CSF. One of the advantages of open MRI scanning at lower field strengths is a notable absence of these artifacts (see Figs. 4, 13).

■ Contrast Agents

Contrast agents improve the diagnostic power of MR in several ways. Both the conspicuity of abnormalities and better demarcation of their borders are achieved through the use of MR contrast agents. The viable areas of neoplasms may be distinguished from surrounding edema in some cases and contrast also helps to date abnormalities, specifically with regards to cerebral infarctions.

The ideal contrast agent must be both effective and safe. The main objective of contrast agents in imaging is to enhance image contrast to render normal and pathological anatomy more conspicuous. Great advances have been made toward both of these ends, and while some drawbacks exist, research and development of new and improved contrast agents persists. Generally there is little difference between the use of contrast agents in children and in adults, the main difference being one of dose, based on weight and age. Children also tend to have a lower incidence of adverse reaction than adults, whether mild or severe, to all contrast agents [22].

Contrast agents are administered to patients in liquid form and function within the bloodstream or CSF. Accordingly the inherent properties of density, viscosity, and osmolality effect their safety and efficacy [23].

The United States Food and Drug Administration has approved three MRI contrast agents for intravenous administration: Magnevist (gadopen-tetate dimeglumine injection, Berlex Laboratories), Omniscan (gadodiamide injection, Nycomed), and ProHance (gadoteridol injection, Bracco Diagnostics). Since the element gadolinium is the base of all of these contrast agents, they all have similar mechanisms of action, biodistribution, and half-lives [24–27]. While these agents appear to have remarkably similar effectiveness and safety profiles, some differences do exist.

There are osmolality differences between Magnevist (1960 mmol/kg of water) [28], Omniscan

(789 mmol/kg water), and ProHance (630 mmol/kg water). The significance of this osmolality difference, however, is proportionally decreased by the administered volume of these agents being typically quite small.

Gadolinium is not normally present in a mammalian system except in trace amounts and has no known natural functions. It is highly toxic in its ionic form to humans, even at low doses. The contrast agents used for MR enhancement in the United States are gadolinium chelates that localize in the extracellular fluid compartment to be then rapidly excreted by the kidney. As the gadolinium ion is toxic, it must be complexed with ligands.

For all of these agents, the adverse reaction rate seems to be less than 4% [25, 29–42]. The adverse reactions that are most commonly experienced seem to be nausea, emesis, hives, headache, and local injection site reactions, such as irritation or a burning or cool sensation. The incidence of the anaphylactoid reactions that have been reported with all three of these FDA-approved intravenous MR contrast agents is so exceedingly rare that it is difficult to attempt to place any significance on these rates. At worst, the rate of this extreme sort of reaction from any of these agents is probably in the 1:100,000 range, and this may be as high as 1:450,000.

The use of Magnevist has been associated with transient elevations in serum bilirubin (3%–4% of patients) that seems to spontaneously reverse within 24–48 h [31, 43]. The use of ProHance has not resulted in reports of such alterations in blood chemistry. All MRI contrast agents have been associated with delayed reactions of hypertension, vasovagal responses, and syncope. There are no known contraindications for Magnevist, Omniscan, or ProHance.

The administration of MRI contrast agents during pregnancy and lactation has not been determined to be without risk. To date no clinical trials have been reported on pregnant women. The studies performed on animals, however, using doses much higher than those employed clinically have produced a number of severe adverse effects on the fetus. Gadopentetate dimeglumine does cross the placenta and has been found in the fetal bladder [44]. The rate of clearance of MRI contrast agents from the amniotic fluid cycle has not been assessed. Until more data become available, routine administration of any of the MRI contrast agents in pregnant patients should not occur, unless the potential benefit justifies the risk to the fetus. It is also recommended that mothers refrain from breast feeding, while continuing to express milk, for 24 h following gadopentetate administration.

Fig. 5. Postcontrast MR (TR 480, TE 26) demonstrating enhancing right-sided acoustic neuroma from a Siemens 0.2-T open MR system. (Mark Leszczynski, RT, Memorial Open MRI, Houston, Texas, used with permission)

Fig. 6. Postcontrast T1 image (TR 650, TE 25) of an extra-axial acoustic neuroma. (Image from a 0.3-T Hitachi open MR system)

Our clinical experience with gadolinium imaging on low-field open-MRI has resulted in the use of a T1-weighted gradient echo technique with a bolus of one half of a 0.1 mmol/kg dose of gadolinium DTPA, with drip infusion of the remaining one-half dose diluted in 50 cc sterile water [45]. Due to the longer scan times required at lower fields, the drip infusion technique provides optimum levels of gadopentetate dimeglumine at the actual times of image acquisition. Some low-field centers report using approximately 0.15–0.2 mmol/kg single injections with similarly improved results. The use of open low-field or 1.5-T bore-type MR appears comparable, in our experience, for cranial central nervous system disease with or without contrast (Figs. 5, 6, 9, 25).

In general, the indications for the use of contrast in the brain are similar for high- and low-field strength systems. The advantage of the

open-design magnets in this regard is the ease of access to the patient for contrast administration and management. It is possible to perform rapid scan sequences on most open design systems, and the role of dynamic sequences in addition to those described in the subsequent section on pituitary imaging remains to be fully established. It is conceivable that dynamic perfusion studies with MR contrast will be an important part of the management of patients with cerebral vascular disease in the future.

■ Safety

Recent reports and at least one survey of MR facilities show potential areas of significant concern regarding safety, with a number of accidents and death associated with MR having been reported [46–50].

Numerous studies have been performed to investigate the potential bioeffects of MRI. The majority of these studies support the widely held view that no significant biological health risks are associated with the use of this modality. The effects on humans and biological systems of strong static magnetic fields are not well understood.

Some of the literature does include data that appear to be contradictory; however, no evidence has demonstrated conclusively any irreversible or hazardous biological effects related to humans being exposed to acute, short-term static magnetic fields of strengths up to 2.0 T [22].

Certain devices must be precluded from entering the magnet room, for reasons of them being mechanically attracted by the field of the magnet or having their function altered by the presence of the fields. The FDA requires labeling of MR systems to indicate that the device is contraindicated for patients who have implants such as internal cardiac pacemakers, implantable cardiac defibrillators, cochlear implants, neurostimulators, bone-growth stimulators, implantable electronic drug infusion pumps, and similar devices, since electromagnetic fields produced by the MR system may seriously interfere with the operation of these devices [51].

Our three 1.5-T sites have had at least four documented incidences of ferromagnetic objects unintentionally entering the magnetic field and being drawn into the magnet. In one of these instances there was minimal injury when during equipment repair, a repairman and his equipment were drawn into the magnet. In a second instance, a significant injury could have occurred if a patient had been present in the magnet when a

metallic writing pen was pulled from a radiologist's pocket as he entered the magnet room. There have been two instances of minor burns related to metallic objects touching the patient during the scan. We have experienced none of these adverse effects in 10 years of open design magnet use at lower field strengths.

Concern for injury from internal or external metallic objects is minimal or nonexistent at very low-field strengths. MR facilities report accidents primarily involving static ferromagnetic objects that became projectiles when subjected to the pull of the magnetic field. Additional injuries have been encountered from MR accessories causing burns [46–50]. A potential injury includes the effect of high magnetic fields that are in general considered safe, but this is unproven. There is a more immediate danger of injury from damage to devices such as implanted pacemakers [47]. An additional problem is that MR accidents are probably grossly underreported [46–50]. Measurements of magnetic forces and torques at 0.064 T support the added safety for patients from both internal and external metal objects when being scanned in open design low-field systems [52].

At higher field strengths several safety concerns exist for scanning patients who have certain ferromagnetic implants, materials, or foreign bodies. Primarily this is because of the possibility of movement or dislodgment of these objects [53–55]. The possibility exists also of current induction, excessive heating, and the misinterpretation as an abnormality of an artifact produced by such an object [53, 55–59]. Several considerations must be taken into account before allowing a patient who has a ferromagnetic object to be scanned, including (a) the strength of the magnetic field to which the patient is exposed, (b) the degree of ferromagnetism manifest by an object, (c) the mass and geometry of the object and its location and orientation in a patient, and (d) the length of time the object has been in place.

For patients who present to the MRI with a history of metallic foreign bodies such as shrapnel, bullets, slivers, or other types of metallic fragments the risk depends on several factors. A patient encountering the static magnetic field of an MR system with an intraocular metallic foreign body, for example, is at significant risk for a serious eye injury. One patient was blinded at the completion of his MR examination on the way out of the MR imager [60]. A patient undergoing an MR examination at one scanner has absolutely no assurance that it is necessarily safe to undergo another MR scan at the same or another location. It has been established that the use of plain film

radiography may be an acceptable technique for identifying or excluding an intraocular metallic foreign body that represents a hazard [61].

The hazard of open-design 0.064-T MR regarding intraocular ferromagnetic metal fragments has been evaluated using both *in vitro* and *in vivo* animal experiments [62]. An important observation during these experiments was the fact that all motion was increased by increasing the speed at which fragments entered or exited the magnetic field. Regardless of field strength, the forces acting on metallic fragments, and the subsequent risk to patients, can be effectively reduced by decreasing the speed of entry into and the exit from a magnetic field. In other words, regardless of field strength, simply moving the patient in and out of the scan field slowly significantly reduces patient risk.

At least two dozen patients with cardiac pacemakers have been placed in MRI systems, either intentionally or inadvertently. The documentation is such that at least five of these individuals have died, although it should be stressed that the cause of death in these patients is unknown. A study demonstrating total pacemaker inhibition [63] and pacemaker malfunction in another [64] has serious safety implications for studying patients who have pacemakers being imaged. It is commonly understood that scanning any patient who has a cardiac pacemaker is contraindicated.

No standardized testing criteria exist by which MR compatibility claims may be assessed [65, 66]. Not even the term “MR compatible” is defined. No standardization exists that ensures that in such devices as implanted intracranial aneurysm clips, for example, that clips produced from one run are identical in ferromagnetic properties to those of another. This explains why some researchers find some clips “MR compatible” and others find the same clip types respond to the presence of a strong magnetic field. At this point several physicians have decided not to scan any patient with an intracranial aneurysm clip in place until firm guidelines are established [22]. If MR scanning is deemed imperative, the lower field open design magnet may offer less risk than the traditional 1.5-T bore-type systems.

The sensations of claustrophobia and a variety of other unpleasant psychological reactions including anxiety and panic are encountered by as many as 5%–10% of patients during or precipitating MRI. The originating factors include the narrow dimensions of the interior of the bore-type of scanner; the length of the examination; the banging, gradient-induced noises; the encompassing and dark conditions within the traditional bore of

the scanner, and other factors [67–75]. Offering an open design magnet is probably the most effective solution to these problems.

■ Cranial Imaging

MR in Brain Disorders

Virtually every type of brain pathology is responded to clinically through the utilization of MR. Since treatment may be dramatically altered, the value of a normal MR scan is not to be underestimated [76]. The decrease in clinic visits, patient concern, and physicians' and other health care professionals' time are relevant in terms of financial and psychological relief [77]. It could be said that the normal brain MR might be one of the most cost-effective studies in all medicine.

Fig. 7. T2-weighted image (TR 3900, TE 120) of a high-grade glioma. (Image from a 0.3-T Hitachi open MR system)

Fig. 8. T1 (TR 68, TE 24, FA 60) open-design, low-field MRI demonstrating ring enhancing mass from metastatic disease following administration of gadolinium. (Image from a 0.64-T Toshiba open MR system)

Considering this is one of the most expensive areas of the health care system, it is certainly warranted to try to exit the patient from this costly system, as well as relieve them of the high stakes that accompany brain disorders [76]. Neoplasms, infections, cerebrovascular disease, head trauma, intracranial hemorrhage, and white matter disease are several disease categories for which the use of MR has proved essential [77].

Neoplasms

Obviously much more attention is given to the abnormal than the normal brain MRI. New primary brain tumors are identified in approximately 40,000 patients in the United States each year, which may result in paralysis, dementia, seizures, and death [77]. Mass effect, edema, hemorrhage, and contrast enhancement are the recognizable characteristics of a neoplasm on MR. Because of the nature of the brain, the classifications of benign or malignant pathology may not apply, as the most "benign" of tumors can be devastating if located in a critical part of the brain [76]. Until recently the location of an intracranial neoplasm was more telling than the cell type of the neoplasm. Even if considered histologically "benign," many intracranial neoplasms are thought to "behave" in a malignant manner.

The availability of functional brain imaging [77] has changed the traditional approach to intracranial masses including neoplasms. Malignant neoplasms once thought to be unresectable because of their close anatomic relationship to vital areas of brain function are now being successfully resected without resulting loss of function. This is due to the location not being as closely related to "vital" brain regions as would be anticipated from

traditional predictions. The number of neoplasms that can be effectively treated is increasing, even though many continue to be refractory to treatment. Although most functional magnetic resonance imaging (fMRI) is currently limited to high-field bore types of systems, fMRI has been performed successfully on lower field strength magnets. The role of fMRI on open design low-field systems remains to be defined.

The two most important criteria for evaluation of images of intracranial neoplasms are age of the patient and location of the mass [77, 78]. On MR brain tumors are often described as being intra-axial, within the brain substance, or extra-axial, outside the brain substance. Benign tumors are frequently extra-axial and easier to resect surgically (Fig. 6). Most often intra-axial, malignant tumors frequently extend far into the brain beyond the appearance on MR (Fig. 7). Surgical cure is difficult, recurrence common, and these tumors include metastatic cancer from other organ systems [76].

Most commonly arising from primary neoplasms of the lung and breast, metastatic cancer represents approximately 25% of all brain tumors (Fig. 8). Metastatic brain tumors may also arise from the gastrointestinal tract, the genitourinary tract, and melanoma [76].

Infections

Infection of the brain is becoming one of the more common indications for brain imaging and may be the result of extension of infectious conditions in the sinuses, ear, orbit, or superficial soft tissues. The bloodstream can carry the infection from various parts of the body. Many of these conditions respond rapidly to treatment which make these some of the most urgent and important scans performed. Early treatment of brain infection may mean the difference between the patient recovering, being severely incapacitated, or dying [76] (Fig. 9).

Often congenital central nervous system (CNS) infections are caused by what is referred to as the TORCH agents: toxoplasmosis, rubella, cytomegalovirus, and herpes simplex virus. Other important causes of congenital CNS infections are human immunodeficiency virus (HIV) and syphilis [79].

The most common form of CNS infection is meningitis [80]. This condition can be divided into three general categories: acute pyogenic meningitis (most often bacterial infections), lymphocytic meningitis (usually viral), and chronic meningitis (examples are tuberculosis and coccidioidomycosis).

Fig. 9. Postcontrast enhanced MR (TR 500, TE 25) demonstrating a ring enhancing inflammatory lesion. (Image from a 0.3-T Hitachi open MR system)

In the evaluation of patients with suspected meningitis, MRI is superior to computed tomography (CT) [22]. Precontrast T1-weighted images may demonstrate obliterated cisterns that enhance strongly following contrast administration. In severe cases extension of enhancing subarachnoid exudate deep into the sulci can be seen.

Meningitis is conspicuous on postcontrast T1-weighted images; however, unenhanced MR images often do not detect active meningeal inflammation [82, 83]. In chronic meningitis contrast-enhanced T1-weighted MR scans reveal the characteristic basal meningeal inflammatory pattern seen on contrast-enhanced CT studies [84].

The earliest stage of purulent brain infection is cerebritis [80]. This diffuse infection often leads to abscess formation with characteristic neuroimaging features [85]. The organisms most frequently isolated from cerebral abscesses are streptococci, including both aerobic and anaerobic, and staphylococci. Gram-negative organisms, however, are an increasing cause of cerebral abscess [86].

In MR the findings in brain abscess vary with time. An ill-defined subcortical hyperintense zone can be noted on T2-weighted images during the initial, early cerebritis stage. In postcontrast T1-weighted studies poorly delineated enhancing areas within the isointense to mildly hypointense edematous region may be disclosed.

The central necrotic area is typically hyperintense to brain on proton-density and T2-weighted sequences during the late cerebritis stage. On T1-weighted images the thick, somewhat irregularly marginated rim appears isointense to mildly hyperintense and isointense to relatively hypointense

Fig. 10. T1 (TR 68, TE 24, FA 60) open-design, low-field MRI demonstrating rim enhancement in a cerebral abscess following gadolinium administration. (Image from a 0.64-T Toshiba open MR system)

on proton density and T2-weighted scans. In nearly all cases peripheral edema is present. Following contrast administration the rim enhances intensely (Fig. 10). Satellite lesions are commonly present [87]. The collagenous abscess capsule is visible on unenhanced scans, during the early and late capsule stages, as a comparatively thin-walled, well-delineated isointense to slightly hyperintense ring that becomes hypointense on T2-weighted sequences.

While encephalitis is usually viral, it may be caused by a broad spectrum of agents. In the United States and Europe this diffuse, nonfocal brain parenchymal inflammatory disease is most commonly caused by herpes simplex encephalitis.

The typical early findings of MR include gyral edema on T1-weighted images and high signal intensity in the temporal lobe or cingulate gyrus on T2-weighted scans. Often the signal abnormalities extend into the insular cortex and spare the putamen. In the early stages enhancement following contrast administration is unusual [88]. While petechial hemorrhages occur, they are uncommonly identified early in the disease process. As previously demonstrated, open low-field MR may be advantageous in the early diagnosis of this and other progressive brain disorders (see Fig. 1).

Fungi are single-celled organisms that are very different from bacteria in size, structural complexity, chemical composition, and their pathological effects on the central nervous system [89]. Imaging findings vary depending on the specific

fungus involved. Gelatinous-appearing pseudocysts are produced by cryptococcus, and these extend along enlarged perivascular spaces, particularly in the basal ganglia. Imaging of aspergillosis usually shows that of multifocal hemorrhagic mycetomas or penetrating or large vessel cerebral infarcts, since this is an angioinvasive fungus. In CNS coccidioidomycosis, what is usually seen is meningeal inflammation with infectious purulent and caseous granulomas. Communicating hydrocephalus is common, and the basal meninges may appear notably thickened [90].

CNS infections can be caused by several different parasites and include toxoplasmosis, cysticercosis, schistosomiasis, sparganosis, amebiasis, and echinococcosis. Imaging findings are related to the stage of the infection at presentation [92]. On imaging studies obtained during the vesicular stage of parenchymal cysticercosis, the larva appears as a round CSF-like cyst with a mural nodule that represents its scolex (head). Edema and cyst wall enhancement occur on imaging studies during the colloidal vesicular stage. In the granular nodular stage, the residual cyst is typically isointense compared to brain on unenhanced T1-weighted images and isointense to hypointense on T2-weighted sequences. By the final, nodular calcified stage, the granulomatous lesion has contracted to a fraction of its initial size and is completely mineralized [91].

Imaging findings of miscellaneous parasitic infections vary with the disease stage, although

multiple conglomerate, ring-enhancing lesions with striking peripheral edema are typical [92]. In sparganosis, imaging findings are not distinguishable from other granulomas or neoplastic masses [93]. In echinococcosis, also known as hydatid disease, the imaging findings are striking. What is typical is a single, thin-walled spherical CSF-density cyst in the parietal area [92]. Rarely multilocular or multiple lesions occur.

Vascular Disease

The third leading cause of death in the United States is cerebrovascular disease, most of which affects individuals over the age of 55, and is related to atherosclerotic disease. Patients presenting for MR with cerebrovascular disorders commonly suffer from one of three conditions: (a) a transient ischemic attack (TIA), a neurological deficit that clears in less than 24 h, (b) a reversible ischemic neurological deficit (RIND), in which the neurological deficit lasts longer than 24 h but clears, or (c) cerebrovascular accident (CVA), or completed stroke, in which the patient does not recover all lost neurological function. A "stroke in progress" is a fourth condition for which MR (and particularly MRA) may be used. This medical emergency is now often treated in a manner similar to a heart attack. Every second counts in this circumstance. It has been possible to entirely reverse strokes that would have otherwise left the patient paralyzed [76].

With standard spin-echo MRI arterial patency may be difficult to assess. Vessel occlusion with intraluminal thrombus is usually present when intraluminal signal that is isointense with brain on long TR/short TE or long TR/long TE is observed [94]. In-flow phenomena, however, as well as slow or in-plane flow in tortuous, ectatic vessels can mimic intraluminal thrombi. The presence of a normal "flow void" does not exclude significant extracranial carotid stenosis [94, 95].

Diminished blood flow to all parts (global) or selected areas (regional or focal) of the brain is referred to as cerebral ischemia [96]. Stroke is a dynamic process that changes over time, involving the location and degree of cerebral ischemia and resulting infarction. The parameters of flow decrement, location, duration, and tissue volume involved [96] are predicated by ischemic manifestations. Progressing in stages, a stroke moves from ischemia to actual infarction [97].

The lay term "stroke" encompasses a heterogeneous group of widely differing cerebrovascular disorders. Four major types include cerebral infarction, primary intracerebral hemorrhage

(ICH), SAH, and venous occlusions. In cerebral ischemia the imaging findings vary significantly over time. More often acute infarcts are identified and localized on MR compared to CT scans (see Fig. 4) [98]. Open low-field imaging may prove particularly helpful in the management of these patients who often require extensive life support assistance. In addition, areas of ischemia can often be detected within minutes of the acute event. On standard spin-echo MR scans obtained within 24 h of the ictus, 80% of acute infarcts are visible [99]. On MR the earliest findings are vascular flow-related abnormalities, including absence of normal flow void and slow flow with intravascular arterial enhancement [100]. Within minutes of symptom onset, these signs are detectable [101, 102]. In nearly three-quarters of acute cortical infarcts, intravascular enhancement is seen [101].

Early on, T1-weighted images also manifest morphological changes, particularly brain swelling. Such anatomic changes may precede the development of increased signal on proton density or T2-weighted sequences. While usually not observed before 8 h on high-field, T2 hyperintensity does occur (Fig. 11). These changes may be detected within the first hour on lower field strength open-design MR systems where tissue contrast is greater. In about one-third of cases abnormal meningeal enhancement is seen adjacent to cortical infarcts that are aged 1–3 days [101]. In 10%–20% of patients standard high-field MRI sequences fail to detect acute stroke [103].

As mentioned above, because cerebral infarction is a dynamic process, its imaging manifesta-

Fig. 11. T2 image (TR 4000, TE 48) in cerebral infarction. Note the cortical and subcortical increased signal intensity of the left hemisphere. (Images from a 0.2-T Siemens MR system. Margareta Arens, MD, St. Barbara Klinik, Hessen, Germany, used with permission)

Fig. 12. A T1-weighted image (TR 540, TE 15) of encephalomalacia from a Siemens 0.2-T MR system. (Margareta Arens, MD, St. Barbara Klinik, Hessen, Germany, used with permission)

tions continue to evolve with time. Within 2–4 days after ictus the two earliest signs of acute infarction of intravascular and meningeal enhancement begin to diminish [101]. The parenchymal contrast enhancement that ensues can persist for weeks. Becoming more prominent, edema appears hypointense to cortex on T1-weighted images and hyperintense on T2-weighted images. Mass effect increases and then gradually diminishes.

A noticeable decrease in signal intensity is sometimes observed on T2-weighted images during the second post-ictal week. The initially high-signal changes may largely regress or even disappear. It is likely that this “fogging” effect is due to

a reduction in edema and leakage of proteins from cell lysis [104, 105].

The end result of the destructive process of prolonged ischemia is chronic infarction. The pathological hallmarks of stroke residua are volume loss and gliosis, both reflected in gross specimens of chronic infarcts. On MR focal well-delineated low-attenuation or encephalomalacic areas are seen in the affected vascular distribution. The loss of cerebral tissue volume is reflected in the prominence of the adjacent sulci and the enlargement of the ipsilateral ventricle (Fig. 12). After 8–10 weeks the enhancement disappears. Rarely dystrophic calcification may occur in the infarcted brain [106].

Since relaxation times are prolonged in both, the MR differentiation of subacute from chronic (<2 weeks) infarction on standard spin-echo sequences may be difficult because relaxation times are prolonged in both [107]. Mass effect and contrast enhancement are absent in old infarcts (>8–10 weeks). Ipsilateral brain stem atrophy and hyperintensity on T2 or FLAIR imaging may result from wallerian degeneration of axons and their myelin sheaths [108] (Fig. 13). Gyriform signal changes can sometimes be identified on T1-weighted images if cortical hemorrhage or secondary calcification has occurred. These are either hypo- or hyperintense depending on the age of the hemorrhage. Old infarcts reveal ribbon-like very hypointense foci on T2-weighted images [109].

Lacunar infarcts, which account for 15%–25% of all strokes [110], are seen as rounded or slitlike lesions on MR that are hypointense to brain on

Fig. 13. **a** FLAIR image (TR 4750, TE 120, TI 1600) demonstrating a right middle cerebral artery infarction. (Image from 0.23-T Picker open MR system.) **b** FLAIR image (TR 4750, TE 120, TI 1600) demonstrating wallerian degenera-

tion associated with the right middle cerebral artery infarction in **a**. Note the abnormal increased signal intensity in the right pons and the absence of artifacts (compare to Fig. 4a). (Image from a 0.23 T Picker open MR system)

T1-weighted images. On T2-weighted sequences well-delineated hyperintense areas are identified. Following contrast administration, some late acute or early subacute lacunar infarcts may enhance [110].

Hypoxic-ischemic encephalopathy (HIE) results from global rather than focal brain injury (see Fig. 12). Common causes of HIE are severe prolonged hypotension, cardiac arrest with successful resuscitation, profound neonatal asphyxia, and carbon monoxide inhalation. Most frequently the sites of brain involvement are the basal ganglia and parasagittal areas. Border zone area hyperintensities are revealed on T2-weighted images. Striking enhancement can occur after contrast administration.

Differentiating between ischemia and a neoplasm can at times be difficult. Often imaging findings that suggest stroke includes a full thickness lesion that affects gray and white matter and follows a typical vascular distribution. The cortex is affected and the underlying white matter spared in a stroke, while tumors tend to involve the white matter and spare the cortex. A stroke tends to be wedge-shaped or serpentine, whereas a tumor is usually round, lobulated, or infiltrating.

MR may also be of benefit in the evaluation of other vascular lesions such as arteriovenous malformations, aneurysms, vasculitis, and direct vessel injury (Fig. 14).

Fig. 14. Gradient echo MR (TR 610, TE 35, FA 30) demonstrating a large arteriovenous malformation. Note the probable area of focal hemorrhage seen as marked hyperintensity. (Imaged from a 0.3-T Hitachi open MR system)

Head Trauma

With two million cases in the United States each year, traumatic brain injury is one of the most common types of insult in the United States. MR and particularly open design MR is frequently becoming utilized for this injury [76]. MR can better identify several types of lesions associated with head trauma than CT, including contusions, shearing injury of the white matter, subdural hematomas, and anoxic injury [111] (Fig. 15).

The reasons emergency patients with head injury were in the past evaluated by CT were both logistical and clinical. Siting requirements at one time dictated that MR scanners be located a considerable distance from emergency rooms. Also, it was difficult and sometimes impossible to manage these acutely injured patients effectively in most MR scanners. However, it is now possible to locate an open-field magnet near an emergency department providing the opportunity to compare patients who undergo examination by the respective modalities [111].

While previous studies of MRI indicated that this modality was more sensitive than CT in detecting many types of traumatic lesions [112–124], blinded studies support the claim that a positive MR is more predictive of actual trauma than a positive CT for all forms of traumatic injury, excluding fracture [111]. The appropriate acute surgical management in cases of head trauma continues for the most part to rely on CT as the diagnostic modality of choice [125–129]. CT appears to be satisfactory as the initial diagnostic test in the comatose or dramatically neurologi-

Fig. 15. T1-weighted MR (TR 650, TE 25) demonstrating a subdural hematoma. (Image from a 0.3-T Hitachi open MR system)

Fig. 16. a CT demonstrating no significant abnormality. (Image from a 0.3-T Hitachi open MR system.). b T2-weighted (TR 2000, TE 105) open-design MRI demonstrat-

ing extensive cerebral contusions performed on the same day as a. (Image from a Toshiba 0.64-T open design MR system)

cally impaired head-injured patient due to current widespread availability, speed, and accessibility. It must be recognized that the inability of CT to detect multiple types of cerebral injury has been substantiated by pathological confirmation [115, 130-132]. Acute brain injury can be more accurately assessed with MR, improving quantitative and qualitative analysis of the extent of acute brain injury. It is no longer adequate to use a normal CT scan as evidence that patients with head injury do not suffer severe neuropsychological or delayed neurological impairments as a result of undetected cerebral lesions (Fig. 16).

In the United States over half of the significant head injuries occur as a result of automobile accidents [133]. A sensitive and objective tool is necessary not only to sort out the relevance of persistent complaints when litigation is in process or pending; more importantly, alteration in medical treatment of these patients may be indicated by lesions that are undetected by CT. Patients with significant cerebral lesions may warrant closer observation, more aggressive and earlier rehabilitation efforts, and a more gradual or prolonged convalescent period, possibly even fluid restriction [111].

In determining the value of an open-field scanner in the emergency setting, what becomes apparent is a need for a systematic approach. These patients should receive initial CT scans as soon as possible, followed by MR within the first 24 h. When MR is performed and CT scans are not available, our protocol calls for an axial T1-weighted scan. This significantly improves the detection of SAH and ICH at lower field strengths

[134-136] (see Fig. 3). To accommodate the large number of cranial MR referrals from this protocol it has been necessary to establish a limited MR examination. This limited examination consists of axial proton density and T2-weighted images and is performed only when a CT scan is available from the preceding 24 h. This is charged as a combination study, and represents a 50% reduction in cost of the two examinations performed separately.

Provided a CT scan has been performed, our study indicates that MRI performed within 24 h of the initial head trauma should be adequate. It has also been demonstrated conclusively that a negative CT scan is not sufficient to exclude large contusions, shearing injury, and extra-axial fluid collection [111]. These disorders may require less acute neurosurgical or medical intervention.

The additional information provided by an MR scanner in the emergency room may alter patient care significantly. The open design system allows the management of acutely injured patients. While CT and MR are complementary in the evaluation of head trauma, MR has been demonstrated to be significantly more sensitive for a broad range of common posttraumatic brain insults [111].

Hemorrhage

The appearance of hemorrhage may be the most difficult area to understand in all of MR brain imaging. The several published studies on the appearance of blood on MR attest that there is as much disagreement as there is agreement on

this topic. To a large extent this is due to the fact that field strength has been ignored when hemorrhage on MR is considered. A common pattern in the appearance of intraparenchymal hemorrhage is identifiable when the field strength of the scanner is included [136].

T1- and T2-weighted images show hyperintensity in the hyperacute stage of hemorrhage (bleeding that is less than 24 h in age). As the field strength decreases, T1 is much more hyperintense, with T2 rapidly losing intensity as the field strength increases. Hyperacute blood is therefore white on T1 at low-field strength and white on T2 at both high and low-field strengths, but not for long at higher field strengths (see Fig. 3) [76].

Acute blood becomes acute (1 day to 1 week) and loses intensity on both T1 and T2 sequences at all field strengths. At higher field strengths it becomes darker more rapidly on T1- and particularly on T2-weighted sequences. This is attributed to a combination of clot retraction and deoxyhemoglobin formation as well as red blood cell settling and packing (Fig. 17) [76].

Blood continues to age and becomes subacute (2 weeks–1 month) as it goes through several phases. Intracellular methemoglobin begins to form, and T1-weighted sequences show the blood as white (increased signal intensity or hyperintensity), while the T2 sequences show decreased signal continually (Fig. 18). Then the methemoglobin becomes extracellular as the red blood cells lyse, and blood becomes hyperintense (white) on T2 sequences also [76].

Blood is generally referred to as chronic when it becomes more than 1 month old. When it is chronic, it remains hyperintense on both T1- and T2- weighted sequences until replaced by CSF. Then it is usually hyperintense (white) on T2 and hypointense (black) on T1. Figure 19 summarizes the changes that blood goes through on MR, and illustrates the effect of field strength on the appearance of blood over time. For the most part, blood exhibits the exact same changes at all field strengths, with a more rapid time course at lower field strengths. This can be summarized on T1 and T2 sequences in the following manner and visualized in Fig. 19.

On T1, blood begins as hyperintense (especially on low field) where this increased signal persists much longer than at high field) and decreases rapidly to hypointensity. During this same time T2 sequences show acute blood also going from hyper- to hypointense but decreasing to a much lower intensity on T2 (black blood) as compared to the signal decrease on T1. This process

Fig. 17. T2 MRI (TR 2000, TE 105) demonstrating decreased signal intensity in a hemorrhagic focus. (Image from a Toshiba 0.64-T open-design MR system)

Fig. 18. High signal intensity of methemoglobin on T2 sequence (TR 3900, TE 117) resulting from an aneurysm. (Image from a 0.3 T Hitachi open MR system)

of signal loss represents well oxygenated intact red blood cells (hyperintense on T1 and T2) going through a process of oxygen loss, red cell dehydration, and clot formation with clot retraction (hypointense on T1 and T2). At this stage the deoxyhemoglobin in the retracted clot filled with dehydrated cells appears of low signal on T1 and black on T2. As methemoglobin begins to form in the intact red blood cells, T1 signal increases until the lesion begins to appear hyperintense (white) while on T2 the lesion remains hypointense (black). With lysis of the red blood cells, free methemoglobin forms, and this is hyperintense on both T1 and T2. The lesion is now there-

Fig. 19. a Graph indicating the temporal pattern of hemorrhage at high field (R, rim of lesion). b Graph indicating the temporal pattern of hemorrhage as seen on low-field open-design systems (R, rim of lesion)

fore white on both T1 and T2. A hemosiderin ring forms around both T1 and T2 but is far more evident on T2 as the blood ages. Finally, if replaced by CSF, the lesion is hypointense on T1 but remains hyperintense on T2.

In conclusion, definite temporal patterns for the evolution of hemorrhage exist. The variability that is so marked and observed in hemorrhages can be explained by several factors including time, biochemical change, and structural alterations in the evolving hematoma [136]. The patterns identified above can aid in the approach, identification, and final diagnosis of an intracranial hemorrhage [136]. In time the heterogeneity in the appearance of hemorrhage may provide insight into the pathophysiological changes occurring in the brain.

White Matter Disease

MR is the most effective imaging technique with regards to white matter disease. White matter disease may be classified as either demyelinating or dysmyelinating. The term dysmyelinating disease is used to describe a group of conditions in which there is a lack of normal myelin (white matter) formulation in the brain. Conditions such as metachromatic leukodystrophy, Krabbe's disease (globoid cell leukodystrophy), Canavan's dis-

ease (spongiform leukodystrophy), Alexander's disease (fibrinoid leukodystrophy), and adrenoleukodystrophy are examples of dysmyelinating disease. All of these disorders have in common a lack or delay in the formation of normal white matter that results in severe neurological abnormalities and/or early death [138].

In contrast to the dysmyelinating diseases, where no normal myelin forms, demyelinating conditions are diseases in which there is a loss of normally formed myelin. These are commonly referred to as primary or secondary. Primary demyelinating diseases are those that destroy the myelin sheath, tend to spare other parts of the nervous system such as nerve cells and supporting structures, and demonstrate a relative lack of wallerian degeneration [139-141]. Secondary refers to conditions that may result in a loss of myelin, and this category includes ischemia, anoxia, infection, toxic agents, and diseases of unknown etiology (Fig. 20). The term "white matter disease" could include most diseases of the central nervous system, when it is used in reference to secondary demyelinating processes [139-145].

Multiple sclerosis (MS) is the most common condition that results in the loss of normally formed myelin [138, 146] (Fig. 21). While the cause of MS remains unknown, it is believed to involve autoimmune-mediated demyelination in

Fig. 20. FLAIR image (TR 5500, TE 112, TI 1550) demonstrating periventricular and subcortical white matter disease on a GE 0.2-T open MRI system

Fig. 21. Axial T2-weighted MR (TR 5605, TE 117) of MS plaques from a 0.2-T Siemens open MR system. (Donald Schnapf, DO, York Imaging Center, Pennsylvania, used with permission)

genetically susceptible individuals [146–150]. The role of inheritance is not understood, even though an increased incidence of subclinical demyelination has been demonstrated in asymptomatic first-order relatives of MS patients [148]. Patients with this disease present with highly variable forms of clinical presentation; indeed, it is the broad variety of neurological symptoms that occur at different times that often lead to a suspicion of MS.

A prospective 2-year study demonstrated the sensitivity of MRI in detecting MS to be nearly 85% and exceeding all other tests, including CT

Fig. 22. A FLAIR image (TR 6000, TE 93) demonstrating “Dawson’s fingers” from a 0.2-T Siemens scanner. (Donald Schnapf, DO, York Imaging Center, Pennsylvania, used with permission)

[151]. On standard MR scans most foci that are identified are clinically silent [152, 153]. Most often MS “plaques” are iso- to hypointense on T1-weighted scans and hyperintense compared to brain on T2-weighted scans (Fig. 4). In order to establish the MR diagnosis of MS most require the presence of three or more discrete lesions that are 5 mm or greater in size, as well as lesions that occur in a characteristic location and have a compatible clinical history [154, 155]. It is typical to find oblong lesions at the calloseseptal interface. Also characteristic is perivascular extension into the deep white matter, the so-called Dawson’s finger [155] (Fig. 22).

The MS lesions often appear as round or ovoid areas with a “beveled” (lesion within a lesion) appearance on T1- and proton density weighted studies. In severe cases confluent periventricular lesions are common (Fig. 23). In about 10% of long-standing severe MS cases, abnormal basal ganglia hypointensity is seen. Following contrast administration enhancement represents blood-brain barrier disruption. Enhancement is seen during the active dysmyelinating stage as highly variable and typically transient [138]. Solid as well as ringlike enhancement patterns are evident [156]. While most MS plaques do not enhance following contrast administration [154], enhanced T1-weighted scans can detect additional lesions that are not apparent on T2 weighted imaging

Fig. 23. A T2 MR (TR 2880, TE 90) demonstrating all features of MS including confluent periventricular lesions. (Image obtained from a 0.3-T Hitachi open MR system)

[152]. Certain solitary or very atypical MS lesions may be indistinguishable from abscess or neoplasm [157, 158].

Optic neuritis particularly and other cranial neuropathies are common in patients with MS. On T2-weighted imaging lesions in the brainstem tracts and nuclei are seen, whereas contrast-enhanced T1-weighted studies may delineate enhancement in the nerves themselves. What proves useful in separating optic nerve enhancement from high-signal orbital fat are fat-saturation and short-inversion recovery scans [159]. The use of black CSF techniques or FLAIR results in white lesions against a black CSF signal that makes missing the lesions nearly impossible (see Figs. 2, 13, 20, 22).

Imaging of internal auditory canal and pituitary structures were in the past limited to high-field systems. However, imaging of these regions is now readily accomplished using open-design low-field scanners (see Figs. 5, 6, 24).

■ Pituitary Imaging

Improved tissue contrast and multiplanar capability make MR the preferred imaging method for evaluating patients with suspected sellar and parasellar abnormalities. In patients with symptoms or signs of pituitary dysfunction or visual field deficits MR is the primary imaging modality,

Fig. 24. Fast spin echo sequence demonstrating seventh and eighth nerves on a 0.2 T Siemens open MR system. (Michael Deimling, PhD, Siemens, Erlangen, Germany, used with permission)

while coronal CT remains the diagnostic imaging method of choice in patients in whom an MR study is contraindicated. The following protocols have been successfully employed at field strengths from 0.6 to 1.5 T for the evaluation of the pituitary. Routine dynamic scanning has been performed regardless of field strength with scans being initiated after IV injection of a bolus of 0.1 mmol/kg gadolinium DTPA. A CT dynamic protocol has also been included here for the rare patient in whom MR is contraindicated.

Protocol: Pituitary High-Field MR (Siemens)

1. Sagittal localizer.
2. T1 coronal dynamic (begin when Gd bolus is started): TR 1200 TE 1 matrix 128×256, FOV 300, thickness 3 mm, ACQ 1, slices 5 (×8), time 29 s ×8.
3. T1 coronal routine: TR 300 TE 15 matrix 192×256, FOV 300, thickness 3 mm, ACQ 4, slices 10 (4 min).
4. Routine T1 sagittal: TR 700, TE 15, matrix 256×256, FOV 240, thickness 5 mm, ACQ 2, slices 23 (6 min).
5. Proton density and T2 axial: TR 2500, TE 22/90 matrix 192×256, FOV 240, thickness 5 mm, ACQ 1, slices 20 (8 min).

Protocol: Pituitary High-Field MR (GE)

1. Sagittal localizer.
2. T1 coronal dynamic (begin when Gd bolus is started): TR 32, TE 6, FA 20 (SPGR), matrix 256×128, FOV 240, thickness 3 mm, ACQ 2 (2 slice locations), single-slice technique, time-25 s (per slice) ×8 (sequence time 1 min; scan time 5 min).
3. T1-coronal routine: TR 600, TE 12, matrix 256×128, FOV 160, thickness 3 mm, ACQ 4, slices 14 (5 min).
4. Routine T1 sagittal: TR 600, TE 12 matrix 256×128, FOV 160, thickness 3 mm, ACQ 4, slices 14 (5 min).

5. Proton density and T2 axial: TR 2800, TE 30/100, matrix 256×192, FOV 200, thickness 5 mm, ACQ 0.075, slices 20 (7 min).

Protocol: Pituitary Open Low-Field MR (Toshiba)

1. Center the pituitary gland by scout view or fluoro-mode.
2. Three-axis locator (scout view).
3. TR 150, TE 30, matrix 256×256, FOV 125, thickness 10 mm, ACQ 1, slices-1 (×8) time 38 s (×8).
4. T1 coronal routine: TR 110, TE 15, FA 60, matrix 256×256, FOV 110, thickness 2.5 mm, ACQ 2, slices 16 (9 min, 56 s).
5. Reconstruct coronal, sagittal, and axial planes at 1.25 mm, film at 4× magnification.

Protocol: Pituitary Open Low-field MR (Picker)

1. Center the pituitary gland by scout view or fluoro-mode.
2. T1 coronal dynamic TR 250, TE 15, FA 35, matrix 25/256, FOV 300, thickness 3 mm, ACQ 1, slices 1×5, time 1:04 (×5).
3. Reconstruct sagittal and axial planes.

Protocol: Coronal Sellar CT

1. Position patient supine with head at maximum extension with shoulder elevation.
2. Scout view.
3. Gantry tilt 140° posterior or true coronal plane.
4. Program dynamic technique (8–13 slices as required for pituitary fossa).
5. Bolus with 40 g iodinated contrast.
6. Begin scanning with thinnest slices as rapidly as possible through the pituitary fossa.
7. Following dynamic scan, repeat high-resolution coronal CT.
8. Photograph at 2× magnification.
9. Reconstruct sagittal and axial images.
10. Measure gland height at stalk and at maximum size.

A wide variety of pathological processes have been described in the sellar and parasellar region [160–163].

The abnormal finding that is most striking on both dynamic and routine neuroimaging of the pituitary gland is a focal defect in the gland following contrast administration. The diagnosis is frequently that of a pituitary adenoma, when this finding is combined with other abnormalities of the gland (Fig. 25) [164]. A pituitary adenoma, clinically categorized as functioning or nonfunctioning, may be defined as a benign neoplasm of

Fig. 25. A T1 postcontrast MR (TR 472, TE 26) demonstrating a pituitary microadenoma identified as a focal area of decreased signal within the enhancing pituitary gland. (Image from a 0.2-T Siemens open MR system. Mark Leszczynski, RT, Memorial Open MRI, Houston, Texas, used with permission)

the anterior pituitary gland (adenohypophysis). Radiologically an adenoma is described as a microadenoma or macroadenoma based on size. A microadenoma is less than 10 mm in diameter and a macroadenoma is greater than 10 mm in diameter. More often the microadenomas are functioning and typically secrete prolactin, growth hormone, or ACTH. Macroadenomas, less often functioning, are more likely to present with neurological signs and symptoms from mass effect on the optic chiasm or cranial nerves (Fig. 26) [164–166]. Prior to contrast enhancement macroadenomas can be expected to demonstrate isointensity or hyperintensity relative to cerebral gray matter. Signal inhomogeneity may present as a result of tumor necrosis, cyst formation, or hemorrhage. Minimal to moderate enhancement is typical following the administration of gadolinium on MR. The objective of an MR examination is primarily to evaluate possible suprasellar or parasellar extension, even though these lesions are readily identifiable without contrast in many instances. It is possible to best evaluate compression of the optic chiasm, invasion of the cavernous sinuses, or extension into the sphenoid sinus following administration of intravenous contrast by MR. The possibility of an aneurysm should be indicated by the presence of a large flow void on MR, and MR angiography can be performed at the same setting.

Findings most commonly encountered in the evaluation of microadenomas, which may be common to both microadenomas and macroadenomas, include: (a) focal defect in the gland follow-

Fig. 26. T1-weighted MR (TR 68, TE 24, FA 30) postgadolinium contrast enhancement demonstrating a pituitary macroadenoma. (Image from on a 0.64-T Toshiba open design MR system)

Fig. 27. T1-weighted MR (TR 600, TE 30) demonstrating a large suprasellar cystic mass. (Image from a 0.35-T Fonar MR system)

ing contrast enhancement (particularly evident on dynamic images), (b) upward convexity of the superior margin of the pituitary gland, (c) asymmetric gland enlargement, (d) increased gland height, (e) stalk deviation, and (f) focal erosion of the floor of the sella (often difficult to appreciate on MR). When more of the findings are present, there is a greater likelihood of pituitary adenoma. However, as stated above, the strongest indicator of pituitary microadenoma is a focal region of hy-

pointensity following contrast administration [164, 165, 167–169].

A precursor of pituitary adenoma may be represented by pituitary hyperplasia. Pituitary hyperplasia or hypertrophy may be the result of normal hormonal influences occurring during early development, puberty, and pregnancy [170, 171]. Abnormal extrapituitary influences may also result in pituitary hyperplasia, occurring as a result of bronchial carcinomas, islet cell tumors, and carcinoid tumors, for example [172]. Following contrast enhancement pituitary hyperplasia demonstrates a uniformly enlarged and enhancing gland without evidence of a focal defect. In a uniformly enlarged pituitary gland, dynamic images are particularly valuable in excluding a focal defect.

The location of craniopharyngiomas may be both intrasellar and suprasellar [161, 167, 173]. Craniopharyngiomas arise from squamous epithelial clefts of Rathke's pouch and are slowly growing benign neoplasms. These tumors present primarily in children or young adults, but may also be seen in middle or later age groups. These neoplasms contain both cystic and solid components with the cystic areas containing cholesterol or blood. The signal intensity of the cystic component is variable on MR but may also be hyperintense as a result of cholesterol or blood. Cystic regions are typically hypodense on CT. Craniopharyngiomas are most often heterogeneous, and this is not related to location [161, 167, 173] (Fig. 27).

In addition to adenomas and craniopharyngiomas, tumors such as meningiomas, metastatic disease, gliomas, lymphomas, pinealomas, choristomas, dermoids, epidermoids, teratomas, and lipomas also occur in this location.

A sella that is partially or completely filled with cerebrospinal fluid is referred to as an "empty sella." Frequently the gland is small and positioned posteriorly and inferiorly against the sellar floor. An empty sella is rarely accompanied by endocrine dysfunction or an associated pituitary adenoma.

■ Diagnostic Yield and Reader Experience

Diagnostic efficacy is considered of primary importance in the evaluation of any imaging modality. This remains a concern regardless of other issues that may be involved, including risk and cost. Therefore imaging systems that may offer a significant reduction in cost and risk would generally be considered of little value unless at least an acceptable level of diagnostic efficacy had been demonstrated. Well-controlled and blinded studies

have shown similar diagnostic accuracy for low, middle-, and high-field MR systems [174].

The development of MRI has been paralleled with controversy regarding optimum field strength since the first clinical applications of MR in 1982 [175, 176]. After more than 15 years of continued research and clinical use this issue remains unresolved [175–178]. In a study comparing the diagnostic efficacy of MRI at 0.064 T with CT and with MRI at 1.5 T in cranial central nervous system disease, statistical measurements of sensitivity, specificity, and reader confidence were addressed [179].

The results from this study indicate that the difference in diagnostic capability of MR imagers at field strengths of 0.064 and 1.5 T is small for most central nervous system diseases and between 0% and 10% in most cases. Many additional factors must be considered when evaluating diagnostic accuracy for clinical care, including the radiologist's experience, the patient population, availability of the clinical history, and effective use of the MR imager, which includes thoroughness of the examination, appropriate use of pulse sequences, and use of MRI contrast material. Instead of establishing the superiority of one imaging system, technique, or field strength, research generally demonstrates that each system provides diagnostically valuable images, and that it is critical to know how to use each system to its best advantage [175, 176, 180–188].

It is important to include consideration not only of the quality of the images but the clinical history of the patient and the capability of the radiologist when assessing diagnostic accuracy. In the above study an incomplete or inadequate history accounted for as much as 100% loss in sensitivity in the category of abscess or infection. We found as much as 15% loss of diagnostic sensitivity as a result of variations in reader capability, diligence, and attention. Therefore issues such as history and reader variability accounted for far more than scanner type in missed diagnoses. Radiologists and physicians in a competitive environment are aware that quality of interpretation, availability of comparative studies, direct and complete clinical history, and radiological training have measureless influence on individual patient care. Issues of quality assurance have been partly deflected by the predominant focus on type of imager and field strength with those issues that actually make the most clinical difference avoided. In other words, both the literature and common experience confirm that no amount of scanner improvements can account for inherent deficiencies in the physician reading the scan.

While inherent scanner limitations do exist, there appear to be little in the way of diagnostic differences between high- and low-field MR images. The specificity of low-field MRI and even CT may be substantially superior to that with high-field MRI in some cases [179].

The literature indicates that bore-type high-field and open-design low-field MR imagers are diagnostically equivalent for detection of central nervous system disease [189]. Many additional factors must be considered when evaluating this conclusion, such as the experience of the radiologist, the type of patient being evaluated, the availability of appropriate history, maximum utilization of the MR scanner, length of the study, and patient safety. Literature studies have generally found that most imaging systems provide diagnostically valuable information at varying field strengths and for a broad range of diseases [1–5, 12, 136, 189–195].

It is not surprising that differences in reader interpretation and the effect of information such as appropriate clinical history are more significant than the diagnostic imaging modality utilized. However, time, cost-effectiveness, and safety are additional factors that should be considered in MR applications.

Even the most technologically advanced and sophisticated imaging technology has serious limitations. We must continue to recognize a patient's uniqueness and the distinctiveness of each individual's condition. Each person's brain is capable of markedly different physiological and functional responses to the presence of pathology; this may significantly influence treatment outcomes and options. Open design MR systems provide yet another tool to assist in the care of our wonderfully complex patients.
