ABSTRACT: We show how to use on-shell unitarity methods to calculate renormalisation group coefficients such as beta functions and anomalous dimensions. The central objects are the form factors of composite operators. Their discontinuities can be calculated via phase-space integrals and are related to corresponding anomalous dimensions. In particular, we find that the dilatation operator, which measures the anomalous dimensions, is given by minus the phase of the S -matrix divided by π . We illustrate our method using several examples from Yang-Mills theory, perturbative QCD and Yukawa theory at one-loop level and beyond.

1 Introduction

On-shell approaches play a central role in many state-of-the-art calculations in perturbative gauge theories. Since only physical degrees of freedom appear on-shell, they enable to build observables in terms of the simplest but meaningful physical building blocks. This is especially advantageous for massless particles with spin, such as gluons, where the focus on the two physical helicities removes the need to introduce gauge redundancies, removing at the same time intricate cancellations among large numbers of Feynman diagrams.

In on-shell approaches, the Lagrangian and Feynman rules of a theory tend to occupy a secondary role, if any. It is therefore crucial to develop a conceptual understanding, directly in the language that is used in calculations, of the phenomena that are traditionally understood from the Lagrangian. In this paper, we discuss a direct connection between the high-energy behavior of the S -matrix of a theory and the running of coupling constants and renormalization of local operators. We will build on recent developments in the context of the dilatation operator in $\mathcal{N} = 4$ super Yang-Mills (SYM) [1–8] and other work based on generalized unitarity [9–11], which we will extend to arbitrary weakly coupled field theories.

Our main physical idea will be the notion that large logarithms signaling the running of couplings originate from states which propagate over a “long distance” in an appropriate

metric, making them effectively on-shell. Quantitatively, we will consider form factors, which are matrix elements between an operator and on-shell states:

$$F_{\mathcal{O}}[p_1, \dots, p_n; \mu] \equiv \langle p_1, \dots, p_n | \mathcal{O} | 0 \rangle, \quad (1.1)$$

where μ is the renormalization scale. Such form factors figure prominently in effective-theory descriptions of weak processes including Higgs production and decay, see e.g. [12, 13]. They convert the scale dependence of the local operator \mathcal{O} into a physically measurable energy dependence of its decay products. The key fact for us will be that the energy dependence and phase are tied to each other, as can be seen from the imaginary part acquired by the logarithms for timelike momentum invariants ($p^2 > 0$) due to Feynman's prescription $p^2 \rightarrow p^2 + i0$:

$$\log\left(\frac{-p^2}{\mu^2}\right) \equiv \log\left(\frac{|p^2|}{\mu^2}\right) - i\pi \quad \Rightarrow \quad p^\mu \frac{\partial}{\partial p^\mu} \log\left(\frac{-p^2}{\mu^2}\right) = -\frac{2}{\pi} \text{Im} \log\left(\frac{-p^2}{\mu^2}\right). \quad (1.2)$$

This is interesting because, as understood from conventional unitarity and the optical theorem, imaginary parts originate physically from the long time propagation of intermediate on-shell states. This suggests that the scale dependence of a process can be understood directly from the propagation of on-shell particles. In this paper, we propose a precise quantitative relationship, which we will verify in a number of classic examples.

This paper is organized as follows. In section 2, we expand on the ideas sketched above, deriving a relation between the S -matrix and the dilatation operator, and we set up our notations. In section 3, we apply these ideas at one-loop level. We calculate the β -functions and anomalous dimensions of various composite operators in pure Yang-Mills, perturbative QCD and $\mathcal{N} = 4$ SYM. In section 4, we extend our study to several features that appear at higher loop orders, in particular the mixing of operators of different lengths. We conclude with a summary of our results and an outlook on future directions in section 5.

2 The S -matrix and the dilatation operator

In this section, we derive a concrete formula, eq. (2.4), which instantiates the above general ideas, and we set up the notations we will use to test it.

The main first step is to connect the phase and energy dependence of form factors. This connection stems from analyticity. The trick is to use a complex scale transformation to relate a form factor to its complex conjugate. We start from a kinematic configuration where all momenta p_i are outgoing, so that all Mandelstam invariants are positive (time-like): $s_{ij\dots k} = (p_i + p_j + \dots + p_k)^2 > 0$. The form factor is not real because the Feynman prescription adds a small positive imaginary part to all invariants: $s_I \mapsto s_I + i0$. But it can be related to its conjugate by an analytic continuation in which all the invariants are rotated along a large circle in the complex plane, with a common phase, as illustrated in figure 1. Such a rotation is generated by the dilatation operator D :

$$F(p_1, \dots, p_n) \rightarrow F(p_1 e^{i\alpha}, \dots, p_n e^{i\alpha}) = e^{i\alpha D} F(p_1, \dots, p_n), \quad \text{where} \quad D \equiv \sum_i p_i^\mu \frac{\partial}{\partial p_i^\mu}. \quad (2.1)$$

Figure 1. Analytic continuation from the complex conjugate using a complex scale transformation.

We do not expect any singularity until the angle reaches π , where all energies are reversed. (This is easily proved in perturbation theory, where the Feynman parameter representation contains denominators of the form $(\sum_j c_j m_j^2 - \sum_J c_J s_J - i0)$ with all c_j, c_J positive. Taking all s_J to have the same phase $e^{2i\alpha}$, the first singularity is at $\alpha = \pi$.) At this point, the invariants are back to the original ones but on the “wrong” side of the cut, giving the conjugate form factor. Thus,

$$F = e^{-i\pi D} F^*, \quad (2.2)$$

where F^* is the form factor computed using anti-time-ordered propagators.

The second fundamental equation we will need is a version of the optical theorem. The conventional optical theorem expresses unitarity of the S -matrix: $SS^\dagger = 1$, where the product contains a phase-space integral over intermediate n -particle states summed over all n . Formally using the physical interpretation of a form factor as a small perturbation to the S -matrix, $\delta S = i\mathcal{F}$, using the calligraphic font here to distinguish the operator \mathcal{F} from its matrix elements to outgoing states F , unitarity becomes $\mathcal{F} = S\mathcal{F}^\dagger S$. For vacuum initial states, this reduces to

$$F = SF^*. \quad (2.3)$$

In this note, we will mostly rely on the imaginary part of this relation to one-loop order, which is easily verified from the Cutkowski rules. The diagrams which contribute to the product SF^* originate by drawing a cut through form factor diagrams, as depicted for example in figure 2. The massless scattering amplitudes contained in S then join the cut to the final states. We note that the other side of the cut involves a complex conjugate amplitude, as is typically the case for Cutkowski rules.

Combining the two relations above gives

$$e^{-i\pi D} F^* = SF^*. \quad (2.4)$$

This will be the central equation in this paper. We will read it as follows: *the dilatation operator is minus the phase of the S -matrix, divided by π .*¹

¹Strictly speaking, we are omitting a CPT transformation here, whose necessity can be seen for example using the commutation relation with the Hamiltonian H . We thank Amit Sever for this observation.

Figure 2. Different contributions to the anomalous dimension $\gamma_{\mathcal{L}}$ of the Lagrangian density and thus the Yang-Mills β -function. This requires form factors for both the Lagrangian density (a) and stress tensor (b), with matter fields (c) contributing only to the latter.

The dilatation operator is of course closely related to renormalization group evolution. Indeed, at high energies, by dimensional analysis, F can depend only on dimensionless ratios s_I/μ^2 , and therefore $D \simeq -\mu\partial_\mu$. Starting from the renormalization group equation

$$\left[\mu\partial_\mu + \beta(g^2)\frac{\partial}{\partial g^2} + \gamma_{\mathcal{O}} - \gamma_{\text{IR}} \right] F = 0, \tag{2.5}$$

one hence obtains

$$DF = \left(\gamma_{\mathcal{O}} - \gamma_{\text{IR}} + \beta(g^2)\frac{\partial}{\partial g^2} \right) F. \tag{2.6}$$

It will be important that ultraviolet and infrared divergences both contribute to the energy dependence of form factors. Their relative sign is simply a convention which ensures that the naturally large logarithms $\log(\mu_{\text{UV}}^2/p^2)$ and $\log(p^2/\mu_{\text{IR}}^2)$ come with the same sign when their renormalization scales are treated independently. Logarithms of momentum-independent masses will be discussed briefly in section 3.2.1 but do not fundamentally affect the discussion.

Inserting (the complex conjugate of) (2.6) into (2.4) yields a relation between the renormalization group coefficients $\gamma_{\mathcal{O}}$, γ_{IR} , β and the S-matrix. Let us focus on the leading approximation to this otherwise exact relation. It is useful to restrict to so-called minimal form factors, which are non-vanishing in the free-theory limit. The β -function term can then be neglected. Writing $S = 1 + i\mathcal{M}$ and inserting (2.6) into (2.4) then gives to leading non-trivial order:

$$\left(\gamma_{\mathcal{O}}^{(1)} - \gamma_{\text{IR}}^{(1)} \right) \langle p_1, \dots, p_n | \mathcal{O} | 0 \rangle^{(0)} = -\frac{1}{\pi} \langle p_1, \dots, p_n | \mathcal{M} \otimes \mathcal{O} | 0 \rangle^{(0)}, \tag{2.7}$$

where \mathcal{M} is the tree-level $2 \rightarrow 2$ S-matrix, and the convolution, to be defined shortly, represents the phase-space integral over intermediate two-particle states in the product $\mathcal{M}F^*$. Note that we have dropped the complex conjugation sign, as the tree-level form factors are naturally real.

In order to use the above equation to extract anomalous dimensions, the infrared contributions must be subtracted. The key fact is that these depend only on the external particles but not on \mathcal{O} . This makes it possible to construct infrared-safe ratios. This is particularly simple in the special case $n = 2$, where one can put the stress-tensor in the

denominator. It has vanishing anomalous dimension in any theory. Ignoring again the β -function, this gives

$$\gamma_{\mathcal{O}} = D \log \frac{\langle p_1, p_2 | \mathcal{O} | 0 \rangle}{\langle p_1, p_2 | T^{\mu\nu} | 0 \rangle} = -\frac{1}{\pi} 2 \operatorname{Im} \log \frac{\langle p_1, p_2 | \mathcal{O} | 0 \rangle}{\langle p_1, p_2 | T^{\mu\nu} | 0 \rangle}, \quad (2.8)$$

which gives rise to the more practical one-loop equation

$$\gamma_{\mathcal{O}}^{(1)} \langle p_1, p_2 | \mathcal{O} | 0 \rangle^{(0)} = -\frac{1}{\pi} \langle p_1, p_2 | \mathcal{M} \otimes \mathcal{O} | 0 \rangle^{(0)} + \frac{1}{\pi} \langle p_1, p_2 | \mathcal{O} | 0 \rangle^{(0)} \frac{\langle p_1, p_2 | \mathcal{M} \otimes T^{\mu\nu} | 0 \rangle^{(0)}}{\langle p_1, p_2 | T^{\mu\nu} | 0 \rangle^{(0)}}. \quad (2.9)$$

This equation is new. Multiple examples and applications will be given in sections 3 and 4. Note that the ratio in (2.9) does not depend on the indices on $T^{\mu\nu}$ because the infrared divergences are blind to these. At higher loops and in the presence of a β -function, the imaginary part of the above logarithm is still useful and detects the anomalous dimensions and coupling dependence of the form factor averaged over the half-circle of figure 1.

The anomalous dimensions of marginal and relevant operators are of particular physical interest due to their relation to the β -functions of corresponding running couplings. For example, in Yang-Mills theory, the anomalous dimension of the Lagrangian density is a derivative of the β -function [14, 15]:

$$\gamma_{\mathcal{L}} = g^2 \frac{\partial}{\partial g^2} \left(\frac{\beta(g^2)}{g^2} \right). \quad (2.10)$$

The two are therefore essentially equivalent, making it possible to use the preceding formulas to obtain β -functions. The multi-coupling case will be discussed further in section 4.

Note that the arguments above are valid in any space-time dimension. In the following, we will restrict ourselves to four dimensions though.

2.1 Notations: form factors and spinor-helicity variables

Form factors provide a map between on-shell states and local operators. In a free theory, they are just polynomials in the momenta. For example, for a free scalar

$$i^n \langle 1_\phi | \partial^{\mu_1} \dots \partial^{\mu_n} \phi | 0 \rangle = p_1^{\mu_1} \dots p_1^{\mu_n}. \quad (2.11)$$

In general, for final state with multiple particles, there is a one-to-one correspondence between such polynomials and local operators modulo equations of motion. Note that we use an abbreviated notation where the bra $\langle 1_h |$ denotes a particle of type h with momentum p_1 .

When dealing with particles with spin, it is useful to use variables which can absorb the phase ambiguities of their polarization vectors and spinors. In four dimensions, this is nicely achieved by the so-called spinor-helicity variables. These are defined by splitting a null four-momentum into two Weyl spinors:

$$p_j^{\alpha\dot{\alpha}} \equiv p_j^\mu \sigma_\mu^{\alpha\dot{\alpha}} = \lambda_j^\alpha \tilde{\lambda}_j^{\dot{\alpha}}, \quad (2.12)$$

where $(\sigma_\mu)^{\alpha\dot{\alpha}}$ are the four-dimensional (2×2) Pauli matrices. The two helicity polarizations of a gluon can be parametrized explicitly in terms of the spinors, see for example [16].

The important fact is that the physics is invariant if spinors and antispinors are rotated by opposite phases, provided the external states are simultaneously rotated according to their helicity:

$$\lambda_j \rightarrow \lambda_j e^{i\alpha_j}, \quad \tilde{\lambda}_j \rightarrow \tilde{\lambda}_j e^{-i\alpha_j}, \quad \langle j_- | \rightarrow e^{2i\alpha_j} \langle j_- |, \quad \langle j_+ | \rightarrow e^{-2i\alpha_j} \langle j_+ |. \quad (2.13)$$

This is called little-group scaling because the same phases would arise from a rotation along the propagation axis of particle j . Thus, form factors are polynomials in the spinor-helicity variables with a specific little-group weight for each particle. This fixes the form of form factors for the self-dual and anti-self-dual parts of the field strength and fermion fields,

$$\langle 1_- | F^{\alpha\beta} | 0 \rangle \equiv \lambda_1^\alpha \lambda_1^\beta, \quad \langle 1_+ | \bar{F}^{\dot{\alpha}\dot{\beta}} | 0 \rangle \equiv \tilde{\lambda}_1^{\dot{\alpha}} \tilde{\lambda}_1^{\dot{\beta}}, \quad \langle 1_{\bar{\psi}} | \psi^\alpha | 0 \rangle \equiv \lambda_1^\alpha, \quad \langle 1_\psi | \bar{\psi}^{\dot{\alpha}} | 0 \rangle \equiv \tilde{\lambda}_1^{\dot{\alpha}}, \quad (2.14)$$

where the state $\langle 1_\psi |$ is a Weyl fermion of positive helicity. We follow conventions where the basic Lorentz invariant combinations are the brackets

$$s_{ij} = 2p_i \cdot p_j = \langle ij \rangle [j i], \quad \text{where} \quad \langle ij \rangle \equiv \epsilon_{\alpha\beta} \lambda_i^\alpha \lambda_j^\beta, \quad [ij] \equiv \epsilon_{\dot{\alpha}\dot{\beta}} \tilde{\lambda}_i^{\dot{\alpha}} \tilde{\lambda}_j^{\dot{\beta}}, \quad (2.15)$$

with the Mandelstam invariant $s_{ij} > 0$ when the invariant is timelike, as is the case for two outgoing particles. For outgoing momenta, there is the complex conjugation relation $\lambda_i = (\tilde{\lambda}_i)^*$.

Like its name suggests, the S -matrix $S = 1 + i\mathcal{M}$ is an operator, which in particular can act on the polynomial states produced by minimal form factors. This action, which we denote as a convolution, is simply the on-shell phase-space integral:

$$\langle 12 | \mathcal{M} \otimes F | 0 \rangle^{(0)} \equiv \frac{1}{16\pi} \sum_{h_1', h_2'} \int \frac{d\Omega}{4\pi} \langle 12 | \mathcal{M} | 1_{h_1}', 2_{h_2}' \rangle^{(0)} \langle 1_{h_1}', 2_{h_2}' | F | 0 \rangle^{(0)}, \quad (2.16)$$

where the sum is over all intermediate helicity states. The following elegant phase-space parametrization using spinors will be useful: one simply rotates the spinors as [1]

$$\begin{pmatrix} \lambda_1' \\ \lambda_2' \end{pmatrix} = \begin{pmatrix} \cos \theta & -\sin \theta e^{i\phi} \\ \sin \theta e^{-i\phi} & \cos \theta \end{pmatrix} \begin{pmatrix} \lambda_1 \\ \lambda_2 \end{pmatrix}, \quad (2.17)$$

together with the complex conjugate rotation for the conjugate spinors $\tilde{\lambda}_1'$ and $\tilde{\lambda}_2'$. It is easy to verify that $p_1' + p_2' = p_1 + p_2$. In a center-of-mass frame where p_1 and p_2 are back-to-back along the z -axis, this reduces to a standard parametrization of spinors in terms of polar half-angle θ and azimuthal angle ϕ . The advantage is that, being covariant, this can be used in any frame. The integration measure is simply

$$\int \frac{d\Omega}{4\pi} \equiv \int \frac{d\phi}{2\pi} \int_0^{\pi/2} 2 \cos \theta \sin \theta d\theta. \quad (2.18)$$

Finally, following general practice in the amplitudes community, we will use crossing symmetry liberally and often express S -matrix elements in a notation where momenta and other quantum numbers are outgoing:

$$(-1)^{n_{\bar{\psi}}} \langle 1_{h_1} 2_{h_2} | \mathcal{M} | 3_{h_3} 4_{h_4} \rangle \equiv \langle 1_{h_1} 2_{h_2} \bar{4}_{-h_4} \bar{3}_{-h_3} | \mathcal{M} | 0 \rangle \equiv \mathcal{M}_{1_{h_1} 2_{h_2} \bar{4}_{-h_4} \bar{3}_{-h_3}}, \quad (2.19)$$

where \bar{j} means minus the momentum p_j (with $\lambda_{\bar{j}} = \lambda_j, \tilde{\lambda}_{\bar{j}} = -\tilde{\lambda}_j$). Reversing the order of fields upon crossing is a useful convention which ensures the proper minus signs for fermion loops. An additional minus sign counts the number of negative-helicity fermions $\bar{\psi}$ in the initial state.

3 Application: Yang-Mills theory at one-loop

To compute all one-loop anomalous dimensions in Yang-Mills theory, the major ingredient will be the on-shell four-gluon amplitude, given by the famous Parke-Taylor expression:

$$\mathcal{M}_{1^-2^-3^+4^+}^{abcd} = -2g^2 \langle 12 \rangle^4 \left[\frac{f^{abe} f^{cde}}{\langle 12 \rangle \langle 23 \rangle \langle 34 \rangle \langle 41 \rangle} + \frac{f^{ace} f^{bde}}{\langle 13 \rangle \langle 32 \rangle \langle 24 \rangle \langle 41 \rangle} \right]. \quad (3.1)$$

For other helicity choices, one simply replaces $\langle 12 \rangle^4$ by $\langle ij \rangle^4$, where i and j are the two negative-helicity gluons; the four-gluon tree amplitude vanishes if there are not exactly two negative-helicity gluons. We will mostly need the case where the initial state is a color-singlet gluon pair, in which case the formula simplifies as the first term vanishes:

$$\mathcal{M}_{1^-2^-3^+4^+}^{abcd} \delta^{cd} = -2g^2 C_A \delta^{ab} \frac{\langle 12 \rangle^4}{\langle 13 \rangle \langle 32 \rangle \langle 24 \rangle \langle 41 \rangle}. \quad (3.2)$$

Here, C_A denotes the Casimir in the adjoint representation, which is N_c for gauge group $SU(N_c)$. Before using it, let us briefly comment on various ways to obtain eq. (3.2), which of course include direct Feynman diagram calculation [17, 18]. It is also a special case of the celebrated MHV n -point amplitude, now understood from a large number of viewpoints including Berends-Giele [19] and BCFW recursion [20, 21], properties of self-dual Yang-Mills [22], the twistor string [23], etc. In fact, the above formula is a direct consequence of basic physical principles, specifically its little-group properties and classical small-angle limits. The key point is that the little-group scaling (2.13) implies that the amplitude can be written as $\frac{\langle 34 \rangle^2}{\langle 12 \rangle^2}$ times a rational function $G(s, t, u)$. Since a tree amplitude cannot have a squared denominator such as $1/\langle 12 \rangle^2$, G needs to be proportional to $s = \langle 12 \rangle [21]$, and since it needs to be dimensionless and only massless poles can appear in its denominator, the most general possibility is $G = c_1 \frac{s}{t} + c_2 \frac{s}{u}$. In the small-angle limit $t \rightarrow 0$, the amplitude has to reproduce the Coulomb-like attractive potential $\mathcal{M} \rightarrow -2g^2 f^{a_1 a_4 b} f^{a_2 a_3 b} \frac{s}{t}$, and similarly at $u \rightarrow 0$, which fixes $c_1 = c_2 = -2g^2 C_A$. This reproduces eq. (3.2) using spinor identities. The absence of polynomial ambiguities for massless particles with spin is a generic consequence of little-group scaling [24, 25].

Plugging in the explicit values for the rotated spinors in eq. (2.17),

$$\langle 1'2' \rangle = \langle 12 \rangle, \quad \langle 12' \rangle = \langle 1'2 \rangle = \langle 12 \rangle \cos \theta, \quad \langle 1'1 \rangle = \langle 12 \rangle \sin \theta e^{i\phi}, \quad \langle 2'2 \rangle = \langle 12 \rangle \sin \theta e^{-i\phi}, \quad (3.3)$$

one thus evaluates using the amplitude (3.2):

$$\langle 1^a 2^b_- | \mathcal{M}^{(0)} | 1'^c 2'^d_- \rangle \delta^{cd} = 2g^2 C_A \delta^{ab} \frac{1}{\cos^2 \theta \sin^2 \theta}. \quad (3.4)$$

For $+-$ pairs, one simply inserts either $\cos^4 \theta$ or $\sin^4 \theta e^{\pm 4i\phi}$ into the numerator, respectively, depending on whether 1 and 1' have the same or opposite helicity; in the latter case, the sign of the phase is given by the helicity of 1'.

3.1 One-loop β -function

The Yang-Mills β -function is now given, according to the infrared-safe ratio in eq. (2.8), by acting with the above tree amplitude on the form factors for the Lagrangian density $\mathcal{L} \equiv -G_{\mu\nu}^a G^{\mu\nu a}/(4g^2)$ and the stress tensor $T^{\alpha\beta, \dot{\alpha}\dot{\beta}}$.

At tree level, for each of these form factors, there is a unique polynomial in spinors that one can write down with the correct dimension, Lorentz indices, and little-group phases:

$$\begin{aligned} \langle 1_-^a 2_-^b | \mathcal{L} | 0 \rangle &= \frac{1}{2} \delta^{ab} \langle 12 \rangle^2, \\ \langle 1_-^a 2_+^b | T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle &= 2\delta^{ab} \lambda_1^\alpha \lambda_1^\beta \tilde{\lambda}_2^{\dot{\alpha}} \tilde{\lambda}_2^{\dot{\beta}}. \end{aligned} \quad (3.5)$$

The overall normalizations are physically meaningful and will be discussed shortly for the latter case, but they play no role for the present discussion.

To evaluate the imaginary part of the corresponding one-loop form factors, we substitute the tree amplitude (3.4) into the phase-space integral in eq. (2.16) as depicted in figure 2a,b:

$$\langle 1_-^a 2_-^b | \mathcal{M} \otimes \mathcal{L} | 0 \rangle^{(0)} = \frac{2g^2 C_A}{16\pi} \int \frac{d\Omega}{4\pi} \frac{1}{\cos^2 \theta \sin^2 \theta} \left(\frac{1}{2} \delta^{ab} \langle 1' 2' \rangle^2 \right), \quad (3.6a)$$

$$\begin{aligned} \langle 1_-^a 2_+^b | \mathcal{M} \otimes T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle^{(0)} &= \frac{2g^2 C_A}{16\pi} \int \frac{d\Omega}{4\pi} \frac{1}{\cos^2 \theta \sin^2 \theta} \left(2\delta^{ab} \lambda_1'^\alpha \lambda_1'^\beta \tilde{\lambda}_2'^{\dot{\alpha}} \tilde{\lambda}_2'^{\dot{\beta}} \cos^4 \theta \right. \\ &\quad \left. + 2\delta^{ab} \tilde{\lambda}_1'^{\dot{\alpha}} \tilde{\lambda}_1'^{\dot{\beta}} \lambda_2'^\alpha \lambda_2'^\beta \sin^4 \theta e^{4i\phi} \right). \end{aligned} \quad (3.6b)$$

Note that the tree form factors are evaluated with the rotated spinors (2.17) parametrizing the two intermediate states in the cut. The two terms in the last line come from the two possible intermediate helicities, of which only one is shown in figure 2b. A priori, they look quite complicated; expanding out the first gives

$$\begin{aligned} \lambda_1'^\alpha \lambda_1'^\beta \tilde{\lambda}_2'^{\dot{\alpha}} \tilde{\lambda}_2'^{\dot{\beta}} &= (\lambda_1 \cos \theta - \lambda_2 \sin \theta e^{i\phi})^\alpha (\lambda_1 \cos \theta - \lambda_2 \sin \theta e^{i\phi})^\beta \\ &\quad \times (\tilde{\lambda}_2 \cos \theta + \tilde{\lambda}_1 \sin \theta e^{i\phi})^{\dot{\alpha}} (\tilde{\lambda}_2 \cos \theta + \tilde{\lambda}_1 \sin \theta e^{i\phi})^{\dot{\beta}}. \end{aligned} \quad (3.7)$$

However, the key is that ultimately the spinor structure is fixed by little-group weights, which are enforced by the azimuthal angle integration. Indeed, we see that all terms with non-vanishing phases are killed by the ϕ integration! Dropping these, the integral becomes simply proportional to the tree form factor, as anticipated below eq. (2.9). Hence, the ratio does not depend on the spinor indices and

$$\frac{\langle 1_-^a 2_+^b | \mathcal{M} \otimes T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle^{(0)}}{\langle 1_-^a 2_+^b | T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle^{(0)}} = \frac{2g^2 C_A}{16\pi} \int_0^{\frac{\pi}{2}} 2 \sin \theta \cos \theta d\theta \frac{\cos^8 \theta + \sin^8 \theta}{\cos^2 \theta \sin^2 \theta}. \quad (3.8)$$

Now we can observe that the divergences in the collinear limits $\theta \rightarrow 0, \pi/2$ cancel precisely against those in the Lagrangian density in (2.9), yielding, as anticipated, a convergent

integral:

$$\begin{aligned}
 \gamma_{\mathcal{L}}^{(1)} &\equiv -\frac{1}{\pi} \left(\frac{\langle 1_-^a 2_-^b | \mathcal{M} \otimes \mathcal{L} | 0 \rangle^{(0)}}{\langle 1_-^a 2_-^b | \mathcal{L} | 0 \rangle^{(0)}} - \frac{\langle 1_-^a 2_+^b | \mathcal{M} \otimes T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle^{(0)}}{\langle 1_-^a 2_+^b | T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle^{(0)}} \right) \\
 &= -\frac{2g^2 C_A}{16\pi^2} \int_0^{\frac{\pi}{2}} 2 \sin \theta \cos \theta \, d\theta \left(\frac{1}{\cos^2 \theta \sin^2 \theta} - \frac{\cos^8 \theta + \sin^8 \theta}{\cos^2 \theta \sin^2 \theta} \right) \\
 &= -\frac{2g^2}{16\pi^2} \times \frac{11C_A}{3}. \tag{3.9}
 \end{aligned}$$

Using the relation between the running of the Yang-Mills Lagrangian and the β -function quoted earlier, eq. (2.10), we have therefore obtained the one-loop β -function:

$$\beta(g^2) = -\frac{2g^4}{16\pi^2} \times \frac{11C_A}{3}, \quad \text{where} \quad \beta(g^2) \equiv \mu \partial_\mu g^2(\mu). \tag{3.10}$$

This is in perfect agreement with the famous result, including, of course, the sign!

This example confirms that one-loop anomalous dimensions can be obtained as suitable differences between eigenvalues of the tree-level S -matrix, or more precisely, of minus the phase of the S -matrix divided by π . In the case above, the scattering phase is positive ($\mathcal{M} > 0$ in eq. (3.4)), which is attributed to the attractive nature of the interaction between opposite color charges (the scattering phase represents, roughly, minus the interaction energy). This is the reason in this framework for the famous negative sign of the β -function. More precisely, the reason is that the attraction is felt more strongly in the s -wave state (Lagrangian density) than in the d -wave state (stress tensor).

3.2 Matter-field contributions

It is instructive to see how the method works in the presence of fermions and scalars coupled to the Yang-Mills field. Naively, since the Yang-Mills part of the Lagrangian density has no tree-level coupling to matter, one might worry that its anomalous dimension would be insensitive to these. However, the infrared structure of the theory is modified and this is detected by the stress tensor in the denominator of the IR-safe ratio (2.8). In QED, this would be the only contribution.

To find out how the stress tensor couples to fermions and scalars, one could construct the stress tensor following the Noether procedure and apply standard Feynman rules. We use a shortcut exploiting the symmetries of the problem. The overall normalization (at least, relative to the gluon contribution) will be important. It is fixed physically by requiring that the expectation value of the stress tensor in a state returns its momentum [26]:

$$\langle 1_\Phi | T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 1_\Phi \rangle = 2p_1^{\alpha\dot{\alpha}} p_1^{\beta\dot{\beta}} = \langle 1_\Phi \bar{1}_\Phi | T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle, \tag{3.11}$$

where in the second step we used crossing symmetry. Thus, the forward limit $p_2 \rightarrow -p_1$ of the form factor is fixed. For fermions there is an analogous equation, but one needs to be mindful of the sign in the crossing relation (2.19) for each $\bar{\psi}$ in the initial state, so the condition is

$$\langle 1_{\bar{\psi}} | T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 1_{\bar{\psi}} \rangle = 2p_1^{\alpha\dot{\alpha}} p_1^{\beta\dot{\beta}} = -\langle 1_{\bar{\psi}} \bar{1}_\psi | T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle. \tag{3.12}$$

The other constraint is that the stress tensor is conserved: it must be orthogonal to (p_1+p_2) . For scalars, as is well-known, this leaves an ambiguity which can be removed by imposing tracelessness (equivalent to symmetry in the spinor indices). For both scalars and fermions, there is then a unique polynomial satisfying these constraints and little-group scaling:

$$\begin{aligned} \langle 1_{\bar{\Phi}} 2_{\Phi} | T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle &= \frac{1}{3} \left(p_1^{\alpha\dot{\alpha}} p_1^{\beta\dot{\beta}} + p_2^{\alpha\dot{\alpha}} p_2^{\beta\dot{\beta}} - p_1^{\alpha\dot{\alpha}} p_2^{\beta\dot{\beta}} - p_1^{\beta\dot{\alpha}} p_2^{\alpha\dot{\beta}} - p_1^{\alpha\dot{\beta}} p_2^{\beta\dot{\alpha}} - p_1^{\beta\dot{\beta}} p_2^{\alpha\dot{\alpha}} \right), \\ \langle 1_{\bar{\psi}} 2_{\psi} | T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle &= \frac{1}{2} \left(\lambda_1^\alpha \lambda_1^\beta \tilde{\lambda}_1^{\dot{\alpha}} \tilde{\lambda}_2^{\dot{\beta}} + \lambda_1^\alpha \lambda_1^\beta \tilde{\lambda}_1^{\dot{\beta}} \tilde{\lambda}_2^{\dot{\alpha}} - \lambda_1^\alpha \lambda_2^\beta \tilde{\lambda}_2^{\dot{\alpha}} \tilde{\lambda}_2^{\dot{\beta}} - \lambda_1^\beta \lambda_2^\alpha \tilde{\lambda}_2^{\dot{\alpha}} \tilde{\lambda}_2^{\dot{\beta}} \right). \end{aligned} \quad (3.13)$$

In accordance with eq. (2.9), we now convolute these form factors with annihilation amplitudes into two gluons, as illustrated in figure 2c for fermions. The relevant tree amplitudes are all concisely encoded in an $\mathcal{N} = 4$ supersymmetric expression using Nair's $\mathcal{N} = 4$ on-shell superspace [27], which generalizes the amplitude (3.2) to

$$\mathcal{M}_{1234}^{abcd} \delta^{cd} = -2g^2 C_A \delta^{ab} \frac{\delta^8(\sum_{i=1}^4 \lambda_i \tilde{\eta}_i)}{\langle 13 \rangle \langle 32 \rangle \langle 24 \rangle \langle 41 \rangle} \equiv -2g^2 C_A \delta^{ab} \frac{\prod_{A=1}^4 \sum_{1 \leq i < j \leq 4} \langle ij \rangle \tilde{\eta}_i \tilde{\eta}_j}{\langle 13 \rangle \langle 32 \rangle \langle 24 \rangle \langle 41 \rangle}. \quad (3.14)$$

To insert a negative-helicity gluon, fermion, scalar or positive-helicity fermion on site j , one extracts, respectively, four, three, two or one powers of $\tilde{\eta}_j$, giving the required amplitudes:

$$\begin{aligned} \langle 1_-^a 2_+^b | \mathcal{M} | 1'_\Phi 2'_\Phi \rangle &= -2g^2 n_s T_s \delta^{ab} \frac{\langle 11' \rangle^2 \langle 12' \rangle^2}{\langle 11' \rangle \langle 12' \rangle \langle 21' \rangle \langle 22' \rangle} = 2g^2 n_s T_s \delta^{ab} \frac{\cos^2 \theta \sin^2 \theta e^{2i\phi}}{\cos^2 \theta \sin^2 \theta}, \\ \langle 1_-^a 2_+^b | \mathcal{M} | 1'_\psi 2'_\psi \rangle &= -2g^2 (2n_f) T_f \delta^{ab} \frac{\langle 11' \rangle \langle 12' \rangle^3}{\langle 11' \rangle \langle 12' \rangle \langle 21' \rangle \langle 22' \rangle} = -4g^2 n_f T_f \delta^{ab} \frac{\cos^3 \theta \sin \theta e^{i\phi}}{\cos^2 \theta \sin^2 \theta}, \\ \langle 1_-^a 2_+^b | \mathcal{M} | 1'_\psi 2'_\psi \rangle &= -2g^2 (2n_f) T_f \delta^{ab} \frac{\langle 11' \rangle^3 \langle 12' \rangle}{\langle 11' \rangle \langle 12' \rangle \langle 21' \rangle \langle 22' \rangle} = -4g^2 n_f T_f \delta^{ab} \frac{\cos \theta \sin^3 \theta e^{3i\phi}}{\cos^2 \theta \sin^2 \theta}, \end{aligned} \quad (3.15)$$

and $\langle 1_-^a 2_+^b | \mathcal{M} | 1'_\Phi 2'_\Phi \rangle = \langle 1_-^a 2_+^b | \mathcal{M} | 1'_\Phi 2'_\Phi \rangle$. Here, anticipating the contraction with the stress tensor, we have re-weighted the color-adjoint amplitude (3.14) in accordance to n_s complex scalars and n_f Dirac fermions (and thus $(2n_f)$ Weyl fermions) in representations where $\text{Tr}[T^a T^b] = T_{s,f} \delta^{ab}$, with $T_F = \frac{1}{2}$ in the fundamental representation. The final step is to integrate this over phase space, weighted by the tree form factors in eqs. (3.13) evaluated with the rotated spinors (2.17). Again, most terms drop out upon azimuthal integration, leaving, as expected, a result proportional to the tree form factor:

$$\begin{aligned} \frac{\langle 1_-^a 2_+^b | \mathcal{M} \otimes T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle^{(0)}}{\langle 1_-^a 2_+^b | T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle^{(0)}} &\simeq \frac{2g^2}{16\pi} \int_0^{\frac{\pi}{2}} \frac{2 \sin \theta \cos \theta d\theta}{\cos^2 \theta \sin^2 \theta} \left[C_A (\cos^8 \theta + \sin^8 \theta) \right. \\ &\quad \left. + 2n_f T_f (\cos^6 \theta \sin^2 \theta + \sin^6 \theta \cos^2 \theta) + 2n_s T_s \cos^4 \theta \sin^4 \theta \right]. \end{aligned} \quad (3.16)$$

As a simple check, one can plug in the matter content of $\mathcal{N} = 4$ SYM (two adjoint Dirac fermions and three complex scalars: $n_f=2, n_s=3, T_f=T_s=C_A$), and see that the bracket reduces to $C_A (\cos^2 \theta + \sin^2 \theta)^4 = C_A$. This reproduces the integrand for the Lagrangian density in eq. (3.6a), as required by supersymmetry since the stress tensor and Lagrangian density are in the same supermultiplet. The vanishing of the β -function in $\mathcal{N} = 4$ is thus automatic in this formalism and can be used as a simple check on the algebra. For other

theories, replacing the subtraction in eq. (3.9) by (3.16) and integrating, we reproduce the well-known one-loop result for general matter content:

$$\beta(g^2) = -\frac{2g^4}{16\pi^2}b_0, \quad b_0 \equiv \frac{11}{3}C_A - \frac{4}{3}n_f T_f - \frac{1}{3}n_s T_s. \quad (3.17)$$

In a theory with fermion masses like QCD, the running of mass parameters is also interesting. At energies much higher than the masses (the situation where “running” is meaningful), we expect this question to be answerable within the massless theory. Writing a Dirac fermion as a combination of positive- and negative-helicity fundamental Weyl fermions $\Psi = (\psi_F, \bar{\psi}_F)$ and complex conjugate $\bar{\Psi} = (\bar{\psi}_F, \psi_F)$, the minimal form factor for the mass operator $\bar{\Psi}\Psi = \bar{\Psi}_a\Psi^a = (\bar{\psi}_F^a\psi_F^a + \psi_F^a\bar{\psi}_F^a)$ is $\langle 1_{\bar{\psi}_F} 2_{\psi_F} | \bar{\Psi}\Psi | 0 \rangle = \langle 12 \rangle$. The required scattering amplitudes between fundamental and antifundamental fermions, for same and opposite helicity respectively, are then

$$\langle 1_{\bar{\psi}_F} 2_{\bar{\psi}_F} | \mathcal{M} | 1'_{\bar{\psi}_F} 2'_{\bar{\psi}_F} \rangle = \frac{2g^2 C_F}{\cos^2 \theta \sin^2 \theta}, \quad \langle 1_{\bar{\psi}_F} 2_{\psi_F} | \mathcal{M} | 1'_{\bar{\psi}_F} 2'_{\psi_F} \rangle = \frac{2g^2 C_F \cos^4 \theta}{\cos^2 \theta \sin^2 \theta}, \quad (3.18)$$

where the fundamental Casimir is $C_F = \frac{N_c^2 - 1}{2N_c}$ for gauge group $SU(N_c)$. The positive signs again reflect the attractive gauge interaction. We also need the pair production amplitude $\langle 1_{\bar{\psi}_F} 2_{\psi_F} | \mathcal{M} | 1'_- 2'_+ \rangle$, equal to minus the complex conjugate of (3.15). Armed with these and the above stress-tensor form factors for gluons and fermions, we compute

$$\begin{aligned} \gamma_{\bar{\Psi}\Psi}^{(1)} &\equiv -\frac{1}{\pi} \left(\frac{\langle 1_{\bar{\psi}_F} 2_{\bar{\psi}_F} | \mathcal{M} \otimes \bar{\Psi}\Psi | 0 \rangle^{(0)}}{\langle 1_{\bar{\psi}_F} 2_{\bar{\psi}_F} | \bar{\Psi}\Psi | 0 \rangle^{(0)}} - \frac{\langle 1_{\bar{\psi}_F} 2_{\psi_F} | \mathcal{M} \otimes T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle^{(0)}}{\langle 1_{\bar{\psi}_F} 2_{\psi_F} | T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle^{(0)}} \right) \\ &= -\frac{2g^2 C_F}{16\pi^2} \int_0^{\frac{\pi}{2}} 2 \sin \theta \cos \theta d\theta \left(\frac{1}{\cos^2 \theta \sin^2 \theta} - \frac{\cos^6 \theta + \sin^6 \theta}{\cos^2 \theta \sin^2 \theta} \right) = -\frac{6g^2 C_F}{16\pi^2}. \end{aligned} \quad (3.19)$$

Again, this is in agreement with the standard result, confirming that running-mass effects at short distances can be computed using unitarity with massless states.

3.2.1 Comments on masses

Our discussions so far have been restricted to the S -matrix of strictly massless particles — the dilatation operator D is only defined on the massless S -matrix! We believe that this is not a significant restriction. Rather, we believe it is entirely consistent with conventional applications of the renormalization group, where a particle is either regarded as heavy and integrated out, or as light, in which case its mass is neglected. These two effective descriptions are connected by so-called matching regions where the masses are important, but which do not produce the kind of large logarithms that the renormalization group resums and which are the focus of this paper. The running of relevant operators such as QCD masses can be correctly calculated within the massless theory in the high-energy regime, as we have just explicitly verified.

With massive particles, one can get in addition momentum-independent logarithms. For example, a massive tadpole integral² gives

$$\int \frac{\mu^{2\epsilon} d^{4-2\epsilon} l}{i(2\pi)^{4-2\epsilon}} \frac{1}{l^2 - m^2} = \frac{m^2}{16\pi^2} \left(\frac{1}{\epsilon} + \log \frac{\mu^2}{m^2} + \dots \right). \quad (3.20)$$

²Such logarithms can appear from any integral with an explicit mass, not necessarily of tadpole topology.

It is common in textbook presentations of the renormalization group to focus on ultraviolet divergences and therefore include such logarithms when computing β -functions. Yet these logarithms lack an imaginary part and so they cannot be detected by unitarity. Does this mean that the unitarity method is incomplete? We believe no, because the renormalization group can answer two distinct questions. The first type of question regards the running of *bare* couplings as a function of the short-distance cutoff. This is clearly of importance to lattice practitioners, for example. The above momentum-independent logarithms are then clearly relevant (and possibly also power divergences as well as details of the short-distance dynamics). The second type of question regards the optimal coupling to use to minimize large logarithms, for example in the perturbative calculation of a cross-section at a given energy scale. This is the typical question of interest to collider physicists. Momentum-independent logarithms are then clearly *not* relevant: once the bare couplings have been tuned to cancel $\log(\mu)$ for one observable, the same tuning removes it from any physical observable. Our conclusion is that unitarity, by throwing away the logarithms (3.20),³ correctly answers the second type of question.

3.3 Twist-two operators and partial-wave amplitudes

A pleasant feature of the unitarity approach is that the S -matrix for just a few basic processes controls the anomalous dimension of essentially any operator. Let us here discuss those operators which can be accessed using a color-singlet pair of partons, as considered so far.

Let us ignore spin for a moment and consider for simplicity two-particle form factors for a complex scalar. Tree form factors are polynomial in p_1^μ, p_2^μ . Factors of $(p_1 + p_2)^\mu$ represent uninteresting total derivatives; these can be projected out by considering the forward case $p_2 = -p_1$. As $p_1^2 = 0$, only traceless tensors then survive. Thus, the interesting polynomials of order j represent operators of spin j and dimension $j + 2$ (the plus two is because any external on-shell parton carries dimension 1). These are the form factors of twist-two operators:

$$\langle 1_\Phi \bar{1}_{\bar{\Phi}} | \mathcal{O}_m | 0 \rangle = p_1^{\mu_1} \cdots p_1^{\mu_m} \Leftrightarrow \mathcal{O}_m = i^n \bar{\Phi} \partial^{\mu_1} \cdots \partial^{\mu_m} \Phi. \quad (3.21)$$

Let us act on these polynomial with the tree-level S -matrix. Note that, even though this action is originally derived assuming that all particles carry positive energy, in the spinor parametrization (2.17) the phase-space integrals can be seamlessly continued to the forward case $p_2 = -p_1$. The rotated form factor in this parametrization is then a multiple of itself, since

$$p_1^{\prime\alpha\dot{\alpha}} \equiv \lambda_1^{\prime\alpha} \tilde{\lambda}_1^{\dot{\alpha}} = \lambda_1^\alpha \tilde{\lambda}_1^{\dot{\alpha}} (\cos\theta - \sin\theta e^{i\phi}) (\cos\theta + \sin\theta e^{-i\phi}) = p_1^{\alpha\dot{\alpha}} (\cos(2\theta) - i \sin(2\theta) \sin\phi). \quad (3.22)$$

Using that the S -matrix for scalars does not depend on the azimuthal part of the scattering angle, the latter can be integrated out immediately. Temporarily rescaling the scattering

³In massless contexts with evanescent operators, a similar distinction between physically observable logarithms versus bare ultraviolet divergences (poles in dimensional regularization) is also important [28].

angle $2\theta \rightarrow \theta$, we find that this produces Legendre polynomials:

$$\int_0^{2\pi} \frac{d\phi}{2\pi} (\cos\theta - i \sin\theta \sin\phi)^m = P_m(\cos\theta). \quad (3.23)$$

For two complex scalars, the basic unitarity relation (2.7) thus becomes

$$\gamma_{\mathcal{O}_m}^{(1)} - \gamma_{\text{IR}}^{(1)} = -\frac{1}{16\pi^2} \int_0^\pi \frac{\sin\theta d\theta}{2} \mathcal{M}^{(0)}(\cos\theta) P_m(\cos\theta) \equiv -\frac{1}{\pi} a_m^{(0)}. \quad (3.24)$$

We recognize a_m as the partial-wave amplitude with angular momentum m , which at leading order can be identified with the phase of the S -matrix, normalized as $S_m = 1 + i\mathcal{M}_m = e^{iam}$. Thus, anomalous dimension are indeed minus the phase of the S -matrix, divided by π , as expected from eq. (2.4), and two-particle states with definite angular momentum map to twist-two operators.

Let us apply this to a few examples. First consider twist-two operators with two identical complex scalars Z in $\mathcal{N} = 4$ SYM: $\mathcal{O}_m = \text{Tr}[Z\partial_m^+ Z]$, where m is even. Because it is in the same multiplet, the tree amplitude is the same as in eq. (3.6a). Using the stress tensor to subtract the infrared divergence via eq. (3.16), the formula becomes

$$\gamma_{\mathcal{O}_m}^{(1)} = -\frac{2g^2 N_c}{16\pi^2} \int_0^\pi \frac{2 d\theta}{\sin\theta} (P_m(\cos\theta) - P_m(1)) = \frac{g^2 N_c}{16\pi^2} \times 8S_1(m), \quad (3.25)$$

where $S_1(m) = \sum_{i=1}^m \frac{1}{i}$ denotes the harmonic sum. This is precisely the known result [29].

In pure Yang-Mills, the similar partial-wave analysis requires partial waves for particles with spin. These are more complicated than Legendre polynomials but the spinor parametrization provides a straightforward way to proceed. Let us first record a formula for the evolution of an arbitrary operator which can decay to two particles at tree level, which follows by combining the unitarity relation (2.9), the matrix element (3.4) and the stress-tensor eigenvalue (3.16):

$$\begin{aligned} \gamma_{\mathcal{O}}^{(1)} \langle 1_{-2-} | \mathcal{O} | 0 \rangle^{(0)} &= \frac{g^2 C_A}{16\pi^2} \int_0^{2\pi} \frac{d\phi}{2\pi} \int_0^{\frac{\pi}{2}} \frac{4 d\theta}{\cos\theta \sin\theta} \begin{bmatrix} (\cos^8\theta + \sin^8\theta) \langle 1_{-2-} | \mathcal{O} | 0 \rangle^{(0)} \\ - \langle 1'_{-2'} | \mathcal{O} | 0 \rangle^{(0)} \end{bmatrix}, \\ \gamma_{\mathcal{O}}^{(1)} \langle 1_{-2+} | \mathcal{O} | 0 \rangle^{(0)} &= \frac{g^2 C_A}{16\pi^2} \int_0^{2\pi} \frac{d\phi}{2\pi} \int_0^{\frac{\pi}{2}} \frac{4 d\theta}{\cos\theta \sin\theta} \begin{bmatrix} (\cos^8\theta + \sin^8\theta) \langle 1_{-2+} | \mathcal{O} | 0 \rangle^{(0)} \\ - \cos^4\theta \langle 1'_{-2'_+} | \mathcal{O} | 0 \rangle^{(0)} \\ - \sin^4\theta e^{4i\phi} \langle 1'_{+2'_-} | \mathcal{O} | 0 \rangle^{(0)} \end{bmatrix}. \end{aligned} \quad (3.26)$$

In Yang-Mills theory, the leading-twist operators can be either in the vector-like Lorentz representation $(\frac{m}{2}, \frac{m}{2})$, or in chiral representations $(\frac{m}{2} + 1, \frac{m}{2} - 1)$ with $m \geq 1$. Focusing on the former, which control the energy dependence of unpolarized parton distribution functions and are associated with the polynomials ($m \geq 2$)⁴

$$\langle 1_{-1+} | \mathcal{O}_{gg,m} | 0 \rangle = (\lambda_1^1 \tilde{\lambda}_2^1)^2 (\lambda_1^1 \tilde{\lambda}_1^1)^{m-2}, \quad (3.27)$$

⁴Note that even though $\lambda_2^\alpha \tilde{\lambda}_2^{\dot{\alpha}} \simeq -\lambda_1^\alpha \tilde{\lambda}_1^{\dot{\alpha}}$ has been used to simplify the form factor in the forward limit, we have not used the stronger condition $\tilde{\lambda}_2^{\dot{\alpha}} \simeq -\tilde{\lambda}_1^{\dot{\alpha}}$ to eliminate $\tilde{\lambda}_2$ because the phase-space integral using eq. (2.17) produces additional little-group phases that do not preserve this relation.

Figure 3. Cut diagrams which contribute to the product $\mathcal{M}F^*$ at two-loop order.

this gives

$$\begin{aligned} \gamma_{gg,m}^{(1)} = & \frac{g^2 C_A}{16\pi^2} \int_0^{2\pi} \frac{d\phi}{2\pi} \int_0^{\frac{\pi}{2}} \frac{4 d\theta}{\cos\theta \sin\theta} \left[\cos^8\theta + \sin^8\theta \right. \\ & - \cos^4\theta (\cos\theta - \sin\theta e^{i\phi})^{m+2} (\cos\theta + \sin\theta e^{-i\phi})^{m-2} \\ & \left. - \sin^4\theta e^{4i\phi} (\cos\theta - \sin\theta e^{i\phi})^{m-2} (\cos\theta + \sin\theta e^{-i\phi})^{m+2} \right]. \end{aligned} \quad (3.28)$$

We have checked for several values of m that this reproduces precisely the moments of the DGLAP parton evolution equation in Yang-Mills theory,

$$\gamma_{gg,m} = - \int_0^1 dx x^{m-1} P_{gg}(x), \quad P_{gg}^{(1)}(x) = \frac{2g^2 C_A}{16\pi^2} \left[2 \frac{1+x^4+(1-x)^4}{x(1-x)_+} + \frac{11}{3} \delta(1-x) \right], \quad (3.29)$$

as expected from the standard relation between twist-two operators and parton distribution functions [26]. Therefore, the tree-level scattering phases in Yang-Mills theory are indeed the same as the anomalous dimensions of twist-two operators. It would be nice to find a more direct mathematical map between eqs. (3.28) and (3.29).

At higher loops, we warn the reader that since S is a matrix, its *phase* (as defined from its eigenvalues) need not agree with the phase of $2 \rightarrow 2$ S -matrix elements! Rather, when evaluating the product $\mathcal{M}F^*$ in the unitarity formula (2.4), as shown in figure 3 one sees that $2 \rightarrow 3$ amplitudes and higher also contribute to the anomalous dimension of twist-two operators. According to our main equation (2.4), anomalous dimensions are then obtained by comparing this product $\mathcal{M}F^*$ with $-i(e^{-i\pi D} - 1)F^*$. Using the dilatation operator D given in eq. (2.6), one sees that at two-loops this removes terms proportional to either the square of one-loop anomalous dimensions or to the one-loop β -function.

3.4 General operators at one-loop level and the $\mathcal{N} = 4$ spin chain

We conclude this section by discussing general operators at one-loop level. The main issue is the cancellation of infrared divergences for multiple external partons. In principle, one could use again matrix elements of the stress tensor, but since they are coupling-constant suppressed this is not so convenient. At one-loop, the tight structure of infrared divergences however makes this unnecessary. The one-loop infrared anomalous dimension (defined by the renormalization group equation (2.5) for the IR- and UV-renormalized form factor)

takes a very specific form in any gauge theory, see for example [30, 31]:

$$\gamma_{\text{IR}}^{(1)}(\{p_i\}; \mu) = \frac{g^2}{4\pi^2} \sum_{i < j} T_i^a T_j^a \log \frac{\mu^2}{-s_{ij}} + \sum_i \gamma_i^{\text{coll.}}, \quad (3.30)$$

where T_i^a denotes the gauge-group generator acting on particle i . The fact that infrared divergences obey a renormalization group equation stems, of course, from the general Wilsonian principle that disparate energy scales decouple; we refer the reader to [32] for a recent explicit proof and further references. Note that, in contrast to the ultraviolet case, infrared anomalous dimensions can depend explicitly on $\log \mu^2$ (at most linearly to any loop order), reflecting double-logarithmic divergences from modes that are simultaneously soft and collinear.

The first term in (3.30), coming from soft wide-angle radiation, can be identified with the integral over the $1/(\sin^2 \theta \cos^2 \theta)$ term in eq. (3.6a), which is the squared matrix element one would get from an integral over real radiation. Therefore, the general one-loop dilatation operator (encoding all one-loop anomalous dimensions) in an arbitrary gauge theory with matter contains a double-sum term, from the sum over unitarity cuts and soft contribution to the anomalous dimension, together with a single-sum term accounting for remaining hard-collinear divergences:

$$\begin{aligned} \gamma_{\mathcal{O}}^{(1)} \langle p_1, \dots, p_n | \mathcal{O} | 0 \rangle^{(0)} &= -\frac{1}{\pi} \langle p_1, \dots, p_n | \sum_{i < j} \left(\mathcal{M}_{ij}^{2 \leftarrow 2} + \frac{2g^2 T_i^a T_j^a}{\sin^2 \theta \cos^2 \theta} \right) \otimes \mathcal{O} | 0 \rangle^{(0)} \\ &+ \langle p_1, \dots, p_n | \mathcal{O} | 0 \rangle^{(0)} \times \sum_{i=1}^n \gamma_i^{\text{coll.}}. \end{aligned} \quad (3.31)$$

Here, \mathcal{M}_{ij} denotes the $2 \rightarrow 2$ amplitude acting on the final-state particles i and j . The two-body phase-space integral, which is represented by the convolution sign and defined in eqs. (2.16)–(2.18), is absolutely convergent for each term.

In QCD, matching and integrating the explicit expressions for the stress-tensor subtractions in eqs. (3.16) and (3.19), we get the one-loop collinear anomalous dimensions $\gamma_g^{\text{coll.}} = -\frac{g^2 b_0}{16\pi^2}$ and $\gamma_\psi^{\text{coll.}} = -\frac{3g^2 C_F}{16\pi^2}$, again in agreement with standard results [31]. The equality of the one-loop β -function and the collinear anomalous dimension (and the coefficient of $\delta(1-x)$ in eq. (3.29)) can be attributed, in this framework, to the simplicity of the Lagrangian form factor (3.6a), which exactly matches the soft (classical) infrared divergences.

An interesting special case of this formula is the planar limit of $\mathcal{N} = 4$ super Yang-Mills. In the planar limit, we consider single-trace operators, and i and j must be color-adjacent. Thus, we set $j = i + 1$ with $n + 1 \equiv 1$ identified following the cyclic invariance of the trace, and $T_i^a T_{i+1}^a \rightarrow -\frac{N_c}{2}$. In this model, all states lie within one supermultiplet and are conveniently labelled by polynomials in superspinors $\lambda_i, \tilde{\lambda}_i, \tilde{\eta}_i$ as in eq. (3.14); summing over internal helicities, one finds that the supermomentum-conserving δ -function simply forces the $\tilde{\eta}'$ to rotate like the $\tilde{\lambda}'$, so the right-hand side here will be evaluated with rotated superspinors (2.17). Finally, the planar $2 \rightarrow 2$ amplitude is equal to the first term in eq. (3.1),

which is larger than the color-singlet amplitude (3.2) by a factor $\cos^2 \theta$. Substituting it into the above formula, we thus get⁵

$$\gamma_{\mathcal{O}}^{(1)} \langle 1, \dots, n | \mathcal{O} | 0 \rangle^{(0)} = \frac{4g^2 N_c}{16\pi^2} \sum_{i=1}^n \int_0^{2\pi} \frac{d\phi}{2\pi} \int_0^{\frac{\pi}{2}} d\theta \cot \theta \begin{pmatrix} \langle 1, \dots, i, i+1, \dots, n | \mathcal{O} | 0 \rangle^{(0)} \\ -\langle 1, \dots, i', (i+1)', \dots, n | \mathcal{O} | 0 \rangle^{(0)} \end{pmatrix}. \quad (3.32)$$

This formula is precisely the one written down by Zwiebel for the one-loop dilatation operator in planar $\mathcal{N} = 4$ SYM [1], which in some way led to this work.

In various subsectors, the expression above reduces for example to the Hamiltonian of the integrable $SU(2)$ or $SL(2)$ Heisenberg spin chain, revealing the integrability of the theory [33, 34]. As far as we know, the original motivation of [1] was based on symmetries: the one-loop dilatation operator and tree-level four-point S -matrix being both completely fixed by Yangian symmetry up to a multiplicative constant, they may be proportional to each other. This was then understood more directly from generalized unitarity [2]. In this paper, we have derived this formula using conventional unitarity and given a quantitative extension to an arbitrary weakly coupled field theory, eq. (3.31).

In large N_c -QCD, we thus expect that upon substituting the appropriate quark and gluon $2 \rightarrow 2$ tree amplitudes as in eq. (3.26), the formula will reproduce the one-loop dilatation operator from ref. [35]. It would also be interesting to specialize the formula to the Standard Model and compare with the dimension-six anomalous dimensions, see for example ref. [36]; certain qualitative features, such as zeros that are not obvious from Feynman diagrams, are nicely explained from unitarity and on-shell tree-level helicity conservation rules [11].

4 Length-changing effects and towards higher loops: Yukawa theory

Let us now look at Yukawa theory, where we will encounter several new effects looking at operators of higher length and at higher loops. These include mixing between operators of different lengths and the cancellation of logarithms between different cuts.

For illustration, it will be sufficient to consider a theory with one real scalar and one Weyl fermion, with interaction Lagrangian

$$\mathcal{L}_{\text{int}} = -\lambda \mathcal{O}_\lambda - y \mathcal{O}_y \quad \text{with} \quad \mathcal{O}_\lambda = \frac{1}{4!} \phi^4 \quad \text{and} \quad \mathcal{O}_y = \frac{1}{2} (\psi \psi \phi + \text{h.c.}). \quad (4.1)$$

The minimal form factors of the operators \mathcal{O}_λ and \mathcal{O}_y are

$$\langle 1_\phi 2_\phi 3_\phi 4_\phi | \mathcal{O}_\lambda | 0 \rangle = 1, \quad \langle 1_{\bar{\psi}} 2_{\bar{\psi}} 3_\phi | \mathcal{O}_y | 0 \rangle = \langle 12 \rangle, \quad \langle 1_\psi 2_\psi 3_\phi | \mathcal{O}_y | 0 \rangle = [12]. \quad (4.2)$$

Correspondingly, the elemental scattering amplitudes are

$$\mathcal{M}_{1_\phi 2_\phi 3_\phi 4_\phi} = -\lambda, \quad \mathcal{M}_{1_{\bar{\psi}} 2_{\bar{\psi}} 3_\phi} = -y \langle 12 \rangle, \quad \mathcal{M}_{1_\psi 2_\psi 3_\phi} = -y [12]. \quad (4.3)$$

⁵In the planar limit, it is conventional to not symmetrize in the two cut particles; it can be verified that after symmetrization, using that $\cot \theta + \tan \theta = \frac{1}{\cos \theta \sin \theta}$, the IR subtraction is exactly as in eq. (3.31) with $\gamma_{\mathcal{N}=4}^{\text{coll.}} = 0$.

One can check that the relative signs between the latter two amplitudes is consistent with unitarity, so that $\langle 1_\phi | 2_{\bar{\psi}} 3_{\bar{\psi}} \rangle \langle 2_{\bar{\psi}} 3_{\bar{\psi}} | 1_\phi \rangle \geq 0$ as it should, using the crossing relation (2.19). Other amplitudes can be obtained using the factorization on poles:

$$\begin{aligned}
 \mathcal{M}_{1_{\bar{\psi}} 2_\psi 3_\phi 4_\phi} &= y^2 \left(\frac{\langle 13 \rangle}{\langle 23 \rangle} + \frac{\langle 14 \rangle}{\langle 24 \rangle} \right), \\
 \mathcal{M}_{1_\psi 2_\psi 3_{\bar{\psi}} 4_{\bar{\psi}}} &= y^2 \frac{\langle 34 \rangle}{\langle 12 \rangle}, \\
 \mathcal{M}_{1_\psi 2_\psi 3_\psi 4_\psi} &= 3y^2 \frac{[34]}{\langle 12 \rangle}, \\
 \mathcal{M}_{1_\psi 2_\psi 3_\phi 4_\phi 5_\phi} &= y\lambda \frac{1}{\langle 12 \rangle} - y^3 \left(\frac{\langle 35 \rangle}{\langle 13 \rangle \langle 25 \rangle} + 5 \text{ permutations of } (345) \right).
 \end{aligned}
 \tag{4.4}$$

The signs of these amplitudes will be significant since in this approach they ultimately determine the sign of the anomalous dimension; they are fixed for example by the factorization of trees $\langle 12 | \mathcal{M} | 34 \rangle \rightarrow \langle 12 | \mathcal{M} | i \rangle \frac{1}{\langle 12 \rangle \langle i2 \rangle} \langle i | \mathcal{M} | 34 \rangle$ in the limit where $p_i = (p_1 + p_2)$ becomes null.

From the above scattering amplitudes and form factors, we will calculate the anomalous-dimension matrix

$$\left(\mu \frac{\partial}{\partial \mu} + \sum_{a=y,\lambda} \beta(a) \frac{\partial}{\partial a} \right) \begin{pmatrix} \mathcal{O}_y \\ \mathcal{O}_\lambda \end{pmatrix} = \begin{pmatrix} \gamma_{yy} & \gamma_{y\lambda} \\ \gamma_{\lambda y} & \gamma_{\lambda\lambda} \end{pmatrix} \begin{pmatrix} \mathcal{O}_y \\ \mathcal{O}_\lambda \end{pmatrix}.
 \tag{4.5}$$

From it one can then get β -functions, using a generalization of the relation (2.10) that we used in the Yang-Mills case. We briefly recall its derivation [14]. First we note that we have normalized the operators so that their form factors (4.2) restricted to zero total momentum are precisely the derivatives of the S -matrix with respect to the corresponding coupling:

$$\mathcal{F}_a = - \frac{\partial}{\partial a} \mathcal{M}.
 \tag{4.6}$$

One now considers the RG equation for the UV (not IR)-renormalized amplitude and form factor (that is, contrary to what was done so far in this paper, here we consider independent ultraviolet and infrared renormalization scales):

$$\left(\mu_{\text{UV}} \frac{\partial}{\partial \mu_{\text{UV}}} + \sum_{b=y,\lambda} \beta(b) \frac{\partial}{\partial b} \right) \mathcal{M} = 0, \quad \left(\mu_{\text{UV}} \frac{\partial}{\partial \mu_{\text{UV}}} + \sum_{b=y,\lambda} \beta(b) \frac{\partial}{\partial b} \right) \mathcal{F}_a = - \sum_{b=y,\lambda} \gamma_{ab} \mathcal{F}_b.
 \tag{4.7}$$

Deriving the first equation with respect to the coupling and comparing with the second equation gives the desired relation:

$$\frac{\partial}{\partial a} \beta(b) = \gamma_{ab}, \quad a, b = \lambda \text{ or } y.
 \tag{4.8}$$

4.1 IR structure and diagonal elements

The diagonal (length-preserving) elements of the mixing matrix can be calculated straightforwardly using the by-now familiar procedure of the preceding section: we act on form

factors with the 2→2 tree amplitudes, employing the stress tensor to remove the infrared (and collinear) contributions. There are no new subtleties but if anything it is instructive to carry through this exercise.

Using the crossing relation (2.19) and the spinor products (3.3), the matrix elements we will need are easily obtained from (4.4):

$$\begin{aligned}
 \langle 1_\phi 2_\phi | \mathcal{M} | 1'_\psi 2'_\psi \rangle &= -\langle 1_{\bar{\psi}} 2_\psi | \mathcal{M} | 1'_\phi 2'_\phi \rangle^* = y^2 \left(\frac{\cos \theta}{\sin \theta} - \frac{\sin \theta}{\cos \theta} \right) e^{-i\phi}, \\
 \langle 1_{\bar{\psi}} 2_{\bar{\psi}} | \mathcal{M} | 1'_\psi 2'_\psi \rangle &= \langle 1_{\bar{\psi}} 2_\psi | \mathcal{M} | 1'_\psi 2'_\psi \rangle = -\langle 1_{\bar{\psi}} 2_\psi | \mathcal{M} | 1'_\psi 2'_\psi \rangle = -y^2, \\
 \langle 1_{\bar{\psi}} 2_{\bar{\psi}} | \mathcal{M} | 1'_\psi 2'_\psi \rangle &= -3y^2, \quad \langle 1_{\bar{\psi}} 2_\phi | \mathcal{M} | 1'_\psi 2'_\phi \rangle = -y^2 \frac{1 + \cos^2 \theta}{\cos \theta}.
 \end{aligned} \tag{4.9}$$

Multiplying the first by the tree form factor for the stress tensor to fermions, given in eq. (3.13), and performing the azimuthal integrals then gives

$$\begin{aligned}
 2\gamma_\phi^{\text{coll.}} &\equiv \frac{1}{\pi} \frac{\langle 1_\phi 2_\phi | \mathcal{M} \otimes T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle^{(0)}}{\langle 1_\phi 2_\phi | T^{\alpha\beta, \dot{\alpha}\dot{\beta}} | 0 \rangle^{(0)}} \\
 &= \frac{1}{16\pi^2} \int_0^{\frac{\pi}{2}} 2 \cos \theta \sin \theta d\theta \left(-\frac{1}{4} \lambda (1 + \cos(4\theta)) + 6y^2 \cos^2(2\theta) \right) = \frac{2y^2}{16\pi^2} \\
 \Rightarrow \gamma_\phi^{\text{coll.}} &= \frac{y^2}{16\pi^2},
 \end{aligned} \tag{4.10}$$

where we have included also the scalar (λ term) and antifermion (factor of 2) in the cut. The λ term integrates to zero: there are no one-loop IR divergences in pure ϕ^4 theory, as expected. Here we remark that, even though the form factors (3.13) contain many terms, because they are fixed by symmetry the algebra is highly redundant and just the coefficient of one term, for example $p_1^{\alpha\dot{\alpha}} p_1^{\beta\dot{\beta}}$, is enough to determine the anomalous dimension. Considering similarly the form factor for two fermions, we find

$$2\gamma_\psi^{\text{coll.}} = \frac{1}{16\pi^2} \int_0^{\frac{\pi}{2}} 2 \cos \theta \sin \theta d\theta (2y^2 \cos^2(2\theta) - y^2 \cos(4\theta)) = \frac{y^2}{16\pi^2} \Rightarrow \gamma_\psi^{\text{coll.}} = \frac{\frac{1}{2}y^2}{16\pi^2}, \tag{4.11}$$

where we have used the second, fourth and fifth of the amplitudes in eq. (4.9).

With the infrared contributions under control, we can now calculate the diagonal matrix elements, which is particularly trivial for the ϕ^4 vertex correction since the four-scalar amplitude is just a constant so each matrix element gives a factor $-\lambda/(16\pi^2)$:

$$\begin{aligned}
 \gamma_{\lambda\lambda}^{(1)} &= 4\gamma_\phi^{\text{coll.}} - \frac{1}{\pi} \frac{\langle 1_\phi 2_\phi 3_\phi 4_\phi | (\mathcal{M}_{12} + \mathcal{M}_{13} + \mathcal{M}_{14} + \mathcal{M}_{23} + \mathcal{M}_{24} + \mathcal{M}_{34}) \otimes \mathcal{O}_\lambda | 0 \rangle^{(0)}}{\langle 1_\phi 2_\phi 3_\phi 4_\phi | \mathcal{O}_\lambda | 0 \rangle^{(0)}} \\
 &= \frac{4y^2}{16\pi^2} + \frac{6\lambda}{16\pi^2}.
 \end{aligned} \tag{4.12}$$

The y^2 term comes entirely from the collinear divergences, following eq. (3.31). In ϕ^4 theory, it would be absent and, reassuringly, the relation (4.8) would give

$$\beta(\lambda) = \frac{3\lambda^2}{16\pi^2} \quad (\phi^4 \text{ theory}), \tag{4.13}$$

which is of course the standard result.

For the Yukawa vertex renormalization, we have some angular integrals to do, involving the third, sixth and two permutations of the seventh term in (4.9):

$$\begin{aligned} \gamma_{yy}^{(1)} &= 2\gamma_{\bar{\psi}}^{\text{coll.}} + \gamma_{\phi}^{\text{coll.}} - \frac{1}{\pi} \frac{\langle 1_{\bar{\psi}} 2_{\bar{\psi}} 3_{\phi} | (\mathcal{M}_{12} + \mathcal{M}_{13} + \mathcal{M}_{23}) \otimes \mathcal{O}_y | 0 \rangle^{(0)}}{\langle 1_{\bar{\psi}} 2_{\bar{\psi}} 3_{\phi} | \mathcal{O}_y | 0 \rangle^{(0)}} \\ &= \frac{2y^2}{16\pi^2} - \frac{1}{16\pi^2} \int_0^{\frac{\pi}{2}} 2 \cos \theta \sin \theta \, d\theta \left(-4y^2 - 2y^2(1 + \cos^2 \theta) - 2y^2(1 + \sin^2 \theta) \right) = \frac{12y^2}{16\pi^2}. \end{aligned} \quad (4.14)$$

Note that, even though the Yukawa interaction between identical fermions is often said to be attractive, the matrix elements here are mostly negative, thus leading to a positive anomalous dimension and a positive contribution to the β -function. The difference is because the conventional statement applies to non-relativistic massive fermions while we are looking here at the ultrarelativistic case where the amplitude involves a helicity flip and is quite different.

4.2 Length-increasing effects: Yukawa coupling contributing to ϕ^4

We now turn to some novel effects not discussed earlier — at one-loop we can also have length-increasing mixing, for example between the operators \mathcal{O}_λ and \mathcal{O}_y . In terms of the unitarity method, this will involve the $2 \rightarrow 3$ amplitude acting on the minimal form factor, as well as the $2 \rightarrow 2$ scattering acting on the *non-minimal* form factor:

$$\begin{aligned} \gamma_{y\lambda}^{(1)} &= -\frac{1}{\pi} \frac{\langle 1_{\phi} 2_{\phi} 3_{\phi} 4_{\phi} | (\mathcal{M}_{12}^{2\leftarrow 2} + \mathcal{M}_{13}^{2\leftarrow 2} + \mathcal{M}_{14}^{2\leftarrow 2} + \mathcal{M}_{23}^{2\leftarrow 2} + \mathcal{M}_{24}^{2\leftarrow 2} + \mathcal{M}_{34}^{2\leftarrow 2}) \otimes \mathcal{O}_y | 0 \rangle^{(0)}}{\langle 1_{\phi} 2_{\phi} 3_{\phi} 4_{\phi} | \mathcal{O}_\lambda | 0 \rangle^{(0)}} \\ &\quad - \frac{1}{\pi} \frac{\langle 1_{\phi} 2_{\phi} 3_{\phi} 4_{\phi} | (\mathcal{M}_{123}^{3\leftarrow 2} + \mathcal{M}_{124}^{3\leftarrow 2} + \mathcal{M}_{134}^{3\leftarrow 2} + \mathcal{M}_{234}^{3\leftarrow 2}) \otimes \mathcal{O}_y | 0 \rangle^{(0)}}{\langle 1_{\phi} 2_{\phi} 3_{\phi} 4_{\phi} | \mathcal{O}_\lambda | 0 \rangle^{(0)}}. \end{aligned} \quad (4.15)$$

The subscripts on the amplitude indicate the final state partons to which it is connected. From the second line we get a rather simple λy term (see the last amplitude in eq. (4.4)), but for y^3 contributions there will be a non-trivial interplay between the two lines. However, the sum of terms should give a polynomial since it is the form factor of a local operator.

Anticipating that this will require cancellations, here we organize the terms into cuts of Feynman diagrams (since Feynman diagrams make locality manifest). For example, consider the three cuts of the fermion box with on-shell scalars p_1, p_2, p_3 shown in figure 4. The first cut is related to $\mathcal{M}_{12}^{2\leftarrow 2}$ multiplied by the non-minimal form factor

$$\langle 1_{\psi} 2_{\bar{\psi}} 3_{\phi} 4_{\phi} | \mathcal{O}_y | 0 \rangle = -y \left(\frac{\langle 13 \rangle}{\langle 23 \rangle} + \frac{\langle 14 \rangle}{\langle 24 \rangle} - \frac{[23]}{[13]} - \frac{[24]}{[14]} \right). \quad (4.16)$$

The sign of this expression can be verified by noting that for zero total momentum this is equal to minus the y derivative of the $2 \rightarrow 2$ S -matrix element given in the first line of eq. (4.4). The first cut comes from the first term in the amplitude (4.4) multiplied by the first term in the form factor:

$$\langle 1_{\phi} 2_{\phi} | \mathcal{M} | 1'_{\psi} 2'_{\bar{\psi}} \rangle_{\text{first term}} \langle 1'_{\psi} 2'_{\bar{\psi}} 3_{\phi} 4_{\phi} | \mathcal{O}_y | 0 \rangle_{\text{first term}} = y^3 \frac{\langle 2'1 \rangle}{\langle 1'1 \rangle} \frac{\langle 1'3 \rangle}{\langle 2'3 \rangle}. \quad (4.17)$$

In the parametrization (2.17), the phase-space integral reads

$$\int \frac{d\Omega}{4\pi} \frac{\langle 2'1 \rangle \langle 1'3 \rangle}{\langle 1'1 \rangle \langle 2'3 \rangle} = \int_0^{2\pi} \frac{d\phi}{2\pi} \int_0^{\frac{\pi}{2}} d\theta 2 \cos^2 \theta \frac{\langle 13 \rangle \cos \theta - e^{i\phi} \langle 23 \rangle \sin \theta}{\langle 13 \rangle \sin \theta + e^{i\phi} \langle 23 \rangle \cos \theta}, \quad (4.18)$$

where we have dropped the prefactor $-\frac{y^3}{16\pi^2}$ in the relation to the anomalous dimension. A good way to perform the ϕ integral is as a contour integral over $z = e^{i\phi}$ along the unit circle, which allows us to use Cauchy's residue theorem, obtaining

$$- \int_0^{\frac{\pi}{2}} d\theta 2 \cos^2 \theta \left(\frac{\cos \theta}{\sin \theta} - \frac{1}{\cos \theta \sin \theta} \Theta \left(1 - \left| \frac{\langle 13 \rangle \sin \theta}{\langle 23 \rangle \cos \theta} \right| \right) \right) = 1 + \log \frac{s_{23}}{s_{13} + s_{23}}. \quad (4.19)$$

The step function Θ arises from whether the pole from the denominator is inside the unit circle. The result from the double cut in the other two-particle channel can be obtained by replacing $1 \leftrightarrow 3$ in (4.19). In this way, we have accounted for 2 out of the $2 \times 6 \times 2 \times 4 = 96$ terms in the first line of eq. (4.15) (one of the 2's is from exchanging $\bar{\psi}$ and ψ).

We now consider the double cut in the three-particle channel. We require both the three-point form factors in (4.2) and the five-particle amplitude in the last line of (4.4). As before, we will focus on one particular term corresponding to the third diagram of figure 4:

$$\langle 1_\phi 2_\phi 3_\phi | \mathcal{M} | 1'_{\bar{\psi}} 2'_{\bar{\psi}} \rangle_{\text{first } y^3 \text{ term}} \langle 1'_{\bar{\psi}} 2'_{\bar{\psi}} 4_\phi | \mathcal{O}_y | 0 \rangle = \frac{\langle 13 \rangle}{\langle 1'1 \rangle \langle 2'3 \rangle} \langle 1'2' \rangle. \quad (4.20)$$

We want to parametrize p'_1 and p'_2 as a rotation of suitable basis spinors. In contrast to the cases above, we cannot simply take the base vectors to be external ones. Instead, we choose

$$p_a = p_1 \frac{s_{123}}{s_{12} + s_{13}}, \quad p_b = p_2 + p_3 - p_1 \frac{s_{23}}{s_{12} + s_{13}}, \quad (4.21)$$

which are both on-shell and satisfy $p_a + p_b = p_1 + p_2 + p_3$. Corresponding spinors are

$$\lambda_a = \lambda_1 \sqrt{\frac{s_{123}}{s_{12} + s_{13}}}, \quad \lambda_b = ([12]\lambda_2 + [13]\lambda_3) \frac{1}{\sqrt{s_{12} + s_{13}}}. \quad (4.22)$$

We then find

$$\int \frac{d\Omega}{4\pi} \frac{\langle 1'2' \rangle \langle 13 \rangle}{\langle 1'1 \rangle \langle 2'3 \rangle} = \int_0^{2\pi} \frac{d\phi}{2\pi} \int_0^{\frac{\pi}{2}} d\theta \frac{2 \cos \theta}{\sin \theta + e^{i\phi} \cos \theta \frac{[12]\langle 23 \rangle}{\langle 13 \rangle \sqrt{s_{123}}}}, \quad (4.23)$$

and, doing the ϕ integral again using Cauchy's theorem, we obtain

$$\int_0^{\frac{\pi}{2}} d\theta 2 \frac{\cos \theta}{\sin \theta} \Theta \left(1 - \left| \frac{[12]\langle 23 \rangle \cos \theta}{\langle 13 \rangle \sqrt{s_{123}} \sin \theta} \right| \right) = \log \left(\frac{(s_{12} + s_{13})(s_{13} + s_{23})}{s_{12}s_{23}} \right). \quad (4.24)$$

Summing (4.19), its image under $1 \leftrightarrow 3$ and (4.19) to get the three cuts in figure 4 finally gives

$$\left(1 + \log \frac{s_{23}}{s_{13} + s_{23}} \right) + \left(1 + \log \frac{s_{12}}{s_{12} + s_{13}} \right) + \log \left(\frac{(s_{12} + s_{13})(s_{13} + s_{23})}{s_{12}s_{23}} \right) = 2. \quad (4.25)$$

Figure 4. Three cuts of the box integral among which logarithms cancel, see eq. (4.25).

As expected, the dependence on the kinematic variables has cancelled! Restoring the factor $-y^3/(16\pi^2)$ and multiplying by 48 then gives the y^3 term in the anomalous dimension. As already mentioned, there is also a simpler piece proportional to $y\lambda$, which comes only from the second line of eq. (4.15) and involves the comparatively simpler amplitude given in the last line of (4.4). In total, we thus get

$$\gamma_{y\lambda} = -\frac{96y^3}{16\pi^2} + \frac{8y\lambda}{16\pi^2}. \tag{4.26}$$

Of course, the first term could have been obtained much more easily by extracting the ultraviolet-divergent part of the fermion box diagram. But this examples shows how, through a non-trivial interplay between S -matrix elements and form factors responsible from the cancellation of logarithms (4.25), the ultraviolet properties of the theories are also encoded in on-shell amplitudes with finite momentum.

Since all cuts ended up being computed by residues using Cauchy’s formula, we can track the cancellations to the fact that the residues on triple cuts agree regardless of the order in which the propagators are cut. Physically, this is a consequence of the factorization of amplitudes and form factors on their poles. Understanding how to systematize such cancellations would be of great help for applications to the dilatation operator at lengths ≥ 3 at higher-loops, especially in gauge theories where the comparative simplicity of on-shell amplitudes adds a practical advantage to the method.

4.3 Length-decreasing effects: a simple two-loop contribution

Finally, we consider the length-decreasing mixing of \mathcal{O}_λ into \mathcal{O}_y . An important feature is that such mixing is not possible at one-loop: it would require a cut in a massless channel (with a $2 \rightarrow 1$ amplitude on one side), which of course is kinematically impossible. Therefore, the first length-decreasing effects occur at two-loops, through a $3 \rightarrow 2$ amplitude integrated over a 3-particle cut.

There exist efficient modern techniques to deal with such two-loop cut integrals, notably by using integration-by-parts techniques and so-called reverse unitarity, see for example [37]. Here, in line with previous examples, we adopt a low-tech approach and parametrize directly the angular integrals. A price to pay is that we have to use different parametrizations for different terms in the amplitude. We use eq. (5.23) and preceding ones from [1]:

$$\begin{aligned} \lambda_1'^\alpha &= \lambda_1^\alpha \cos \theta_2 - e^{i\phi} \lambda_2^\alpha \cos \theta_1 \sin \theta_2, \\ \lambda_2'^\alpha &= \lambda_1^\alpha \sin \theta_2 \cos \theta_3 + e^{i\phi} \lambda_2^\alpha (\cos \theta_1 \cos \theta_2 \cos \theta_3 - e^{i\rho} \sin \theta_1 \sin \theta_3), \\ \lambda_3'^\alpha &= \lambda_1^\alpha \sin \theta_2 \sin \theta_3 + e^{i\phi} \lambda_2^\alpha (\cos \theta_1 \cos \theta_2 \sin \theta_3 + e^{i\rho} \sin \theta_1 \cos \theta_3). \end{aligned} \tag{4.27}$$

This has a simple physical interpretation in terms of collinearly splitting p_2 into two daughters with momentum fractions $\cos^2 \theta_1$ and $\sin^2 \theta_1$, followed by applying the rotation (2.17) on two different pairs. A nice feature is that the propagators in the first y^3 term in eq. (4.4) become elementary trigonometric functions:

$$\langle 1_\psi 2_\psi | \mathcal{M}^{2\leftarrow 3} | 1'_\phi 2'_\phi 3'_\phi \rangle |_{\text{first } y^3 \text{ term}} = -\frac{y^3}{\langle 12 \rangle} (e^{i\rho} \tan \theta_1 \cot \theta_2 \csc \theta_2 \cot \theta_3 + \cot^2 \theta_2 + 1). \quad (4.28)$$

In order to calculate the phase-space integral, we also require the measure factor, given as $(-1/\pi)$ times the phase-space volume. It is given by

$$-\frac{s_{12}}{(4\pi)^4} d\mu \quad \text{with} \quad d\mu = 2 \sin \theta_1 \cos \theta_1 d\theta_1 4 \sin^3 \theta_2 \cos \theta_2 d\theta_2 2 \sin \theta_3 \cos \theta_3 d\theta_3 \frac{d\rho}{2\pi} \frac{d\phi}{2\pi}. \quad (4.29)$$

In order to check the normalization of (4.29), we compute

$$\begin{aligned} \int d\mu &= \int_0^{\frac{\pi}{2}} 2 \sin \theta_1 \cos \theta_1 d\theta_1 \int_0^{\frac{\pi}{2}} 4 \sin^3 \theta_2 \cos \theta_2 d\theta_2 \int_0^{\frac{\pi}{2}} 2 \sin \theta_3 \cos \theta_3 d\theta_3 \int_0^{2\pi} \frac{d\rho}{2\pi} \int_0^{2\pi} \frac{d\phi}{2\pi} \\ &= 1, \end{aligned} \quad (4.30)$$

and we compare this to the discontinuity of the sunrise integral

$$\begin{aligned} -\frac{1}{\pi} \text{Im} \left[\text{Sunrise}(s_{12}, \mu^2) \right] &= -\frac{2}{\pi} \text{Im} \left[\frac{1}{(4\pi)^{4-2\varepsilon}} \frac{\Gamma(1-\varepsilon)^3 \Gamma(1+2\varepsilon)}{2\varepsilon(1-2\varepsilon)\Gamma(3-3\varepsilon)} (-s_{12}) \left(-\frac{s_{12}}{\mu^2} \right)^{-2\varepsilon} \right] \\ &= -\frac{s_{12}}{(4\pi)^4}, \end{aligned} \quad (4.31)$$

finding perfect agreement. Integrating the amplitude (4.28) against the measure (4.29) with an additional symmetry factor of $\frac{1}{3!}$ for the three-particle phase space, we thus find

$$\begin{aligned} &-\frac{s_{12}}{(4\pi)^4} \frac{1}{3!} \int d\mu \langle 1_\psi 2_\psi | \mathcal{M}^{2\leftarrow 3} | 1'_\phi 2'_\phi 3'_\phi \rangle |_{\text{first } y^3 \text{ term}} \langle 1'_\phi 2'_\phi 3'_\phi 3_\phi | \mathcal{O}_\lambda | 0 \rangle \\ &= -\frac{2y^3}{3!(4\pi)^4} \langle 1_\psi 2_\psi 3_\phi | \mathcal{O}_y | 0 \rangle. \end{aligned} \quad (4.32)$$

The contributions from the five permutations are identical. Finally, the contribution from the term in the amplitude proportional to λy can be integrated trivially, as it does not depend on the phase-space parameters. Adding all seven terms, we find

$$\gamma_{\lambda y} = -\frac{2y^3}{(4\pi)^4} + \frac{1}{6} \frac{y\lambda}{(4\pi)^4}. \quad (4.33)$$

4.4 Summary

In total, we find

$$\begin{pmatrix} \gamma_{yy} & \gamma_{y\lambda} \\ \gamma_{\lambda y} & \gamma_{\lambda\lambda} \end{pmatrix} = \frac{1}{16\pi^2} \begin{pmatrix} 12y^2 + O(y^4) & -96y^3 + 8y\lambda + O(y^5) \\ -\frac{2y^3}{16\pi^2} + \frac{1}{6} \frac{y\lambda}{16\pi^2} + O(y^5) & 6\lambda + 4y^2 + O(y^4) \end{pmatrix}, \quad (4.34)$$

where for simplicity we quote the errors in the technically natural power counting $\lambda \sim y^2$. All of these entries are one-loop except for the lower-diagonal one, $\gamma_{\lambda y}$, for which we have included the two-loop contribution which is leading.

Integrating the relation (4.8) between anomalous dimensions and β -function, $\gamma_{ab} = \partial_a \beta(b)$, in particular yields the one-loop β -functions

$$\beta^{(1)}(y) = \frac{1}{16\pi^2} (4y^3), \quad \beta^{(1)}(\lambda) = \frac{1}{16\pi^2} (-24y^4 + 4y^2\lambda + 3\lambda^2), \quad (4.35)$$

which is the standard textbook result for the considered theory of one Weyl fermion and one real scalar; see for example [17], up to minor modifications to reflect our matter content. The computed two-loop entry also yields some simple two-loop contributions

$$\beta^{(2)}(y) = \frac{1}{(16\pi^2)^2} \left(-2y^3\lambda + \frac{1}{12}y\lambda^2 + \text{undetermined terms proportional to } y^5 \right), \quad (4.36)$$

which can be compared for example with eq. (3.3) of [38], finding perfect agreement. This demonstrates in a non-trivial way the correct handling of length-changing effects in the dilatation operator by the proposed unitarity relation (2.4): $SF^* = e^{-i\pi D} F^*$.

It is noteworthy that the relation between β -function and anomalous dimension is *overconstrained*: the $4y^2\lambda$ term in $\beta(\lambda)$ is encoded in two different matrix elements of eq. (4.34). Since we obtained anomalous dimensions effectively as eigenvalues of the S -matrix, this must be viewed as a constraint satisfied by the S -matrix. In fact, looking at the calculation, the $8y\lambda$ term in $\gamma_{y\lambda}$ is obtained from the $2 \rightarrow 3$ amplitude in the last line of eq. (4.4), whereas the equivalent $4y^2$ term in $\gamma_{\lambda\lambda}$ comes from the collinear anomalous dimension (4.10), itself obtained from the $2 \rightarrow 2$ amplitudes acting on the stress tensor. It was not a-priori obvious why these S -matrix elements should be related, so it would be interesting to investigate such relations further.

It is interesting to see also that certain two-loop calculations in this section are actually simpler than one-loop calculations. This is because, as presently formulated, calculating the anomalous dimension of high-length operators requires dealing with a multi-scale problem (see eq. (4.25)) and so the number of legs has a strong impact on the complexity.

5 Discussion and conclusion

In this paper, we have proposed a simple relation between the S -matrix of a theory at high energies and its dilatation operator:

$$e^{-i\pi D} F^* = SF^*. \quad (5.1)$$

In essence, this states that the time evolution from asymptotic past to future, as encoded by the S -matrix, is equivalent to following a half-circle generated by a complex scale transformation as shown in figure 1. This means that *the dilatation operator is minus the phase of the S -matrix, divided by the circumference of the half-circle (π)*.

At one-loop in Yang-Mills theory, this provides a surprisingly efficient way to calculate the β -function of the theory. Starting with the famous Parke-Taylor tree-level amplitude for

scattering four on-shell gluons in eq. (3.1), and performing elementary operations such as integrating over the two-body phase space, one reproduces the famous result proportional to $-11C_A/3$ in section 3.1. In particular, as usual with on-shell methods, only physical on-shell gluon states enter the calculation. Furthermore, the sign is directly tied to the positive sign of the amplitude, itself stemming from the attractive force between opposite charges. The extension to QCD including masses is discussed in subsection 3.2 and poses no significant problem. We also found a correspondence between twist-two anomalous dimensions and the phase of $2 \rightarrow 2$ angular-momentum partial waves, and obtained a novel formula, eq. (3.31), for the one-loop dilatation operator in any gauge theory. A pleasant feature is that the one-loop anomalous dimensions of all operators are generated by the same building blocks, the $2 \rightarrow 2$ tree amplitudes of the theory.

Of course, in QCD the technology to calculate twist-two anomalous dimensions and β -functions is already very well developed: for example, three-loop anomalous dimensions have been known for some time [39, 40] and the four- and even five-loop β -function are now known [41–43]. On the other hand, for more general operators such as dimension-six operators in the Standard Model effective theory, one-loop results have only been obtained recently [36]. An advantage of the present method is that it treats all operators of the theory on the same footing, which could help automation in this context. In addition, certain qualitative features such as helicity selection rules are automatically manifest [11]. As mentioned in the main text, the present method could also be advantageous at higher loops in the context of theories with extended symmetries, since the symmetries of the S -matrix are naturally maintained (including integrability in planar $\mathcal{N} = 4$ SYM).

We have also investigated Yukawa theory at one-loop and beyond, confirming the general validity of the approach. This is a phenomenologically important theory which allows us to study effects which generically will be present at higher loops in any theory. Of course, since on-shell amplitudes in this case are not simpler than the corresponding Feynman diagrams, we did not expect a significant advantage to using this method. The main new effect is that, while the β -function of Yang-Mills could be determined using an operator which decays to two partons at tree level (the gluon density $\text{Tr}[G^2]$), measuring the couplings in Yukawa theory requires more external legs interacting together, which makes the problem multi-scale and causes individual cuts to be more complicated. The simplest case where this occurs is the length-increasing mixing at one-loop studied in section 4.2; here, logarithms cancel non-trivially between cuts (see eq. (4.25)). We expect such effects to be generic for higher-twist operators in any theory beyond one-loop, and a formalism where such canceling transcendental functions could be discarded in individual cuts would greatly simplify calculations. We note however that for twist-two operators and β -functions in QCD, the problem is always single-scale and such difficulties are absent.

In this work, we have taken the renormalization group equation as an input, but it is interesting to ask if it could be derived in an on-shell framework using physical principles like unitarity of the S -matrix. For example, there might be a recursive way to construct the scale dependence of the amplitudes and form factors on each side of a cut. In general, the formalism exposes interesting relationships between form factors and the S -matrix, and it would be fascinating to study this interplay in explicit examples at two loops and higher.

Acknowledgments
