ABSTRACT: T-branes are a non-abelian generalization of intersecting branes in which the matrix of normal deformations is nilpotent along some subspace. In this paper we study the geometric remnant of this open string data for six-dimensional F-theory vacua. We show that in the dual M-theory / IIA compactification on a *smooth* Calabi-Yau threefold X_{smth} , the geometric remnant of T-brane data translates to periods of the three-form potential valued in the intermediate Jacobian of X_{smth} . Starting from a smoothing of a singular Calabi-Yau, we show how to track this data in singular limits using the theory of limiting mixed Hodge structures, which in turn directly points to an emergent Hitchin-like system coupled to defects. We argue that the physical data of an F-theory compactification on a singular threefold involves specifying both a geometry as well as the remnant of three-form potential moduli and flux which is localized on the discriminant. We give examples of T-branes in compact F-theory models with heterotic duals, and comment on the extension of our results to four-dimensional vacua.

1 Introduction

Recently there has been renewed interest in F-theory, both as a starting point for model building efforts, as well as for addressing more conceptual questions connected with non-perturbative phenomena in string compactifications. In F-theory, the IIB axio-dilaton is interpreted as a modulus of a twelve-dimensional geometry, thus providing a geometric characterization of vacua with order one string coupling as well as non-perturbative bound states of seven-branes [1].

From a model building standpoint, an attractive feature of F-theory is that it can simultaneously accommodate the flexibility of intersecting brane constructions with the promising GUT phenomenology of exceptional gauge symmetries. In a suitable decoupling limit, the task of constructing realistic string vacua in F-theory reduces to the specification of intersection patterns for seven-branes. In this way, GUT model building [2–5], flavor physics [6–16] and various string-motivated scenarios for physics beyond the Standard Model can all be accommodated in a single local formulation. For recent reviews on F-theory model building, see e.g. [17–21].

This allows a division of labor in building up phenomenologically viable models. The basic outline in this programme (cf. [2, 4, 22–26]) is to first identify the local aspects of an intersecting seven-brane gauge theory necessary to realize the gauge theoretic data of a field theory, i.e. an “open string sector”. Second, there is the recoupling to gravity, i.e. the “closed string sector” of the model. For recent efforts in constructing global F-theory compactifications, see e.g. [5, 27–44].¹

A powerful tool in understanding the open string sector is the effective field theory of a seven-brane coupled to defects [2, 4, 47]. In this field theory, an adjoint-valued complex field Φ controls the position of the stack of seven-branes in the local geometry normal to the brane. Of particular significance for flavor physics models are configurations where Φ has position dependent eigenvalues with branch cuts [8, 48–53]. In a holomorphic presentation of Φ i.e. without branch cuts, this means $[\Phi, \Phi^\dagger] \neq 0$ (see [51]). The non-zero commutator means the seven-brane has puffed up to a dielectric nine-brane, and the eigenvalues of Φ do not fully characterize the configuration. A T-brane is any such configuration where Φ is nilpotent (i.e. upper or lower triangular as a matrix) along some subspace of the

¹As a brief aside on the philosophy of the “local to global” programme of F-theory model building, we note that there could in principle be several global completions of a local model, and these global completions may not even be geometric. Rather, the global model serves more as a proof of concept, i.e. UV consistency. From this perspective, the relevant question is how well one might expect to distinguish these different choices of UV completion. For recent perspectives on this issue, see for example [45, 46].

worldvolume of the brane. Such nilpotent Higgs fields in bound states of branes were first introduced in [54], and in the context of F-theory in [51] (see also [16, 52, 53, 55]).

To move forward with the second stage of F-theory model building where gravity is recoupled, it is necessary to match the data of the seven-brane gauge theory back to the geometry of an F-theory compactification. However, since T-brane data is not visible in holomorphic Casimir invariants, it has remained an open and surprisingly basic question as to how to identify its geometric remnant in global models.²

In this paper we show how to identify the geometric remnants of T-branes. We view the open string sector and closed string sectors as defining overlapping patches for the full moduli space of an F-theory compactification. Our aim will be to determine the “transition functions” which interpolate between these two coordinate systems.³

Our focus in this paper will be on T-branes in six-dimensional F-theory vacua with eight real supercharges.⁴ In this case, the internal dynamics of the seven-brane gauge theory is governed by a Hitchin-like system coupled to point-like defects. These defects are often associated with localized matter fields, but can also reflect couplings to a theory of tensionless strings.

To find the geometric remnants of T-brane data, we first show how to identify the data of the Hitchin system with defects in geometric terms. Locally, we model this by a curve of ADE singularities with possible higher order singularities at some marked points. We view this local threefold X as the limit of a family of smoothings $X_t \rightarrow X$ so that as $t \rightarrow 0$ we recover the singular space X . These smoothings physically correspond to moving the stack of seven-branes around to more general positions. We find that in the smoothing, the remnant of T-brane data is captured by the intermediate Jacobian of X_t :

$$J(X_t) = H^3(X_t, \mathbb{R}) / H^3(X_t, \mathbb{Z}) \tag{1.1}$$

which fibers over the complex structure moduli M_{cplx} . Indeed, after compactifying on a further T^2 , there is a dual description in terms of IIA supergravity. There, the intermediate Jacobian and complex structure moduli (along with the universal axion and dilaton) combine to form the hypermultiplet moduli space. The holomorphic Casimir invariants of the Higgs field give coordinates on the complex structure moduli, while the remnants of T-brane data corresponds in the dual IIA / M-theory picture to integrating the three-form potential over three-cycles.

However, this description is inadequate in the singular limit $t \rightarrow 0$, since it is not even possible to speak of the classical intermediate Jacobian. It is nevertheless possible to study the limiting behavior of these constructs using the theory of limiting mixed Hodge structures (LMHS), which directly points to the Hitchin system coupled to defects. In other words, we are going to use the theory of limiting mixed Hodge structures to construct the transition functions between the “open string patch” and “closed string patch”.

²See [41, 43] for some recent work.

³We view this as developing the dictionary entries in a gauge / gravity correspondence involving gauge theory on stack(s) of seven-brane(s), and the non-singular locus of an F-theory base manifold. This is in line with the interpretation of local F-theory model building given in [26].

⁴In supersymmetric compactifications to eight dimensions, T-branes do not exist because the seven-brane equation of motion reduces to $[\Phi, \Phi^\dagger] = 0$.

Figure 1. Depiction of the moduli space of F-theory in six dimensions. The intermediate Jacobian $J(X_{\text{smth}})$ fibers over the complex structure moduli M_{cplx} . At singular points of the complex structure, the classical intermediate Jacobian description breaks down and is replaced by an emergent Hitchin system which captures the T-brane data. At the singular point in moduli space where both the complex structure and T-brane data are switched off, one can instead perform a Kähler resolution of the geometry, moving onto the Coulomb branch of the low energy theory. The two branches only meet at singular loci in the moduli space.

This begs the question: what is the defining data of a 6D F-theory model at large volume? The standard procedure in much of the literature is to start with a singular Calabi-Yau X , and to view it as the limit of either a blowdown $\tilde{X} \rightarrow X$, or as the limit of a smoothing $X_t \rightarrow X$. In fact, our analysis shows that just specifying X is ambiguous from a physics standpoint: the T-brane data must also be included. On the smoothing side, this is reflected in the three-form potential moduli valued in the intermediate Jacobian.

Turning to the characterization as a blowdown, we find that T-branes *obstruct* some Kähler resolutions, simply because the theory is still at a non-trivial point of the Higgs branch. In the low energy effective theory, this is the statement that the vevs of the three-form moduli continue to give a mass to states in the theory.

To repair this ambiguity, we propose to supplement the definition of compactification of F-theory on a singular threefold X by appropriate “T-brane data”. This data consists of the singular limit of an intermediate Jacobian, as well as abelian flux data of the Hitchin system. In configurations which admit a Kähler resolution, this would translate to a four-form flux in the dual M-theory description. Now, in compactifications to six dimensions on *smooth* Calabi-Yau threefolds, such fluxes are inconsistent with the supergravity equations of motion. However, in singular limits, such fluxes *can* be activated. In fact, it is known that for a smooth Calabi-Yau, the three-form moduli, and flux data are naturally packaged in terms of a single object, the Deligne cohomology $H_{\mathcal{D}}^2(X_{\text{smth}}, \mathbb{Z}(2))$ [56]. From this perspective, the emergent Hitchin-like system gives a definition of this object in certain singular limits. See figure 1 for a depiction of the moduli space.

As a check of our proposal, we present examples of compact F-theory models which contain T-branes. We focus on the specific case of F-theory compactified on a Hirzebruch base \mathbb{F}_n for $n \in \mathbb{Z}$ and $-12 \leq n \leq 12$. These F-theory vacua have a dual description in terms of the $E_8 \times E_8$ heterotic string compactified on a K3 surface with $(12 + n, 12 - n)$ instantons in each vector bundle factor (see e.g. [57–59]).⁵

⁵When we write \mathbb{F}_n with $n < 0$, we mean $\mathbb{F}_{|n|}$ with the sections of self-intersection $\pm n$ switched.

Quite remarkably, some of the simplest heterotic string compactifications are dual to T-branes in F-theory! For example, the singular local geometry:

$$y^2 = x^3 + g_{12+n}(z')z^5 \tag{1.2}$$

is ambiguous, and can actually refer either to a theory with small instantons, or to a *smooth* vector bundle which happens to have a *singular* spectral cover. An important example of this type is the standard embedding of the spin connection in one of the E_8 factors. This is a perfectly smooth vector bundle which has a singular spectral cover. This ambiguity was noted in [60], and was recently revisited in [53]. More generally, heterotic theory abounds with examples of smooth vector bundles with singular spectral covers [61] (see also [62–64]). Our plan will be to show how to identify the geometric remnants of T-brane data in these and related situations.

As a final remark, we note that the main aim of our work is to carefully track the behavior of the relevant geometric structures in singular limits. Indeed, though some aspects of our discussion, especially in relation to spectral covers, are well-known for *smooth* spectral covers and their associated threefold duals in F-theory, comparatively far less is known in singular limits.

The rest of this paper is organized as follows. First, in section 2, we review two complementary perspectives of F-theory vacua based on a global “closed string” description and the local “open string” description. Next, in section 3, we study the effective field theory of a seven-brane using the associated Hitchin system with defects. In section 4 we show how the limiting behavior of a local curve of singularities directly points to an emergent Hitchin system, and in section 5 we give a revised prescription for how to analyze the effective field theory associated with F-theory on a singular threefold X . We provide realizations of T-branes in compact F-theory models in section 6. We conclude in section 7. Some additional review and technical details are deferred to the appendices.

2 Global and local models in 6D F-theory

In preparation for our later discussions, in this section we review two complementary approaches to 6D F-theory compactification based on the local geometry of a stack of seven-branes, and the closed string description of such vacua.

F-theory [1] provides a non-perturbative generalization of type IIB superstring theory in which the axio-dilaton:

$$\tau = C_0 + \frac{i}{g_s} \tag{2.1}$$

is now interpreted as the modular parameter of an auxiliary elliptic curve:

$$y^2 = x^3 + fx + g, \tag{2.2}$$

where f and g can have non-trivial dependence on the positions of the ten spacetime dimensions. In physical terms, the position dependence in the axio-dilaton is induced by the presence of non-perturbative bound states of seven-branes.

Supersymmetric compactifications of F-theory to flat space can be obtained as follows. We split up the ten dimensional spacetime of string theory as the product $M_{10-2m} \times B$, where M_{10-2m} designates the $10 - 2m$ uncompactified directions and B is a compact manifold of complex dimension m . This can be arranged by assuming that the elliptic fibration only depends on B so that the Weierstrass model defines an elliptic fibration with section $\mathbb{E} \rightarrow X \rightarrow B$, where X is a Calabi-Yau $(m + 1)$ -fold. In this geometric description, seven-branes are associated with the locations where the elliptic fibration degenerates. This occurs when some of the roots of the cubic in x collide, i.e. at the vanishing of the discriminant:

$$\Delta = 4f^3 + 27g^2. \tag{2.3}$$

The components of the discriminant locus $(\Delta = 0) \subset B$ define complex codimension one subspaces inside B , which should be thought of as submanifolds which are wrapped by seven-branes. This defines the location of the “open string sector”. The “closed string sector” is associated with the complement, i.e. the non-singular parts of the elliptic fibration. One of the remarkable features of F-theory is the close interplay between the open and closed string sectors. Our primary interest in this paper will be the special case of compactifications to six dimensions, i.e. $m = 2$, with X a Calabi-Yau threefold.

In the remainder of this section we describe two complementary descriptions of such six-dimensional vacua. First, we consider the closed string description, focussing on the M-theory / IIA dual compactifications on X a smooth Calabi-Yau threefold. In the limit of moduli where X develops singularities, the supergravity description breaks down and must be supplemented by additional light degrees of freedom. In local patches of B it is then fruitful to switch to a second description based on the gauge theory of a seven-brane. It is in this second patch that we will see the appearance of T-branes. Part of our aim in this work will be to provide a patchwork of different coordinate systems for the moduli space, and to then describe how these different patches fit together in overlapping regions of validity.

2.1 Closed string description

One way to characterize some compactifications of F-theory is in terms of a dual description in M-theory. The lift of T-duality between IIA and IIB vacua then becomes a statement about duality between M-theory on a smooth Calabi-Yau threefold X_{smth} and F-theory compactified on $S^1 \times X$. A further circle compactification then relates IIA string theory compactified on X_{smth} to F-theory compactified on $T^2 \times X$. In both the IIA and M-theory descriptions, we reach the F-theory limit by shrinking the volume of the elliptic fiber to zero size.

The vacua of IIA compactified on a Calabi-Yau threefold has been extensively studied, so we shall be brief. For additional review, see for example the review [65] and references therein. The effective theory in four dimensions has eight real supercharges, i.e. $\mathcal{N} = 2$ supersymmetry. In the IIA supergravity, we get gauge fields from integrating the three-form potential over the $h^{1,1}(X_{\text{smth}})$ independent two-cycles. The vector multiplet moduli are controlled by the special geometry of the complexified Kähler moduli. There are $(1/2)h^3(X)$ hypermultiplet moduli, i.e. $2h^3(X)$ real degrees of freedom. Working about a fixed choice

of holomorphic three-form Ω , there are $h^{2,1}(X_{\text{smth}})$ complex structure moduli, and two additional real moduli from the dilaton and the universal axion (from dualization of $B_{\mu\nu}$ in the $\mathbb{R}^{3,1}$ directions). The other $h^3(X)$ real degrees of freedom come from periods of the Ramond-Ramond three-form potential over the A- and B-cycles of X_{smth} . Since the dilaton sits in a hypermultiplet, the geometry of the hypermultiplet moduli space will generically receive various perturbative and non-perturbative corrections in string theory.

For this paper, our main focus will be on the geometric moduli space specified by the intermediate Jacobian $J(X_{\text{smth}})$, and its fibration over M_{cplx} , the complex structure moduli. The three-form potential moduli take values in the fiber $J(X_{\text{smth}})$, i.e. the intermediate Jacobian:

$$J(X_{\text{smth}}) = H^3(X_{\text{smth}}, \mathbb{R})/H^3(X_{\text{smth}}, \mathbb{Z}), \tag{2.4}$$

that is, we view $H^3(X_{\text{smth}}, \mathbb{R})$ as a vector space, and then mod out by the integral lattice $H^3(X_{\text{smth}}, \mathbb{Z})$.⁶ In the IIA supergravity, the hypermultiplet moduli space is given by a \mathbb{C}^* bundle which is fibered over the intermediate Jacobian introduced by Griffiths $\mathcal{J}_G(X_{\text{smth}})$, i.e. the total space of the fibration $J(X_{\text{smth}}) \rightarrow \mathcal{J}_G(X_{\text{smth}}) \rightarrow M_{\text{cplx}}$, with $\mathcal{J}_G(X_{\text{smth}}) = (H^{3,0}(X) \oplus H^{2,1}(X))^*/H_3(X, \mathbb{Z})$. This intermediate Jacobian specifies the correct complex structure on the real torus (2.4).⁷ In the low energy effective field theory, we can expand around some point of the quaternionic Kahler moduli space, with fluctuations taking values in the tangent space. For example, the infinitesimal variations of complex structure moduli live in $H^{2,1}(X) \equiv \text{Def}(X)$, and the $SU(2)$ R-symmetry acts on the tangent space, rotating the different components of the hypermultiplet fluctuations into one another.

The supergravity description requires all volumes on X to be large compared with the Planck scale. Away from this limit additional light degrees enter the effective theory. Starting from a smooth X_{smth} , we can reach a singular geometry either by tuning the Kähler moduli or by tuning complex structure moduli of X_{smth} . By abuse of notation, we shall refer to this singular Calabi-Yau as X . The main condition to have an F-theory compactification is that X admits an elliptic fibration with section. From this perspective, there is more than one possible \tilde{X}_{smth} which could degenerate to X . We can approach X either via a blowdown $\tilde{X} \rightarrow X$, or by switching off a family of smoothings $X_t \rightarrow X$.

2.2 Open string description

In local regions of the twofold base B , there is a complementary description of an F-theory compactification in terms of the gauge theory of a seven-brane. In the local description, a seven-brane wraps a genus g curve C . The curve comes with some number of marked points p_1, \dots, p_k corresponding to locations where other components of the discriminant intersect C .

⁶Here we are ignoring possible torsional contributions to $H^3(X, \mathbb{Z})$.

⁷Note that $H^{3,0}(X)$ is the tangent space to the moduli of the dilaton and $H^{2,1}(X)$ is the tangent space to the moduli of complex structures, so the tangent space to the intermediate Jacobian naturally pairs with the tangent space to the complex structure plus dilaton, as must be the case for the complex halves of hypermultiplet moduli. This is not the case for the Weil intermediate Jacobian, which is sometimes incorrectly used in the physics literature as a description of the RR moduli.

In M-theory terms, some of the field content of the effective field theory on the seven-brane descends from variations in the complex structure $\delta\Omega_{(2,1)}$, and variations in the three-form potential δC_3 . Assuming we have a curve of ADE singularities, we can, at a heuristic level, consider a basis of $(1, 1)$ forms ω^α for the fiber, and then locally decompose these modes as:

$$\delta\Omega_{(2,1)} \sim \sum_{\alpha} \Phi_{(1,0)}^{\alpha} \wedge \omega^{\alpha} \quad \text{and} \quad \delta C_3 \sim \sum_{\alpha} A^{\alpha} \wedge \omega^{\alpha}, \tag{2.5}$$

where $\Phi_{(1,0)}^{\alpha}$ is a collection of $(1, 0)$ forms on C , and A^{α} is a connection on C . These fields should be viewed as taking values in the abelian subalgebra of some non-abelian gauge algebra \mathfrak{g} . The rest of the states in the adjoint representation come from M2-branes wrapped over collapsing cycles.

Taking these additional degrees of freedom into account, the effective theory for this system is controlled by a Hitchin-like system coupled to defects [2, 4, 47]. For a seven-brane with gauge group G , this is given by a principal G bundle E , and an adjoint-valued $(1, 0)$ -form Higgs field Φ , which satisfy the equations of motion:

$$F + [\Phi, \Phi^{\dagger}] = \sum_p \delta_{(p)} \mu_{\mathbb{R}}^{(p)} \quad \text{and} \quad \bar{\partial}_A \Phi = \sum_p \delta_{(p)} \mu_{\mathbb{C}}^{(p)}, \tag{2.6}$$

where here, $F = dA + A \wedge A$ is the curvature of E , δ_p is a delta function (i.e. $(1, 1)$ current) localized at the point $p \in C$, and $\mu_{\mathbb{R}}^{(p)}$ and $\mu_{\mathbb{C}}^{(p)}$ form a triplet of adjoint valued moment maps. In most cases, these moment maps can be associated with bilinears in the vevs of ‘‘bifundamentals’’.

Some of the moduli of the Hitchin system have a clear geometric interpretation in the local geometry of the F-theory compactification. It is helpful to illustrate this unfolding by way of example. To this end, consider a curve of singularities:

$$y^2 = x^3 + z^5 \tag{2.7}$$

so that $x = y = z = 0$ denotes the location of the curve C . We view this as a seven-brane with gauge group E_8 wrapping the curve C . A Higgs field such as:

$$\Phi = \begin{bmatrix} \phi & \\ & -\phi \end{bmatrix} \tag{2.8}$$

valued in the $\mathfrak{su}(2)$ factor of $\mathfrak{e}_7 \times \mathfrak{su}(2) \subset \mathfrak{e}_8$ corresponds to the unfolding of E_8 to E_7 :

$$y^2 = x^3 + z^5 + \phi^2 x z^3, \tag{2.9}$$

where ϕ^2 is the quadratic Casimir of the $\mathfrak{su}(2)$ valued Higgs field. More generally, the holomorphic Casimir invariants $\mathcal{C}_{(i)}(\Phi)$ of Φ give gauge invariant coordinates on the moduli space of the Hitchin system via the map:

$$\Phi \rightarrow \mathcal{C}_{(i)}(\Phi). \tag{2.10}$$

In the curve of singularities, such deformations show up as unfolding parameters.

A natural way to characterize the local neighborhood of the seven-brane is in terms of the total space $\mathcal{O}(K_C) \rightarrow C$. Then, after activating a vev for the Higgs field, the location of the seven-brane is captured by the spectral equation:

$$\det(s - \Phi) = 0 \tag{2.11}$$

where s is a section of $\mathcal{O}(K_C) \otimes \mathbf{Id}$. The key point is that in the spectral equation, the holomorphic Casimir invariants of line (2.10) directly show up.

But the holomorphic geometry fails to capture all of the moduli of the Hitchin system. We define ‘‘T-brane data’’ [51] as any gauge invariant data of the Hitchin system which is absent from the map (2.10). Roughly speaking, such data is associated with a nilpotent Higgs field and cannot show up as a complex structure deformation.

To give an example, consider again the Hitchin system defined by the local model of equation (2.7). We assume the Higgs field again takes values in the $\mathfrak{su}(2)$ factor of $\mathfrak{e}_7 \times \mathfrak{su}(2) \subset \mathfrak{e}_8$. Then, a nilpotent Higgs field such as:

$$\Phi = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \tag{2.12}$$

will satisfy the equations of motion on a genus $g > 1$ curve [66]. To solve the Hitchin system of equations, we need a non-trivial flux, corresponding to the rank two bundle $E = K_C^{1/2} \oplus K_C^{-1/2}$. In this case, all of the $\mathfrak{su}(2)$ gauge symmetry is broken. Observe, however, that all holomorphic Casimir invariants vanish. So, the complex geometry remains as:

$$y^2 = x^3 + z^5, \tag{2.13}$$

which would suggest a singular geometry with \mathfrak{e}_8 gauge symmetry, even though the $\mathfrak{su}(2)$ factor in $\mathfrak{e}_7 \times \mathfrak{su}(2) \subset \mathfrak{e}_8$ has already been broken. Let us note that instead of taking $g > 1$ we could instead add multiple punctures to a genus zero curve. We will encounter the latter situation repeatedly in the context of F-theory models.

In the related context of four-dimensional compactifications of F-theory, such T-brane data can also be detected through D3-brane probes [67–73]. In that context, the resulting superconformal fixed points are determined by the Jordan block structure of the Higgs field.

3 Seven-branes wrapping Riemann surfaces

In preparation for our later geometric analysis, we now discuss in more detail the low energy effective field theory associated with a seven-brane wrapping a Riemann surface which is coupled to defect modes. To set the stage, here we study the low energy effective field theory defined by a seven-brane with gauge group G wrapping a genus g curve which is coupled to matter localized at points of the curve. For each point $p \in C$, let $R_{(p)}$ denote the representation of the matter fields. This system has been studied from various perspectives, including [2, 59, 74].

Let us now turn to the six-dimensional effective theory defined by this system. For ease of exposition, we assume that no background fields have been switched on. For details

on less trivial backgrounds, see [2, 51]. The massless field content is given by all zero mode fluctuations around this background. First of all, we have a single 6D vector multiplet with gauge group G . Additionally, we have a number of hypermultiplet moduli. The zero modes of the Higgs field satisfy the equation of motion $\bar{\partial}\Phi = 0$, and are associated with global sections of the canonical bundle, which has complex dimension $h^0(C, K_C) = g$. Additionally, the holonomies of the gauge field around the $2g$ one-cycles of C produce another $2g$ real degrees of freedom. We therefore conclude that the zero mode content of the system produces g adjoint-valued hypermultiplets. Additionally, we have the localized hypermultiplets at points of C .

It is also instructive to compactify on a T^2 to reach a four-dimensional system. This yields a theory with $\mathcal{N} = 2$ supersymmetry, with the same number of hypermultiplets. The only difference in the mode content is that now the vector multiplet also contains a complex adjoint-valued scalar φ . In $\mathcal{N} = 1$ language, the associated superpotential for this system is:

$$W = \sum_{i=1}^g \text{Tr}_{\mathfrak{g}} \left(\varphi \cdot [X_i, \tilde{X}_i] \right) + \sum_p \tilde{q}_{(p)} \cdot \varphi \cdot q_{(p)}, \tag{3.1}$$

and the D-term constraint is:

$$\sum_{i=1}^g \text{Tr}_{\mathfrak{g}} \left(T \cdot [X_i, X_i^\dagger] \right) + \sum_p q_{(p)}^\dagger \cdot T \cdot q_{(p)} - \sum_p \tilde{q}_{(p)} \cdot T \cdot \tilde{q}_{(p)}^\dagger = 0 \tag{3.2}$$

modulo gauge transformations. Here, $\text{Tr}_{\mathfrak{g}}$ is shorthand for contraction using the Killing form of the Lie algebra \mathfrak{g} , T is a generator of the Lie algebra \mathfrak{g} , $X_i \oplus \tilde{X}_i$ denotes the g adjoint valued hypermultiplets, and $q_{(p)} \oplus \tilde{q}_{(p)}$ denotes a hypermultiplet transforming in a representation $R_{(p)} \oplus R_{(p)}^*$, which descends from a localized point $p \in C$.

The Higgs branch corresponds to activating vevs for the hypermultiplets, and the Coulomb branch corresponds to giving vevs to the complex scalars in the vector multiplet. There can also be mixed Coulomb / Higgs branches. In an $\mathcal{N} = 2$ theory, these “mixed” pieces still factorize (see e.g. [75]). Jumping ahead to a geometric characterization, the Coulomb branch corresponds to activating a Kähler resolution, while the Higgs branch corresponds to activating a smoothing and non-trivial periods for the three-form moduli.

The total dimension of the hypermultiplet moduli space is given by adding up the dimensions and representations of all points, and modding out by the hyperkahler quotient defined by G . The complex dimension of the hypermultiplet moduli space is:

$$\dim_{\mathbb{C}} M_{\text{hyper}} = 2(g - 1) \cdot \dim G + \sum_p 2 \dim R_{(p)}. \tag{3.3}$$

3.1 $SU(N)$ example

Let us illustrate some additional aspects of the above remarks in the case $G = SU(N)$. For simplicity, we assume there are k localized hypermultiplets in the fundamental representation. Then, the dimension of the hypermultiplet moduli space is:

$$\dim_{\mathbb{C}} M_{\text{hyper}} = 2(g - 1) \cdot (N^2 - 1) + 2kN. \tag{3.4}$$

We can geometrically engineer an example of this type with a curve of A_{N-1} singularities:

$$y^2 = x^2 + z^{N+1} + \alpha_k(z')z^N, \tag{3.5}$$

where z' denotes a local coordinate on C , and $\alpha_k(z')$ has k zeroes, indicating the points of localized matter.

Once we switch on background values for the defects, we induce delta function supported curvature in the gauge field flux, and poles in the Higgs field. A meromorphic Higgs field of the form:

$$\Phi = \text{diag}(\phi_1, \dots, \phi_k, \underbrace{-\frac{1}{N-k}\Sigma\phi_i, \dots, -\frac{1}{N-k}\Sigma\phi_i}_{N-k}), \tag{3.6}$$

where:

$$\phi_i = \frac{\mu_i dz'}{z' - p_i} \tag{3.7}$$

corresponds to activating a bifundamental vev for the localized matter fields at the roots p_i of $\alpha_k(z')$. As explained in [2], the A_{N-1} singularity then unfolds to:

$$y^2 = x^2 + z^{N+1} + z^{N-k} \left(\alpha_k(z')z^k + \alpha_{k-1}(z')z^{k-1} + \dots + \alpha_0(z')z^0 \right). \tag{3.8}$$

The α_i for $i = 0, \dots, k-1$ correspond to holomorphic Casimir invariants of $SU(k)$ built from the vevs of the defect modes. So in other words, we can capture all the effects of unfolding by a suitable $SU(k)$ Higgs field with poles along the localized matter of a parent $SU(N)$ gauge theory.

4 Geometric remnants of T-branes

In this section we argue that T-brane data should be viewed in the dual M-theory and type IIA descriptions as the remnants of three-form potential moduli. This is in accord with $\mathcal{N} = (1, 0)$ supersymmetry in six dimensions, where the three-form potential moduli fiber over the complex structure moduli. By abuse of notation, we shall sometimes refer to the three-form potential moduli simply as ‘‘RR moduli’’.

Since we are now asking how to go from the closed string moduli space back to the open string moduli of a T-brane configuration, we will assume that we have started with a compact Calabi-Yau threefold X_{cpt} , and that we have taken a local limit for this system which consists of a curve of ADE singularities possibly coupled to defects. In this section, we shall therefore confine our discussion to a family of non-compact smooth Calabi-Yau threefolds X_t such that the $t \rightarrow 0$ limit defines a curve of ADE singularities. In fact, since these local models can be embedded in F-theory, it will be enough for us to consider the related compactification of IIA string theory on the background X_t .

The plan should now be clear: we shall study the degeneration of the hypermultiplet moduli space, and in particular the intermediate Jacobian $J(X_t)$ as $t \rightarrow 0$. There are at least two difficulties with this approach. First, there is no well-defined notion of a limit of a family of complex tori, and second, naive definitions of this limit do not match the

expected properties of the RR moduli space, and in particular the hypermultiplet moduli space of the low energy effective theory.

Both issues are symptoms of the fact that near the singular points of the moduli space, some of the three-cycles are about to disappear from the classical geometry. This is also reflected in monodromies in the basis of three-cycles around the singular points in moduli space. To study this behavior, we apply the machinery of limiting mixed Hodge structures. Using this, we can introduce a trajectory dependent notion of the intermediate Jacobian as it approaches a singular point in moduli space. This will allow us to establish that as $t \rightarrow 0$, the geometric characterization becomes singular, but that the geometry points to the appearance of a Hitchin system. We stress that in this discussion we do not put the Hitchin system in “by hand” ahead of time. Rather, we will see this structure *emerge*!

Our plan in this section will be to describe in more precise terms this limiting operation. The main mathematical tool we use is known as the theory of “limiting mixed Hodge structures” (LMHS). Since this may be unfamiliar to some readers, we illustrate some elementary aspects of this theory in the case of the conifold. We then apply this machinery to the cases of interest for geometric engineering in string theory. We illustrate how to recognize the appearance of a Hitchin system for an isolated curve of ADE singularities, building on the work of [76, 77]. Then, we illustrate how to extend this to geometries which include collisions with other singularities. In physical terms, this corresponds to a situation where the seven-brane is coupled to charged defect modes. When these modes get a vev, we induce poles in the gauge field and Higgs field of the Hitchin system. We show that our analysis of limiting mixed Hodge structures extends to this case as well, and that the remnants of the RR moduli are accounted for by a parabolic Hitchin system.

4.1 Limiting mixed Hodge structures

Before launching into our analysis, we would first like to give some general background on why the theory of limiting mixed Hodge structures is the relevant machinery for our analysis. For additional details, we refer the interested reader to appendix A.

Our basic claim is that T-brane data comes about from the limiting behavior of the intermediate Jacobian. The idea here is to consider not a single Calabi-Yau threefold, but rather, a whole family of them X_t , with t a smoothing parameter. The singular limit corresponds to taking $t \rightarrow 0$. The straightforward approach would be to simply compute $J(X_t)$ for each non-zero t and to then extrapolate to the singular limit.

Now, for *generic* points of complex structure moduli, there is indeed a natural notion of parallel transport for the complex structure given by the Gauss-Manin connection. We can extend this to the intermediate Jacobian, so we can also naturally consider how this space responds to variations in the complex structure.

Subtleties materialize in singular limits. Indeed, at a singular point in complex structure moduli, some elements in the basis of three-cycles will start to disappear. One way to see this is by considering monodromies in the parameter t around the singular point $t = 0$. Such monodromies can reshuffle the original basis of three-cycles, and can also mix the spaces $H^{p,q}(X)$ of the Kähler manifold.

To isolate the effects of monodromy we need a refined notion of how to define a family of intermediate Jacobians. The basic idea is to have a notion of complex structure moduli and intermediate Jacobian in which we can “untwist” the effects of monodromy, i.e. by going to a suitable cover. This is where the theory of mixed Hodge structure, and in particular limiting mixed Hodge structure comes to the fore. To have a natural notion of a holomorphic family of Hodge structures, we can take $H^{p,q}(X)$, and add to it all other spaces which can mix with it under parallel transport with respect to the Gauss-Manin connection. In the case of a Kähler manifold, a well-known example of this type is the Hodge filtration:

$$F^p H^k(X, \mathbb{C}) = \bigoplus_{p' \geq p} H^{p', k-p'}(X). \tag{4.1}$$

This has the property that $F^p \subset F^{p'}$ for $p > p'$, i.e. it defines a decreasing filtration. It is common to refer to the entire filtration as F^\bullet . By a similar token, we can also introduce an increasing filtration W_\bullet , known as the “weight filtration”.

Now, the utility of introducing this additional formalism is that as we move around in the parameter t , this filtration structure remains intact, so we have a well-defined notion of parallel transport on the vector spaces. We can then define various limits of this Hodge structure by a choice of trajectory $t \rightarrow 0$. To this degeneration is associated a limiting mixed Hodge structure which is denoted by H_{lim}^3 . Details are reviewed in appendix A.2.

Since the intermediate Jacobian fibers over the complex structure moduli, we can extend these considerations fiberwise. Along these lines, we can introduce a generalized notion of the intermediate Jacobian for a cohomology theory H by quotienting $H_{\mathbb{C}}$, the complexification of the integral cohomology:

$$J^p H = H_{\mathbb{C}} / (F^p H_{\mathbb{C}} + H_{\mathbb{Z}}). \tag{4.2}$$

where $H_{\mathbb{Z}}$ refers to the cohomology theory with integer coefficients. When $p = 2$ and X is smooth, we get back our previous notion of the intermediate Jacobian $J(X_t)$, though now, we can track the behavior of this space as we move towards a singular limit. In what follows, we shall refer to this limiting behavior as $J^2(H_{\text{lim}}^3)$, in the obvious notation.

By now, it should hopefully be clear that the theory of limiting mixed Hodge structure is the appropriate tool for tracking the behavior of the intermediate Jacobian as we move towards singular limits. We now illustrate how this machinery works in progressively more involved examples, and show that it matches to the expected behavior of T-branes.

4.2 Warmup: the conifold

By way of example, in this subsection we show how to calculate the limiting behavior of the intermediate Jacobian in the case of conifold singularities. See appendix A for additional details.

Before we describe the deformation theory of conifold singularities, we digress by reviewing the deformation theory of a general affine hypersurface singularity. Given any affine hypersurface X defined by $f(x_1, \dots, x_r) = 0$ in \mathbb{C}^r , the space of first order deformations of

X is identified with the vector space underlying the Jacobian ring

$$\mathcal{J}_f = \mathbb{C}[x_1, \dots, x_r] / \left(\frac{\partial f}{\partial x_i} \right). \quad (4.3)$$

Now, the first order deformations of an arbitrary variety X are given by the vector space $\text{Ext}^1(\Omega_X^1, \mathcal{O}_X)$. The local to global spectral sequence leads to

$$0 \rightarrow H^1(X, \underline{\text{Ext}}^0(\Omega_X^1, \mathcal{O}_X)) \rightarrow \text{Ext}^1(\Omega_X^1, \mathcal{O}_X) \rightarrow H^0(X, \underline{\text{Ext}}^1(\Omega_X^1, \mathcal{O}_X)). \quad (4.4)$$

Here, $\underline{\text{Ext}}^i$ denotes “local Ext” and is a sheaf on X . In particular given sheaves F and G on X , the sheaf $\underline{\text{Ext}}^0(F, G)$ is the sheaf whose sections on sufficiently small open sets are just the local homomorphisms from F to G .

Since Ω_X^1 is locally free on the smooth locus of X , it follows that the sheaf $\underline{\text{Ext}}^1(\Omega_X^1, \mathcal{O}_X)$ vanishes there, hence is supported on the singular locus of X . We put

$$\mathcal{T}^1 = \underline{\text{Ext}}^1(\Omega_X^1, \mathcal{O}_X) \quad (4.5)$$

and the last map in (4.4) describes the restriction of a first order deformation of X to a first order deformation of the singular locus of X . Note that this map need not be surjective. In more detail, it is natural to study the limiting mixed Hodge structure H_{lim}^3 of a generic degeneration, to which a Jacobian is associated:

$$J^2(H_{\text{lim}}^3) = H_{\text{lim}}^3 / (F^2 H_{\text{lim}}^3 + H_{\text{lim}, \mathbb{Z}}^3), \quad (4.6)$$

where $F^2 H_{\text{lim}}^3$ denotes a piece of the Hodge filtration and $H_{\text{lim}, \mathbb{Z}}^3$ denotes the integer lattice of the mixed Hodge structure H_{lim}^3 .

Let us now illustrate these aspects for the case of a conifold singularity. From (4.3), a single conifold singularity

$$w^2 + x^2 + y^2 + z^2 = 0, \quad (4.7)$$

has a ring of first order deformations:

$$\mathbb{C}[w, x, y, z] / (w, x, y, z) \simeq \mathbb{C}, \quad (4.8)$$

which tells us that the first order deformations of the conifold are all given by

$$w^2 + x^2 + y^2 + z^2 = t, \quad (4.9)$$

as is well-known.

More generally, let us now consider the case of X a Calabi-Yau threefold with only conifold singularities. The calculation (4.8) shows that \mathcal{T}^1 is a skyscraper sheaf supported at the conifolds whose stalks are all isomorphic to \mathbb{C} . Returning to the exact sequence of (4.4):

$$0 \rightarrow H^1(X, \underline{\text{Ext}}^0(\Omega_X^1, \mathcal{O}_X)) \rightarrow \text{Ext}^1(\Omega_X^1, \mathcal{O}_X) \rightarrow H^0(X, \underline{\text{Ext}}^1(\Omega_X^1, \mathcal{O}_X)), \quad (4.10)$$

the term $H^1(X, \underline{\text{Ext}}^0(\Omega_X^1, \mathcal{O}_X))$ is the space of first-order deformations which preserve the conifold singularities, $\text{Ext}^1(\Omega_X^1, \mathcal{O}_X)$ is the space of all first order deformations, and

$H^0(X, \underline{\text{Ext}}^1(\Omega_X^1, \mathcal{O}_X))$ is the space of local deformations of the conifolds. By abuse of notation, we shall refer to a smoothing of X by X_t , so that $t \rightarrow 0$ denotes the singular case.

For expository purposes, we assume that X has a small Kähler resolution \tilde{X} , in which case a smoothing X_t of X completes a conifold transition. We now show in this case that the intermediate Jacobian $J(X_t)$ has a canonical limiting behavior as $t \rightarrow 0$.

Basically, we need to find a basis of three-cycles to calculate the periods of the RR moduli, and then track the behavior of these periods as $t \rightarrow 0$. Associated with each conifold point is a vanishing cycle in $H^3(X_t, \mathbb{Z})$, Poincaré dual to the class in $H_3(X, \mathbb{Z})$ of the familiar vanishing S^3 near the conifold point. In general, if there are m such conifold points they will typically only span a lattice \mathcal{W} of rank $m - r$ for some $0 \leq r < m$. This number r is nothing other than the jump in the Hodge numbers in passing from the deformed side of the conifold to the resolved side [78–80]:

$$h^{1,1}(\tilde{X}) = h^{1,1}(X_t) + r, \quad h^{2,1}(\tilde{X}) = h^{2,1}(X_t) + r - m. \quad (4.11)$$

We also have in this case that $\dim H^0(X, \underline{\text{Ext}}^1(\Omega_X^1, \mathcal{O}_X)) = m - r$.

For example, in the conifold transition of the quintic acquiring 16 conifolds, we have $h^{1,1}(X_t) = 1, h^{2,1}(X_t) = 101, m = 16, r = 1$. So the Hodge numbers of \tilde{X} in that case are $h^{1,1}(\tilde{X}) = 2$ and $h^{2,1}(\tilde{X}) = 86$.

Next, let H_{lim}^3 denote the limiting mixed Hodge structure of the smoothing of a conifold (which is a mixed Hodge structure on $H^3(X_t)$). For now, all we need to know is that a mixed Hodge structure H has an increasing filtration, the weight filtration, which we denote by $W_i H_{\mathbb{Q}}$ since it is a vector space defined over the rationals. Letting $Gr_k H_{\mathbb{Q}} = W_k H_{\mathbb{Q}} / W_{k-1} H_{\mathbb{Q}}$ be the associated graded vector space, we compute in appendix A that

$$\begin{aligned} Gr_4 H_{\text{lim}}^3 &\simeq \mathcal{W}_{\mathbb{Q}} \\ Gr_3 H_{\text{lim}}^3 &\simeq H^3(\tilde{X}, \mathbb{Q}) \\ Gr_2 H_{\text{lim}}^3 &\simeq \mathcal{W}_{\mathbb{Q}}, \end{aligned} \quad (4.12)$$

where $\mathcal{W}_{\mathbb{Q}} = \mathcal{W} \otimes \mathbb{Q}$.

Now, recall that to any mixed Hodge structure H , we can associate for each p a generalized Jacobian

$$J^p H \equiv H_{\mathbb{C}} / (F^p H_{\mathbb{C}} + H_{\mathbb{Z}}). \quad (4.13)$$

So, returning to the smoothing X_t from the conifold transition, instead of examining the limiting mixed Hodge structure, which is a limit of third cohomologies, for the purpose of computing RR moduli we study the limit of the intermediate Jacobians $J(X_t)$. This can be determined from $J^2 H_{\text{lim}}^3$. In appendix A, we compute that

$$J^2 H_{\text{lim}}^3 \text{ is a } (\mathbb{C}^*)^{m-r} \text{ fibration over } J(\tilde{X}), \quad (4.14)$$

independent of the choice of smoothing X_t . We further show in appendix A that the extension class of the mixed Hodge structure $W_3 H_{\text{lim}}^3$ determines the global structure of this $(\mathbb{C}^*)^{m-r}$ fibration. Thus, we conclude that the $(\mathbb{C}^*)^{m-r}$ fiber over $J(\tilde{X})$ is the moduli space of the RR fields on X associated with the singularities.

Near X , the hypermultiplet moduli space of X fibers over the complex $m - r$ dimensional moduli space parametrizing the smoothings of the conifolds (the space whose tangent space is the image of the rightmost map in (4.4)). The fibers of this map in turn fiber over the hypermultiplet moduli space of \tilde{X} , with fibers $(\mathbb{C}^*)^{m-r}$. Locally, the two complex $m - r$ dimensional spaces just described combine into $m - r$ quaternionic moduli.

If we do not assume that X has a small Kähler resolution \tilde{X} , we simply replace $J(\tilde{X})$ with $J(\hat{X})$, where \hat{X} is the (non-Calabi-Yau) blowup of the conifolds of X . Note that $J(\hat{X}) = J(\tilde{X})$ when \tilde{X} exists, since no new 3-cycles are created in blowing up \tilde{X} to \hat{X} .

4.3 Isolated curve of ADE singularities

We now turn to the first case of interest with non-abelian gauge symmetry, given by a curve of ADE singularities in IIA string theory. Such singularities generate the corresponding ADE gauge theory in the six-dimensional effective theory. Non-simply laced gauge theories occur when there is an appropriate monodromy action in the fiber [59].

In contrast to the previous case of the conifold, all of our examples from this point on have the property that the limiting mixed Hodge structure analysis depends on the trajectory we take as $t \rightarrow 0$. Physically, this is to be expected, because each choice of trajectory corresponds to a different identification of the W - and Z - bosons of an $\mathfrak{su}(2)$ factor. By sweeping over all possible trajectories, however, we can extract the trajectory independent data associated with the limiting mixed Hodge structures. In the physical theory, these different trajectories correspond to conjugation by elements of the broken gauge symmetry.

To begin our geometric analysis, we recall the local presentation for the different ADE singularities:

$$A_N : xy = z^{N+1} + \dots \tag{4.15}$$

$$D_N : y^2 = x^2z + z^{N-1} + \dots \tag{4.16}$$

$$E_6 : y^2 = x^3 + z^4 + \dots \tag{4.17}$$

$$E_7 : y^2 = x^3 + xz^3 + \dots \tag{4.18}$$

$$E_8 : y^2 = x^3 + z^5 + \dots \tag{4.19}$$

where the curve C is defined by $x = y = z = 0$ and x, y, z lie in respective line bundles L_x, L_y, L_z on C . The Calabi-Yau condition together with the adjunction formula and homogeneity of the above equations constrains the bundle assignments for L_x, L_y , and L_z . For example, in the A_N singularity we have $L_x \otimes L_y \simeq K_C^{\otimes N+1}$ and $L_z \simeq K_C$. For additional explanation and the relation to gauge theory on a seven-brane, see for example [2].

The first order smoothing deformations of the singularities are captured by \mathcal{T}^1 of equation (4.5). In physical terms, we know that this unfolding corresponds to activating a non-zero adjoint-valued Higgs field, and explicit checks between the two descriptions have been carried out, for example in [2, 4, 47, 76, 77]. Here, $H^0(\mathcal{T}^1)$ corresponds to the base of the Hitchin fibration with gauge group corresponding to the singularity type.⁸

In fact, even more is true. In [76, 77] it was observed that away from the discriminant locus, the Hitchin system is identified with the Calabi-Yau integrable system whose fibers

⁸In [76, 77] only the local case was considered, but $H^0(\mathcal{T}^1)$ only depends on a neighborhood of C .

are the local contributions to the intermediate Jacobian.⁹ In this context, the discriminant locus equivalently parametrizes singular Calabi-Yaus, or singular spectral covers.

Our assertion is that the local RR moduli space over $H^0(\mathcal{T}^1)$ is completed over the discriminant locus by the Hitchin system. As with the case of conifolds, this part of the moduli space can be realized globally inside a moduli space associated with a limiting mixed Hodge structure. Similar to the case of conifolds, the hypermultiplet moduli space can be related to the hypermultiplet moduli space of the blowup \tilde{X} of X by two fibrations.

4.3.1 Example: a curve of A_N singularities

Let us now illustrate these general considerations in the specific case of a curve of A_N singularities:

$$xy = z^{N+1}. \tag{4.20}$$

If we view this as the equation of a hypersurface in \mathbb{C}^4 with coordinates (w, x, y, z) , the ring of first order deformations becomes

$$\mathbb{C}[w, x, y, z]/(x, y, z^N) \simeq \mathbb{C}[w, z]/(z^N), \tag{4.21}$$

where w is a local coordinate on C . Thus, to first order, deformations can be written as

$$xy = z^{N+1} + \sum_{j=2}^{N+1} a_j(w)z^{N+1-j}. \tag{4.22}$$

Since z is a section of K_C (via the Calabi-Yau condition), equation (4.22) must now be interpreted as a section of $\mathcal{O}(K_C^{\otimes N+1})$, so we conclude that the $a_j(w)$ are to be understood as sections of $\mathcal{O}(K_C^{\otimes j})$. We therefore see that

$$\mathcal{T}^1 = i_* \left(\bigoplus_{j=2}^{n+1} \mathcal{O}(K_C^{\otimes j}) \right), \tag{4.23}$$

where $i : C \hookrightarrow X$ is the inclusion.

Specializing further, we now verify the claim that in the case of an A_1 singularity, the remnant of the RR moduli is captured by the Hitchin system. More precisely, our proposal is that the RR moduli of X combined with the moduli of global deformations of the complex structure which preserve the singularity are fibered over the intermediate Jacobian of the small resolution, with fiber the corresponding Prym in the fiber of the Hitchin system. In other words, the Hitchin system describes the missing piece of the RR moduli. A consequence of this proposal is that T-branes arise naturally from Pryms of singular spectral covers. A similar but more involved analysis holds for the case of A_N singularities for all N .

Reverting to IIA language, we want to see the local contribution to the RR moduli of X when we have a curve C of A_1 singularities. So we want to see the fiber over the origin of the $SU(2)$ Hitchin system, i.e. the nilpotent cone defined by $\text{Tr}(\Phi^2) = 0$, which

⁹There are subtle differences in comparing families of complex tori between isomorphism and a torsorial relationship; we ignore these issues here.

was worked out in detail in [81]. The nilpotent cone has many components; the component called N_0 in [81] corresponds to T-branes whose Higgs fields do not vanish anywhere. One such example is given in [66] by the bundle $E = K_C^{1/2} \oplus K_C^{-1/2}$, with Higgs field

$$\Phi = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \tag{4.24}$$

where 1 is identified with a section of $\text{Hom}(K_C^{1/2}, K_C^{-1/2} \otimes K_C)$ in the natural way.

The general point of N_0 corresponds to a rank 2 bundle E fitting into an exact sequence:

$$0 \rightarrow K_C^{-1/2} \rightarrow E \rightarrow K_C^{1/2} \rightarrow 0. \tag{4.25}$$

The corresponding Higgs field Φ is given by the composition

$$E \rightarrow K_C^{1/2} \simeq K_C^{-1/2} \otimes K_C \rightarrow E \otimes K_C. \tag{4.26}$$

The extensions (4.25) are parameterized by $\text{Ext}^1(K_C^{1/2}, K_C^{-1/2}) \simeq H^1(-K_C)$, which is Serre dual to $H^0(2K_C)$ and has dimension $3g - 3$, as expected. Note that $\Phi^2 = 0$, although Φ can no longer be described in a block diagonal form, as E need not be decomposable.

We now smooth the A_1 singularity and calculate the limiting mixed Hodge structure. We have

$$H^0(\mathcal{T}^1) \simeq H^0(X, i_*(\mathcal{O}(2K_C))) = H^0(C, \mathcal{O}(2K_C)), \tag{4.27}$$

the space of quadratic differentials, where $i : C \hookrightarrow X$ is the inclusion. Then, a smoothing is given by $xy = z^2 + q$, with $q \in H^0(C, \mathcal{O}(2K_C))$. For technical reasons, we consider the degeneration

$$xy = z^2 + t^2q \tag{4.28}$$

as $t \rightarrow 0$. We work out the limiting mixed Hodge structure in appendix A. We will see, as already follows from [76, 77], that the limiting mixed Hodge structure is actually a pure Hodge structure of weight 3. We compute that the local contribution to $J^2 H_{\text{lim}}^3$ is the Prym variety of $z^2 + q = 0$, the fiber of the Hitchin map over $\text{Tr}(\Phi^2) = q$.

To define this Prym variety, let $Z \subset C$ be the zero set of q , assumed to be $4g - 4$ distinct points. We introduce the double cover:

$$\pi : \tilde{C} \rightarrow C, \tag{4.29}$$

which is branched along Z , so that \tilde{C} has genus $4g - 3$. Letting $J_{g-1}(\tilde{C})$ denote the space of line bundles of degree $g - 1$ on \tilde{C} , then the Prym is given by:

$$\text{Prym}(\tilde{C}/C) = \left\{ L \in J_{2g-2}(\tilde{C}) \mid \iota^* L \simeq \pi^* K_C \otimes L^{-1} \right\} \tag{4.30}$$

where $\iota : \tilde{C} \rightarrow \tilde{C}$ is the involution which interchanges the two sheets of the double cover. The space $\text{Prym}(\tilde{C}/C)$ can be seen to have dimension $3g - 3$.¹⁰

¹⁰The computation of the limiting mixed Hodge structure gives more in fact: the limiting intermediate Jacobian fibers over the intermediate Jacobian of the blowup of X , with fiber the Prym variety discussed here.

This situation is directly related to the $SU(2)$ Hitchin system as follows. First of all, q is naturally identified with a point of the Hitchin base, and \tilde{C} is the associated spectral cover, as given by the equation

$$\tilde{C} = \{y \in \text{Tot}(K_C) \mid y^2 = q\}. \tag{4.31}$$

Then the Higgs bundle is reconstructed by the usual procedure, putting $E = \pi_*(L)$ and deducing the Higgs field $E \rightarrow E \otimes K_C$ from the embedding $\tilde{C} \subset \text{Tot}(K_C)$.

This computation makes clear that, in contrast to the conifold case, the limiting mixed Hodge structure *cannot* be the correct identification of the RR moduli, since it depends nontrivially on the choice of q . As already mentioned, this choice effectively dictates a trajectory for the smoothing to approach the singular limit.

However, we can also see that by sweeping over all different trajectories of smoothings, that the calculation points directly to the Hitchin system. Note that the fiber of the Hitchin system over t^2q is independent of t (as $z^2 + q = 0$ is seen to be isomorphic to $z^2 + t^2q = 0$ by rescaling z), which explains why naively taking the limit as $t \rightarrow 0$ gives a spurious result. Nevertheless, the Hitchin system itself provides a well-defined notion of RR moduli, within which the $t \rightarrow 0$ limit makes perfect sense and is independent of q .

4.3.2 Example: unfolding an A_1 factor

In the previous example we focussed on recovering the remnant of T-brane data for a curve of A_1 singularities. More generally, given X a curve of ADE singularities corresponding to a gauge theory of rank r , we can blow up $r - 1$ of the fiber \mathbb{P}^1 's to reach a still singular space \tilde{X}_{sing} . The remaining gauge symmetry in the Hitchin system is $U(1)^{r-1} \times SU(2)$, and indeed, there is a single smoothing deformation in this case as well. Since we are performing a blowup on some factors, and a smoothing on others, we refer to this smoothing as \tilde{X}_t . As a consequence, the analysis of the previous section easily extends to the unfolding patterns:

$$A_N : xy = z^{N-1}(z^2 + t^2q) \tag{4.32}$$

$$D_N : y^2 = x^2z + z^{N-2}(z + t^2q) = 0, \tag{4.33}$$

$$E_6 : y^2 = x^3 + z^2(z^2 + t^2qx) \tag{4.34}$$

$$E_7 : y^2 = x^3 + xz(z^2 + t^2qx) \tag{4.35}$$

$$E_8 : y^2 = x^3 + z^3(z^2 + t^2qx) \tag{4.36}$$

where in each case, q corresponds to a quadratic differential for the $\mathfrak{su}(2)$ valued Higgs field, i.e. $q = \text{Tr}(\Phi^2)$. Note that in all cases, this quadratic differential is a section of K_C^2 .

In the A_N case, we see directly that the associated $SU(2)$ spectral curve \tilde{C} is given by $z^2 + t^2q = 0$. Since in the other cases there are only cameral covers rather than spectral covers, we do not expect to see the embedded $SU(2)$ spectral cover directly from the equation, but it can be checked that in each case, the spectral cover is indeed $z^2 + t^2q = 0$.¹¹ The main point is that after a change of variables, the deformation after

¹¹We caution the reader that here, z is valued in $\mathcal{O}(K_C)$, so differs from the coordinate z appearing in (4.33)–(4.36).

the partial blowup can be rewritten in the form $xy = z^2 + t^2q$ in each case [82]. It is now clear that we construct $\text{Prym}(\tilde{C}/C)$ in the same way as before. Taking the limit $t \rightarrow 0$, we again see that the limiting behavior of the intermediate Jacobian $J(\tilde{X}_t)$ again points back to the T-brane data of the Hitchin system.

A similar analysis also allows us to cover some situations where the Hitchin system couples to defect modes. Indeed, we can consider the deformation X_t associated with the partial smoothing of the singularity. Following the general procedure of [59, 83], in all of these cases there are matter fields localized at the intersections of the component curves. Initiating a further unfolding pattern, we can now in principle track the RR moduli by a further unfolding.

Let us give a concrete example of this type. We derive the moduli space in the special case of breaking $\text{SU}(3)$, i.e. a curve of A_2 singularities which we unfold via:

$$xy = (z - \omega)^2(z + 2\omega), \tag{4.37}$$

where ω is a section of K_C . There are now two factors, which we denote by \tilde{C}' given by $z = -2\omega$, and the multiplicity 2 curve \tilde{C}'' given by $z = \omega$.

In this new system, there is localized matter trapped at the zeroes of ω . So, we get an $S(\text{U}(2) \times \text{U}(1))$ Hitchin system coupled to defects which transform as bifundamentals of the algebra $\mathfrak{su}(2) \times \mathfrak{u}(1)$. The $\mathfrak{su}(2)$ factor of the algebra is localized on the component $z = \omega$, while the $\mathfrak{u}(1)$ factor is spread over both $z = \omega$ and $z = -2\omega$.

The vevs of the trapped matter can generate localized T-brane data in the original $\text{SU}(3)$ Hitchin system. Alternatively, one can view this as “gluing data” in the sense of [52, 53]. To see this, observe that the Hitchin base for the $\text{SU}(3)$ system is $H^0(2K_C) \oplus H^0(3K_C)$, and the associated spectral curve \tilde{C} has equation:

$$(z - \omega)^2(z + 2\omega) = 0. \tag{4.38}$$

We pick a line bundle L on \tilde{C} such that π_*L is an $\text{SU}(3)$ bundle, where π is the projection to the base curve. Let Z be the intersection $\tilde{C}' \cap \tilde{C}''$, which is a length 2 scheme at each of the $2g - 2$ points of intersection, corresponding to the zeroes of ω . Turning next to the classification of line bundles on \tilde{C} , the exact sequence

$$0 \rightarrow \mathcal{O}_{\tilde{C}}^* \rightarrow \mathcal{O}_{\tilde{C}'}^* \oplus \mathcal{O}_{\tilde{C}''}^* \rightarrow \mathcal{O}_Z^* \rightarrow 0 \tag{4.39}$$

yields

$$0 \rightarrow H^0(\mathcal{O}_{\tilde{C}}^*) \rightarrow H^0(\mathcal{O}_{\tilde{C}'}^*) \oplus H^0(\mathcal{O}_{\tilde{C}''}^*) \rightarrow H^0(\mathcal{O}_Z^*) \rightarrow H^1(\mathcal{O}_{\tilde{C}}^*) \rightarrow H^1(\mathcal{O}_{\tilde{C}'}^*) \oplus H^1(\mathcal{O}_{\tilde{C}''}^*) \rightarrow 0 \tag{4.40}$$

The first two terms are just constant functions, and the third has dimension $2(2g - 2)$, so the net contribution to the dimension of the group $H^1(\mathcal{O}_{\tilde{C}}^*)$ of line bundles L on C is $4g - 5$. Next we have $g + (4g - 3)$ parameters from the next H^1 's (since they are the fibers of a $\text{U}(1)$ and $\text{U}(2)$ Hitchin system, respectively). Finally, we have to reduce these moduli by g since we want π_*L to be an $\text{SU}(3)$ bundle rather than just a $\text{U}(3)$ bundle. The conclusion is that we have $8g - 8$ parameters in all, and we have accounted for the entire fiber of the $\text{SU}(3)$ Hitchin system.

4.4 More general defects

In this subsection we extend our match of the limiting behavior of the intermediate Jacobian to more general configurations where the Hitchin system supports defect modes. In contrast to the analysis of the last subsection, we do not assume the existence of a globally defined parent gauge theory which Higgses down to the configuration of intersecting branes.

In field theory terms, we will now be interested in a Hitchin system on a curve C which is coupled to k defects modes located at points $p_1, \dots, p_k \in C$. We saw in section 3 that activating a vev for a localized matter field generates a pole for the Higgs field, and a delta function concentrated flux. The mathematical object which captures this pole data is a parabolic Higgs bundle. For an introduction to this construction, see for example [84].

Here, we illustrate this for the case of A_{N-1} singularities whose general sections at finitely many points are A_N singularities. This is the situation which would arise in F-theory at transverse collision points of I_N and I_1 components of the discriminant.

Let $P = p_1 + \dots + p_k$ denote the divisor associated with the $k = |P|$ points on C where there is a defect. For ease of exposition, suppose that near any p_i , the local equation of the singularity can be put in the form:

$$xy = z^{N+1} + wz^N, \tag{4.41}$$

where the curve C is defined by $x = y = z = 0$ and w restricts to a local coordinate on C centered at p_i . We now study the deformation theory of this singularity. Locally, the sheaf \mathcal{T}^1 is given by the Jacobian ring, which in this case is

$$\mathbb{C}[x, y, z, w]/(x, y, (N+1)z^n + Nwz^{N-1}, z^N) = \mathbb{C}[x, y, z, w]/(x, y, z^N, wz^{N-1}). \tag{4.42}$$

Now, \mathcal{T}^1 is not a line bundle at $w = 0$ due to the presence of torsion: $z^{N-1} \in \mathcal{T}^1$ is a torsion element of \mathcal{T}^1 supported at p_i , as it is annihilated by the maximal ideal (x, y, z, w) at p_i . Modding out by this torsion element gives

$$\mathcal{T}^1 / (\mathbb{C} \cdot z^{N-1}) \simeq \mathbb{C}[x, y, z, w]/(x, y, z^N) \simeq \mathbb{C}[z, w]/z^N. \tag{4.43}$$

Since the quotient is a vector bundle as before, there can be no torsion element other than scalar multiples of z^{N-1} .

Globally, the torsion subsheaf $\text{Tors}(\mathcal{T}^1)$ of \mathcal{T}^1 is a skyscraper sheaf supported on P , one-dimensional over each $p_i \in P$, and the quotient $\mathcal{T}^1/\text{Tors}(\mathcal{T}^1)$ is a vector bundle on C . We can infer the global structure of this bundle from the term wz^N in (4.41), which is a section of $\mathcal{O}(NK_C)$ times a local equation for $p_i \in P$. Globally, this is a section of $\mathcal{O}(NK_C + P)$.

The deformations of (4.41) corresponding to the local generators $(z^{N-1}, z^{N-2}, \dots, z, 1)$ of $\mathcal{T}^1/(\text{Tors}(\mathcal{T}^1))$ as an \mathcal{O}_C bundle (cf 4.43) can be written as

$$xy = z^{N+1} + wz^N + \sum_{j=2}^N a_j(w)z^{N-j}. \tag{4.44}$$

Globally, the equation needs to hold in $\mathcal{O}(NK_C + P)$, and so can be written as

$$xy = rz^{N+1} + sz^N + \sum_{j=2}^N a_j z^{N-j}, \tag{4.45}$$

where z as before is in the bundle $\mathcal{O}(K_C)$, s is a global section of $\mathcal{O}(P)$ vanishing at P , $r \in H^0(\mathcal{O}(P - K_C))$, and $a_j \in H^0(\mathcal{O}(jK_C + P))$.

This calculation shows that

$$\mathcal{T}^1/(\text{Tors}(\mathcal{T}^1)) \simeq i_* (\mathcal{O}_C(2K_C + P) \oplus \mathcal{O}_C(3K_C + P) \oplus \cdots \oplus \mathcal{O}_C(NK_C + P)). \quad (4.46)$$

For later use, note that if we set $s = a_i = 0$ (and add higher order terms), we get an $SU(N + 1)$ theory with matter localized at the zeros of r . Turning on s corresponds to partially Higgsing to $SU(N)$. If we use a parabolic Hitchin system to describe the $SU(N + 1)$ theory, then we will see later that the complex structure deformation given by s partners with RR moduli and can collectively be described by a parabolic $SU(2)$ Hitchin system with singularities at the zeros of r .

Returning to our main line of development, we therefore get an exact sequence

$$0 \rightarrow \text{Tors}(\mathcal{T}^1) \rightarrow \mathcal{T}^1 \rightarrow i_* (\mathcal{O}_C(2K_C + P) \oplus \mathcal{O}_C(3K_C + P) \oplus \cdots \oplus \mathcal{O}_C(nK_C + P)) \rightarrow 0. \quad (4.47)$$

As a check, we have an $SU(N)$ gauge symmetry with g adjoints and $|P|$ fundamentals. From our analysis in subsection 3.1, we know that we should find $(N^2 - 1)(g - 1) + N|P|$ complex structure deformations. We check this against $H^0(\mathcal{T}^1)$. From (4.47) we get:

$$0 \rightarrow H^0(\text{Tors}(\mathcal{T}^1)) \rightarrow H^0(\mathcal{T}^1) \rightarrow \bigoplus_{j=2}^N H^0(\mathcal{O}(jK_C + P)) \rightarrow 0. \quad (4.48)$$

But $h^0(\text{Tors}(\mathcal{T}^1)) = |P|$, while $h^0(\mathcal{O}(jK_C + P)) = (2j - 1)(g - 1) + |P|$ by Riemann-Roch, and so $h^0(\mathcal{T}^1) = |P| + \sum_{j=2}^N ((2j - 1)(g - 1) + |P|) = (N^2 - 1)(g - 1) + N|P|$, as expected.

Now we turn to the RR moduli for the smoothed system and track their behavior in the limit where we switch off the smoothing parameters. We will show that a parabolic Hitchin system emerges from the limiting mixed Hodge structure. For each point $p \in P$ we associate a vector space V_p with a flag $0 \subset W_p \subset V_p$ with $\dim W_p = 1$. The parabolic Hitchin system allows Higgs fields Φ which are meromorphic along P , and whose residues are nilpotent with respect to the flag. The nilpotency condition assures that the Casimirs of Φ are sections of $\mathcal{O}(jK_C + P)$, which should be compared to (4.48).

In appendix A we present a special example where $N = 2$. We then compute the limiting mixed Hodge structure of the degeneration

$$xy = rz^3 + sz^2 + t^2q, \quad (4.49)$$

where $q \in H^0(\mathcal{O}(2K_C + P))$. As in the conifold case, the limiting mixed Hodge structure has weights 2, 3, and 4. The weight 2 part is $|P|$ -dimensional. For the Jacobian of H_{lim}^3 , we get a $(\mathbb{C}^*)^{|P|}$ fibration over the Jacobian of the ordinary weight 3 Hodge structure $Gr_3 H_{\text{lim}}^3$. We also see that the contribution of the singularity to $J^2(Gr_3 H_{\text{lim}}^3)$ is precisely the fiber over $q \in H^0(2K_C + P)$ of an $SU(2)$ parabolic Hitchin system.

We therefore assert that the local part of the hypermultiplet moduli space in which the location of the points P are fixed fibers over a parabolic Hitchin system with fibers the local RR moduli of complex dimension $|P|$. The $|P|$ -dimensional RR moduli are computed in appendix A. These RR moduli combine with the $|P|$ complex moduli corresponding to complex structure deformations moving the points P (i.e. to $H^0(\text{Tors}(\mathcal{T}^1))$) to form $|P|$ quaternionic moduli.

4.4.1 Example: a local F-theory model

To illustrate the considerations of the previous subsection, we now turn to a local F-theory model involving a seven-brane wrapping a \mathbb{P}^1 with some number of punctures. Along these lines, we consider the elliptic Calabi-Yau threefold with base the Hirzebruch surface \mathbb{F}_n :

$$y^2 = x^3 + g_{12+n}(z')z^5 + f_8(z')xz^4 + g_{12}(z')z^6 + g_{12-n}(z')z^7 \quad (4.50)$$

where (z, z') are respectively coordinates in the fiber and base of \mathbb{F}_n . To get a consistent F-theory model (i.e. not violate the Calabi-Yau condition after blowing up), we need to take $-12 \leq n \leq 12$. For additional review, see [57–59] and our later discussion of T-branes in global models in subsection 6.1.

For our present purposes, the main point is that there is an E_8 singularity located at $z = 0$ and another one at $z = \infty$.¹² These are associated with a seven-brane wrapping a divisor given by a \mathbb{P}^1 . So, without loss of generality, we shall focus on the non-compact model defined by the equation:

$$y^2 = x^3 + g_{12+n}(z')z^5. \quad (4.51)$$

Following up on our previous discussion, we see that there is an associated parabolic Higgs bundle with poles located at the zeroes of $g_{12+n}(z')$. In contrast to previous cases where we could associate these poles with vevs of bifundamental vevs, in the case of an E_8 gauge theory, here these poles are induced by condensing modes of a tensionless string theory with degrees of freedom localized at these intersection points. This is simply because we cannot embed our E_8 gauge theory in a unitary theory with a bigger simple gauge group. We can track the behavior of the intermediate Jacobian locally by switching on a lower order deformation to an E_7 singularity:

$$y^2 = x^3 + g_{12+n}(z')z^5 + f_{8+n}(z')xz^3. \quad (4.52)$$

Let us note that to activate this unfolding, we need to assume that $8 + n \geq 0$. When this is not satisfied there is no unfolding, i.e. Higgsing, available.

Assuming an unfolding to E_7 is possible, we can consider the $SU(2)$ parabolic Hitchin system in the limit that we switch off the smoothing, i.e. send the coefficient f_{8+n} to zero. Working in a patch of the \mathbb{P}^1 which contains the zeroes of f_{8+n} , we can describe the T-brane configuration as a Higgs field taking values in the $\mathfrak{su}(2)$ factor of the $\mathfrak{e}_7 \times \mathfrak{su}(2) \subset \mathfrak{e}_8$ subalgebra with matrix representative:

$$\Phi = \begin{bmatrix} 0 & f_{8+n} \\ \varepsilon & 0 \end{bmatrix} \quad (4.53)$$

where the T-brane is reached by sending $\varepsilon \rightarrow 0$. The system therefore contains $8 + n$ localized matter fields, corresponding to the number of half hypermultiplets in the $\mathbf{56}$ of \mathfrak{e}_7 . To turn the $\varepsilon \rightarrow 0$ limit into a globally well-defined configuration on the compact \mathbb{P}^1

¹²The E_8 at $z = \infty$ can be put in standard ADE form by switching to a different affine coordinate patch.

base wrapped by the seven-brane, we need to also mark the points where g_{12+n} vanishes. Doing so, we can view the Higgs field as a map:

$$\Phi : E \rightarrow E \otimes K(g_{12+n}) \tag{4.54}$$

where $K(g_{12+n})$ is the bundle of differentials with poles on g_{12+n} .

If Φ is nilpotent but nonzero, the methods of [81] exhibit E as an extension of line bundles

$$0 \rightarrow L^{-1} \rightarrow E \rightarrow L \rightarrow 0. \tag{4.55}$$

The Higgs field Φ is determined by the additional data of a nonzero section $s \in H^0(\mathbb{P}^1, K(g_{12+n}) \otimes L^{-2})$ as the composition

$$E \rightarrow L \rightarrow L^{-1} \otimes K(g_{12+n}) \rightarrow E \otimes K(g_{12+n}). \tag{4.56}$$

In (4.56), the second map comes from multiplication by s , and the other maps are deduced from (4.55).

At this stage, it is convenient to further divide the analysis according to whether n is even or odd, since we are dealing with half hypermultiplets. For n even, there is a natural choice given by:

$$L = \mathcal{O}((10+n)/2). \tag{4.57}$$

In this case, the bundle $\mathcal{O}(K(g_{12+n})) \otimes L^{-2}$ is trivial, so that s and hence Φ may be taken to be nowhere vanishing.

For n odd, we can see that there is a small subtlety, because there is no such line bundle. Indeed, this is related to the fact that in the six-dimensional effective theory, one cannot give a vev to a single half hypermultiplet. We can, however, still consider the moduli space of rank two bundles consistent with our requirements on localized matter and poles.

Now, we can also see that there are $9+n$ degrees of freedom for deforming these bundle (RR) moduli preserving nilpotency. In the case of n even, these are given by the space of extensions

$$0 \rightarrow \mathcal{O}(-(10+n)/2) \rightarrow E' \rightarrow \mathcal{O}((10+n)/2) \rightarrow 0 \tag{4.58}$$

which is dual to $H^0(\mathbb{P}^1, \mathcal{O}(8+n))$. The latter characterization also works for n odd. Now, if we approach the E_8 locus by adding a term $\varepsilon f_{8+n}(z')xz^3$ and let ε go to zero, that will constrain the RR moduli to Higgs fields that vanish along f and for which E' splits as $\mathcal{O}(1) \oplus \mathcal{O}(-1)$ by the above description of extensions.

To summarize, we see that from the perspective of the parabolic Higgs bundle, we work over a \mathbb{P}^1 with $12+n$ punctures. At these punctures, we can specify additional non-normalizable boundary data for the Hitchin system, such as the asymptotic behavior of the Higgs field and gauge field holonomies. We also have moduli from the positions of the localized matter, i.e. $9+n$ such moduli associated with the choice of polynomial f_{8+n} . These are associated with the breaking pattern $\mathfrak{e}_8 \rightarrow \mathfrak{e}_7$, i.e. a choice of unfolding in the generic case. We also see that the extensions in line (4.58) are the $9+n$ partners in the quaternionic Kahler moduli space for the $h^0(\mathbb{P}^1, \mathcal{O}(8+n))$ deformations. Additionally,

once we fix a choice of background Higgs field and gauge bundle, we have matter fields localized at the zeroes of f_{8+n} .

Turning next to the characterization in the limiting mixed Hodge structure analysis, we can see a similar split between the treatment of the moduli associated with g_{12+n} and the moduli associated with f_{8+n} . The moduli associated with the pole data, i.e. the zeroes of g_{12+n} combine to form a $12+n$ -dimensional quaternionic Kahler moduli space. Here, these are associated with the complex structure moduli from moving around the zeroes of g_{12+n} (which was the data \mathcal{T}^1 of the $SU(N)$ example encountered previously) and the limiting behavior of the weight two part of the intermediate Jacobian $J^2(H_{\text{lim}}^3)$. Additionally, we have the $9+n$ moduli associated with the choice of f_{8+n} . Altogether, these combine to fill out a $21+2n$ dimensional quaternionic Kahler moduli space.

The distinction between the contributions to the moduli space from g_{12+n} and f_{8+n} reflected in the filtration of the limiting mixed Hodge structure is naturally reflected in the mass hierarchies of the physical theory. Indeed, the background values at the zeroes of g_{12+n} specify a UV cutoff for our local analysis (the background data of the parabolic Hitchin system), and when we unfold from E_8 to E_7 , we are tilting the stack of E_8 seven-branes. The moduli associated with this breaking pattern correspond to activating a choice of solution to the parabolic Hitchin system, with boundary data at the zeroes of g_{12+n} . For a given choice of background, the zeroes of f_{8+n} lead to localized matter fields in the **56** of \mathfrak{e}_7 . In our present discussion we have kept the vevs of the localized matter switched off.

Once we recouple to gravity, however, we should really view all contributions to the moduli space on an equal footing. The reason is that in this limit, the “boundary data” of the parabolic Higgs bundle is associated with a mass scale which cannot be taken arbitrarily large, the upper bound being the Planck scale. So more generally, we expect the two contributions to the quaternionic Kahler moduli space to combine into a single moduli space of quaternionic dimension $21+2n$. In fact, we can see how this regrouping has to work by initiating a further unfolding from E_7 down to E_6 by activating a vev for some combination of the **56**'s of \mathfrak{e}_7 . In this case, the local profile of the spectral equation for the Higgs field in the non-compact geometry $\mathcal{O}(K_C) \rightarrow C$ takes the form:

$$g_{12+n}s^3 + f_{8+n}s + q_{6+n} = 0 \tag{4.59}$$

where s is a normal bundle coordinate such that $s = 0$ is the curve C . This is simply the spectral equation for an $SU(3)$ parabolic Hitchin system with pole data at the zeroes of g_{12+n} . At each zero of q_{6+n} we have a **27** of \mathfrak{e}_6 . In the limit where the vevs of the **56** of \mathfrak{e}_7 are taken to be very large compared to fluctuations in the **27** of \mathfrak{e}_6 , we see that this amounts to additional “boundary data” for the system. Indeed, we have the complex structure moduli associated with deformations of the polynomials g_{12+n} and f_{8+n} , and the remnants of the three-form potential moduli are now packaged together in the limiting behavior of the weight two part of $J^2(H_{\text{lim}}^3)$.

Anticipating our later discussion in section 6, we will later show that the case $n = 12$ corresponds to the F-theory dual of the standard embedding of the spin connection in an E_8 factor for heterotic strings on a K3 surface. Our treatment in this paper should therefore also be viewed as generalizing as well as clarifying the heuristic treatment provided in [53].

5 Defining data in six dimensions

Having identified the geometric remnant of T-brane data, we can now give a more precise statement on the defining data of an F-theory compactification. For the most part, this agrees with the operative definition used in the literature, though in singular limits, our analysis demonstrates that additional care is necessary. In fact, part of the point of this work is that the local gauge theory provides a clean definition of various singular limits of the closed string moduli space.

At a practical level, it is typically challenging to start from a fully smooth X_{smth} and then track various degeneration limits. Indeed, in much of the literature on F-theory compactification, the logical order is actually reversed: one starts from a singular threefold X and either “unfolds” or “blows up” the singularities of X . There is a fly in the ointment, though, because T-branes can obstruct such blowups! To properly define an F-theory compactification on a singular space X , it is therefore necessary to supplement this geometry by additional physical data.

We propose that in addition to the singular space X , we must also specify some T-brane data. In the Hitchin system, this is associated with the “discrete flux data” and choice of a flat connection. In the lift to a IIA / M-theory compactification, this will be captured by a four-form flux and three-form potential moduli. For *smooth* X , this data is captured by the Deligne cohomology of X [56].¹³ Motivated by our earlier analysis, we shall in fact propose the local Hitchin system as the limiting behavior of the Deligne cohomology for *singular* X .

The rest of this section is organized as follows. First, we show that the standard operation of “blowing up in the fiber” is actually obstructed by T-branes. Then, we turn to our proposal for how to unambiguously specify an F-theory vacuum on a singular threefold X .

5.1 Obstruction to a blowup

A standard way to understand the gauge symmetry and matter content of F-theory on a singular threefold X is to consider the dual M-theory compactification and perform a sequence of blowup operations to a smooth Calabi-Yau \tilde{X} . In this section we show that the presence of a T-brane can obstruct this sort of blowup operation.¹⁴

We can see this obstruction by considering the physical origin of the blowup modes and the T-brane moduli. It is simplest to consider F-theory compactified on $S^1 \times X$. At low energies this yields a five-dimensional theory with eight real supercharges. The blowup parameters then correspond to the vevs of the real scalars in the 5D vector multiplets. Activating a vev for the vector multiplets moves the theory onto the Coulomb branch, while activating a vev for the hypermultiplets moves the theory onto the Higgs branch.

Now, the key point is that once we move onto the Higgs branch, we have given a mass to the vector multiplet. As a consequence, we cannot give a vev to the scalar in the vector multiplet, and so we cannot activate a blowup mode. Said differently, activating a T-brane breaks the gauge symmetry, so the vector multiplet has a mass.

¹³This defining data is well-known for M-theory compactified on a smooth eight manifold [85, 86].

¹⁴Observations of a similar spirit have been made in the context of Green-Schwarz anomalous U(1)’s in F-theory [87, 88].

It is instructive to illustrate this for the four-dimensional effective field theory defined by wrapping a seven-brane over $T^2 \times C$. Then, the superpotential for this system is:

$$W = \sum_{i=1}^g \text{Tr}_{\mathfrak{g}} \left(\varphi \cdot [X_i, \tilde{X}_i] \right) + \sum_p \tilde{q}_{(p)} \cdot \varphi \cdot q_{(p)}, \tag{5.1}$$

so once we activate a vev for one of the hypermultiplets, we induce a mass term for some components of φ , the vector multiplet complex scalar. We can also track the fate of the previously massless gauge bosons of the vector multiplet. In the dimensional reduction in the IIA / M-theory descriptions, these gauge bosons come from integrating the three-form potential along the fiber \mathbb{P}^1 for the resolution. The equation of motion for the three-form potential is:

$$(\Delta_{4D} + \Delta_{\text{internal}})C_{(3)} = 0, \tag{5.2}$$

with Δ_{4D} the 4D Laplacian, and Δ_{internal} the Laplacian in the internal directions. So, upon expanding $C_3 = A_{4D} \wedge \omega_{\text{internal}}$, with A_{4D} the 4D gauge field and ω_{internal} a two-form dual to the fiber \mathbb{P}^1 , we see that once the gauge boson has picked up a mass, ω_{internal} is no longer a harmonic two-form.

Similar considerations hold in the purely geometric context. Indeed, in the limiting mixed Hodge structure analysis, we can see that at a generic point of complex structure moduli, there is no singularity to speak of, and so there is no blowup to perform.

5.2 Disambiguation

We now give a proposal for what additional data needs to be attached to a singular threefold X to unambiguously define the corresponding effective field theory derived from F-theory.

We motivate our proposal by first summarizing the evidence accumulated so far. In the local models defined by a Hitchin system, the extra data needed to specify the theory is associated with the remnants of the three-form potential moduli, and the choice of an abelian flux. In compactifications to four dimensions, such seven-brane fluxes can be lifted to a corresponding four-form flux \mathcal{G} in the resolved geometry. Indeed, taking $T^2 \times X$ with no T-brane data switched on, we can consider the blowup of some singular ADE fiber to reach the geometry $T^2 \times \tilde{X}$. Then, we can consider the difference of two four-form fluxes, $\mathcal{G}_1 - \mathcal{G}_2$ which by quantization needs to be valued in $H^4(T^2 \times \tilde{X}, \mathbb{Z})$. The main requirement is that integrating the difference $\mathcal{G}_1 - \mathcal{G}_2$ over the two-cycle in the fiber of the ADE singularity descends to the corresponding abelian flux in the Hitchin system. Observe that for a rank r gauge group, there are precisely r linearly independent combinations of $U(1)$ generators, and there r homologically distinct \mathbb{P}^1 's in the ADE fiber.

Now, there are a few potential issues with defining an F-theory compactification in this way. First of all, since we have already argued that T-branes can obstruct a Kähler resolution, how can we speak of the geometry $T^2 \times \tilde{X}$? The point is that although there is no Kähler parameter which allows us to perform a blowdown $\tilde{X} \rightarrow X$, we can still construct the topological space $T^2 \times \tilde{X}$, even when a T-brane is switched on. The construction is simply to delete the singular ADE fibers and replace them with the blown

up fibers. Since we only need the integrality condition for the difference of two G-fluxes, this is sufficient for our purposes.¹⁵

The second potential issue is that at least when X is a *smooth* Calabi-Yau threefold, it is well-known that the supergravity equations of motion forbid the presence of any four-form flux. The reason this is bypassed when T-branes are switched on is that we are working with a *singular* geometry. Indeed, in the Hitchin system equations of motion, the flux often balances against the nilpotent Higgs field. Turning the discussion around, specifying a G-flux in this way gives a necessary and sufficient condition to recognize the appearance of a T-brane in the geometry.

Finally, in the context of compactifications to four dimensions, there are tight global consistency conditions related to tadpole cancellation for D3-brane charge. So, we might expect similar constraints in the six-dimensional case. In fact, we can see that the fluxes we are activating always descend from a non-abelian gauge group. This means, for example, that the net amount of five-brane charge induced on a seven-brane is zero, since $\text{Tr}_{\mathfrak{g}}(F) = 0$. On the other hand, we do not know the full list of consistent G-fluxes which can be switched on. What we can assert is that when we can take a local degeneration limit $X_t \rightarrow X$, it is possible to consistently switch on such a G-flux. In fact, we can see that this flux should loosely be thought of as a (2, 2)-form, since it must descend to a (1, 1)-form flux in the Hitchin system.

Putting these remarks together, we propose that in the geometry \tilde{X} , the remnant of T-brane data is a four-form G-flux, while on the smoothed side X_t , the remnant of T-brane data is the three-form potential moduli valued in the intermediate Jacobian $J(X_t)$. Giving this data is then enough to specify the effective six-dimensional theory of an F-theory compactification.

Now, as noted in [56], in the case of a *smooth* Calabi-Yau X_{smth} , the (2, 2)-flux data and intermediate Jacobian can actually be packaged in terms of a *single* mathematical object known as the Deligne cohomology $H_{\mathcal{D}}^4(X_{\text{smth}}, \mathbb{Z}(2))$ (see appendix B for a brief introduction). For our current purposes, the main point is that it fits into the short exact sequence:

$$0 \rightarrow J^2(X_{\text{smth}}) \rightarrow H_{\mathcal{D}}^4(X_{\text{smth}}, \mathbb{Z}(2)) \rightarrow H_{\mathbb{Z}}^{2,2}(X_{\text{smth}}) \rightarrow 0. \tag{5.3}$$

So we see that $H_{\mathcal{D}}^4(X_{\text{smth}}, \mathbb{Z}(2))$ captures both the discrete flux data $H_{\mathbb{Z}}^{2,2}(X_{\text{smth}})$, as well as the data of the intermediate Jacobian $J(X_{\text{smth}})$. Actually, the more precise statement is that to account for the possibility of half integer shifts in the quantization condition we should only require that the difference of this flux data across a domain wall is an element of the Deligne cohomology.

But in the case of a *singular* manifold X , the usual definition of Deligne cohomology breaks down. This motivates a conjecture: we propose that the Hitchin system provides the correct definition of Deligne cohomology in certain singular limits. To see this, we observe that the Hitchin system data captures both the discrete flux data of the blowdown $\tilde{X} \rightarrow X$ as well as the limiting behavior of the RR moduli valued in $J(X_t)$ in the limit $t \rightarrow 0$. So in the singular limit, the Hitchin system unifies these two contributions.

¹⁵For a recent approach to reading off matter from geometry from a deformation-theoretic perspective, see [89].

6 Global models and heterotic duals

In this section we present some global examples of T-brane phenomena. Our strategy will be to show how to go from the globally defined geometry to a local limit. In particular, we will explain how to isolate the relevant contributions to the three-form potential moduli of the dual M-theory / IIA description in taking the local limit of the geometry.

Now, in the global setting we face some additional complications, because it is typically not possible to globally smooth away all singularities. So, while we can still unfold some component of the discriminant locus, other components may intersect it. A common circumstance in F-theory is the collision with additional I_1 components, which generically contains various cusps. To deal with these cases, we shall therefore need to show how to isolate the relevant contributions to the three-form potential moduli in taking the local limit of the geometry. Though more technically involved, in principle we can simply carry over our previous discussion of the theory of limiting mixed Hodge structures to this case as well.

To give some concrete examples of global models with T-branes, we focus on some simplifying cases where a heterotic dual description exists. In technical terms, the reason this leads to a simplification is that the task of computing the relevant contributions to the intermediate Jacobian $J(X)$ reduces to the calculation of the Jacobian $J(\tilde{C})$ of an algebraic curve \tilde{C} . This curve \tilde{C} is nothing other than the spectral curve which figures in both the heterotic string construction of the vector bundle, as well as in the local behavior of intersecting seven-branes on the F-theory side.

Another benefit of this analysis is that we will be able to see what T-brane data turns into in the dual heterotic description. As one might expect, this corresponds to situations where the spectral curve used in the spectral cover construction of bundles on K3 has become singular.

More striking is that this occurs in a host of rather ordinary and well-known cases! For example, the standard embedding of the spin connection in an E_8 vector bundle is a perfectly smooth vector bundle which nevertheless has a singular spectral curve [60] (see also [53]). We provide compact examples along these lines which illustrate various features of T-brane data and their manifestation in both the F-theory and heterotic descriptions.

The rest of this section is organized as follows. First, we give a brief review of heterotic / F-theory duality in six dimensions, and show how the elements of the intermediate Jacobian relevant for T-branes reduce to related questions in the associated spectral curve. After this, we turn to some examples of T-branes and their heterotic duals.

6.1 Review of 6D heterotic F-theory duality

Since we shall be making heavy use of it later, in this subsection we briefly review some aspects of the duality in six-dimensions between heterotic strings compactified on a K3 surface and F-theory compactified on a Hirzebruch \mathbb{F}_n base. Most checks of this duality have been performed at *generic* points in the moduli space. Indeed, we will see that certain ambiguities crop up in singular limits, and need to be treated with additional care.

Loosely speaking, the six-dimensional duality is obtained by applying fiberwise the eight-dimensional duality between the $E_8 \times E_8$ heterotic string on T^2 and F-theory on an

elliptic K3 surface. Fibered over a common \mathbb{P}^1 , we arrive at a K3 surface on the heterotic side, and on the F-theory side, an elliptically fibered Calabi-Yau threefold with Hirzebruch surface as the base. We recall that the Hirzebruch surfaces are given for $n \in \mathbb{Z}$ by a fibration $\mathbb{P}^1_{\text{fiber}} \rightarrow \mathbb{F}_n \rightarrow \mathbb{P}^1_{\text{base}}$ defined by projectivizing the rank 2 bundle $\mathcal{O}_{\mathbb{P}^1} \oplus \mathcal{O}_{\mathbb{P}^1}(n)$. For physics applications, we need to restrict to $-12 \leq n \leq 12$. In the heterotic dual description, the parameter n indicates the number of instantons $(12+n, 12-n)$ in the $E_8 \times E_8$ bundle. For additional details on the proposed duality and numerous previous checks, see e.g. [57–59].

The F-theory threefold, $\pi : X \rightarrow B$ can be described in minimal Weierstrass form as

$$y^2 = x^3 + fx + g \tag{6.1}$$

where $f \in H^0(B, K_B^{-4})$, $g \in H^0(\mathbb{F}_n, K_B^{-6})$, K_B is the canonical bundle of the base $B = \mathbb{F}_n$. Introducing affine coordinates (z, z') for the fiber and base, respectively, we can perform a further expansion:

$$f = \sum_i f_{8+n(4-i)}(z')z^i \quad \text{and} \quad g = \sum_j g_{12+n(6-j)}(z')z^j \tag{6.2}$$

where the sum on i and j is over all non-negative degree terms. Here, $z = 0$ specifies the base $\mathbb{P}^1_{\text{base}}$ of the Hirzebruch surface degree. The discriminant locus:

$$\Delta = 4f^3 + 27g^2 \tag{6.3}$$

defines a divisor in the Hirzebruch surface, and components of the discriminant locus indicate the locations of seven-branes in the geometry.

For our present purposes, the primary advantage of this class of examples is the existence of a globally defined K3 fibration.¹⁶ In a suitable limit of moduli for the Calabi-Yau metric, the K3 fiber can be split into two “1/2 K3’s”, i.e. del Pezzo nine (dP_9) surfaces where the fiber $\mathbb{P}^1_{\text{fiber}}$ asymptotes to a cylinder, i.e a sphere with two punctures. In the stable degeneration limit, X splits up into the components $X = \mathcal{X}_1 \cup \mathcal{X}_2$, where each \mathcal{X}_i is given by a dP_9 fibration over the base $\mathbb{P}^1_{\text{base}}$. In the dual heterotic description, these two factors are associated with the two E_8 vector bundles.

In the dual heterotic M-theory description [1, 57, 58], the heterotic dilaton is given to leading order by the expression:

$$\exp(-2\phi_{\text{het}}) = \frac{\text{Vol}(\mathbb{P}^1_{\text{base}})}{\text{Vol}(\mathbb{P}^1_{\text{fiber}})} \tag{6.4}$$

Moreover, we can also recognize the dual heterotic K3 surface. In the middle region of the cylinder, we can locally approximate the Calabi-Yau threefold as:

$$y^2 = x^3 + f_8(z')z^4x + g_{12}(z')z^6 \tag{6.5}$$

which for z held fixed defines an elliptically fibered K3 surface in the variables x, y, z' . In fact, these middle coefficients should be viewed as defining the moduli of the K3 surface in

¹⁶For a recent proposed extension of heterotic / F-theory duality which does not require a global K3 fibration, see [90].

the dual heterotic string description:¹⁷

$$v^2 = u^3 + f_8(z')u + g_{12}(z'), \tag{6.6}$$

where to make the context clear, we reserve (x, y, z, z') for coordinates in the F-theory geometry, and (u, v, z') for coordinates in the dual heterotic K3.

The other complex structure moduli of equation (6.1) translate to deformations of the vector bundles $\mathcal{V}_1, \mathcal{V}_2$ of the two E_8 factors. The terms in f and g of respective degrees less than four and six (i.e. concentrated near $z = 0$) correspond to moduli for \mathcal{V}_1 , while the terms of higher degree (i.e. concentrated near $z = \infty$) correspond to moduli for \mathcal{V}_2 . A quick way to see this is to start from the singular model:

$$y^2 = x^3 + g_{12+n}(z')z^5 + f_8(z')xz^4 + g_{12}z'z^6 + g_{12-n}(z')z^7, \tag{6.7}$$

and to then unfold by switching on deformations of the singularity near $z = 0$ and $z = \infty$. In [57, 58], the further unfolding to a lower singularity was interpreted as dissolving the small instantons located at the zeroes of $g_{12+n}(z')$ and $g_{12-n}(z')$ back into smooth vector bundle moduli.¹⁸ As the astute reader will have no doubt noticed, there is an ambiguity in just specifying the physical system by the singular geometry of equation (6.7), since T-brane data could be hiding in the discriminant. We return to this in subsection 6.3.1.

6.1.1 The spectral cover construction

Some of the most detailed checks of heterotic / F-theory duality have been performed for vector bundles produced via the spectral cover construction. Here we shall be interested in the case of heterotic strings compactified on a K3 surface. As we shall repeatedly stress, sometimes a singular spectral cover description can correspond to a perfectly smooth vector bundle.

We are mainly interested in vector bundles on the K3 surface, so for now we simply reference a vector bundle \mathcal{V} with structure group $G \subset E_8$. For ease of exposition, we shall take $G = \text{SU}(N)$, though nothing depends on this restriction. Now, for an elliptically fibered K3 surface, the defining data of the spectral cover consists of a pair $(\tilde{C}, L_{\tilde{C}})$ where \tilde{C} is a compact curve inside of K3, given by an r -sheeted cover of the base \mathbb{P}^1 , and $L_{\tilde{C}}$ is a rank 1 sheaf defined over the curve \tilde{C} (See appendix C and [91] for a review). We turn this into a vector bundle on the elliptic K3 by applying a fiberwise T-duality, i.e. Fourier-Mukai transform (see e.g. [92, 93]). The number $r = rk(\mathcal{V})$ then corresponds to the rank of the vector bundle. One can also go the other way, starting from a general vector bundle \mathcal{V} and

¹⁷There is a slight subtlety with this statement owing to the non-trivial fibration over the base $\mathbb{P}_{\text{base}}^1$. We have $9 + 13$ complex coefficients, but we have fixed the locations $z = 0$ and $z = \infty$, where the two stacks of branes are located. This means that the total number of moduli is given by $22 - 2 = 20$. This accounts for the 18 complex structure moduli of the heterotic K3, as well as the two complexified Kähler moduli of the elliptic K3 in the heterotic dual description.

¹⁸In slightly more detail, the idea is that when all unfolding parameters have been switched off, we should perform a blowup at each intersection of $g_{12+n}(z') = 0$ with $z = 0$. These blowups corresponding to pulling an M5-brane off the end of the world nine-brane in the heterotic M-theory description. Similar considerations hold for the blowups at the intersections of $g_{12-n}(z') = 0$ with $z = \infty$.

Het/Spectral Cover	F-theory/Global
$Def(\tilde{C})$	$Def(\mathcal{X})$
$J(\tilde{C})$	$J(\mathcal{X})$

Table 1. Summary of six-dimensional heterotic F-theory duality and moduli matching for smooth spectral covers. On the heterotic side, we have the deformations of the spectral curve $Def(\tilde{C})$, and the Jacobian of the curve, $J(\tilde{C})$. On the F-theory side, we have the space $Def(\mathcal{X})$, which refers to the space of complex structure deformations of (the resolution of) \mathcal{X} , and $J(\mathcal{X})$ refers to the intermediate Jacobian. Implicit in the definition and the correspondence is the assumption that all quantities are non-singular.

by applying a Fourier-Mukai transform producing some pair $(\tilde{C}, L_{\tilde{C}})$, though this may lead to a singular spectral curve \tilde{C} .

For an $SU(N)$ vector bundle, we can write the associated spectral curve \tilde{C} as the zero set [91]:

$$\tilde{C} = \{a_0 w^N + a_2 u w^{N-2} + a_3 v w^{N-3} + \dots = 0\} \tag{6.8}$$

ending in $a_N u^{N/2}$ for N even and $a_N u^{(N-3)/2} v$ for N odd. Here, the a_i are given as sections:

$$a_i \in H^0(\mathbb{P}^1, K_{\mathbb{P}^1}^{\otimes i} \otimes \mathcal{O}(12+n)). \tag{6.9}$$

Anticipating our discussion of the F-theory geometry, we note that $a_i(z')$ specifies a degree $12+n-2i$ polynomial in the variable z' . The class of the curve \tilde{C} is $[\tilde{C}] = N\sigma_0 + (12+n)f$ where σ_0 is the class of the zero-section of K3 and f is the fiber class. The two classes satisfy $\sigma_0 \cdot f = 1$, $f \cdot f = 0$ and $\sigma_0 \cdot \sigma_0 = -2$. The genus of the spectral curve \tilde{C} follows from an application of intersection theory:

$$2g(\tilde{C}) = -2N^2 + 2N(12+n) + 2 = -2(N^2 - 1) + 2Nc_2(V) = h^1(K3, \text{End}_0(V)) \tag{6.10}$$

where the right hand side follows from an index computation. This match is not an accident, and reflects the fact that the vector bundle moduli space of the $\mathcal{N} = 2$ theory appears as a pairing in the degrees of freedom parameterized by deformations of the curve \tilde{C} , $Def(\tilde{C})$ with those in its Jacobian, $J(\tilde{C})$. The space of local deformations is counted by $h^0(\tilde{C}, \mathcal{O}(K_{\tilde{C}})) = g(\tilde{C})$, while the Jacobian is simply the set of all locally free sheaves (i.e. line bundles) on \tilde{C} and $\dim_{\mathbb{C}} J(\tilde{C}) = g(\tilde{C})$.

Now, we have already encountered a rather similar pairing in F-theory between complex deformations of the geometry, and the associated intermediate Jacobian of the Calabi-Yau threefold. As explained in more detail in appendix C, we can again track the behavior of this structure in the stable degeneration limit, where the relevant correspondence now involves the complex deformations and intermediate Jacobian of \mathcal{X} , one of the factors in $X = \mathcal{X}_1 \cup \mathcal{X}_2$. We summarize the correspondence between the relevant heterotic and F-theory structures in table 1.

Of course, in many cases of interest for physics we cannot expect to remain at a completely generic point of the moduli space. In these limits, we need to extend the correspondence of table 1 to cover singular limits as well. From our analysis in earlier

Figure 2. Depiction of the spectral curve \tilde{C} and some possible degenerations. In the figure, we illustrate in the case of a three-sheeted cover of a curve C . Possible degenerations include a non-reduced scheme of length three, as indicated by $\tilde{C} \rightarrow 3\tilde{C}_1^{\text{nr}}$, by a factorization into two smooth reducible components, as indicated by $\tilde{C} \rightarrow \tilde{C}_1 \cup \tilde{C}_2$, and a factorization into two reducible components, one of which is a non-reduced scheme, as indicated by $\tilde{C} \rightarrow 2\tilde{C}_1^{\text{nr}} \cup \tilde{C}_2$.

sections, we know that such singular limits arise when we turn off smoothing parameters. In the dual heterotic description, this translates to limiting behavior for the spectral curve, and there are two basic ways this can occur:

- \tilde{C} becomes reducible, i.e. splits into a collection of factors $\tilde{C} \rightarrow \tilde{C}_1 \cup \tilde{C}_2 \cup \dots$
- \tilde{C} becomes a non-reduced scheme, i.e. it contains a factor $w^n = 0$ for some function w .

In principle, both types of behavior could be present for a given spectral curve. See figure 2 for an illustration of such degenerations.

But in spite of this apparent singular behavior, the resulting heterotic vector bundle *could still be perfectly smooth* [60]. Indeed, it is worth noting that there are a wide range of smooth heterotic bundles on K3 surfaces and Calabi-Yau threefolds that give rise to singular spectral covers. For example, according to [61], most bundles built via the monad construction (see also [62–64]) will yield a degenerate spectral cover. An important example of this type is the tangent bundle on K3 [53, 94]. The extra data that makes it possible to obtain a smooth bundle under the Fourier-Mukai transform is that for such singular curves, the Jacobian of \tilde{C} is no longer a smooth torus and can now contain more exotic rank 1 sheaves. The new types of rank 1 sheaves that can be defined over such singular curves have been well-studied in the mathematics literature (see e.g. [81, 95–97]). Of course, we should

expect something like this to occur in the heterotic description, because on the F-theory side of the duality, these singular limits are correlated with the possibility of T-brane data.

6.2 From $J(X)$ to $J(\tilde{C})$

Having reviewed some basic elements of heterotic / F-theory duality, in this subsection we now show how T-branes fit into this correspondence. One pragmatic reason for carrying out this detailed match is that in practice it is often far simpler to calculate the limiting behavior of the Jacobian of a spectral curve compared with the limiting behavior of the intermediate Jacobian of a Calabi-Yau threefold.

To this end, we first explain how to embed the compact spectral curve \tilde{C} in \mathcal{X} , one of the dP_9 fibered components appearing in the stable degeneration limit. Using this, we show how the data of the intermediate Jacobian filters down to the spectral curve, and moreover, how to track the singular behavior of the spectral curve. We should note that for *non-singular* heterotic / F-theory pairs, this correspondence is by now well established [57, 58, 91–93] and continues to yield new insights [27, 48, 98]. Our aim is to track the behavior of this correspondence in various *singular* limits.

6.2.1 Projectivization

In order to facilitate our analysis, it will prove convenient to switch to a different presentation of an elliptic curve. As is standard in much of the F-theory literature, up to now we have presented the elliptic fiber on both the heterotic and F-theory sides of the correspondence as a weight six hypersurface in the weighted projective space $\mathbb{P}_{1,2,3}^2$. To avoid unnecessary complications from the orbifold singularities we now consider a presentation of the elliptic fiber in a \mathbb{P}^2 bundle. At the expense of introducing spurious orbifold singularities, we can of course switch back and forth between these presentations.

Let us now turn to the parametrization of the elliptic fibration, viewed as a \mathbb{P}^2 bundle over a base curve $C = \mathbb{P}_{\text{base}}^1$ on the heterotic side, and over the base Hirzebruch surface $B = \mathbb{F}_n$ on the F-theory side. Along these lines, we introduce the \mathbb{P}^2 bundles:

$$\mathcal{P} = \mathbb{P}(\mathcal{O}_C \oplus \mathcal{O}_C(4) \oplus \mathcal{O}_C(6)) \tag{6.11}$$

for the heterotic configuration, and:

$$\mathcal{Y} = \mathbb{P}(\mathcal{O}_B \oplus \mathcal{O}_B(-4\tilde{K}_B) \oplus \mathcal{O}_B(-6\tilde{K}_B)) \tag{6.12}$$

for the F-theory configuration. In (6.12), \tilde{K}_B is the log canonical divisor $K_B + D_{\text{glue}}$ of the log pair (B, D_{glue}) , where D_{glue} is the divisor along which the other component of the stable degeneration is glued. Then, we can present the heterotic K3 surface as:

$$V^2W = U^3 + f_8(z')UW^2 + g_{12}(z')W^3 \tag{6.13}$$

where (W, U, V) are fiber coordinates:

$$W \in H^0(\mathcal{P}, \mathcal{O}_{\mathcal{P}}(\xi)), \quad U \in H^0(\mathcal{P}, \mathcal{O}_{\mathcal{P}}(\xi + 4h)), \quad V \in H^0(\mathcal{P}, \mathcal{O}_{\mathcal{P}}(\xi + 6h)), \tag{6.14}$$

where h is a fiber class and $\xi = c_1(\mathcal{O}_{\mathcal{P}}(1))$. Similar considerations hold for the F-theory geometry \mathcal{X} , where by abuse of notation, we use the fiber coordinates (λ, x, y) . The context will be clear when we are using the \mathbb{P}^2 bundle versus $\mathbb{P}_{1,2,3}^2$ bundle fiber coordinates. For the \mathbb{P}^2 fiber bundle coordinates, we have sections:

$$\lambda \in H^0(\mathcal{Y}, \mathcal{O}_{\mathcal{Y}}(\xi)), \quad x \in H^0(\mathcal{Y}, \mathcal{O}_{\mathcal{Y}}(\xi + 2\sigma_b + (2n+4)\sigma_f)), \quad y \in H^0(\mathcal{Y}, \mathcal{O}_{\mathcal{Y}}(\xi + 3\sigma_b + (3n+6)\sigma_f)). \quad (6.15)$$

and $\xi = c_1(\mathcal{O}_{\mathcal{Y}}(1))$. Here, σ_b is a section of the Hirzebruch surface with $\sigma_b \cdot \sigma_b = -n$, which is where the other component of the stable degeneration will be glued. The E_7 singularity is located at a disjoint section, whose class is $\sigma_b + n\sigma_f$. Introducing homogenous coordinates (z_0, z_1) on the fibers of \mathbb{F}_n with z_1 vanishing on σ and z_0 vanishing on the E_7 locus, the F-theory model on \mathcal{X} is:

$$y^2 \lambda = x^3 + (f_{8+n}(z')z_0^3 z_1 + f_8(z')z_0^4) x \lambda^2 + (g_{12+n}(z')z_0^5 z_1 + g_{12}(z')z_0^6) \lambda^3. \quad (6.16)$$

In this presentation, the spectral curve also appears somewhat differently. For example, for an $SU(N)$ vector bundle, we can write, for $k = \lceil N/3 \rceil$ the associated spectral curve \tilde{C} as:¹⁹

$$\tilde{C} = \{\alpha_{k,0,0}W^k + \alpha_{k-1,1,0}W^{k-1}U + \dots + \alpha_{0,0,k}V^k = 0\}, \quad (6.17)$$

i.e. a general homogeneous polynomial of degree k in (W, U, V) . Here, the coefficients $\alpha_{a,b,c}$ are sections:

$$\alpha_{a,b,c} \in H^0(\mathbb{P}^1, \mathcal{O}(12+n) \otimes \mathcal{O}(-4b-6c)) \quad (6.18)$$

where $a + b + c = k$, as required by homogeneity. Indeed, the general form is deduced by requiring overall homogeneity of (6.8) after assigning W, U, V the respective weights 0, 4, 6.

In this presentation, the geometric characterization depends on the value of $N \bmod 3$. For $N = 3k$, there are no further restrictions, while for $N = 3k - 1$, the same form as equation (6.8) holds with $\alpha_{0,0,k} = 0$, but an explanatory point is needed. Since the zero section is given by $w = u = 0$, the spectral equation vanishes on the zero section when $\alpha_{0,0,k} = 0$. The $SU(N)$ spectral cover is obtained by removing the zero section from the solution curve of (6.8). Finally, if $N = 3k - 2$, we still have the equation (6.8), but we require the zero section to be a solution with multiplicity 2, and then remove two copies of the zero section. This requires the vanishing of $\alpha_{0,0,k}$ as well as the coefficient of UV^{k-1} , i.e. $\alpha_{0,1,k-1}$.

6.2.2 Embedding \tilde{C} in \mathcal{X}

Having set up our notation, we now proceed to the embedding of the spectral curve \tilde{C} directly in the F-theory geometry. Using this correspondence, we will be able track the limiting behavior of the intermediate Jacobian for \mathcal{X} in terms of the limiting behavior of $J(\tilde{C})$.

Let $\rho : S \rightarrow \mathbb{P}^1$ be an elliptically fibered K3, and \mathcal{V} be an E_8 bundle on S . Then \mathcal{V} restricts to an E_8 bundle on the elliptic fiber E_p over any $p \in \mathbb{P}^1$, and hence gives rise to D_p , a dP_9 which contains E_p as a fiber. Varying p gives rise to a dP_9 fibration $\mathcal{X} \rightarrow \mathbb{P}^1$. The

¹⁹For $k \geq 3$, this representation is not unique, as a multiple of the Weierstrass equation can be freely added.

threefold \mathcal{X} can be viewed as dP_9 fibered over \mathbb{P}^1 or elliptically fibered over a Hirzebruch surface \mathbb{F}_n , where $c_2(\mathcal{V}) = 12 + n$.

Now suppose that the structure group of \mathcal{V} can be reduced to $SU(N) \subset E_8$.²⁰ Then for each $p \in \mathbb{P}^1$, we have that $\mathcal{V}|_{E_p}$ is an $SU(N)$ bundle on E_p , which can be represented by points $p_i = p_i(p) \in E_p$ satisfying $\sum_{i=1}^N p_i(p) = p_0(p)$. For additional details, see appendix C. Varying p , the points $p_i(s)$ sweep out the $SU(N)$ spectral cover

$$\begin{array}{ccc} \tilde{C} & \subset & S \\ & \downarrow & \\ & & \mathbb{P}^1 \end{array} \tag{6.19}$$

On the F-theory side, to each point $p_i(p)$ of \tilde{C} , we get a section $E_i(p)$ of the dP_9 $D(p)$, the fiber of $\mathcal{X} \rightarrow \mathbb{P}^1$ over p . Thus \tilde{C} parameterizes a family of curves in \mathcal{X} .²¹ The coincidence of the points $p_{N+1}(p) = \dots = p_8(p) = p_0(p)$ leads to the conclusion there there is a curve of singularities in \mathcal{X} , located along the zero section $S_0 \subset S \subset \mathcal{X}$, with $S_0 \simeq \mathbb{P}^1$.

For clarity of exposition, let us first perform a small resolution of the singularity of \mathcal{X} to get a smooth $\tilde{\mathcal{X}}$. Then \tilde{C} parameterizes a family of curves in $\tilde{\mathcal{X}}$, the pullback of the family of curves in \mathcal{X} to a family of curves in $\tilde{\mathcal{X}}$ (recall that the fibers of $\tilde{\mathcal{X}} \rightarrow \mathcal{X}$ are curves). So we get an Abel-Jacobi mapping

$$J(\tilde{C}) \rightarrow J(\tilde{\mathcal{X}}) \tag{6.20}$$

whose image is an explicit description of the RR moduli associated with the $SU(N)$ part of the geometry of $\tilde{\mathcal{X}}$.

But now we can think of elements of $J(\tilde{C})$ as line bundles on \tilde{C} , which is precisely the additional data needed to reconstruct \mathcal{V} from the $\{\mathcal{V}|_{E_p}\}$, which is all that is determined by the complex structure of \mathcal{X} . So the Abel-Jacobi mapping gives an explicit description of heterotic / F-theory duality in this context.

Now, blowing up to get $\tilde{\mathcal{X}}$ was really just a crutch, at least as far as the physics is concerned. In the spirit of the appendices, we can define an Abel-Jacobi mapping

$$J(\tilde{C}) \rightarrow J(\mathcal{X}), \tag{6.21}$$

where $J(\mathcal{X})$ denotes the three-form potential moduli of \mathcal{X} , which are in principle determined by a limiting mixed Hodge structure analysis as in the appendices.

This last point can be made more precise *if* the family of curves in \mathcal{X} parameterized by \tilde{C} is disjoint from the singular locus S_0 . However, this is typically not the case, since whenever \tilde{C} meets S_0 at a point $p_0(p)$, i.e. when $p_i(p) = p_0(p)$ for some $i \leq N$, the corresponding curve $E_i(p) \subset \mathcal{X}$ intersects $S_0 \subset \mathcal{X}$. In fact, this apparent complication can be turned into a virtue. Let

$$Z = \rho \left(\tilde{C} \cap S_0 \right) \subset \mathbb{P}^1. \tag{6.22}$$

²⁰The method employed here does not require this restriction and applies in principle. Details are left for future work.

²¹This is the same family of curves found by Aspinwall in an explicit situation using the Mordell-Weil group [99]. The analysis here holds more generally.

Now, as we saw in the context of the local models of section 4 and the appendices, the collection of points Z correspond to the poles of the $SU(N)$ parabolic Higgs bundle. In this context, the spectral curve \tilde{C} should be viewed as an abstract cover of the locus C wrapped by the physical seven-brane. What we have just seen is that $\text{Pic}(\tilde{C})$ should then be identified with the corresponding fiber of this parabolic Hitchin system.

Let us now show how this construction works for the case of $SU(2)$ spectral covers. Recall that in section 4, we showed how to see the emergence of a parabolic Higgs bundle from the geometry of a local curve of singularities. The main idea there was to isolate an $\mathfrak{su}(2)$ subalgebra, and perform the corresponding unfolding. Our aim here will be to show how to recover this description in the compact setting.

Consider the $SU(2)$ spectral cover. Recall that we can describe $SU(2)$ bundles on an elliptic curve E in terms of points $\kappa_1, \kappa_2 \in E$ such that $\kappa_1 + \kappa_2 = 0$ in the group law for E . If E is a Weierstrass fiber, the origin of the group law is $\kappa_0 = (W, U, V) = (0, 0, 1)$, and $\kappa_1 + \kappa_2 = 0$ if and only if κ_0, κ_1 , and κ_2 are collinear. The coordinates of κ_0 show that this line must be of the form:

$$aU + bW = 0. \tag{6.23}$$

Now varying the fibers, we identify a and b with homogeneous polynomials on C , and then equation (6.13) shows that the degrees of a and b must differ by 4. In fact, if the $SU(2)$ bundle \mathcal{V} has $c_2(\mathcal{V}) = 12 + n$, then globally the equation defining the spectral cover is of the form:²²

$$f_{8+n}U + g_{12+n}W = 0. \tag{6.24}$$

The spectral curve \tilde{C} meets S_0 (given by $X = z = 0$) over the points in $C = \mathbb{P}_{\text{base}}^1$ where $f_{8+n} = 0$. Let $Z \subset \mathbb{P}_{\text{base}}^1$ be the set of points given by the zeros of g_{12+n} .

Let us note that the base of an $SU(2)$ parabolic Hitchin system with poles on Z is

$$H^0(\mathbb{P}_{\text{base}}^1, 2K + Z) \simeq H^0(\mathbb{P}_{\text{base}}^1, \mathcal{O}(-4 + n + 12)) = H^0(\mathcal{O}(n + 8)), \tag{6.25}$$

corresponding precisely to the moduli of f_{8+n} in (6.24). The spectral cover (6.24) is isomorphic to the Hitchin spectral cover as can be seen by comparing branch points. The moduli of g_{n+12} are precisely the complex structure part of the quaternionic moduli in the hypermultiplet space which are the fibers over the parabolic Hitchin system. We will return to this explicitly below.

We now describe the F-theory dual corresponding to unfolding E_8 to E_7 . Returning to our general discussion near equation (6.12), we consider projective fiber coordinates so that the associated F-theory model on \mathcal{X} is:

$$y^2\lambda = x^3 + (f_{8+n}(z')z_0^3z_1 + f_8(z')z_0^4)x\lambda^2 + (g_{12+n}(z')z_0^5z_1 + g_{12}(z')z_0^6)\lambda^3 \tag{6.26}$$

We now consider a slight modification of equation (6.24):

$$f_{8+n}(z')x + g_{12+n}(z')\lambda z_0^2 = 0. \tag{6.27}$$

²²We are not claiming that the spectral cover is a complete intersection of (6.13) and (6.24). In fact both of these equations vanish on the zero section $U = W = 0$. The complete intersection has two components, one of which is the zero section, the other one being the spectral cover.

The equations (6.26) and (6.27) both contain the zero section. As with the spectral cover, the complete intersection of (6.26) and (6.27) contains the zero section, and another component, which we call S .

We claim that the surface S is ruled by a family of (rational) curves which are sections of \mathcal{X} over the fibers of \mathbb{F}_n , and that the parameter space for these curves is precisely the heterotic spectral cover.²³ To see this, let (λ_0, x_0, y_0) be the coordinates of a point p of the spectral cover lying over a point $p \in C$, i.e. satisfying (6.13) and (6.24). Then the point $(\lambda_0, x_0 z_0^2, y_0 z_0^3)$ satisfies (6.26) and (6.27). We verify this by rewriting (6.26) as

$$y^2 \lambda = (x^3 + f_8 z_0^4 x \lambda^2 + g_{12} z_0^6 \lambda^3) + z_0^3 z_1 \lambda^2 (f_{n+8} x + g_{n+12} \lambda z_0^2). \quad (6.28)$$

Then (6.27) vanishes at $(\lambda_0, x_0 z_0^2, y_0 z_0^3)$ because (6.24) vanishes at (λ_0, x_0, y_0) , and the indicated regrouping shows (6.26) vanishes at $(\lambda_0, x_0 z_0^2, y_0 z_0^3)$ because of the vanishing of (6.13) and (6.24) at (λ_0, x_0, y_0) . Now $z_0 \mapsto (\lambda_0, x_0 z_0^2, y_0 z_0^3)$ parameterizes a curve C_p , which is visibly a section of \mathcal{X} over the Hirzebruch fiber over p (which is parameterized by z_0). This completes the proof of the claim.

6.3 Examples

Having illustrated the general map from the Jacobian of the spectral curve to the intermediate Jacobian of the F-theory geometry, we now turn to several examples which illustrate different types of T-brane phenomena. First, we present some examples based on a spectral curve which is a non-reduced scheme, and we then present an example where the spectral curve is reducible.

6.3.1 Standard embedding versus small instantons

A rather striking example of T-brane phenomena in the heterotic string already occurs for $\mathcal{V} = T_{K3}$, i.e. the standard embedding of the spin connection in one of the E_8 factors [60, 94]. This corresponds to a rank two vector bundle with $c_2(\mathcal{V}) = 24$. A helpful feature of the standard embedding is that the heterotic anomaly constraint is automatically satisfied.

In the general spirit of our approach, we work at a generic point in the moduli space, and then show how T-brane data arises at some singular loci in the spectral cover construction. To this end, first consider heterotic strings on K3, in the presence of a rank two vector bundle with instanton number 24 which breaks one of the E_8 factors to the commutant subgroup E_7 . The hypermultiplet matter is completely fixed by the topological condition $c_2(\mathcal{V}) = 24$ and consists of the following quaternionic degrees of freedom:

$$H^1(T_{K3}) = 20 \text{ (singlets corresponding to the deformations of the K3 surface)} \quad (6.29)$$

$$H^1(\mathcal{V}) = 20 \text{ (charged-matter fields: 1/2 hypers in the } \mathbf{56} \text{ of } E_7) \quad (6.30)$$

$$H^1(\text{End}_0(\mathcal{V})) = 90 \text{ SU}(2) \text{ (bundle moduli: 1/2 hypers which are singlets of } E_7) \quad (6.31)$$

A generic $\text{SU}(2)$ bundle of this type can be described via the two-sheeted spectral cover:

$$g_{24}(z')w^2 + f_{20}(z')u = 0 \quad (6.32)$$

²³This assertion may be viewed as a concrete verification of a general claim made in appendix C.1.

where we view the heterotic K3 as embedded in a $\mathbb{P}_{1,2,3}^2$ -bundle over the base curve C . Viewing the heterotic K3 as embedded in a \mathbb{P}^2 -bundle over C , we can also write:

$$g_{24}(z')W + f_{20}(z')U = 0 \tag{6.33}$$

where we recall our convention that the spectral cover is obtained by removing the zero section. For later use, note that the Weierstrass equation shows that $W = 0$ defines the zero section with multiplicity 3, since substituting $W = 0$ into the Weierstrass equation forces $U^3 = 0$.

A surprise arises, however, in the case of the standard embedding. Recall that this is given by the tangent bundle of K3, i.e. we embed the spin connection of K3 in one of the E_8 factors. As was demonstrated in [60], performing a Fourier-Mukai transform on the tangent bundle of the K3 surface, the spectral equation takes a very particular and singular form:

$$g_{24}(z')w^2 = 0. \tag{6.34}$$

Here, $g_{24} \in H^0(\mathbb{P}_{\text{base}}^1, \mathcal{O}(24))$, it is the coefficient a_0 appearing in equation (6.8), or equivalently the coefficient $\alpha_{k,0,0}$ appearing in equation (6.17).

This defines a spectral curve which is both a non-reduced scheme, and reducible. It is reducible since it is the union of the base \mathbb{P}^1 (given by $w = 0$ in K3), and 24 vertical components given by the zeros of g_{24} . In fact, for the tangent bundle the 24 fibers appearing in the spectral cover are the 24 singular I_1 fibers of the K3 [60, 92]. It is non-reduced because $w^2 = 0$. Equivalently, since $W = 0$ contains the zero section with multiplicity 3 and we have removed one copy of the zero section, we see that $g_{24}(z')W = 0$ contains the zero section with multiplicity 2.

The spectral data in (6.34) appears degenerate and indeed, is exactly what would be expected from one very singular point in bundle moduli space: the limit in which the $SU(2)$ bundle is dissolved into 24 point-like instantons on K3 [60, 94]. Indeed, if the location of the instantons is given by the zeros of g_{24} , the Fourier-Mukai transform of $\bigoplus_{r=1}^{24} \mathcal{I}_r$ yields exactly the vertical (I_1 fiber) components of (6.34).

But how is it that one spectral cover can describe two very different gauge configurations, one of which corresponds to highly non-perturbative physics and tensionless strings? A resolution to this puzzle was proposed in [60] by considering the values of the three-form potential moduli. More precisely, non-zero vevs for the three-form potential moduli prevent the effective theory of the standard embedding from approaching the singular small-instanton limit.

As we can see from table 1, the remnants of the three-form potential moduli in the dual M-theory description arise in the heterotic geometry via the rank 1 sheaves, $L_{\tilde{C}}$ over the spectral cover. In the case of a non-reduced spectral cover, the Jacobian of this degenerate curve can have multiple, disjoint components. It is this extra geometric data in $J(\tilde{C})$ which guarantees that the singular spectral curve still gives rise to a smooth bundle (in this case T_{K3}) under the Fourier-Mukai transform.

More explicitly, it was pointed out in [81] that the Jacobian $J(C)$ of a non-reduced curve could contain rank 1 sheaves with exotic origins. In particular, if C is a smooth

curve of genus $g > 2$ and \mathcal{V}_C a vector bundle of rank n and degree $k + (n^2 - n)(1 - g)$ on C , then \mathcal{V}_C may also be viewed as *coherent, rank 1 sheaf*, $\mathcal{V}_C = L_{nC}$, on the non-reduced curve nC . As we will see below, it is exactly such rank 1 sheaves (the remnants of higher rank bundles on the base curve) which appear in non-reduced heterotic spectral covers and can explain mysteries like the one above.²⁴

For the tangent bundle, the spectral sheaf, $L_{\tilde{C}}$ is characterized by the fact that $T_{K3}|_E$, the restriction to the elliptic fiber, generically does not split as a sum of two line bundles $\mathcal{O}_E \oplus \mathcal{O}_E$, but instead the non-trivial extension

$$0 \rightarrow \mathcal{O}_E \rightarrow T_{K3}|_E \rightarrow \mathcal{O}_E \rightarrow 0 \tag{6.35}$$

while the 24 point-like instantons trivially decompose.

Likewise, for the instantons, the spectral sheaf trivializes (see section 3.3 of [60]). In contrast, for the tangent bundle, the sheaf over the spectral cover is indecomposable. As explained in [53], the rank one sheaf \mathcal{L}_C on the non-reduced and reducible curve can be defined via the following short exact sequences:

$$0 \rightarrow i_* T\mathbb{P}^{1V} \rightarrow L_{\tilde{C}} \rightarrow \mathcal{K} \rightarrow 0 \tag{6.36}$$

$$0 \rightarrow \bigoplus_{i=1}^{24} \mathcal{O}_{E_i} \rightarrow \mathcal{K} \rightarrow i_* T\mathbb{P}^1 \rightarrow 0 \tag{6.37}$$

where i imbeds the zero section into K3. This rank 1 sheaf then is defined via line bundles over each of the 24 vertical fibers as well as a rank 1 sheaf over the double cover of \mathbb{P}^1 . At each of the 24 points of intersection we must define non-trivial extensions of the form given in (6.36). This “gluing data” identifies the sheaves at each point of intersection. As was shown in [53], the gluing data at the 24 points of intersection are not all independent. In fact, only 21 degrees of freedom are sufficient to specify the non-trivial extensions defining the spectral sheaf, $L_{\tilde{C}}$. These gluing vevs, together with the choice of 24 line bundles on the singular fibers give rise to the 45 degrees of freedom in the Jacobian of the singular curve in (6.34).

Having given a detailed discussion of the heterotic string side of the story, let us now turn to the dual F-theory description. Here, we have the Hirzebruch base \mathbb{F}_n , where $n = 12$ as required by the value of the instanton number in the heterotic description. The associated Weierstrass model is:

$$y^2 = x^3 + g_{24}(z')z^5 + f_8(z')xz^4 + g_{12}(z')z^6 + g_0z^7. \tag{6.38}$$

In this case, the coefficient multiplying z^7 is a constant, reflecting the fact that one of the E_8 factors is frozen to a “non-Higgsable” E_8 factor. On the other E_8 factor, however, we see a high degree coefficient, reflecting the fact that there are many moduli available to unfold the singularity.

Now, the important point for our present discussion is that equation (6.38) could refer to two *completely different vacua*. In the heterotic dual description, these two vacua are the standard embedding and the limit of small instantons.

²⁴For other work on Jacobians of non-reduced curves (frequently called “ribbons”) see for example [100].

To illustrate, consider first the small instanton limit. As proposed in [57, 58] one can consider blowing up in the base the 24 points where the zeroes of $g_{24}(z')$ and $z = 0$ intersect. In the dual heterotic M-theory dual description, these blowups correspond to pulling the M5-branes off of the E_8 wall, and moving them into the bulk. The distance of each M5-brane from the wall corresponds to the size of the Kähler resolution parameter. After performing these blowups in the base, we reach a new F-theory model, with base \tilde{B} such that $h^{1,1}(\tilde{B}) = h^{1,1}(B) + 24$. These blowup modes correspond to additional tensor multiplets in the six-dimensional supergravity theory. After blowing up the E_8 singularities, we reach the “Coulomb branch” of the theory.

Now, we can go back to the origin of the Coulomb branch by blowing down all the Kähler classes, which in the dual heterotic M-theory description includes moving all the M5-branes back to the E_8 wall. At this point, we can dissolve the small instantons back into smooth vector bundles, moving onto the Higgs branch. However, only *some* of these moduli will show up as complex deformations of equation (6.38), with the rest captured by the three-form potential moduli.

Returning to our general discussion in subsection 4.4.1, we saw there that locally, the dynamics of the gauge theory are controlled by a parabolic Higgs bundle with pole data localized at the zeroes of g_{24} . These poles should be viewed as specifying background vevs for modes in a tensionless string theory with degrees of freedom charged under the E_8 gauge theory. We can next perform a smoothing to an E_7 singularity:

$$y^2 = x^3 + f_{20}(z')xz^3 + g_{24}(z')z^5 + f_8(z')xz^4 + g_{12}(z')z^6 + g_0z^7. \quad (6.39)$$

Then as expected, the T-brane moduli are captured by the $SU(2)$ parabolic Higgs bundle, with poles at the locus $Q = \{g_{24} = 0\} \cap \{z = 0\}$. The 21-dimensional space of non-trivial extensions:

$$0 \rightarrow \mathcal{O}(-11) \rightarrow E \rightarrow \mathcal{O}(11) \rightarrow 0 \quad (6.40)$$

which pair with $H^0(\mathbb{P}^1, \mathcal{O}(20))$ to form a hypermultiplet are dual to the heterotic degrees of freedom in the Jacobian given in (6.36).

To summarize our discussion, we can see that in the correspondence between the heterotic / F-theory pairs, the deformations of the spectral curve \tilde{C} agree with the appropriate deformations of \mathcal{X} . However, we can also see that the behavior of the Jacobian $J(\tilde{C})$ exhibits more structure in the singular limit, and that this is matched by the degeneration of the limiting behavior of the intermediate Jacobian $J(\mathcal{X})$. Indeed, the 24 vertical components of the spectral curve associated with small instantons correspond in the F-theory description to the location of the poles of the Higgs field, which is the point set Z of (6.22). In the limiting mixed Hodge structure analysis, this corresponds to the weight two part of the mixed Hodge structure, associated with $J^2(H_{\text{lim}}^3)$. The moduli of the intermediate Jacobian correspond to choices of line bundles on the nonreduced scheme of multiplicity 2 which arises as the spectral cover associated to the origin in the base of the corresponding parabolic Hitchin system. Moreover, the 20 locations of gluing data in the spectral cover simply translate to the limiting behavior of the three-form potential moduli, just as we already observed in the local configurations of subsection 4.4.1.

It is also instructive to compare this with the structure of the hypermultiplet moduli space in the heterotic string description. There, all of the 45 moduli are on an equal footing, even though in the parabolic Higgs bundle there is a natural split between the “boundary data” fixed at the zeroes of g_{24} , and the dynamical moduli associated with f_{20} . As we observed at the end of section 4.4.1, once we move away from the decoupling limit of the seven-brane gauge theory by recoupling to gravity, these moduli get put back on an equal footing.

There are some clear generalizations of our analysis. For example, we can see that similar phenomena will arise for other choices of instanton numbers, i.e. choices of n . Additionally, it is worth pointing out that in making the heterotic / F-theory comparison above, we have focused on rank 2 heterotic bundles. It is equally possible to consider higher rank bundles with degenerate spectral covers. For example, if we include another copy of the zero section, $W = U = 0$ in the definition of the spectral cover given in (6.34) and compare the F-theory geometry given in (6.38) with a heterotic spectral cover of the form

$$g_{24}(z')W = 0, \tag{6.41}$$

we have the union of the zero section with multiplicity 3 with the fibers located over the zeros of g_{24} . In the equivalent presentation with fiber coordinates (w, u, v) for $\mathbb{P}_{1,2,3}^2$, this would read as:

$$g_{24}(z')w^3 = 0. \tag{6.42}$$

In this case, once again it is possible for the degenerate spectral cover to be have a smooth SU(3) bundle as its Fourier-Mukai transform. The Jacobian of the non-reduced curve would lead to an additional 19 degrees of freedom, corresponding in the dual F-theory geometry to the three-form potential moduli partners of the smoothing parameters $q_{18}z^2x$ in the Weierstrass equation. See appendix C.2 for further details of such SU(3) examples.

Similar degenerate spectral covers can correspond to smooth, higher rank vector bundles. For example, given an $\mathfrak{su}(N) \subset \mathfrak{e}_8$ subalgebra, we can produce an N -sheeted spectral cover with degenerate spectral equation:

$$g_{12+n}w^N = 0 \tag{6.43}$$

This would likewise give rise to a rich possible structure of rank 1 sheaves on \tilde{C} . In this case, some choice of smoothing, connected with a choice of limiting behavior for the three-form potential moduli would again differentiate between small instantons and specific smooth SU(N) bundles.

The above example clearly illustrates one important lesson in heterotic / F-theory duality: in considering a degenerate spectral cover and its F-theory dual, we must first decide what F-theory smoothing deformation, or equivalently, heterotic bundle moduli space, we want to compare. We have already encountered this ambiguity in section 4 and appendix A.4. This freedom is precisely the choice of smoothing that must be included to fix the limiting mixed Hodge structures and define the emergent parabolic Hitchin system.

6.3.2 Reducible spectral covers

T-brane data can also arise when the spectral curve becomes reducible, i.e. factors into two or more components. Here we focus on the case where the spectral curve factors into two

components $\tilde{C} = \tilde{C}_1 \cup \tilde{C}_2$. Now, the naive expectation would be that since the spectral cover splits into two components, so does the vector bundle, $V \rightarrow \mathcal{V}_1 \oplus \mathcal{V}_2$. From the point of view of the moduli space of properly slope-stable sheaves [101], a poly-stable bundle $\mathcal{V}_1 \oplus \mathcal{V}_2$ would correspond to a singular point, at which we would expect an enhancement of symmetry in the heterotic effective theory, and possibly additional light states (see e.g. [102–104]).

However, such a splitting of the bundle only occurs if the *full data of the spectral cover is reducible*. That is, it is not enough to consider just the split form of the spectral cover \tilde{C} . To illustrate, consider an $SU(N)$ bundle, \mathcal{V} , and its characterization as a spectral cover. This will be captured by a pair $(\tilde{C}, L_{\tilde{C}})$. For this to become a direct sum $\mathcal{V}_1 \oplus \mathcal{V}_2$ of stable bundles with $c_1(\mathcal{V}_1) = -c_1(\mathcal{V}_2)$ and $rk(\mathcal{V}_1) + rk(\mathcal{V}_2) = N$, the spectral cover must become reduced, i.e. we need to have two independent pairs $(\tilde{C}_1, L_{\tilde{C}_1})$ and $(\tilde{C}_2, L_{\tilde{C}_2})$. So in other words, in addition to the condition that \tilde{C} degenerates to two components $\tilde{C}_1 \cup \tilde{C}_2$, to get a reducible bundle we must also demand that the rank one sheaf $L_{\tilde{C}}$ splits up as a direct sum. More generally, all we can say is that we have a pair $(\tilde{C}_1 \cup \tilde{C}_2, L_{\tilde{C}_1 \cup \tilde{C}_2})$ where $L_{\tilde{C}_1 \cup \tilde{C}_2}$ is some rank one sheaf with support on $\tilde{C}_1 \cup \tilde{C}_2$.

As should now be clear, it is possible to have a reducible spectral curve $\tilde{C} \rightarrow \tilde{C}_1 \cup \tilde{C}_2$, but an irreducible vector bundle \mathcal{V} . This will occur whenever the rank one sheaf $L_{\tilde{C}_1 \cup \tilde{C}_2}$ does not trivialize at the intersection points $\{p_i\} = \tilde{C}_1 \cap \tilde{C}_2$. Indeed, to define $L_{\tilde{C}_1 \cup \tilde{C}_2}$ we must, for each point $p \in \tilde{C}_1 \cap \tilde{C}_2$ choose an isomorphism $\phi : L_{\tilde{C}_1}|_p \rightarrow L_{\tilde{C}_2}|_p$. The map ϕ is referred to as the “gluing data” and the triple, $(L_{\tilde{C}_1}, L_{\tilde{C}_2}, \phi)$ determines the line bundle $L_{\tilde{C}}$.

Schematically, we can describe the bundle \mathcal{V} over the whole K3 by considering $D = \pi^{-1}(\pi(\tilde{C}_1 \cap \tilde{C}_2))$ (the collection of points viewed now as points in K3), and the short exact sequence

$$0 \rightarrow \mathcal{V} \rightarrow \mathcal{V}_1 \oplus \mathcal{V}_2 \rightarrow \mathcal{T} \rightarrow 0 \tag{6.44}$$

where \mathcal{T} is a torsion sheaf supported at the points $p \in D$. In the case that $\mathcal{T} = (\mathcal{V}_1)|_D = (\mathcal{V}_2)|_D$ the bundle \mathcal{V} splits as $\mathcal{V} \rightarrow \mathcal{V}_1 \oplus \mathcal{V}_2(-D)$ (where the sum has now been modified by the familiar dualizing sheaf). Thus, in order for the bundle to decompose as a direct sum globally, we must not only describe the factorization of the spectral cover, but also the gluing data and the decomposition of the line bundles over \tilde{C}_1 and \tilde{C}_2 . Returning to our discussion near equation (6.10), we can see that these extra moduli are accounted for by the intersection points. Indeed, applying the intersection theoretic genus formula, we learn:

$$g(\tilde{C}) = g(\tilde{C}_1) + g(\tilde{C}_2) + \tilde{C}_1 \cdot \tilde{C}_2 + 1. \tag{6.45}$$

Since the genus tracks the complex dimension of the Jacobian, we see that roughly speaking, the intersection points make up the additional degrees of freedom for the gluing data.

We now turn to a specific example. On the heterotic side, we consider an $SU(4)$ vector bundle which initiates a breaking pattern in the second factor of $\mathfrak{so}(10) \times \mathfrak{su}(4) \subset \mathfrak{e}_8$. For generic bundle valued moduli, this will leave us with an $\mathfrak{so}(10)$ gauge symmetry factor. By tuning the vector bundle moduli, we can reach a spectral curve which factorizes, and so would naively correspond to a breaking pattern $\mathfrak{so}(12) \times \mathfrak{so}(4) \subset \mathfrak{e}_8$. However, once we include the gluing data, we will be able to see that in spite of the reducible form of the

spectral curve this could still be a perfectly smooth SU(4) vector bundle. In other words, further tuning must be specified to get a reducible bundle. We then turn to the F-theory description of these models, where the appearance of the gluing data is reflected in the choice of a T-brane configuration.

Consider first the heterotic side of the correspondence. We construct a smooth vector bundle with structure group SU(4) via the four-sheeted spectral cover of $\mathbb{C}\mathbb{P}^1$. In this and more involved cases, it proves convenient to adopt the presentation with fiber coordinates (W, U, V) for a \mathbb{P}^2 bundle. The spectral curve can then be written as:

$$g_{12+n}W^2 + f_{8+n}UW + q_{6+n}VW + h_{4+n}U^2 = 0, \tag{6.46}$$

where the subscripts on g_{12+n} , f_{8+n} , q_{6+n} and h_{4+n} indicate their degrees viewed as polynomials in the coordinate z' of $\mathbb{P}_{\text{base}}^1$. Recalling our discussion near the end of subsection 6.2.1, since $N = 3k - 2$ with $k = 2$, here we have removed two copies of the zero section which in turn requires the vanishing of V^2 and UV . For the sake of comparison, we also give the spectral curve in a presentation with fiber coordinates (w, u, v) for a $\mathbb{P}_{1,2,3}^2$ bundle:

$$g_{12+n}w^4 + f_{8+n}uw^2 + q_{6+n}vw + h_{4+n}u^2 = 0, \tag{6.47}$$

In what follows, however, we shall stick to the \mathbb{P}^2 -bundle presentation.

Applying Fourier-Mukai to the pair $(\tilde{C}, L_{\tilde{C}})$, we get a rank 4 bundle of instanton number $c_2(\mathcal{V}) = 12 + n$, leaving us with an unbroken $\mathfrak{so}(10) \subset \mathfrak{e}_8$ subalgebra. Now, we next consider a specific limit where the curve factorizes. We arrange this by switching off q_{6+n} , and setting $g_{12+n} = \alpha_{4+r}\gamma_{8+n-r}$, $f_{8+n} = \beta_r\gamma_{8+n-r} + \alpha_{4+r}\delta_{4+n-r}$ and $h_{4+n} = \beta_r\delta_{4+n-r}$, for some r . The equation for the spectral curve then factors as:

$$(\alpha_{4+r}W + \beta_rU)(\gamma_{8+n-r}W + \delta_{4+n-r}U) = 0 \tag{6.48}$$

to two components $\tilde{C} = \tilde{C}_1 \cup \tilde{C}_2$.

We might be tempted to say from this reducible curve alone that the resulting heterotic theory has gauge symmetry SO(12) (see [59] for such a heterotic / F-theory pair). However, by careful choices of line bundle $L_{\tilde{C}}$ on the spectral cover it is possible for the bundle V to be a smooth, indecomposable bundle with either an SU(4) or SO(5) structure group, leading to SO(10) or SO(11) theories.

Next, let us explain how this shows up in the case of the dual F-theory description. Following the general outline in earlier sections, we first give the Hitchin-like system description, and then turn to the global model. Our interest is in the unfolding of the $\mathfrak{su}(4)$ factor in the decomposition $\mathfrak{so}(10) \times \mathfrak{su}(4) \subset \mathfrak{e}_8$. It is therefore enough to focus on an $\mathfrak{su}(4)$ Hitchin system on the curve $C = \mathbb{P}_{\text{base}}^1$ with punctures. The punctures are specified by the zero set $g_{12+n}(z') = 0$ on the curve, and indicate the existence of possible poles and delta function supported fluxes.

We first take a pair of independent SU(2) Higgs bundles, and then explain how to glue them back together. Along these lines, we introduce two SU(2) bundles E_1 and E_2 , and two Higgs fields:

$$\Phi_1 : E_1 \rightarrow E_1 \otimes K(\alpha_{4+r}) \tag{6.49}$$

$$\Phi_2 : E_2 \rightarrow E_2 \otimes K(\gamma_{8+n-r}), \tag{6.50}$$

where $K(\alpha_{4+r})$ corresponds to the sheaf of differentials with a pole along $\alpha_{4+r} = 0$, with similar notation for $K(\gamma_{8+n-r})$. We can now start to construct much more general SU(4) Higgs bundles:

$$\Phi : E_{\text{SU}(4)} \rightarrow E_{\text{SU}(4)} \otimes K(g_{12+n}) \tag{6.51}$$

by taking extensions of the parabolic Higgs bundles for the SU(2) case. This corresponds to gluing the two factors back together.

Our primary interest is in those cases where this gluing retains the original form of the reducible spectral curve. To do this, we first begin with the construction of the bundles E_i , viewed as appropriate extensions:

$$0 \rightarrow L_1^{-1} \rightarrow E_1 \rightarrow L_1 \rightarrow 0 \tag{6.52}$$

$$0 \rightarrow L_2^{-1} \rightarrow E_2 \rightarrow L_2 \rightarrow 0, \tag{6.53}$$

where the line bundles L_i are chosen so as to satisfy the analogue of the degree requirements seen on the heterotic side for equation (6.48), i.e.:

$$L_1 = K_C^{-1/2} \otimes \mathcal{O}(r/2) \quad \text{and} \quad L_2 = K_C^{-1/2} \otimes \mathcal{O}((4+n-r)/2). \tag{6.54}$$

Here, we assume that all degrees are integers, though the count of the number of moduli associated with these extensions holds more generally.

To produce a more general SU(4) bundle, we can then perform a further gluing by activating some choice of vevs for the localized matter trapped at the zeroes of β_r and δ_{4+n-r} . So in other words, we can pick a non-trivial extension in either $\text{Ext}^1(E_1, E_2)$ or alternatively in $\text{Ext}^1(E_2, E_1)$. In these cases, we can retain the condition of T-brane data which remains hidden from the spectral equation. To give an example of this type, we could consider, in some local patch of C , the Higgs field:

$$\Phi = \begin{bmatrix} 0 & \beta_r/\alpha_{4+r} & T_{10+n}/g_{12+n} & 0 \\ \varepsilon_1 & 0 & 0 & -T_{10+n}/g_{12+n} \\ 0 & \varepsilon_2 & 0 & \delta_{4+n-r}/\gamma_{8+n-r} \\ 0 & 0 & \varepsilon_3 & 0 \end{bmatrix}. \tag{6.55}$$

where notation is as in equation (6.48), and $T_{10+n} \in H^0(\mathbb{P}^1, \mathcal{O}(10+n))$. The degree is fixed by the condition of homogeneity in the spectral equation:

$$g_{12+n} \det(s - \Phi) = (\alpha_{4+r}s^2 - \varepsilon_1\beta_r)(\gamma_{8+n-r}s^2 - \varepsilon_3\delta_{4+n-r}) + \varepsilon_2(\varepsilon_3 - \varepsilon_1)sT_{10+n} = 0. \tag{6.56}$$

When $\varepsilon_2 = 0$, the moduli associated with T_{10+n} do not appear at all. Of course, following our previous discussion, we can track these moduli by first working at generic values of ε_2 , and then passing to a singular limit.

Now we turn to the F-theory realization of these configurations. We first consider the case of the smooth spectral cover, as described by equation (6.47). Using the fact that we can embed \tilde{C} in \mathcal{X} , we can write the threefold \mathcal{X} as:

$$y^2\lambda = (x^3 + f_8xz^4\lambda^2 + g_{12}z^6\lambda^3) + z\lambda(g_{12+n}z^4\lambda^2 + f_{8+n}xz^2\lambda + q_{6+n}zy\lambda + h_{4+n}x^2) \tag{6.57}$$

where (λ, x, y) are fiber coordinates for a \mathbb{P}^2 bundle. So, we see as in earlier cases that we get a surface in the F-theory geometry ruled by a family of (rational) curves which are sections of \mathcal{X} over the fibers of \mathbb{F}_n . In this presentation, we have grouped the terms into two contributions to reflect their different roles in the duality. If the second term had been switched off, we would be describing the equation for the heterotic K3 surface. With the second term switched on, we can clearly identify the contribution from the spectral equation. To put this in minimal Weierstrass form, we would need to complete the square in x .

Next, consider the case where we tune the moduli of the spectral equation, as in equation (6.48). In this case, the model for \mathcal{X} becomes:

$$y^2\lambda = (x^3 + f_8xz^4\lambda^2 + g_{12}z^6\lambda^3) + z\lambda(\alpha_{4+r}z^2\lambda + \beta_r x)(\gamma_{8+n-r}z^2\lambda + \delta_{4+n-4}x). \quad (6.58)$$

To track the behavior of the intermediate Jacobian in this limit, we can now blow up the $SO(10)$ factor, and see what happens as $q_{6+n} \rightarrow 0$ and the other components of the spectral cover factorize. Since we have essentially reduced the problem to a more involved example along the same lines considered in section 4, we see that the remnants of the three-form potential moduli descend to T-brane data of the local $SU(4)$ Hitchin system on the curve C with punctures at the zeroes of g_{12+n} .

7 Conclusions

In F-theory, the interplay between open and closed string degrees of freedom provides a vast generalization of perturbative IIB vacua. T-branes correspond to a class of non-abelian bound states which are straightforward to construct in the open string description, but are surprisingly subtle to identify in the closed string moduli. In this paper we have argued that the geometric remnants of T-brane data are, in the dual M-theory description, associated with periods of the M-theory three-form potential. To track this data in a singular limit, we have applied the theory of limiting mixed Hodge structures, showing in particular how it directly points to the emergence of an associated Hitchin system coupled to defects.

While the structure of the hypermultiplet moduli space (pairing complex structure degrees of freedom with RR-moduli) has long been understood in six-dimensional compactifications of F-theory in the case of smooth resolutions of Calabi-Yau threefolds, the degrees of freedom in singular limits of the geometry have remained largely unexplored. In this paper we have investigated for the first time the definition and structure of this moduli space in the *singular* limit, including singular Calabi-Yau geometries which admit no Kähler resolution.

We have found that a generalization of the results of [77] to the compact setting provides a remarkable new tool in this study. The periods of the three-form potential valued in the intermediate Jacobian of X_{smth} can be tracked in singular limits using the theory of limiting mixed Hodge structures and lead to an emergent Hitchin-like system coupled to defects on the discriminant locus of X_{sing} . Our results concretely link the degrees of freedom in local/global F-theory compactifications and can also be non-trivially verified in the case of theories with heterotic duals (corresponding to singular/degenerate spectral covers). This work provides not only a (singular) geometric description of the notion of T-branes [51–53], but also resolves a number of outstanding puzzles in heterotic/F-theory duality [60].

To unambiguously characterize an F-theory compactification on a singular threefold X , we have found that it is necessary to include additional discrete “flux” and continuous “three-form potential moduli”. This data is a natural generalization of Deligne cohomology to the case of a singular threefold. We have provided some explicit checks of our proposal in the case of compact models, finding agreement with the heterotic dual description, when it exists. In the remainder of this section we discuss some potential avenues of future investigation.

Our strategy in this paper has been to study deformations of the closed string sector to track the remnant of T-branes in geometry. In this sense, all of the branches of T-brane vacua discussed in this paper fit within known (albeit singular limits of) geometric phases of F-theory, in accord with the classification results given in [105]. From the perspective of the six-dimensional effective field theory, however, this is not strictly necessary. It would be interesting to study possible T-brane solutions which do not have a geometric remnant. Such vacua would correspond to new, non-geometric phases of F-theory.

Clearly it would be important to extend our considerations to four-dimensional supersymmetric F-theory vacua. In this setting, we have a theory with four real supercharges, so we should not expect the intermediate Jacobian to fill out half the degrees of freedom of a quaternionic Kahler moduli space, as would happen in a theory with eight real supercharges. Even so, the intermediate Jacobian will still fiber over the space of complex deformations, so the general theory of limiting mixed Hodge structures still enables us to study the limiting behavior of the three-form potential moduli in this setting. Based on this, it is reasonable to propose that the geometric remnant of T-brane data in a smooth four-fold is captured by the Deligne cohomology, and that in the limit where we degenerate to a singular component of the discriminant locus, the Vafa-Witten theory (see e.g. [2, 47, 106]) coupled to defects and pointlike Yukawas fills in the remnants of the three-form potential moduli and flux. What this means is that the results of this paper should persist to four-dimensional vacua, but will need to be further restricted by compatibility conditions associated with superpotential obstructions. It would be quite interesting to explore these details in future work.

Acknowledgments

A Limits of the intermediate Jacobian

In this appendix we review some basic features of the intermediate Jacobian for X a Calabi-Yau threefold. We shall be particularly interested in how to make sense of this structure in limits where X develops singularities, since this is where T-brane data can hide.

To begin, let X be a *smooth* compact Kähler threefold. Then the real dimension of $H^{3,0}(X) + H^{2,1}(X)$ is the same as the rank of $H_3(X)$. The map

$$\phi : H_3(X, \mathbb{Z}) \rightarrow (H^{3,0}(X) + H^{2,1}(X))^*, \quad \phi(\gamma) : \omega \mapsto \int_{\gamma} \omega \tag{A.1}$$

is easily seen to map $H_3(X, \mathbb{Z})$ to a full rank lattice in $(H^{3,0}(X) + H^{2,1}(X))^*$. The quotient

$$J(X) = (H^{3,0}(X) + H^{2,1}(X))^* / H_3(X, \mathbb{Z}), \tag{A.2}$$

is a complex torus, the *intermediate Jacobian* of X . The intermediate Jacobian is not an Abelian variety if $H^{3,0}(X) \neq 0$, so in particular, it is not an abelian variety when X is Calabi-Yau. The intermediate Jacobian varies holomorphically in X . When we are only concerned with the real structure of $J(X)$, we will sometimes write it more simply as $J(X) = H^3(X, \mathbb{R}) / H^3(X, \mathbb{Z})$.

If X becomes singular, the intermediate Jacobian need not be defined. We can, however, still sometimes make sense of a limit of intermediate Jacobians. Our plan in the remainder of this appendix will be to explain how to track this behavior. To this end, we first review some background on mixed Hodge structures. Then, we show how to apply this in some simple examples. In the cases of primary interest for applications to F-theory, this prescription becomes incomplete, and is supplemented by the emergence of a Hitchin-like system.

A.1 Background on mixed Hodge structures

In preparation for our later discussion, we now give some background details on mixed Hodge structures. See also [42] for additional discussion on applications to F-theory.

We recall that a Hodge Structure of weight k consists of the following data:

- A finitely generated abelian group $H_{\mathbb{Z}}$
- A decreasing filtration F^{\bullet} on $H_{\mathbb{C}} \equiv H_{\mathbb{Z}} \otimes \mathbb{C}$

The filtration is required to satisfy

$$F^p \cap \overline{F^{k-p+1}} = 0. \tag{A.3}$$

The filtration F^{\bullet} is called the Hodge filtration. The prototypical example is $H^k(X)$, where X is a compact Kähler manifold. We put $H_{\mathbb{Z}} = H^k(X, \mathbb{Z})$ and

$$F^p H^k(X, \mathbb{C}) = \bigoplus_{p' \geq p} H^{p', k-p'}(X). \tag{A.4}$$

The Hodge decomposition of X can then be recovered from the Hodge filtration by

$$H^{p,q}(X) = F^p \cap \overline{F^q}. \tag{A.5}$$

The Hodge filtration varies holomorphically in families, while the Hodge decomposition does not. An element of $H^{p,q}(X)$ is said to have *Hodge type* (p, q) .

There is a natural space of Hodge structures, which is not compact. In order to study limits of Hodge structures, we will need a more general notion. A *mixed Hodge structure* consists of

- A finitely generated abelian group $H_{\mathbb{Z}}$
- An increasing filtration W_{\bullet} on $H_{\mathbb{Q}} = H_{\mathbb{Z}} \otimes \mathbb{Q}$, called the weight filtration
- A decreasing filtration F^{\bullet} on $H_{\mathbb{C}} \equiv H_{\mathbb{C}} \otimes \mathbb{C}$, called the Hodge filtration

Let $\text{Gr}_{\ell}^W = W_{\ell}/W_{\ell-1}$, which is obtained from the finitely generated abelian group $(\text{Gr}_{\ell}^W)_{\mathbb{Z}} = (H_{\mathbb{Z}} \cap W_{\ell})/(H_{\mathbb{Z}} \cap W_{\ell-1})$ by tensoring with \mathbb{Q} . Furthermore, F^{\bullet} induces decreasing filtrations $F^{\bullet}(\text{Gr}_{\ell}^W \otimes \mathbb{C})$. The data $(\text{Gr}_{\ell}^W)_{\mathbb{C}}, F^{\bullet}(\text{Gr}_{\ell}^W \otimes \mathbb{C})$ is required to be a Hodge structure of weight ℓ for each ℓ .

Now, we can associate generalized Jacobians to any mixed Hodge structure:

$$J^p(H_{\mathbb{Z}}, F^{\bullet}, W_{\bullet}) = F^p \setminus (H_{\mathbb{Z}} \otimes \mathbb{C}) / H_{\mathbb{Z}}. \tag{A.6}$$

This generalized Jacobian does not depend on the weight filtration. These generalized Jacobians are functorial in the sense that we can define natural categories of mixed Hodge structures and of generalized Jacobians. Observe that if X is a compact Kähler threefold, then J^2 of the usual Hodge structure on $H^3(X)$ is just the usual intermediate Jacobian $J(X)$:

$$J^2 = (H^{3,0}(X) + H^{2,1}(X)) \setminus H^3(X, \mathbb{C}) / H^3(X, \mathbb{Z}). \tag{A.7}$$

Note that by Poincaré duality, we can write $(H^{3,0}(X) + H^{2,1}(X)) \setminus H^3(X, \mathbb{C}) \simeq (H^{3,0}(X) \oplus H^{2,1}(X))^*$.

A.2 Limiting mixed Hodge structure

We review the limiting Mixed Hodge Structure of a semistable degeneration $\pi : \mathcal{X} \rightarrow \Delta$, where \mathcal{X} and $X_t \equiv \pi^{-1}(t)$ are smooth for $t \neq 0$, while $X_0 = Y_1 \cup \dots \cup Y_c$ is a union of smooth normal crossings divisors Y_i .

The cohomology groups $H^k(X_t, A)$ for $t \neq 0$ form the fibers of local systems \mathcal{H}_A^k over Δ^* for $A = \mathbb{Z}, \mathbb{Q}$, or \mathbb{C} . The Hodge filtrations on $H^k(X_t, \mathbb{C})$ give rise to a decreasing filtration \mathcal{F}^{\bullet} of the vector bundle $\mathcal{H}_{\mathbb{C}}^k \otimes \mathcal{O}_{\Delta^*}$ on Δ^* by subbundles. The local system gives rise to a flat connection ∇ on $\mathcal{H}_{\mathbb{C}}^k \otimes \mathcal{O}_{\Delta^*}$, which obeys Griffiths transversality: $\nabla \mathcal{F}^p \subset \mathcal{F}^{p-1} \otimes \Omega_{\Delta^*}^1$. This is the prototypical example of a variation of Hodge structure.

We would like to take the limit of the Hodge filtration as $t \rightarrow 0$, but monodromy can prevent us from doing so. Instead, we pull back to the universal cover where we can disentangle the monodromy. Let \mathbb{H} be the upper half plane, which we realize as the

universal cover of Δ^* via $u : \mathbb{H} \rightarrow \Delta^*$, where $t = u(\tau) = \exp(2\pi i\tau)$. The pullback $u^*\mathcal{H}_{\mathbb{C}}^k \otimes \mathcal{O}_{\mathbb{H}}$ of the vector bundle to the universal cover becomes trivial, so we can and will trivialize the bundle as $H^k(X_t, \mathbb{C}) \otimes \mathcal{O}_{\mathbb{H}}$ for some fixed $t \neq 0$. The flat connection need not be the trivial one, but the covering map $\tau \mapsto \tau + 1$ leads to a monodromy transformation $T : H^k(X, \mathbb{Z}) \rightarrow H^k(X, \mathbb{Z})$ which naturally extends over \mathbb{Q} or \mathbb{C} . For each $\tau \in \mathbb{H}$, the fiber $\mathcal{F}_{\tau}^{\bullet}$ of \mathcal{F}^{\bullet} at τ together with $H^3(X_t, \mathbb{Z})$ defines a Hodge structure of weight k , which undergoes monodromy as $\tau \mapsto \tau + 1$.

In the situation of a semistable degeneration, T is known to be unipotent, $(T - I)^{n+1} = 0$ for some $n \geq 0$ [107]. For a unipotent transformation T , we can define its logarithm as

$$N = \log(T) = (T - I) - \frac{(T - I)^2}{2} + \frac{(T - I)^3}{3} - \dots, \tag{A.8}$$

which is a finite sum. The transformation N is nilpotent. We can then define a filtration

$$\exp(-\tau N) \mathcal{F}^{\bullet} \tag{A.9}$$

which by construction is invariant under $\tau \mapsto \tau + 1$. It can be shown that the limit

$$F_{\lim}^{\bullet} = \lim_{\tau \rightarrow i\infty} \exp(-\tau N) \mathcal{F}^{\bullet} \tag{A.10}$$

exists.

This filtration does not define a Hodge structure, but is the Hodge filtration of a mixed Hodge structure with respect to a suitably defined weight filtration W_{\bullet} on $H^k(X_t, \mathbb{Q})$. The weight filtration is uniquely characterized by

$$N(W_{\ell}) \subset W_{\ell-2}, \quad N^{\ell} : \text{Gr}_{k+\ell}^W \simeq \text{Gr}_{k-\ell}^W. \tag{A.11}$$

The mixed Hodge structure $(H^k(X_t, \mathbb{Z}), F^{\bullet} \lim, W_{\bullet})$ is called the *limiting mixed Hodge structure* and will be denoted H_{\lim}^k for brevity. For example, if $N^2 = 0$, we have

$$\begin{aligned} W_{k+1} &= H^k(X_t, \mathbb{Q}) \\ W_k &= \ker N \\ W_{k-1} &= \text{Im} N \\ W_{k-2} &= 0 \end{aligned} \tag{A.12}$$

so that $\text{Gr}_{k+1}^W \simeq \text{coker}(N)$, $\text{Gr}_k^W \simeq \ker N / \text{Im} N$, $\text{Gr}_{k-1}^W \simeq \text{Im} N$ and all other graded pieces of the weight filtration vanish.

The limiting mixed Hodge structure is related to the mixed Hodge structure on $H^*(X_0)$ by the Clemens-Schmid sequence. We sketch this connection in the case of interest, where there are two components, $X_0 = Y_1 \cup Y_2$.

Let $Y_{12} = Y_1 \cap Y_2$. Then for any k , $H^k(X_0)$ has a mixed Hodge structure whose only nonvanishing graded pieces are of weights $k - 1$ and k :

$$\text{Gr}_k H^k(X_0) = \ker \left(H^k(Y_1) \oplus H^k(Y_2) \rightarrow H^k(Y_{12}) \right) \tag{A.13}$$

$$Gr_{k-1}H^k(X_0) = \text{coker} \left(H^{k-1}(Y_1) \oplus H^{k-1}(Y_2) \rightarrow H^{k-1}(Y_{12}) \right). \quad (\text{A.14})$$

The mixed Hodge structure on $H^k(X_0)$ is related to the mixed Hodge structure on H_{lim}^k by the Clemens-Schmid sequence. Letting $n = \dim(X_0) = \dim(X_t)$, the Clemens-Schmid sequence reads

$$\cdots \rightarrow H_{2n+2-k} \xrightarrow{\alpha} H^k(X_0) \xrightarrow{i^*} H_{lim}^k \xrightarrow{N} H_{lim}^k \xrightarrow{\beta} H_{2n-k}(X_0) \xrightarrow{\alpha} H^{k+2}(X_0) \rightarrow \cdots \quad (\text{A.15})$$

In (A.15), the map i^* is deduced from the inclusion of X_0 into the total space of the family, while α and β are deduced from Poincaré duality. All maps are morphisms of mixed Hodge structures, which means that they shift the Hodge types by a fixed amount, called the *Hodge type* of the morphism. The maps α , i^* , N , and β have respective Hodge types $(n+1, n+1)$, $(0, 0)$, $(-1, -1)$, and $(-n, -n)$ respectively. See [108] for more details.

A.3 The conifold transition

Let us illustrate the computation of limiting mixed Hodge structure in the case of a degeneration of a smooth threefold to a conifold singularity. We refine this later to the case of a conifold transition. We assume that X_t is Calabi-Yau which defines a smoothing of X_0 , the conifold. While X_t is not a semistable degeneration, one arrives at a semistable degeneration by blowing up the conifold point of X_0 . This blowup does not affect the X_t for $t \neq 0$ which is all that the limiting mixed Hodge structure depends on. So we can still construct a limiting mixed Hodge structure as above.

It is well known that X_0 can be obtained from X_t by contracting an S^3 . By Poincaré duality, this corresponds to a vanishing cycle $A_0 \in H^3(X_t, \mathbb{Z})$. The monodromy is given by

$$T(\gamma) = \gamma + (\gamma \cdot A_0)A_0 \quad (\text{A.16})$$

Sometimes the monodromy transformation is written by extending A_0 to a symplectic basis (A_i, B_i) for $H^3(X_t, \mathbb{Z})$ with $0 \leq i \leq h^{2,1}(X_t)$.²⁵ We then have

$$\begin{aligned} T(A_i) &= A_i \\ T(B_0) &= -A_0 + B_0 \\ T(B_i) &= B_i, \quad i \neq 0. \end{aligned} \quad (\text{A.17})$$

Since $(T - I)^2 = 0$, we have $N = T - I$ and $N^2 = 0$. From (A.17) we get for the log of monodromy

$$\begin{aligned} N(A_i) &= 0 \\ N(B_0) &= -A_0 \\ N(B_i) &= 0, \quad i \neq 0. \end{aligned} \quad (\text{A.18})$$

We immediately get for the weight filtration

$$\begin{aligned} W_4 &= H^3(X_t, \mathbb{Q}) \\ W_3 &= \text{span}_{\mathbb{Q}} \{A_0, \dots, A_{h^{2,1}}, B_1, \dots, B_{h^{2,1}}\} \\ W_2 &= \mathbb{Q} \cdot A_0 \\ W_1 &= 0, \end{aligned} \quad (\text{A.19})$$

²⁵This is where we first use the Calabi-Yau condition.

where $h^{21} = h^{21}(X)$. We immediately get

ℓ	$\dim \text{Gr}_\ell^W$	basis
4	1	$\{B_0\}$
3	$2h^{21}$	$\{A_1, \dots, A_{h^{21}}, B_1, \dots, B_{h^{21}}\}$
2	1	$\{A_0\}$

(A.20)

Since Gr_4^W and Gr_2^W are each 1-dimensional and defined over the rationals (in particular they are real), they must have Hodge type $(2, 2)$ and $(1, 1)$, respectively.

For the limiting Hodge filtration we have

p	$\dim F_{\text{lim}}^p$
0	$2h^{21} + 2$
1	$2h^{21} + 1$
2	$h^{21} + 1$
3	1

(A.21)

Note that Gr_3^W is an ordinary Hodge structure of weight 3 and dimension $2h^{21}$. So its Jacobian $J^2(\text{Gr}_3^W)$ is an ordinary complex torus of dimension h^{21} .²⁶ A straightforward calculation using the Clemens-Schmid sequence shows that $J^2(\text{Gr}_3^W)$ is isomorphic to the intermediate Jacobian $J(\widetilde{X}_0)$ of the (non-Calabi-Yau) blow up of X_0 at the conifold point.

Claim. $J^2(H_{\text{lim}}^3)$ is a \mathbb{C}^* fibration over $J(\widetilde{X}_0)$.

This follows from two claims.

- $J^2(H_{\text{lim}}^3) = J^2(W_3)$, the second generalized Jacobian of the sub-mixed Hodge structure W_3 .²⁷
- $J^2(W_3)$ is a \mathbb{C}^* -bundle over $J^2(\text{Gr}_3^W)$.

To see the first subclaim, we first note that since Gr_4^W has Hodge type $(2, 2)$, we have for the induced Hodge filtration on Gr_4^W that $F^2\text{Gr}_4^W = \text{Gr}_4^W$. In terms of the limiting Hodge filtration this means:

$$H^3(X_t, \mathbb{Z}) = F^2 + W_3. \tag{A.22}$$

For brevity, in (A.22) and the sequel, F^2 denotes $F^2H^3\text{lim}$.

The inclusion $W_3 \subset H^3(X_t, \mathbb{Z})$ induces a map

$$(F^2 \cap W_3) \setminus W_3 / (W_3 \cap H^3(X_t, \mathbb{Z})) = J^2(W_3) \rightarrow J^2(H_{\text{lim}}^3) = F^2 \setminus H^3(X_t, \mathbb{C}) / H^3(X_t, \mathbb{Z})$$

which we now show is an isomorphism.

²⁶The notion of a *polarization* of a mixed Hodge structure is needed to confirm this assertion. We omit further discussion of polarizations for brevity.

²⁷In fact, by Clemens-Schmid, the mixed Hodge structure W_3 is precisely the mixed Hodge structure on X_0 and so is independent of the chosen degeneration of X_t to X_0 .

First of all, surjectivity follows immediately from (A.22). Consider next injectivity. Suppose $\omega \in W_3 \cap (F^2 + H^3(X_t, \mathbb{Z}))$. We must show that $\omega \in (F^2 \cap W_3) + (H^3(X_t, \mathbb{Z}) \cap W_3)$. Now consider $F^2 \cap \overline{F^2} \cap H^3(X_t, \mathbb{Z})$. Since Gr_4^W has type (2, 2) and is spanned by B_0 , we have a element $\widetilde{B}_0 \in F^2 \cap \overline{F^2} \cap H^3(X_t, \mathbb{Z})$ which is equivalent to $B_0 \bmod W_3$. We have $N\widetilde{B}_0 = NB_0 = -A_0$.

Write

$$\omega = \phi + \eta, \quad \phi \in F^2, \quad \eta \in H_{\mathbb{Z}} \tag{A.23}$$

Applying N to (A.23), we have $0 = N\omega = N\phi + N\eta$, where the first equality holds since $\omega \in W_3$. Thus $N\phi = -N\eta$ hence is an element of $W_2 \cap H_{\mathbb{Z}}$, and we conclude that

$$N\phi = kA_0 \tag{A.24}$$

for some integer k . Then we can rewrite (A.23) as

$$\omega = \left(\phi + k\widetilde{B}_0 \right) + \left(-k\widetilde{B}_0 + \eta \right) \tag{A.25}$$

Each of the two terms in parentheses in (A.25) is in W_3 since they were constructed to be contained in the kernel of N . Also $\phi + k\widetilde{B}_0 \in F^2$ since it is a sum of terms in F^2 , and $-k\widetilde{B}_0 + \eta \in H^3(X_t, \mathbb{Z})$ since it is a sum of integral terms.

For the second subclaim, we consider the natural map

$$(F^2 \cap W_3) \setminus W_3 / (W_3 \cap H^3(X_t, \mathbb{Z})) = J^2(W_3) \rightarrow J^2(\text{Gr}_3^W) \tag{A.26}$$

which is surjective by the surjectivity of $W_3 \rightarrow \text{Gr}_3^W$. Further, we have

$$J^2(\text{Gr}_3^W) = ((F^2 \cap W_3) / (F^2 \cap W_2)) \setminus \text{Gr}_3^W / ((W_3 \cap H^3(X_t, \mathbb{Z})) / (W_2 \cap H^3(X_t, \mathbb{Z}))) \tag{A.27}$$

We let $\phi \in W_3$ be such that

$$\phi \in (F^2 \cap W_3) + (H^3(X_t, \mathbb{Z}) \cap W_3) + W_2 \tag{A.28}$$

and we need to classify the possible ϕ modulo $(F^2 \cap W_3) + (H^3(X_t, \mathbb{Z}) \cap W_3)$. Clearly the only flexibility is to add an element of W_2 to ϕ , i.e. a complex multiple of A_0 , modulo an integer multiple of A_0 , which is a \mathbb{C}^* , as claimed.

It is now straightforward to extend this analysis to the type IIA conifold transition in the situation where m hypermultiplets charged under $U(1)^r$ get Higgsed. Geometrically, we have a smooth Calabi-Yau threefold \widetilde{X} containing m curves $C_i \simeq \mathbb{P}^1$ s whose homology classes span an r -dimensional subspace of $H_2(\widetilde{X})$. We simultaneously contract these curves to obtain a threefold X_0 which has m conifold singularities and is smooth elsewhere. We then deform X_0 to a smooth X_t for $t \neq 0$.

For t near 0, we get for each conifold point $p_i \in X_0$ a vanishing cycle $A_i \in H^3(X_t, \mathbb{Z})$. The monodromy is given by the Picard-Lefschetz transformation

$$T(\gamma) = \gamma + \sum_i (\gamma \cdot A_i) A_i. \tag{A.29}$$

The vanishing cycles satisfy r independent relations in cohomology

$$\sum_{i=1}^m c_{ij} A_i = 0, \quad j = 1, \dots, r, \tag{A.30}$$

so that the A_i span an $m - r$ -dimensional space of vanishing cycles $\mathcal{V} \subset H^3(X_t, \mathbb{Z})$.

Repeating the previous analysis, we get a weight filtration with $W_2 = \text{Gr}_2^W = \mathcal{V}$, $\text{Gr}_4^W \simeq \text{Gr}_2^W$ (via N) and $\text{rank Gr}_3^W = 2h^{2,1} + 2 - 2(m - r)$. In this case, $J^2(\text{Gr}_3^W)$ is the ordinary intermediate Jacobian of \tilde{X} . Our result is that:

$$J^2(H_{\text{lim}}^3) \text{ is a } (\mathbb{C}^*)^{m-r} \text{ fibration over } J(\tilde{X}). \tag{A.31}$$

Finally, we have to explain the global structure of this $(\mathbb{C}^*)^{m-r}$ fibration in order to give a complete picture of the RR moduli. This is again given by the limiting Hodge structure, specifically its extension class.

Recall the result of [109] in a special case adapted to our purposes. Given a mixed Hodge structure H , consider the exact sequence

$$0 \rightarrow \text{Gr}_k^W H \rightarrow H \rightarrow H/\text{Gr}_k^W H \rightarrow 0 \tag{A.32}$$

This exhibits H as an extension of the mixed Hodge structure $H/\text{Gr}_k^W H \rightarrow 0$ by the mixed Hodge structure $\text{Gr}_k^W H$. It is shown in [109] that such extensions are classified by the generalized complex torus $J^0 \text{Hom}(H/\text{Gr}_k^W H, \text{Gr}_k^W H)$ defined as

$$\text{Hom}((H/\text{Gr}_k^W H), \text{Gr}_k^W H) / (F^0 \text{Hom}((H/\text{Gr}_k^W H), \text{Gr}_k^W H) + \text{Hom}_{\mathbb{Z}}), \tag{A.33}$$

where $F^0 \text{Hom}(H/\text{Gr}_k^W H, \text{Gr}_k^W H)$ is defined as

$$\{\phi \in \text{Hom}((H/\text{Gr}_k^W H), \text{Gr}_k^W H) \mid \phi(F^p H/\text{Gr}_k^W H) \subset F^p \text{Gr}_k^W H \forall p\} \tag{A.34}$$

and $\text{Hom}_{\mathbb{Z}}$ denotes the homomorphisms preserving the integral lattices.

Letting H be W_3 of the limiting mixed Hodge structure above, and $k = 2$, then (A.32) becomes

$$0 \rightarrow \mathcal{V}_{\mathbb{C}} \rightarrow W_3 H_{\text{lim}}^3 \rightarrow H^3(\tilde{X}) \rightarrow 0. \tag{A.35}$$

Passing to Jacobians, we see that the extension class (A.33), combined with an arbitrary character of $(\mathbb{C}^*)^{m-r} = \mathcal{V}_{\mathbb{C}}/\mathcal{V}_{\mathbb{Z}}$ produces an element of $\text{Hom}(H_{\text{lim}}^3/F^2, \mathbb{C})/H^3(\tilde{X}, \mathbb{Z})$, a complex torus dual to $J(\tilde{X})$, with points which parameterize line bundles on $J(X)$. This completely characterizes the bundle structure. Finally, note that the weight 3 part only depends on X_0 and not on the choice of the smoothing X_t , so we have intrinsically described a space that we assert are the RR moduli.

A.4 Emergent SU(2) Hitchin-like system

In this appendix we provide some additional technical details on the analysis of limiting mixed Hodge structures for a curves of ADE singularities given in section 4. These methods are borrowed from techniques used in a related collaboration of the third author with

D. Morrison and R. Plesser [110]. The main point is that in contrast to the case of a conifold, for a curve of ADE singularities, the classical intermediate Jacobian does not have a canonical limit. However, the theory of limiting mixed Hodge structures directly points to the appearance of a Hitchin-like system.

Along these lines, we first present some additional details on the case of an isolated curve of A_1 singularities discussed in section 4. This analysis is performed from another perspective in [76, 77]. The primary novelty here is that in preparation for our application F-theory, we will couch this analysis in the formalism of limiting mixed Hodge structures. Additionally, we shall extend the analysis of [76, 77] to cover Hitchin-like systems coupled to defect modes.

To begin, we return to a Calabi-Yau threefold X containing a curve C of A_1 singularities and no enhancements. We deform it using a quadratic differential q as in (4.28). We make the simplifying assumption that q has simple zeros, so the zero set Z of q has $|Z| = 4g - 4$. We study the limiting mixed Hodge structure and identify it with the fiber of the $SU(2)$ Hitchin system over the point q of the Hitchin base. It is known that this fiber can be identified with a generalized Prym variety of the associated spectral cover $z^2 = q$.

To achieve a normal crossings situation, we make the substitution $\epsilon = t^2$ to get

$$xy + z^2 = t^2q \tag{A.36}$$

and blow up the singularity along $C \times \{0\}$ defined by $x = y = z = t = 0$. The central fiber X_0 has two smooth components: \tilde{X} , the blowup of X along C , in which C is replaced by a family of \mathbb{P}^1 s parametrized by C , and the exceptional divisor E , which can conveniently be thought of as being defined by the same equation (A.36), with (x, y, z, t) now interpreted as homogeneous coordinates on the projective bundle $\mathbb{P}(L_x \oplus L_y \oplus L_z \oplus \mathcal{O}_C)$ over C , with line bundle assignments as in subsection 4.3. So the threefold E is fibered over C , with generic fiber isomorphic to a smooth quadric surface in \mathbb{P}^3 . But the fibers over Z are singular quadrics, isomorphic to the quadric cone $xy + z^2 = 0$ in \mathbb{P}^3 . The intersection $F = \tilde{X} \cap E$ is just the exceptional divisor of the blowup of X (without the product with $t \in \mathbb{C}$) and is a \mathbb{P}^1 -bundle over C . Thus we have achieved normal crossings.

We now compute the mixed Hodge structure of $H^3(X_0)$. We have

$$\begin{aligned} Gr_3 H^3(X_0) &= \ker \left(H^3(\tilde{X}) \oplus H^3(E) \rightarrow H^3(F) \right) \\ Gr_2 H^3(X_0) &= \text{coker} \left(H^2(\tilde{X}) \oplus H^2(E) \rightarrow H^2(F) \right) \end{aligned} \tag{A.37}$$

From this it follows by direct computation that $Gr_2 H^3(X_0) = 0$ and the “local” part of $Gr_3 H^3(X_0)$ is isomorphic to $H^3(E)$ (with its Hodge structure). In a little more detail, the map $H^3(\tilde{X}) \rightarrow H^3(F)$ is surjective, and its kernel is the “non-local part” of $H^3(\tilde{X})$.

The description of E together with a Mayer-Vietoris calculation gives $8g - 6$ for the 3rd Betti number of E . It follows that the 3rd (local) Betti number of X_0 is $8g - 6$. So the Jacobian associated to this Hodge structure is just the intermediate Jacobian $J(E)$, a compact complex torus of dimension $4g - 3$. In fact, this is an abelian variety since $h^{3,0}(E) = 0$. We show that this abelian variety is isogenous to the Jacobian of the spectral cover C_q with equation $z^2 = q$.

To see this, we rewrite the spectral cover in projective coordinates as $z^2 = t^2q$, where the homogeneous coordinates (z, t) live in $K_C \oplus \mathcal{O}_C$. Then, for each point of the spectral cover, we get two \mathbb{P}^1 s in E : substituting $z^2 = t^2q$ in (A.36) gives $xy = 0$. Either of these families of \mathbb{P}^1 s gives an Abel-Jacobi map

$$J(C_q) \rightarrow J(E), \tag{A.38}$$

which can be shown to be surjective by the surjectivity of the related map $H^1(C_q) \rightarrow H^3(E)$. It follows that (A.38) is an isogeny, being a surjective map of abelian varieties of the same dimension.

To identify the limiting mixed Hodge structure of (A.36), we use the Clemens-Schmid sequence, which includes the terms

$$H_5(X_0) \rightarrow H^3(X_0) \rightarrow H_{\text{lim}}^3 \xrightarrow{N} H_{\text{lim}}^3. \tag{A.39}$$

Looking at graded pieces gives

$$Gr_{-6}H_5(X_0) \rightarrow Gr_2H^3(X_0) \rightarrow Gr_2H^3 \rightarrow 0 \tag{A.40}$$

and

$$Gr_{-5}H_5(X_0) \rightarrow Gr_3H^3(X_0) \rightarrow Gr_3H_{\text{lim}}^3 \rightarrow 0 \tag{A.41}$$

Another Meyer-Vietoris calculation gives $Gr_{-6}H_5(X_0) = 0$ and $Gr_{-5}H_5(X_0) \simeq H_1(C)$. The conclusion is that the local part of H_{lim}^3 is a quotient of $H^3(E)$ by the image of a map $H^1(C) \rightarrow H^3(E)$. On Jacobians, we get a map $J(C) \rightarrow J(X)$.

Since $J(X)$ is isogenous to $J(C_q)$, the local part of the the limiting mixed Hodge structure is a quotient of $J(C_q)$ by $J(C)$ up to finite order.

The generalized Prym of C_q is the fiber of the Hitchin map over q , and up to a finite group is the quotient of $J(C_q)$ by $J(C)$ (the mapping $J(C) \rightarrow J(C_q)$ being given by pullback after a shift). So, it is natural to expect the local part of H_{lim}^3 to be the generalized Prym of C_q and local part of the full hypermultiplet moduli space to be equal to the Hitchin system. In fact, this has already been verified in [77] away from the discriminant locus.

Having covered the case of an isolated curve of A_1 singularities, we now extend our analysis to the case where the Hitchin-like system is coupled to defect modes. To this end, we now consider the case of X a non-compact threefold given by a curve C of A_1 singularities. Let $P \subset C$ be the location of the localized matter associated with the zeroes of the section $\beta \in \mathcal{O}_C(P)$. The geometry we consider is:

$$xy = \alpha z^3 + \beta z^2. \tag{A.42}$$

Now, we saw in section 4.4 that there are two complex structure moduli for each point of P , one arising from torsion in \mathcal{T}^1 and the other comes from replacing $2K_C$ with $2K_C + P$ in deforming A.42. So the count of complex structure moduli is $3g - 3 + 2k$ where $k = |P|$, as one would expect from Higgsing g $SU(2)$ adjoints and k fundamentals.

We now describe the most general complex structure deformation. From the analysis in section 4.4, the parameters are:

- q : a section of $2K_C + P$
- γ : a section of $K_C + P$. Only $\gamma|_P$ is a true modulus, but we need to fix a choice of γ for a concrete model. These deformations correspond to the torsion in \mathcal{T}^1 .

The equation of the deformation can be taken to be

$$xy = \alpha z^3 + \beta z^2 + t\gamma z + t^2 q. \tag{A.43}$$

We compute the limiting mixed Hodge structure as $t \rightarrow 0$. To achieve a semistable degeneration, we blow up $x = y = z = t = 0$ inside the fourfold which is the total space of the deformation. There are now two components over $t = 0$: the blowup \tilde{X} of X , and the exceptional divisor E of the blowup. E is fibered over C , with fiber having equation

$$xy = \beta z^2 + t\gamma z + t^2 q. \tag{A.44}$$

In (A.44), x, y, z, t are now coordinates in a *projective* bundle over C , so that E is a bundle of quadric surfaces over C . The generic fibers are smooth quadrics, but the fibers are singular over the discriminant locus Δ with equation $\beta q - 4\gamma^2 = 0$. As this is a section of $2K + 2P$, there are $4g - 4 + 2k$ singular fibers, where $k = |P|$. In the generic situation, all singularities are quadric cones.

Recall that H^2 of a smooth quadric is two-dimensional, as there are two families of \mathbb{P}^1 s on a smooth quadric. Also H^2 of a quadric cone is one-dimensional, corresponding to the unique family of lines (which all pass through the vertex of the cone) on the quadric cone. Next, letting $F = E \cap \tilde{X}$, we see that F is just the exceptional divisor of \tilde{X} , which is a \mathbb{P}^1 bundle over C which degenerates to a union of two \mathbb{P}^1 s over P .

We now compute the limiting mixed Hodge structure. The relevant pieces are already visible in the mixed Hodge structure on the central fiber $X_0 = \tilde{X} \cup E$. The weight three part is

$$W_3 H^3(X_0) = \ker \left(H^3(\tilde{X}) \oplus H^3(E) \rightarrow H^3(F) \right) \tag{A.45}$$

and the weight two part is

$$W_2 H^3(X_0) = \text{coker} \left(H^2(\tilde{X}) \oplus H^2(E) \rightarrow H^2(F) \right) \tag{A.46}$$

We now specialize to the case $C = \mathbb{P}^1$, the case that is relevant for heterotic / F-theory duality. For W_3 , note that $H^3(F) = 0$, so $W_3 = H^3(\tilde{X}) \oplus H^3(E)$. The “local” part comes from $H^3(E)$, so we compute this. From the Leray spectral sequence, we look at the part $H^1(R^2\pi_*\mathbb{Z})$, where $\pi : E \rightarrow C$ is the projection. The contribution we need is from the locus where the quadrics are smooth. These have a pair of H^2 classes in the fiber, corresponding to the lines ℓ', ℓ'' of the respective rulings on the quadrics. The class $\ell' - \ell''$ is odd under monodromy around points of Δ (where the two rulings come together: a generic singular quadric surface is a cone with a singular ruling give by the lines through the singular point). Let \tilde{C} be the double over of C branched along Δ , and let $\tilde{\Delta} \subset \tilde{C}$ be the ramification locus. Let $H^1(\tilde{C} - \tilde{\Delta})^-$ be the part of cohomology which is odd under

monodromy. Then the relevant classes in W_3H^3 are given by $p \otimes ([\ell'] - [\ell''])$. These classes correspond to the Prym and will relate to the Hitchin system.

Let us now count the degrees of freedom associated with our system:

- $\text{euler}(C - \Delta) = (2 - 2g) - (4g - 4 + 2k) = 6 - 6g - 2k$
- $\text{euler}(\tilde{C} - \tilde{\Delta}) = 2(6 - 6g - 2k) = 12 - 12g - 4k$
- $h^1(C - \Delta) = 6g + 2k - 7$; $h^1(\tilde{C} - \tilde{\Delta}) = 12g + 4k - 13$
- $\dim H^1(\tilde{C} - \tilde{\Delta})^- = (12g + 4k - 13) - (6g + 2k - 7) = 6g - 6 + 2k$
- The corresponding part of the intermediate Jacobian of the limiting MHS has dimension half of that: $3g - 3 + k$. This can be matched to the fibers of a parabolic Hitchin system.

The missing k moduli come from W_2H^3 . For each point $p \in P$, consider the difference of the pair of lines over p in F . This is a class in $H^2(F)$ which survives in the cokernel. Like the conifold calculation, in the corresponding intermediate Jacobian, we got a \mathbb{C}^* factor. So in conclusion, the net count of RR moduli is $3g - 3 + 2k$, matching the complex structure moduli, as expected in the physical theory.

To summarize then, in this section we have seen that the Hitchin System is contained in the local part of the Calabi-Yau integrable system. This result can be succinctly summarized by the following diagram:

$$\begin{array}{ccc}
 & M & \\
 & \nearrow \downarrow & \\
 \pi^* H & \rightarrow \widetilde{M}_{\text{cplx}} & \tag{A.47} \\
 \downarrow & & \downarrow \pi \\
 H & \rightarrow M_{\text{loc}} &
 \end{array}$$

where H is the Hitchin moduli space, $\widetilde{M}_{\text{cplx}}$ the complex structure moduli space of the resolved geometry, and the maps are defined such that the bottom map is the Hitchin fibration and the top map is an inclusion.

B Brief introduction to Deligne cohomology

In the context of the Hitchin-like system and its lift to a global F-theory geometry, there is a natural sense in which one can unify the space of flat connections with flux data. Here we briefly this unified description for a smooth analytic variety X . As we now explain, the relevant mathematical object is the Deligne cohomology of X . For a review of Deligne cohomology, see for example [111].

The starting point for our considerations is a *smooth* analytic variety X . We then form the Deligne complex $\mathbb{Z}(p)_{\mathcal{D}}$:

$$0 \rightarrow \mathbb{Z}(p) \rightarrow \Omega_X^0 \rightarrow \Omega_X^1 \cdots \rightarrow \Omega_X^{p-1} \tag{B.1}$$

where $\mathbb{Z}(p) = (2\pi i)^p \mathbb{Z}$, and Ω_X^j refers to the sheaf of holomorphic j -differentials on X . For each value of p , we can define an associated cohomology theory, which we label as:

$$H_{\mathcal{D}}^q(X, \mathbb{Z}(p)) \equiv H^q(X, \mathbb{Z}(p)_{\mathcal{D}}) \tag{B.2}$$

i.e. the Deligne cohomology is defined by the hypercohomology of the complex.

For the purposes of this paper, the key feature of Deligne cohomology is that it provides a unified perspective on the discrete data of fluxes, and three-form potential moduli. Indeed, for any p , we have the short exact sequence:

$$0 \rightarrow J^p(X) \rightarrow H_{\mathcal{D}}^{2p}(X, \mathbb{Z}(p)) \rightarrow H_{\mathbb{Z}}^{p,p}(X) \rightarrow 0. \tag{B.3}$$

where $J^p(X)$ is the intermediate Jacobian in the sense of Griffiths [112–114].

For details on the geometric interpretation of the various Deligne cohomology groups, see for example [115]. At least for low values of p , there is a simple geometric interpretation of this data. For example, for C an algebraic curve and $p = 1$, we can see that the sequence reduces to:

$$0 \rightarrow J(C) \rightarrow H_{\mathcal{D}}^2(C, \mathcal{O}_C^*) \rightarrow H_{\mathbb{Z}}^{1,1}(C) \rightarrow 0, \tag{B.4}$$

i.e. the Deligne cohomology captures the space of flat connections and discrete flux data as well. This provides a simple way to characterize the gauge theoretic data of the Hitchin system. Similar though more involved considerations hold for higher Deligne cohomology groups.

Now, an important caveat in this discussion is that it works for *smooth* varieties X . Of course, in the applications to F-theory, we typically do not have this luxury. In fact, the analysis of this paper motivates the conjecture that a Hitchin-like system provides a *definition* of Deligne cohomology in certain singular limits of Calabi-Yau threefolds. A similar proposal holds for singular Calabi-Yau fourfolds, where now we have the Vafa-Witten theory coupled to matter fields and Yukawas.

C Intermediate Jacobians and stable degeneration

In section 6 we considered a class of examples where the calculation of the relevant components of the intermediate Jacobian $J(X)$ could be reduced to a simpler calculation of the Jacobian of a spectral curve. In this appendix we present some additional details on this limiting behavior of the intermediate Jacobian in the stable degeneration limit. We shall explain how to apply this analysis in some specific examples of singular spectral curves.

First, consider the simplest case where X is a smooth, generic elliptically fibered Calabi-Yau threefold over a Hirzebruch base \mathbb{F}_n . We consider the stable degeneration limit so that it becomes a union of two elliptic fibrations $\mathcal{X}_1, \mathcal{X}_2$ over \mathbb{F}_n , intersecting over an elliptically fibered K3 surface, S . We assume that the \mathcal{X}_i and S are all generic, and in particular smooth. We want to understand what happens to $J(X)$ in this process.

Letting X_t be a smooth Calabi-Yau with $t \neq 0$, and let $X_0 = \mathcal{X}_1 \cup \mathcal{X}_2$ as above, then $H^3(X_t, \mathbb{Z})$ undergoes monodromy as t goes around zero. The monodromy T is unipotent, so $N = \log(T)$ is nilpotent. It can be shown that $N^2 = 0$, so $\text{Im} N \subset \ker N$.

The transformation N defines the *monodromy weight filtration* $\cdots \subset W_i \subset W_{i+1} \subset \cdots \subset H^3(X_t, \mathbb{C})$ by

$$\begin{aligned} W_4 &= H^3(X_t, \mathbb{C}) \\ W_3 &= \ker N \\ W_2 &= \text{Im} N \\ W_1 &= 0 \end{aligned} \tag{C.1}$$

Next, letting $\text{Gr}_i = W_i/W_{i-1}$ be the associated graded pieces of the weight filtration, we have:

$$\begin{aligned} \text{Gr}_4 &\simeq H^2(S, \mathbb{C}) \\ \text{Gr}_3 &\simeq H^3(\mathcal{X}_1, \mathbb{C}) \oplus H^3(\mathcal{X}_2, \mathbb{C}) \\ \text{Gr}_2 &\simeq H^2(S, \mathbb{C}) \\ \text{Gr}_i &= 0, \quad i \neq 2, 3, 4 \end{aligned} \tag{C.2}$$

The Hodge numbers of X_t can be related to these graded pieces, with shifts on Gr_2 and Gr_4 . The computation is:

$$\begin{aligned} H^2(S, \mathbb{C}) & \begin{pmatrix} 1 & 20 & 1 & 0 \end{pmatrix} && \text{(from Gr}_4) \\ H^3(\mathcal{X}_1, \mathbb{C}) & \begin{pmatrix} 0 & 111 & 111 & 0 \end{pmatrix} \\ H^3(\mathcal{X}_2, \mathbb{C}) & \begin{pmatrix} 0 & 111 & 111 & 0 \end{pmatrix} \\ H^2(S, \mathbb{C}) & \begin{pmatrix} 0 & 1 & 20 & 1 \end{pmatrix} && \text{(from Gr}_2) \end{aligned} \tag{C.3}$$

and the columns add up to the Hodge numbers $(1, 243, 243, 1)$ of X_t , as they must. More precisely, let

$$F_{\text{lim}}^\bullet = \lim_{t \rightarrow 0} \exp\left(-\frac{1}{2\pi i} \log(t)N\right). \tag{C.4}$$

Then this limit exists and induces the familiar Hodge structures on each of the graded pieces (C.2). The usual Hodge structures can be recovered asymptotically as $t \rightarrow 0$ as $\exp\left(\frac{1}{2\pi i} \log(t)N\right) F_{\text{lim}}^\bullet$.

Next, suppose that X_t has a singular limit X_0 . We assume that this is a semistable degeneration (a mild requirement, often achievable by a substitution $t \mapsto t^n$ and a blowup of X_0). Then the Hodge structure approaches a *limiting mixed Hodge structure* H_{lim}^3 , a complex vector space of the same dimension as $H^3(X)$, equipped with a Hodge filtration and a finite increasing weight filtration $\cdots \subset W_i \subset W_{i+1} \subset \cdots \subset H_{\text{lim}}^3$. We put $\text{Gr}_i = W_i/W_{i-1}$ (see [42] for details for Calabi-Yau fourfolds). For example, suppose $X_0 = \mathcal{X}_1 \cup \mathcal{X}_2$ is the usual stable degeneration limit to two dP_9 fibrations. Then we can return to line (C.2). In this and similar cases, W_3 represents the part of $H^3(X_t)$ that survives in the limit as $t \mapsto 0$.

C.1 Spectral covers and dP_9 fibrations

Having reduced the computation of the limiting mixed Hodge structure to a calculation of the intermediate Jacobian of \mathcal{X}_1 , one of the components appearing in the stable degeneration, we can now specialize further to a discussion of spectral covers and dP_9 fibrations.

To begin, we reviewing the dictionary between E_8 bundles on an elliptic curve E and dP_9 's containing E as an elliptic fiber. For additional discussion, see e.g. [91, 92]. Let G be a semisimple group and let $\mathcal{M}_G(E)$ be the moduli space of semistable G -bundles on E . Let $T \subset G$ be a maximal torus. Then the structure group of any G bundle can be reduced to T , leading to a description

$$\mathcal{M}_G(E) \simeq \mathcal{M}_T(E)/W, \tag{C.5}$$

where W is the Weyl group of G . Now, if χ is a character of T and \mathcal{P} is a principal T -bundle on E , we get an induced line bundle \mathcal{V}_χ on E , giving rise to a homomorphism

$$\Lambda \rightarrow \text{Pic}^0(E), \quad \chi \mapsto \mathcal{V}_\chi, \tag{C.6}$$

where Λ is the lattice of characters of T , which we identify with the weight lattice Λ_G of G . The degree zero constraint follows from the condition that our flux has vanishing first Chern class. Then, we can rewrite (C.5) as

$$\mathcal{M}_G(E) = \text{Hom}(\Lambda_G, \text{Pic}^0(E)) / W. \tag{C.7}$$

Now let D be a dP_8 containing E as an anticanonical divisor. The anticanonical linear system on a dP_8 has a unique base point p_0 , which we require to be the origin of the group structure on E . We sometimes blow up p_0 to get a dP_9 with an elliptic fibration containing E as a fiber. Next, we define

$$H^2(D, \mathbb{Z})^\perp \equiv \{\gamma \in H^2(D, \mathbb{Z}) \mid \gamma \cdot E = 0\}. \tag{C.8}$$

Then $H^2(D, \mathbb{Z})^\perp$ is isomorphic to Λ_{E_8} . The isomorphism is not canonical but is determined up to the action of $W(E_8)$ on Λ_{E_8} . Further, we see that the pair (D, E) determines an E_8 bundle on E as follows. Composing the homomorphism

$$H^2(D, \mathbb{Z}) \rightarrow \text{Pic}^0(E), \quad \gamma \mapsto \mathcal{O}_D(\gamma)|_E \tag{C.9}$$

with the isomorphism $\Lambda_{E_8} \simeq H^2(D, \mathbb{Z})$, we get a homomorphism $\Lambda_{E_8} \rightarrow \text{Pic}^0(E)$, which determines an E_8 bundle. If we modify the choice of isomorphism by an element of $W(E_8)$, we still get the same E_8 bundle.

Conversely, given an E_8 bundle \mathcal{V} on E , we can represent \mathcal{V} by a T -bundle $\bigoplus_{i=1}^8 \mathcal{O}_E(p_i - p_0)$. We construct a dP_8 containing E as an anti-canonical section as follows. First, embed $E \hookrightarrow \mathbb{P}^2$ as a Weierstrass cubic using the linear system $|3p_0|$, i.e. write E in Weierstrass form with p_0 corresponding to $(x, y, z) = (0, 1, 0) \in \mathbb{P}^2$. Then blow up the points p_1, \dots, p_8 inside \mathbb{P}^2 to obtain the desired dP_8 , or blowup p_0, p_1, \dots, p_8 to obtain a dP_9 containing E as a fiber.

We can similarly describe $SU(N)$ bundles on E as

$$\bigoplus_{i=1}^N \mathcal{O}_E(p_i - p_0), \quad \sum p_i = p_0, \tag{C.10}$$

where in (C.10) the sum $\sum p_i$ denotes addition in the group structure of E . So, when $\sum_{i=1}^N p_i = p_0$ and $p_{N+1} = \dots = p_8 = p_0$, then the structure group of the corresponding E_8 bundle can be reduced to $SU(N)$. More generally, any T -bundle which can be brought to this form by an element of the Weyl group has an associated E_8 bundle whose structure group can be reduced to $SU(N)$. These two constructions are inverse to each other and identify E_8 bundles on E with dP_9 fibrations containing E as a fiber.

C.2 An SU(3) example

In section 6 we explained how to embed the spectral curve associated to an SU(2) spectral curve into the geometry of the elliptic fibration $\pi : \mathcal{X}_i \rightarrow \mathbb{F}_n$ associated with the stable degeneration limit of an elliptic Calabi-Yau threefold $X = \mathcal{X}_1 \cup \mathcal{X}_2$. In this subsection we perform a similar analysis for an SU(3) spectral curve. As per our discussion in subsection 6.2.1, we use a presentation of the minimal Weierstrass model embedded in a \mathbb{P}^2 bundle over an appropriate base space.

To begin, we start on the heterotic side of the duality, associated with compactification of the heterotic string on a K3 surface in the presence of a vector bundle \mathcal{V} with structure group SU(3). Now, an SU(3) bundle on an elliptic curve E is described in terms of three points $p_1, p_2, p_3 \in E$ such that $p_1 + p_2 + p_3 = 0$. If E is in Weierstrass form, this just means that the points p_i are collinear. Comparing to the SU(2) case, we just have to replace (6.23) with

$$f_{8+n}U + q_{6+n}V + g_{12+n}W = 0, \tag{C.11}$$

where the relationship between the degrees of f, q, g is determined by (6.14). Note that with $Z \subset \mathbb{P}^1$ as before, we have

$$\begin{aligned} H^0(\mathbb{P}^1, 2K + Z) &\simeq H^0(\mathcal{O}(n + 8)) \\ H^0(\mathbb{P}^1, 3K + Z) &\simeq H^0(\mathcal{O}(n + 6)), \end{aligned} \tag{C.12}$$

perfectly matching the parameters f_{8+n} and q_{6+n} in (C.11) as in the SU(2) case. The spectral cover (C.11) is isomorphic to the corresponding Hitchin spectral cover as can be seen by comparing branch points.

Let us turn next to the F-theory description. To begin, recall that the Weierstrass equation is

$$y^2\lambda = x^3 + (f_{8+n}z_0^3z_1 + f_8z_0^4)x\lambda^2 + (q_{6+n}^2z_0^4z_1^2 + g_{12+n}z_0^5z_1 + g_{12}z_0^6)\lambda^3. \tag{C.13}$$

On the F-theory side, to get the homogeneity required by (6.15), we must modify (C.11) to

$$f_{8+n}x + q_{6+n}y + g_{12+n}z_0^2\lambda = 0. \tag{C.14}$$

We uncomplete the square in y to rewrite the Weierstrass equation in new coordinates as

$$y^2\lambda + 2y\lambda^2q_{6+n}z_0^2z_1 = x^3 + (f_{8+n}z_0^3z_1 + f_8z_0^4)x\lambda^2 + (g_{12+n}z_0^5z_1 + g_{12}z_0^6)\lambda^3, \tag{C.15}$$

Redefining q by rescaling to take care of the factor of 2 and the sign to match the spectral cover, we rewrite this as

$$y^2\lambda = x^3 + f_8z_0^4x\lambda^2 + g_{12}z_0^6\lambda^3 + (f_{8+n}xz_0 + q_{6+n}y + g_{12+n}z_0^3\lambda)z_0^2z_1\lambda^2 \tag{C.16}$$

so as in the SU(2) case, the spectral cover parameterizes a family of curves in the F-theory model, giving an Abel-Jacobi mapping from the Jacobian of the spectral curve to $J(\mathcal{X})$.

We now tune the coefficient q to 0. This forces the spectral curve to become reducible, with the zero section of the heterotic K3 as a component. We want to understand the limit of the Abel-Jacobi mapping as $q \rightarrow 0$. The two components of the spectral curve intersect

at $8 + n$ pairs of points where $f_{8+n} = 0$, and the E_6 enhances to E_7 . The corresponding curve in the F-theory model is the zero section over the fiber of \mathbb{F}_n corresponding to a point of \mathbb{P}^1 at which $f_{8+n} = 0$. Note that this curve intersects the E_7 locus by our explicit parametrization of this curve.

We resolve the E_6 singularity and see what we are left with. This can be done explicitly by resolving the E_6 singularity, but there is an easier way: the E_6 or E_7 singularities live at $x = y = z_0 = 0$, but the zero section is at $x = \lambda = 0$. Hence the curve is disjoint from the singularity. By explicit calculation, the Hilbert scheme of these curves is supported on the reducible spectral curve, and also contains embedded points at the intersections.
